Treatment of patient with spinal deformities can be operative or nonoperative. Nonoperative treatment usually consists of observation or bracing. With the recognition that some conditions cause iatrogenic deformities, another treatment option exists—prevention. Operative treatment usually consists of spinal fusion and can include instrumentation for correction and stability. Some deformities may necessitate osteotomy to obtain satisfactory balance and a good long-term outcome.

Etiologic Principles

Spinal deformity can be caused by an imbalance of vertebral growth or spinal instability that cannot withstand normal physiologic forces. Deformities also can be caused directly by manipulation of the spine or its supporting structures, the pelvis and lower extremities. By understanding these principles, we can determine whether iatrogenic deformity is likely to occur, observe the patient for development of deformity, and recommend appropriate treatment if deformity does occur.

Classification of Iatrogenic Spinal Deformities on the Basis of Etiologic Principle

i. Growth imbalance
  A. Growth arrest
    1. Direct
    2. Indirect
  B. Growth acceleration

ii. Instability
  A. Posterior column
    1. Bilateral
    2. Unilateral
  B. Anterior column
  C. Loss of muscular support—spinal cord injury
iii. Direct manipulation of the spine
  A. Manipulation away from physiologic contour
  B. Manipulation toward physiologic contour
iv. Manipulation of the foundation for the spine
  A. Pelvis
  B. Lower extremities
    1. Length differences
    2. Range of motion

Type I: Growth Imbalance

Growth imbalance implies either interruption of normal growth or acceleration of growth. Deformity occurs only when alteration of growth potential is asymmetric. Asymmetric growth is caused by surgical manipulation of growth centers, formation of tethering anterior or posterior vertebral bony bars or rib tethers, or partial removal of a growth center in one portion of a vertebra and leaving the other portion intact. Irradiation of a growing spine can interfere with normal growth and cause deformity. For example, stimulation of growth by extrinsic growth hormone can cause deformity, but it is likely that a smaller deformity had existed and was made worse or more noticeable after acceleration of growth. Unlike findings about the long bones, there is no clear evidence of stimulation of growth centers of vertebrae by trauma or hyperemia that causes deformity or marked asymmetry, although it is conceivable that this could occur and produce deformity. Typical deformities from growth imbalance are scoliosis, kyphosis, lordosis, and crankshaft phenomenon (rotation). Treatment is based on restoration of balance of growth, usually by means of fusion and when necessary by means of release, osteotomy, external immobilization, or internal fixation.

Type II: Instability

Instability implies loss of structural integrity of the spinal column or cylinder. Mechanically, the articulated spine can be thought of as a curved column. Each segment has components that provide axial support and tensile resistance. In the anterior aspect, the vertebral body and disc resist the compressive load, and the anterior and posterior longitudinal ligament and disc anulus resist distractive forces. In the posterior aspect, the facet joint complex resists axial load, lateral bending, and depending on the level, shear forces. The ligament complex (supraspinal, interspinal, capsular facet ligaments, and ligamentum flavum) act as tension wires to stabilize the spine. Normal muscle tone in the paraspinal muscles complements the posterior ligament complex. Gravity normally exerts a flexion force on the cervical and thoracic portions of the spine, which is counteracted by the posterior ligament complex and spinal extensor muscles.

Removal of or injury to any of the supporting structures of the spine alters the stability of the spine. Depending on the degree of change, permanent alterations can occur. The most obvious alteration occurs when the spine is rendered unstable and subluxation occurs. Growth disturbances can occur when an increase in the load on the cartilaginous ossification center causes wedged vertebrae.

Spinal deformity can occur after removal of a portion of the anterior supporting column or the posterior stabilizing complex or by means of alteration of the facet joints. In a high percentage of cases, loss of muscular control of the trunk following spinal cord or neurologic injury causes deformity in the growing child. Kyphosis, lordosis, scoliosis, and combinations thereof are possible, but kyphosis is most common after laminectomy. When scoliosis occurs, it usually is associated with kyphosis. If the anterior column is not reconstructed after partial or complete vertebrectomy, collapse into kyphosis should be expected. If the resection is not symmetric, lateral angulation and scoliosis will occur in addition to the kyphosis.

The best treatment remains avoiding the deformity by restoring stability, which is done by replacing or augmenting weakened structures. Stability can be restored by means of internal fixation or external stabilization with braces. Late treatment necessitates fusion of the deformity and possibly correction of the deformity, possibly with osteotomy or internal fixation.

Type III: Direct Manipulation of the Spine

Manipulation of the spine implies application of distractional, compressional, rotational, or translational forces to one or more motion segments. Application of these forces can be external or internal. Examples of external forces are casts, braces, or even positioning at the time of surgery. Internal forces usually are applied with fixation devices during surgery, frequently for the correction of a deformity or instability. Application of these forces has direct consequences to the area treated and indirect consequences to the compensatory areas of the spine. Depending on the nature and magnitude of the force vectors, not all direct changes are desirable. Some of the changes are likely to be in a physiologic plane, and others may direct the spine out of a physiologic plane. For example, correction of scoliosis by means of distraction within the concavity of a curve on the dorsal side of the spine also induces kyphosis. This can be desirable in the thoracic spine but is deleterious in the lumbar spine. Anterior compression of a scoliotic curve likewise reduces scoliosis and produces kyphosis, which would be in the physiologic plane of the thoracic spine but away from the physiologic contour in the thoracolumbar and lumbar spine. Even translation, whether by cantilever forces, in situ bending, or rod rotation, imparts stress on the next adjacent segment and is likely to cause junctional kyphosis or scoliosis if the force applied is too powerful. Indirect changes occur either when correction of a curve is greater than the ability of the compensatory curve to compensate or when the curve is corrected to an inappropriate end fusion level. These changes usually result in truncal decompensations that were not present earlier, and they represent a new deformity.

Type IV: Manipulation of the Foundation for the Spine

The spine terminates in the sacrum, and the sacrum is wedged as a keystone in the pelvis. The pelvis and legs therefore are the thoracic spine but away from the physiologic contour in the thoracolumbar and lumbar spine. Even translation, whether by cantilever forces, in situ bending, or rod rotation, imparts stress on the next adjacent segment and is likely to cause junctional kyphosis or scoliosis if the force applied is too powerful. Indirect changes occur either when correction of a curve is greater than the ability of the compensatory curve to compensate or when the curve is corrected to an inappropriate end fusion level. These changes usually result in truncal decompensations that were not present earlier, and they represent a new deformity.

Type IV: Manipulation of the Foundation for the Spine

The spine terminates in the sacrum, and the sacrum is wedged as a keystone in the pelvis. The pelvis and legs therefore are the foundation of the spine. Alteration of the foundation by means of manipulation of the pelvis or leg length may produce spinal deformity. In the treatment of patients with fractures and leg length discrepancies, failure to maintain balance by keeping the foundation level can cause deformity. Contractures of the knee and hip alter the orientation of the pelvis and can imbalance and deformity. Tumors of the sacrum or pelvis may require extensive resection. If reconstruction is not possible, collapse of the spine into the void produced by resection can cause a new deformity.

Described Etiologic Factors

Spinal Fusion

The most common and direct cause of tethering is spinal fusion. Partial fusion for preexisting deformities or instabilities caused by tumor excision stops growth in the area fused. Although this fused area of the spine has had the growth potential removed, other growth centers of the vertebrae in the fusion can cause the spine to bend in conjunction with their growth. If the fused area is unilateral, this in essence is a unilateral bar. If the fusion is posterior and the growth potential of the anterior column is great, lordosis or crankshaft deformity can occur, as described by Dubousset (22). The direction of the deformity and its effect on the patient vary depending on many factors. The deformity can be kyphotic, lordotic, or rotational and scoliotic depending on the area tethered and the area that can grow. The resulting change can be in appearance alone or can have an effect on function and spinal balance.

Whenever arthrodesis is performed on a growing child, the child should be observed to maturity. If the chance of progressive deformity is identified, an attempt should be made to determine whether this deformity has clinical significance. If there is evidence that progression of this deformity will cause undesirable consequences, further surgery to stop growth is necessary. This surgery usually takes the form of an anterior fusion, but if the resulting deformity has been allowed to proceed too far, osteotomy of the fusion may be necessary.

Spinal Deformity Following Radiation Therapy

Vertebral bodies grow axially by means of endochondral ossification, as do the epiphyseal plates of long bones. Epiphyseal cartilage is radiosensitive tissue, and growth zone cartilage cells in immature bones become disorganized after irradiation. Radiation in sufficient concentration prevents normal endochondral maturation (3 ,4 ,82). The degree of growth inhibition with higher doses is related to the age of the child and the dose. The younger the bone and the greater the radiation dosage, the greater is the ultimate deformity (24 ,40 ,41 ,66 ,73 ,85 ,88 ,105 ,106).

Therapy for numerous malignant tumors of childhood includes the use of radiation therapy. Neuroblastoma and Wilms tumor occur close to the vertebral column, and thus the spinal column can be included in the treatment beam. Low linear energy transfer radiation, such as gamma and roentgen rays, can be associated with serious disturbances of skeletal growth. Alterations of vertebral growth patterns can be found as early as 6 months after therapeutic irradiation. Any patient with an immature skeleton who receives more than 1,000 cGy radiation to the vertebral column is at risk of spinal deformity. Less than 1,000 cGy usually produces no detectable changes in the vertebral body (60). Mild curves occur frequently among patients who 2,000 cGy, and the most severe spinal deformities have been associated with 3,000-cGy exposure. Irradiation to asymmetric fields has been associated with increased number and severity of spinal deformities, whereas use of symmetric portals for spinal irradiation more commonly causes kyphosis (61 ,70 ,82).

The most severe changes occur among patients 2 years or younger at the time of irradiation. Permanent growth plate inhibition manifests as irregularity or scalloping of vertebral end plates with diminished axial height or as gross abnormalities with flat-beaked vertebral bodies. These changes are produced by 2,000 to 3,000 cGy radiation or more (41 ,73 ,84 ,85 ,88 ,93 ,103). There is little correlation between the individual changes in the vertebral body and the severity of the curvature, but a direct relation exists between absorbed radiation and subsequent spinal deformity.

It is well established that the younger the patient at exposure, the greater is the probability of spinal deformity. Patients who undergo irradiation when they are younger than 2 years have the most serious disturbances. Patients older than 4 years undergoing radiation treatment rarely have appreciable spinal deformity unless the spine has been surgically destabilized, either with laminectomy or through bony erosion of the primary tumor. Any child undergoing therapeutic irradiation to the spine should undergo follow-up examinations until skeletal maturity.

The incidence and importance of spinal deformity after radiation therapy was studied by Riseborough et al. (85), who found that among 81 patients who had undergone irradiation for Wilms tumor, 59 with scoliosis, 19 had kyphoscoliosis, and 2 had kyphosis alone. Fourteen of those patients had curves greater than 25 degrees. Riseborough et al. also found that no child younger than 10 years had a curvature more than 20 degrees. Donaldson and Wissinger (20) conducted a study with 37 children who had undergone radiation therapy for Wilms tumor or neuroblastoma. They found that scoliosis had developed among 70% of the patients and that 2 of these patients needed surgery. Other authors have reported that as many as 40% of patients have scoliosis and 65% have kyphotic deformities (Fig. 1).

Spinal deformity among patients who have received radiation is not always caused by vertebral body distortion from growth abnormalities. The cause of the deformity can be soft-tissue fibrosis and contractures, rib and iliac hypoplasia, or a primary result of the tumor or the surgical intervention. Deformities clearly can develop among patients with Wilms tumor who do not receive radiation. In one study, such patients treated with radiation had scoliosis seven times more often (35 of 57) than did those who did not undergo radiation (5 of 53) (68).

Spinal deformity can occur later in life among patients with spinal tumors who received radiation therapy many years previously. In this situation, the deformity can be caused by the tumor itself or even the surgery, rather than the radiation therapy (87). It is difficult to determine the precise cause.

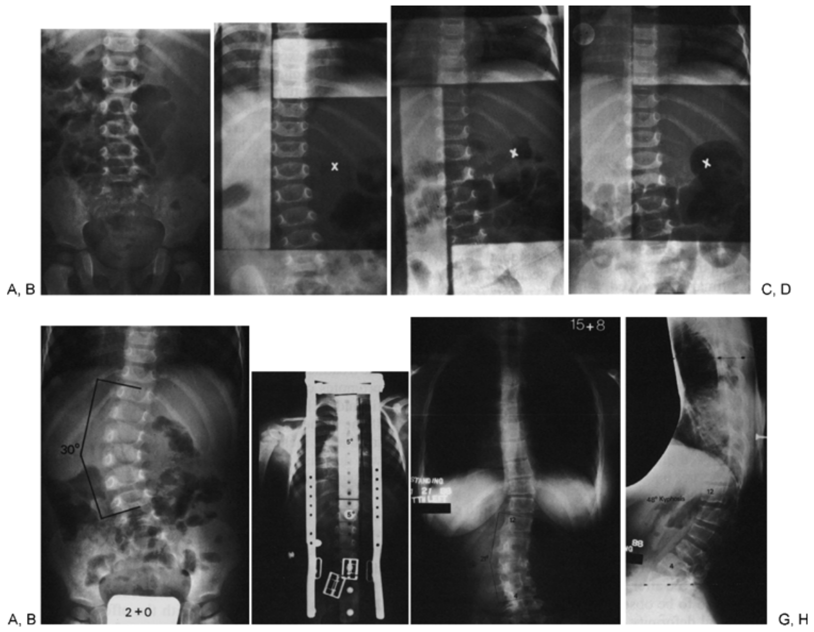

FIGURE 1. A girl with Wilms' tumor treated by nephrectomy and irradiation developed scoliosis controlled by a brace. **A:** Age 1 year 2 months; preoperative anteroposterior radiograph of lumbar spine and pelvis. Bone structures are normal; note straight spine and symmetry of vertebrae, particularly pedicles. At time of right nephrectomy, tumor was found to extend outside kidney. **B, C, and D:** Posteroanterior scout radiographs taken on the fourteenth, fifteenth, and nineteenth postoperative days to aid in determining portals for radiation therapy. Primary treatment field (x) lay lateral to the spine, but a portion of the spine was included within the area to be irradiated, as determined by these scout films. Presumably, the portals were altered to exclude or include the entire spine after these scout films were made. However, a second scout film was not made before radiation therapy, and a portion of spine may still have been included in radiation field. Mild lumbar scoliosis in **B** could be positional or related to the opertive wound. Dosage was 1,975 rads in 12 doses over 20 days. **E:** Age 2 years 0 months; posteroanterior radiograph made 8 months after irradiation. Note lumbar scoliosis, minimal vertebral rotation, pedicle size discrepancy, and asymmetry of each vertebra (vertebral body shape is irregular, and the height of each vertebral body is less on the right side than on the left). A Milwaukee brace was applied. **F:** Age 3 years 6 months; posteroanterior radiographs after wearing of Milwaukee brace with only a left lumbar pad for 16 months. Note satisfactory alignment of spine. Milwaukee brace was changed to a body jacket at age 6 years 3 months. The body jacket was discontinued at age 14 years 9 months. **G:** Age 15 years 8 months. Mild (21-degree) residual left lumbar scoliosis. **H:** The patient is normally active but has occasional low back pain, possibly related to residual upper lumbar kyphosis (48 degrees). Note sagittal wedging of lumbar vertebral bodies 1, 2, and 3. (Figures A–F reproduced with permission from Peterson HA (1985): Spinal deformity secondary to tumor, irradiation, and laminectomy. In: Bradford DS, Hensinger RN, eds. *The pediatric spine.* New York: Thieme-Stratton, pp. 273–285.)

Treatment

Marked scoliosis rarely is present before the age of 10 years. As a patient enters adolescent growth acceleration, curves that have been relatively static in previous years can have a dramatic increase. As with idiopathic scoliosis, when a curve exceeds 25 degrees as measured by the Cobb method, orthotic treatment is used. Whether this prevents progression of certain curves or merely delays progression is unclear. Prolonged observation of a progressive radiation-induced spinal deformity is not indicated. Careful assessment of the soft tissue is necessary for each patient, and extensive scarring or contracture may obviate use of an orthosis. Bracing continues until skeletal maturity. The age at which skeletal maturity occurs does not differ from that among patients with spines that have not been exposed to radiation. If the coronal plane deformity exceeds 45 degrees, surgical intervention should be considered; however, the risk of pseudarthrosis and infection increases when surgery is performed on a previously irradiated spine (41). The choice of fusion limits does not differ from that for idiopathic scoliosis. This generally includes the caudalmost vertebra that rests within the stable zone and one level cephalic to the upper neutral vertebra. Careful attention to the sagittal plane deformity must be used in determining fusion and instrumentation levels.

Healing normally takes a great deal of time. If there is poor evidence of posterior fusion, repetition of bone grafting 6 months after the initial operation has been recommended. The use of third-generation spinal fixation provides sufficient strength and fixation, so pseudarthrosis may be difficult to detect. Therefore a high index of suspicion must be maintained. Use of an autogenous cancellous bone graft from a donor site that has not been irradiated is desirable.

Circumferential anteroposterior fusion is required when the kyphotic component of the deformity is greater than 35 degrees in the lumbar area. A vascularized rib graft transferred from an area that has not been irradiated is ideal as an autogenous, rapidly healing anterior bone strut. Supplemental grafting seldom is needed in circumferential fusion.

A total contact, low-profile orthosis has been routinely used for the 6 months after the operation. The use of newer segmental spinal instrumentation provides good fixation and may allow brace-free convalescence. It is suspected that this type of management improves the fusion rate, but the improvement cannot be confirmed. If fixation is questionable or if fusion healing has not advanced satisfactorily, bracing can be continued or supplementary bone grafting can be performed.

Spinal Deformity Following Thoracotomy Or Rib Resection

The rib cage provides stability to the spine because of its composite structure and because it is a cylinder with a large radius rather than because of its many articulations and ligamentous connections. The cause of spinal deformity following thoracotomy or rib resections seems to be either instability or tethering.

Several ribs or articulations have to be removed to reduce the stability of the spine. Although mild lateral deviation of the thoracic spine can occur in cases of rib resection, it is rare for the deviation to produce a deformity of clinical importance (10 ,23 ,94). It has been difficult to predict who will have a substantial curve, but it has been observed that a direct correlation exists between the number of ribs resected and the curve produced (the more resected, the greater the deformity). Resection of upper ribs produces smaller curves than resection of lower ribs (18 ,94). In addition, the major curve is limited to the segments of the thoracic spine adjacent to the resected ribs, and the apex of the curve is centrally placed in the region of the resected ribs (94). Patients who undergo transversectomy have greater curvature.

The age of the patient is also a factor (18 ,23). In adult patients, most of the angular deformity develops 1 week after surgery, and there is almost no progression after 1 year (94). Scoliosis among children who undergo chest wall resection is progressive during growth. The degree of curvature is related to the number of ribs resected (15). Anterior resection of ribs does not produce marked scoliosis, but posterior resection of the ribs promptly produces scoliosis that is convex toward the side of the ribs resected (instability) (18 ,51). The scoliosis is concave toward the side operated on if there is chest wall resection with scarring, tethering or marked pleural thickening caused by recurrent tumor, radiation scarring, or underlying pulmonary metastasis (18). Scoliosis associated with empyema and chest wall osteomyelitis is likewise concave toward the side operated on and may respond to removal of this tether in a growing child.

That scoliosis follows open heart surgery among patients with congenital heart disease is well known. Some authors have assumed that thoracotomy is responsible for the development of the curve. In one large study, however, no correlation was found between the appearance or side of the scoliosis and either the number and type of thoracotomy incisions or the number and side of ribs removed (81). No more than two ribs were removed from any patient in this study.

Prevention of scoliosis after major en bloc chest wall excision is difficult. Autogenous tissue such as fascia lata, contralateral rib graft, transposed omentum, or a latissimus dorsi muscle flap can be used, as can prosthetic materials such as metallic plates, acrylics, and synthetic mesh fabrics, such as Marlex, Prolene, Silastic, Teflon, or Gortex. Gortex allows incorporation of tissue, is soft and easy to use, and does not fragment (31).

Once deformity is substantial, spinal fusion with instrumentation is the usual treatment. This may improve pulmonary function (34). The correction may be maximized by rib osteotomy or resection on the contralateral concave side (34 ,59 ,95 ,100) (Fig. 2).

Spinal Deformity Following Multilevel Laminectomy

With aggressive management of malignant tumors by means of laminectomy and excision, radiation therapy, and chemotherapy, a large number of children survive and come to orthopedic surgeons with severe postlaminectomy spinal deformity. Overall, the younger the patient and the more cephalic the laminectomy (excluding the occiput, C1, and C2), the more likely is deformity (78 ,96).

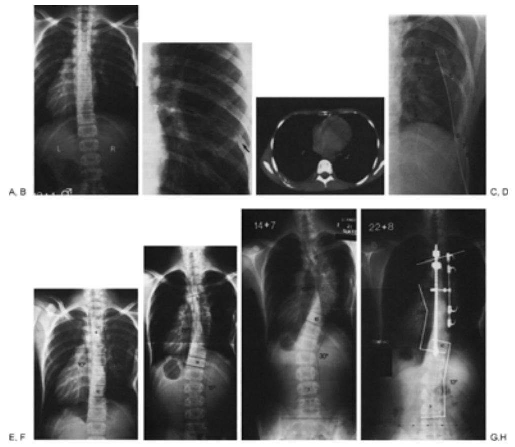

FIGURE 2. Scoliosis following rib resection. **A:** Boy aged 13 years 1 month with lytic lesion in posterior aspect of right seventh rib. Note straight spine. **B:** Close-up radiograph. Note lytic destruction of seventh rib (between *arrows*). This was regarded as malignant. **C:** Computed tomographic appearance also suggested malignancy. **D:** Operative radiograph at time of en bloc excision of posterior portions of ribs 6 through 9, and osteotomy of fifth rib. Thoracic wall reconstruction utilized silastic sheeting. Note straight spine. **E:** Eight weeks postop. Beginning of scoliosis. **F:** Eight months postop. Note little, if any, vertebral body rotation. **G:** Eighteen months postop. Posterior fusion with Harrington distraction and compression rods was performed three days later. **H:** Age 22 years 8 months; 9 years 7 months after rib resection, 8 years 1 month after spinal fusion.

Incidence

Spinal deformity following multilevel laminectomy is rare among adults but occurs among approximately 50% of children treated for spinal cord tumors. Bette and Englehardt (8) first reported this problem in 1955 with three cases of postlaminectomy deformity. In 1959, Haft et al. (32) reported the cases of 30 children who had undergone laminectomy for spinal cord tumors. Among 17 children who underwent complete follow-up evaluation, 10 (33% of the total) experienced spinal deformity. In Tachdjian and Matson's (98) series of 115 children with spinal cord tumors, 46 (40%) acquired spinal deformity. Boersma (12) reported that 50% of the 51 children in his series had spinal deformity after laminectomy for spinal cord tumor.

In 1970, Dubousset et al. (21) reported on 55 children, 78% of whom had late postlaminectomy spinal deformity. Fraser et al. (26) reported in 1977 that 35% of 29 children acquired postlaminectomy spinal deformity. Yasuoka et al. (111) reported that 46% of patients younger than 25 years who underwent laminectomy acquired postlaminectomy deformity. Taking all these series together, the incidence of deformity is 50%.

The most common deformity following multiple-level laminectomy among children is kyphosis, although scoliosis and rotatory deformities can occur (99). The incidence of spinal deformity caused by multiple-level laminectomy alone is difficult to determine, because many laminectomies are performed for conditions that in themselves can cause progressive spinal deformity (78). In one large study, all cases in which the underlying condition was one that could cause spinal deformity were excluded (112). It was found that the occurrence of spinal deformity after multiple-level laminectomy correlated with two factors—the age of the patient (spinal deformity following laminectomy is in part dependent on growth) and the anatomic level of the laminectomy. In the study, 46% of the patients younger than 15 years had deformity, but only 6% of those between 15 and 24 years of age did so, and all those who did were 18 years or younger. Spinal deformity occurred in all patients who underwent cervical laminectomy, 36% of those who underwent thoracic laminectomy, and none of the patients who underwent lumbar laminectomy. No correlation was found between occurrence of the deformity and sex of the patient, number of laminae removed, neurologic condition after laminectomy, or length of time after surgery. Deformity was found as late as 6 years after surgical intervention (32 ,112). Long-term follow-up evaluation is necessary to identify all cases.

Among children, three types of kyphosis can develop after laminectomy: instability after facetectomy, wedging of vertebral bodies caused by abnormal compressive forces on immature, growing structures, and hypermobility between vertebral bodies associated with gradual rounding of the spine. The importance of facets for stability of the spine is well recognized and has been demonstrated in animal and cadaver experiments (69 ,74). Facet injury can cause spinal instability with vertebral body subluxation in both children and adults, even without laminectomy or facetectomy. During laminectomy, the facet joints and their capsule should be preserved in their entirety whenever possible. Use of the technique of Dubousset et al. shows a correlation between facet integrity and the deformity (21). If the facets are completely removed at one level, sharp, angular kyphosis develops with the apex at this level. If the facet is partially removed on one side, sharp, angular scoliosis develops in addition to the kyphosis. If the facets are preserved, either completely or in part, gradual rounding kyphosis develops (see later). With careful evaluation of postlaminectomy x-ray films and examination of the facet joints, an accurate prediction of the potential deformity can be made.

Removal of the posterior supporting structures causes transmission of more of the weight load to the anterior column. The immature vertebral body is composed of a relatively small ossification center and a large proportion of cartilage. The compressive force is greatest anteriorly, inhibits cartilage growth and ossification, and produces gradual vertebral body wedging as the more posterior aspects of the body and of the vertebra continue to grow. The deformity is short, angular, and limited to the level of the laminectomy. This mechanism of deformity depends on growth and therefore occurs more often among more immature patients (Figs. 3 , 4 , 5 , 6).

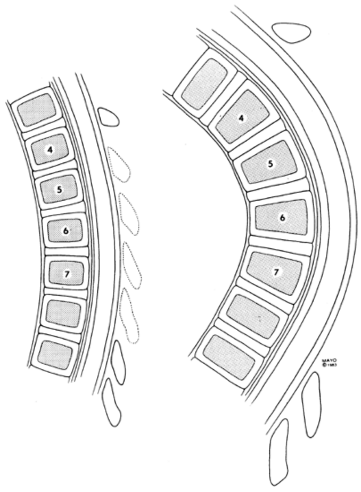

FIGURE 3. Thoracic vertebrae, theoretical drawing. Left: Before laminectomy. Note rectangular configuration of ossified portion of vertebral body, entire vertebral body (ossification center and surrounding growth cartilage), and intervertebral discs. Right: After laminectomy of T4–T7 and subsequent growth. Note kyphosis and wedging of ossified portions of involved vertebrae. Growth plates have been under increased compression anteriorly because of loss of posterior supporting (tension) structures. This compression allows less growth on anterior portion of body than on posterior portion. With time, vertebral end plates and intervertebral discs also become wedge shaped. (Reproduced with permission from Peterson HA (1985): Spinal deformity secondary to tumor, irradiation, and laminectomy. In: Bradford DS, Hensinger RN, eds. *The pediatric spine.* New York: Thieme-Stratton, pp. 273–285.)

Hypermobility associated with gradual rounding of the spine can occur without deformation or actual subluxation of vertebral bodies. This is called *pseudosubluxation.* The plane of facet joints is more horizontal in children and becomes more vertical with maturity. The ligamentous and capsular tissues also are more viscoelastic in children than in adults. After removal of the posterior supporting complex by means of laminectomy, the load shifts anteriorly. The viscoelastic capsular tissue around the facet joints and remaining ligaments gradually stretches to allow gradual rounding of the spine that may extend cephalad and caudad to exceed the actual levels of the multilevel laminectomy. If the vertebral bodies are very immature, wedging can occur.

These same mechanisms do not seem to occur in the lumbar spine when it has a normal lordotic curve. Removal of the posterior tension band does not place an abnormally high compressive load on the anterior supporting column. Thus kyphosis is much less likely to occur (112).

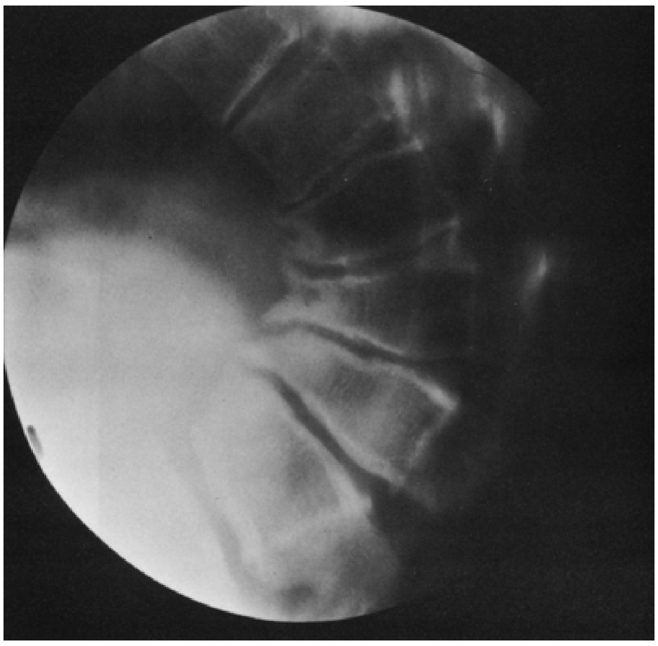

FIGURE 4. Girl aged 16 years 9 months. Thoracic spine was normal when the patient underwent laminectomy at T9–L1 at age 5 years for an astrocytoma. Rdiograph, taken 11 years after multilevel laminectomy, shows wedged vertebrae with only mildly irregular disc spaces. There has been compensatory increased circumferential growth of vertebral bodies (noted anteriorly on this lateral radiograph), much like the increased circumferential growth of the femoral head and neck after early closure of proximal femoral physis with Perthes' disease. (Reproduced with permission from Yasuoka S, Peterson HA, Laws ER Jr, et al. (1981): Pathogenesis and prophylaxis of postlaminectomy deformity of the spine after multiple level laminectomy: difference between children and adults. *Neurosurg* 9:145–152.)

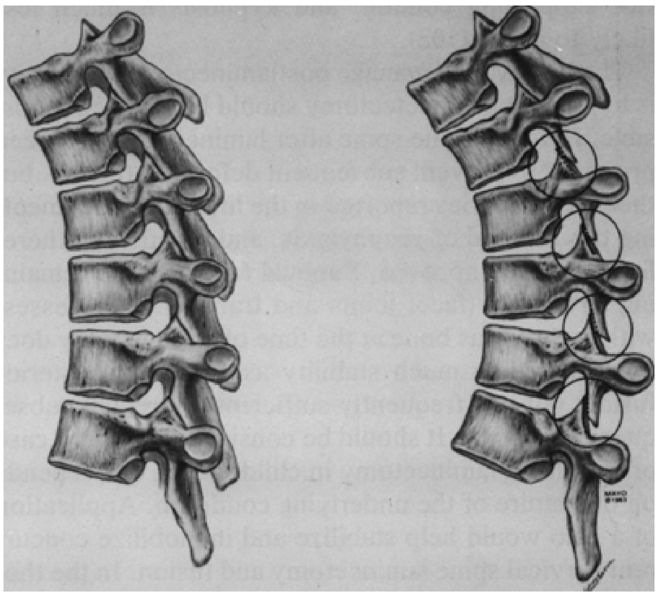

FIGURE 5. Thoracic vertebrae, anatomic drawing. Left: Normal vertebrae before laminectomy. Note congruent apposition of opposing facet joints. Right: After four-level laminectomy, loss of posterior (tension) supporting structures has allowed each involved facet joint surface to slide and subluxate on its opposing surface (circles) and produce increased compressive force on the anterior portion of each vertebral body. There is no deformation or subluxation of vertebral bodies. (Reproduced with permission from Peterson HA (1985): Spinal deformity secondary to tumor, irradiation, and laminectomy. In: Bradford DS, Hensinger RN, eds. *The pediatric spine.* New York: Thieme-Stratton, pp. 273–285.)

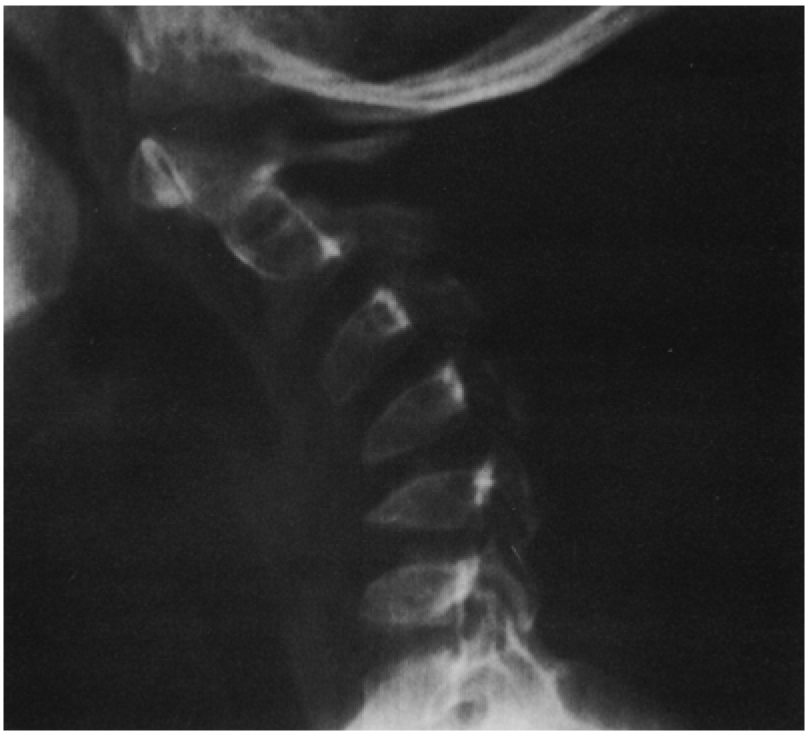

FIGURE 6. Boy aged 12 years 9 months, who had a normal cervical spine before laminectomy of C2–C6 at age 10 years. Two years after laminectomy, there is gradual rounding of the spine, with shearing distraction of the facet joints but not the vertebral bodies. With growth, compressive force on the anterior portion of vertebral bodies will cause them to become wedged also. (Reproduced with permission from Yasuoka S, Peterson HA, Laws ER Jr, et al. (1981): Pathogenesis and prophylaxis of postlaminectomy deformity of the spine after multiple level laminectomy: difference between children and adults. *Neurosurg* 9:145–152.)

Treatment

Prevention is the best way to manage postlaminectomy deformity. Facetectomy should be avoided if possible. Although bracing of the spine after laminectomy has been proposed to prevent subsequent deformity (92 ,96), no series reported in the literature documents this method of prophylaxis, and its efficacy remains unproven. Surgical fusion of the remaining structures (facet joints and transverse processes) with autogenous bone at the time of laminectomy usually is sufficient to prevent subsequent deformity and should be considered in every case of multilevel laminectomy on a child. Whether this procedures is used depends on the nature of the underlying condition. Application of external immobilization helps stabilize and immobilize concurrent laminectomy and fusion. Instrumentation is sometimes appropriate in the thoracic and lumbar spine and, when the anatomic configuration allows, in the cervical spine (36 ,71). Winter (108) even recommends prophylactic anterior spinal fusion after posterior laminectomy in certain circumstances.

Laminoplasty is another procedure that can prevent deformity after operations on the spinal canal (63 ,69 ,79 ,91 ,96). In this procedure, both laminae are divided as close to the pedicle as possible at each level. The two laminae and the connecting spinous process of each vertebra are removed as one piece and preserved. At the conclusion of the procedure, they are reinserted and sutured in place. The procedure is followed by immobilization with a brace or cast to prevent deformity and instability. The effectiveness of the procedure for prevention of deformity among children has not been established, and additional experience and follow-up study are necessary. The aforementioned hypothesis about the mechanism of development of kyphosis among children supports the rationale for this procedure.

If fusion in situ at the time of laminectomy is not feasible, the patient should be observed closely with repeated radiographic examinations of the spine in the standing position. Early intervention with surgical fusion is recommended as soon as deformity is recognized, especially among young children.

Once spinal deformity has appeared after laminectomy, bracing does not correct it. Correction and stabilization of the deformity necessitate surgical fusion. The surgical approaches are the posterior, the anterior, and the combined approach. Only a small amount of bone surface is available posteriorly after wide laminectomy. This makes fusion difficult. A review of the treatment of 48 patients at my center showed the pseudarthrosis rate was 50% with posterior fusion alone, 25% with anterior fusion alone, and 9.5% with combined anterior and posterior fusions (60). The combined approaches are thus the treatment of choice.

For anterior fusion in an immature patient, the entire disc must be excised back to the posterior longitudinal ligament to eliminate posterior vertebral growth because posterior fusion tends to be thin. This growth causes pseudarthrosis or increasing deformity, the anterior fusion acting as the bar in type 2 congenital kyphosis. The disc and cartilage are thus completely removed, and the fusion is performed with the rib as an inlay strut graft. The vertebral bone and any additional chips of rib bone are placed in the disc spaces. Posterior fusion is performed either during the same operation or 1 week later. This fusion extends into the compensatory lordotic curve. Posteriorly instrumentation frequently is impossible because the bony anatomic features have been altered, the bone is too soft in a young child, or the angle of kyphosis is too great.

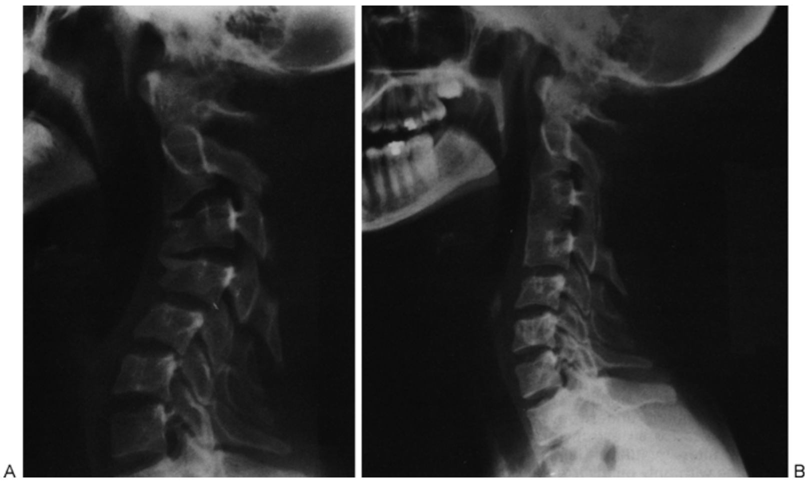

FIGURE 7. Girl with cervical kyphosis successfully treated with anterior interbody fusion. **A:** Age 15 years 8 months, two year after suboccipital craniectomy and laminectomy at C1–C3 for syringomyelia with Arnold Chiari malformation. Note normal anterior portions of C1 and C2 but wedging of the bodies of C3 and C4 due to asymmetric growth of vertebral bodies. **B:** Age 18 years 8 months, three years after anterior interbody fusion at C2–C4. Cervical spine motion is 75% of normal. (Reproduced with permission from Yasuoka S, Peterson HA, MacCarty CS. (1982): Incidence of spinal column deformity after multilevel laminectomy in children and adults. *J Neurosurg* 57:441–445.)

A halo cast often is used postoperatively because the deformity is frequently in the high thoracic area, and internal fixation is extremely difficult. When instrumentation cannot be performed or if kyphosis is unstable, the patient may need to stay nonambulatory for 3 to 4 months. After this time, the cast is removed and the patient can walk in a Milwaukee brace. In the cervical spine, anterior fusion with bone grafts between the vertebral bodies usually produces a satisfactory outcome. In the thoracic spine, mild early deformity can be stabilized by means of posterior fusion alone (Fig. 7).

Spinal Cord and Central Nervous System Injury

Whether spinal cord injury causes spinal deformity in a growing child depends on the level of the injury and the growth remaining. Iatrogenic causes of spinal cord injury among children are far less common than traumatic or neoplastic causes. Possible iatrogenic causes include spinal cord ischemia and stretch or trauma from surgical manipulation. The loss of muscular control of the trunk is the presumed primary mechanism for the development of spinal deformity. Central nervous system injuries can change the muscle tone of a child. The changes are well known to be associated with and probably cause spinal deformities, such as those associated with cerebral palsy.

Spinal Cord Ischemia

Spinal cord ischemia with resultant paraplegia usually is accompanied by substantial progressive spinal deformity. The deformity usually is scoliosis, and lumbar lordosis or lumbar kyphosis can be associated with it. Iatrogenic causes of spinal cord ischemia include clamping or compression of the aorta during a surgical procedure, hypotension during or after a surgical procedure, altered vascular supply to the spinal cord due to surgical ligation of segmental vessels and hypotension, and transumbilical catheter injection of the aorta (6 ,33 ,47).

The primary treatment of spinal cord ischemia is avoidance. A common cause of spinal cord injury during operation on the spine is believed to be ischemia due to hypotension and the altered blood flow dynamics of surgery. Avoidance of induced hypotension and appropriate monitoring and fluid resuscitation can minimize the likelihood of spinal cord ischemia.

Umbilical artery catheterization frequently is used for both maintenance of fluid balance and administration of medications in neonatal intensive care units. If the catheter is advanced cephalad to T12, it is believed that a large bolus of fluid can cause ischemia owing to spasm, thrombosis, embolization of the anterior spinal vasculature or so-called artery of Adamkiewicz, or injection of hypertonic fluids or drugs into the spinal cord circulation (5 ,27 ,33 ,90). If the insult is of sufficient degree, spinal cord ischemia or infarction can occur (50). To avoid this complication, a catheter with a radiopaque tip is used, and a radiograph is obtained to ascertain the superior location of the tip of the catheter. If it is caudad to T12, spinal cord ischemia is unlikely.

Spinal Manipulation

Manipulation of the spine has direct consequences to the area treated and indirect consequences to the compensatory areas of the spine. Depending on the nature and magnitude of the force vectors, the changes may not all be desirable. For example, correction of scoliosis by means of distraction on the dorsal side of the spine induces kyphosis. This may be desirable in the thoracic spine but is deleterious in the lumbar spine. Correction of a scoliotic curve that is greater than the ability of the compensatory curve to compensate or that is corrected to an inappropriate end fusion level can cause truncal decompensation not present earlier and represents a new deformity. Spinal fusion for spinal deformity once was performed without instrumentation. Von Lackum (104), of the New York Orthopaedic Hospital, was among the pioneers and was highly aware of the risk of decompensation following spinal fusion. He started to apply surgical casts with the patient in the prone position to maintain lumbar lordosis and avoid a flat back.

Flat-Back Syndrome

Doherty (19) first described the problem of flat-back syndrome in 1973. In 1976, Moe and Denis (64) described a series of 16 patients with iatrogenic loss of lumbar lordosis; they coined the term *flat-back syndrome.* Moe and Denis commented on the little attention given to the flattening of the normal lumbar lordosis that occurs when a straight Harrington distraction rod is used to correct lumbar or thoracolumbar lateral curvature of the spine. When the entire lumbosacral spine is flattened, the patient cannot assume a normal erect stance and stoops forward, finding it necessary to bend both knees to bring the trunk into alignment with the pelvis. Moe and Denis found that this problem became particularly troublesome in the presence of pseudarthrosis or whenever the thoracic or thoracolumbar spine showed an increased amount of kyphosis. Denis (17a) later discussed the importance of hip flexion contracture in the pathogenesis of symptomatic flat-back syndrome.

Few children or adolescents are bothered by the typical syndrome as described, probably because they are flexible and have good compensatory mechanisms. Patients often compensate until they reach the middle of the fourth decade of life and then tend to stoop forward more, possibly because of decreasing muscle tone. This posture often is associated with evidence of early disc narrowing at the levels below the fusion; the result is an increasingly flat back. The lower the lumbar fusion, the more marked is the flattening (75 ,97). An increase in lordosis below the fusion does not compensate for the overall loss of lordosis (97). As patients age, the symptoms develop with a deformity characterized by decreased or absent lumbar lordosis, fixed forward inclination of the trunk, compensatory hyperextension of the cervical spine, inability to stand erect without flexion of the knees, and increasing fatigue and pain as the day progresses. The pain is muscular and is located in the upper back, lower cervical area, and knees. The most common problem, however, is inability to stand erect (48 ,49).

The primary cause of iatrogenic loss of lumbar lordosis is posterior distraction instrumentation of the lumbar spine that produces flexion forces. Several authors have examined the specific effects of posterior distraction on lumbar lordosis. Aaro and Ohlen (1) analyzed a series of 96 patients specifically in regard to the effect of Harrington distraction instrumentation on lumbar lordosis. The authors found that the loss of lumbar lordosis was proportional to the chosen distal level of fusion—the best case scenario being fusion that stopped at T12 and the worse case scenario being fusion that stopped at the sacrum. Other authors described the importance of positioning during instrumented fusions into the lumbar spine. Jackson and Denis (36a) both advocate placing the legs in extension to maintain lumbar lordosis. Third-generation, segmental instrumentation used to its potential should decrease the likelihood of loss of lordosis.

Loss of lordosis is not limited to posterior instrumentation. It has been found to occur after anterior Dwyer and Zielke instrumentation. The use of rigid rod anterior systems should decrease the kyphogenic nature of the older anterior instrumentation and thus maintain more physiologic lordosis.

Treatment

Maintenance of physiologic lordosis and, when possible, avoiding fusion into the lumbar spine can decrease the likelihood of development of flat-back syndrome later in life. Precautions taken during the operation, such as careful attention to detail, preservation of lumbar lordosis, hyperextension of the spine and hips, avoidance of distraction for correction, and appropriate contouring of the rods, pays dividends in the long run. Segmental fixation with hooks, wires, or screws secures and maintains lordosis. When anterior surgical intervention and fixation are indicated, solid rod designs and good interbody grafting techniques should minimize the kyphosing tendency of anterior correction of scoliosis.

Conservative therapy for symptomatic flat-back syndrome has proved over time to be less than satisfactory and usually is insufficient in relieving symptoms. Extensor strengthening exercises, hip capsule stretching, and analgesics can be prescribed in an attempt to decrease the symptoms in the hope that this might decrease the tendency to stoop. Bracing rarely is indicated unless the brace is expected to stabilize pseudarthrosis and decrease the related symptoms. Whenever bracing temporarily alleviates the symptoms, it tends to further weaken the extensor musculature and thus contribute to the problem.

Treatment of flat-back syndrome has been directed at restoring an upright position. Bilateral innominate osteotomy has been used, but no long-term results have been documented (19). Primary surgical treatment consists of realigning the spine in the sagittal plane by means of posterior closing wedge osteotomy or combined anterior spinal fusion (frequently to the sacrum because of degeneration in the lumbosacral discs) and multiple closing wedge osteotomies. Failure to restore balance in the sagittal plane predisposes to pseudarthrosis, which is associated with recurrent deformity.

Posterior closing wedge osteotomy is indicated in cases of mild to moderate iatrogenic loss of lumbar lordosis in the absence of marked thoracic hyperkyphosis. Return to true lordotic alignment of the lumbar spine after osteotomy is more likely to lead to solid fusion. Incomplete correction with persisting lumbar kyphosis is known for its greater likelihood of being complicated by pseudarthrosis, particularly among patients with osteoporosis.

Anterior spinal fusion combined with one or more closing wedge osteotomies is used when the lumbosacral discs have degenerated and iatrogenic loss of lumbar lordosis exists, particularly when there is a large amount of lumbar kyphosis. Anterior fusion combined with posterior osteotomy is more likely to maintain correction of lordosis (49). Anterior fusion is performed to decrease the rate of pseudarthrosis and to allow multiple levels for correction. Vertebrectomy or pedicle subtraction osteotomy can be used to obtain greater correction at one level. Some surgeons have recommended a simultaneous anterior and posterior approach, making it possible to use anterior struts after correction through a posterior osteotomy. Other surgeons recommend a three-stage procedure to allow for anterior structural grafts with less chance of displacement. Still other surgeons have not found this to be necessary and prefer cancellous grafts for the anterior fusion to avoid the risk of secondary displacement of anterior struts at the stage of posterior extension immediately after osteotomy.

Junctional Problems

Junctional problems are the presence of an angular change between two vertebrae. They usually occur at the end of an instrumented fusion between two curves. Junctional problems are most commonly occur and are described as a kyphotic problem, but a lateral change can be caused by the same mechanism. When a junctional problem is sharp forward angulation, it typically occurs at the cephalic or caudal end of a fused spine or between two scoliotic curves, usually at the thoracolumbar junction. Junctional kyphosis usually is associated with instrumented fusion and typically is associated with distraction against the end vertebra of the fusion. It can occur, however, with any type of instrumentation. In the transition between curves of different directions, forces are concentrated on opposing sides of the neutral axis and usually are in balance. Distraction or compression forces applied by instrumentation can upset the balance of forces on a motion segment and causes the sharp angular change. It appears plausible that these problems may be related to changes that affect the ability of the spine to maintain equilibrium of the forces on a spinal motion segment. Patients with underlying neurologic disorders or collagen diseases in which the tensile strength of tissue is reduced may be more prone to this deformity than are others (1a) (Fig. 8). The changes can be made worse if surgical exposure destabilizes the area. Imbalance also occurs if the correction of one curve exceeds the ability of a compensatory curve to correct, thus focusing stress on the transition vertebra. The change can occur immediately after the operation or many years thereafter, because the fusion can allow a concentration of stress at the ends of the fusion, which can cause early degenerative changes or instability.

Junctional kyphosis is most likely to occur at the site of preexisting kyphosis. It is therefore more likely to occur at the mid- or upper thoracic spine, where kyphosis normally is present. Use of distraction hooks that apply an excessive distraction force to the most cephalic vertebra can increase kyphosis. Excessive intraoperative distraction can tear the supraspinous, intraspinous, and posterior longitudinal ligaments of the upper- or lowermost vertebra. This was much more common in the era of the Harrington rod and is less so with use of third-generation spinal instrumentation, which does not depend on distraction as the primary method of correction. If ligamentous injury is suspected, wiring of the two adjacent end spinous processes has been advocated as a way to prevent this complication.

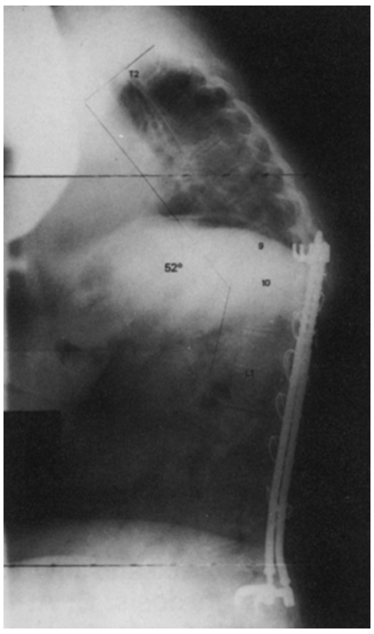

FIGURE 8. Junctional kyphosis in a 17-year-2-month-old nonambulatory female with myelodysplasia fused six years previously for a 58-degree right thoracolumbar scoliosis. Even though mild lumbar lordosis was maintained, junctional kyphosis occurred at the site of normal thoracic kyphosis apex.

Treatment

Prevention remains the best treatment to avoid the potential need for additional reconstructive surgery. To prevent these junctional problems from developing, the surgeon must attempt to identify situations that cause risk and take steps to avoid the complication. These steps should include avoidance of overdistraction, overcorrection beyond the compensatory curve, and an attempt to not terminate instrumentation at the mid- or low thoracic level (1a ,54 ,83). If junctional kyphosis exists between two curves, the fusion should cross this kyphosis and represent an attempt to correct it when possible. Neutral coronal and sagittal alignment should be obtained to minimize decompensation and excessive stress on the fusion or instrumentation; the stress can cause instrumentation failure and pseudarthrosis. Late reconstruction of junctional curves necessitates extension of the fusion and possibly osteotomy for correction of the curve and restoration of balance to the spine (13).

Wrong Levels and Overcorrection

Judgment errors in the choice of level of fusion in correction of spinal deformities can cause new deformities. The choice of which curves to fuse, which levels to include, and which mechanism to use for correction and stabilization is not without controversy (54). The controversy arises from the problems some patients have had with decompensation and new deformity after correction of scoliosis. The two curve patterns that have the most controversy surrounding them are the King II and King V curves. King and Moe (41a) described the King V curve, also known as the *double thoracic curve pattern* to bring attention to the high thoracic curve and the problems that occur if this curve is not identified and addressed. When the structurally high thoracic curve is not corrected and is fused along with the larger lower thoracic curve, the left shoulder typically becomes noticeably elevated (52). Although this elevation may not be evident to the family and others before the operation, it usually is evident afterward. Inclusion of this curve with fusion to T2 avoids this problem.

The King II curve has been the subject of controversy related to decompensation with third-generation spinal instrumentation (54). The controversy is not yet resolved but seems to relate to the correction power and mechanism of the newer instrumentation systems and the size and flexibility of the lumbar curve. Several reports regarding decompensation after third-generation instrumentation at the fusion levels recommended by King have caused some authors to advocate new “rules” for the management of these curves (see Chapter 21). If decompensation occurs after surgery for the King II curve, the options for treatment include bracing to see whether the spine becomes balanced over time and extension of the fusion further caudad to obtain balance (13).

Alteration of the Base of the Spine (Pisa Principle)

The spine arises from its base, the sacrum, as a tower. The sacrum is suspended in the pelvis as the foundation for the spine. Changes in the orientation of this foundation cause deformity of the spine. The spine attempts to hold the head erect above the pelvis. If the sacrum starts to incline to the right, the spine either decompensates to the right or develops a curve to bring the head back in line. Lordosis and kyphosis likewise usually keep the head above the sacrum. Flexing or extending the sacral inclination changes the lordosis or kyphosis and can take the head out of balance.

A stable foundation for the spine necessitates symmetry in leg length and pelvis and symmetric and normal motion of the hips and knees. Changes to the foundation can cause iatrogenic deformities. Contractures of the hips and knees and leg length discrepancy are the most likely causes of this deformity. Changes in the size of the pelvis, possibly after surgical treatment, also can cause deformity. Treatment is aimed at restoring a stable and balanced spine and pelvis. This can be done with lifts or with adjustment of leg length by means of growth arrest or other lengthening or shortening procedures. Joint contractures should be addressed with stretching and, when necessary, surgical release.

Marfan Syndrome

S. Jay Kumar

James T. Guille

S.J. Kumar: Departments of Orthopaedics, Thomas Jefferson University Hospital, Philadelphia, Pennsylvania 19107.

J.T. Guille: Medical College of Pennsylvania–Hahnemann University Program in Orthopaedic Surgery, Philadelphia, PA 19120.

Marfan syndrome is a generalized disorder of connective tissue that affects the supporting structures of the body, especially those in the musculoskeletal system. In 1896, Marfan published his report of a girl who had the features of what is now eponymically known as *Marfan syndrome* (29 ,32). The syndrome is defined by the clinical features that have become the hallmark of the condition, especially the phenotypic body habitus. Because of the wide pleiotropic expression of this autosomal dominant disorder, patients usually are considered to belong to one of two groups—those having Marfan syndrome and those having the Marfan habitus (marfanoid). The variability in this expression can make prognostication and genetic counseling difficult and indecisive (8 ,40 ,42). Marfan syndrome often is misdiagnosed as homocystinuria, Ehlers-Danlos syndrome, congenital contractural arachnodactyly, and many other conditions because of the wide expression of the gene (3 ,6 ,7 ,19 ,26 ,56). Ligamentous laxity and joint hypermobility with muscular underdevelopment can appear as primary myopathy among children (15). Patients with Marfan syndrome are of normal intelligence. Any variations in this factor should lead one to suspect another cause of the condition, such as homocystinuria, in which mental retardation is common. Careful examination and history taking, with special attention to specific diagnostic details, should avoid any errors in diagnosis. A collaborative multidisciplinary approach should be used in the care of these patients.

Epidemiology

The prevalence of Marfan syndrome has been estimated to be one case among in 10,000 persons in the United States (14). Because there is considerable variability in this syndrome, one must question the true incidence, considering the possible inclusion of those with the Marfan habitus or misdiagnoses in older studies. There is no ethnic or racial predilection for Marfan syndrome, and men and women are affected equally. Marfan syndrome is inherited as an autosomal dominant gene, and spontaneous new mutations account for approximately 25% of cases among persons who do not have a family history of the disorder (37). The average life expectancy among persons with Marfan syndrome once was 40 years for men and 45 years for women. These figures may be inaccurate today. They were calculated before improvements were made in treatment modalities, especially in cardiovascular surgery, that can extend the life span of these individuals (36).

Etiology

The genetic defect that causes Marfan syndrome has been identified (10 ,23 ,30 ,31). A mutation of the fibrillin gene seems to be the key factor, and the specific locale of the gene FBN1 has been mapped to the q arm of chromosome 15 (15q21.1). Fibrillin is a large glycoprotein component of the microfibrillar system associated with elastin and is thus present in connective tissues.

Clinical Features

Even though there is extensive phenotypic variation, Marfan syndrome has one of the most recognizable of all phenotypes. Recognition of the characteristics of this phenotype is of the utmost importance, because the syndrome is defined predominantly by its clinical features. A diagnostic tree has been published by the American Academy of Pediatrics that lists major and minor criteria of the following areas: skeletal system, ocular system, cardiovascular system, pulmonary system, skin and integument, dura, and family and genetic history (8). The requirements for the diagnosis of Marfan syndrome are as follows. If there is no family history, there needs to be a major criterion in two different organ systems and involvement of a third organ system. If there is a family history, there need be only one major criterion in an organ system and involvement of a second organ system. Patients who have the phenotypic features but who do not meet the aforementioned criteria are considered to have the Marfan habitus. Patients who are evaluated in the orthopaedic clinic with typical findings should be referred for pediatric, genetic, cardiac, and ophthalmologic evaluations as well.

Spinal Deformities

Scoliosis

The spine is involved in most patients with Marfan syndrome. Scoliosis is the most common spinal deformity among these patients, and it is also the most insidious (1 ,5 ,22 ,43 ,44). It is difficult to assess the exact prevalence of scoliosis in Marfan syndrome, because many of the reports are from tertiary referral centers for scoliosis, and different studies use different terms and diagnostic criteria. Scoliosis is common among the infantile and juvenile age groups, and 50% of patients who have scoliosis have it by 6 years of age; almost all have it by 9 years of age (15). Many curves progress early and rapidly. The curve types have been said to resemble those of patients with idiopathic scoliosis. They include single curves, double structural curves, triple curves, or long, sweeping C-shaped thoracolumbar curves. Unlike idiopathic scoliosis, however, these curves continue to progress throughout adolescence (Fig. 1). Many of these curves are quite rigid, although one would expect flexible curves because of ligamentous laxity. Ligamentous laxity is considered one of the causes of scoliosis (15 ,44). Lateral subluxation and dysplasia of vertebrae are frequent (Fig. 2).

The following sections on scoliosis have been divided as they relate to patients with Marfan syndrome and those with the Marfan habitus (so-called marfanoid), because the two should be considered as separate entities. Treatment, however, is standard for patients in either category.

Marfan Syndrome

Course of Condition

The course of spinal deformity in Marfan syndrome is not well delineated. Many studies are flawed by the inclusion of patients with Marfan habitus. Despite this shortcoming, several tenets are generally accepted. It appears that men and women are affected almost equally. The curve patterns are similar to those of idiopathic scoliosis, although double major curves seem to be more common in Marfan syndrome. Scoliosis manifests itself during the infantile and juvenile periods, and some children may come to medical attention early adolescence with curves of large magnitude. Most authors on the subject have found that scoliosis in Marfan syndrome is severe, painful, progressive, and can cause respiratory problems (5 ,28 ,43 ,44). Scoliosis among patients with Marfan syndrome should not be considered idiopathic scoliosis; it behaves more as neuromuscular scoliosis.

The prevalence of scoliosis among patients with Marfan syndrome ranges from 52% to 100% (5 ,20 ,28 ,39 ,43 ,47). The curves are progressive. If the patients are left untreated, it is not uncommon to see curves of 180 degrees (43 ,44 ,52). The average age at diagnosis of the scoliosis has ranged from birth to 15 years, most cases being diagnosed in the late juvenile period (28 ,43 ,44 ,46 ,47 ,48 ,52).

Presentation

Pain was a presenting symptom for 20 of the 27 patients (74%) in the series of Makin et al. (28). The combined data for both patients with Marfan syndrome and patients with Marfan habitus in the series of Robins et al. (43) revealed that 74% of patients had pain. The patients in the series of Sponseller et al. (48) reported their back pain to be localized to the area of the curve, not in the low back. The subject of back pain among these patients appears inconsistently in the literature, and its nature is vague and unknown. The importance of the pain is unclear other than that Marfan syndrome may be one cause of painful scoliosis.

Curve Types

There is debate in the literature whether single or double curves are more common, although it is generally accepted that double major curves often are severe and rigid. Double major curves predominate in most series, and when single curves exist, the apex is usually in the right thoracic area. There is also an increased prevalence of triple curves and thoracolumbar curves among these patients (5 ,20 ,22 ,28 ,43 ,44 ,47 ,52 ,57). Fixed pelvic obliquity has not been reported among Marfan patients (43 ,52 ,59).

Curve Magnitude and Progression

Curve progression in patients with Marfan syndrome is rapid, often to the point of severe deformity. In LeDelliou's (22) series of 59 patients, 11 patients had curves greater than 100 degrees, 19 had curves less than 50 degrees, and only eight had curves less than 30 degrees. The average curve magnitude at the time of presentation (average age, 9.3 years) was 53.5 degrees for the patients with Marfan syndrome in the series of Taneja and Manning (52), who calculated an average rate of progression of 10.2 degrees per year. Robins et al. (43) did not differentiate the values for patient with Marfan syndrome and those with Marfan habitus, but for both groups the mean preoperative curve was 72 degrees and rigid, as demonstrated by a side-bending correction of only 50%. They also found curve progression to be most rapid during the early adolescent period. In Daudon's series (9), the greatest curve progression was observed during the adolescent period. Male patients had an average curve progression of 7.2 degrees per year and female patients 5.8 degrees per year. Sponseller et al. (47) calculated the mean yearly progression of scoliosis for different age groups. There was a mean progression of 19 ± 17 degrees in the 0 to 3 years age group, 3 ± 4 degrees in the 4 to 10 years age group, 6 ± 9 degrees in the 11 to 16 years age group, 1 ± 2 degrees in the 17 to 30 years age group, 1 ± 7 degrees in the 31 to 40 years age group, 1 ± 1 degree in the 41 to 50 years age group, and 3 ± 5 degrees in patients older than 50 years. These authors showed that all curves greater than 30 degrees progressed at least 10 degrees, and all curves were at least 40 degrees by skeletal maturity.

Infantile Scoliosis

Sponseller et al. (48) reported on 14 patients with scoliosis diagnosed before the patient was 3 years old. Unlike idiopathic infantile scoliosis, no curve resolved spontaneously, there was no left thoracic curve, and there was an almost equal distribution of boys and girls. Thirteen of the 14 patients did not have a family history of Marfan syndrome, and all 14 had exaggeration of the syndromic features. The mean curve magnitude was 38 degrees, and 11 of the curves were double major. Bracing had no effect, and instrumentation without fusion was recommended only for patients without marked kyphosis. These authors suggested that surgery not be performed on children younger than 4 years, because many with large curves die of cardiac problems early in life.

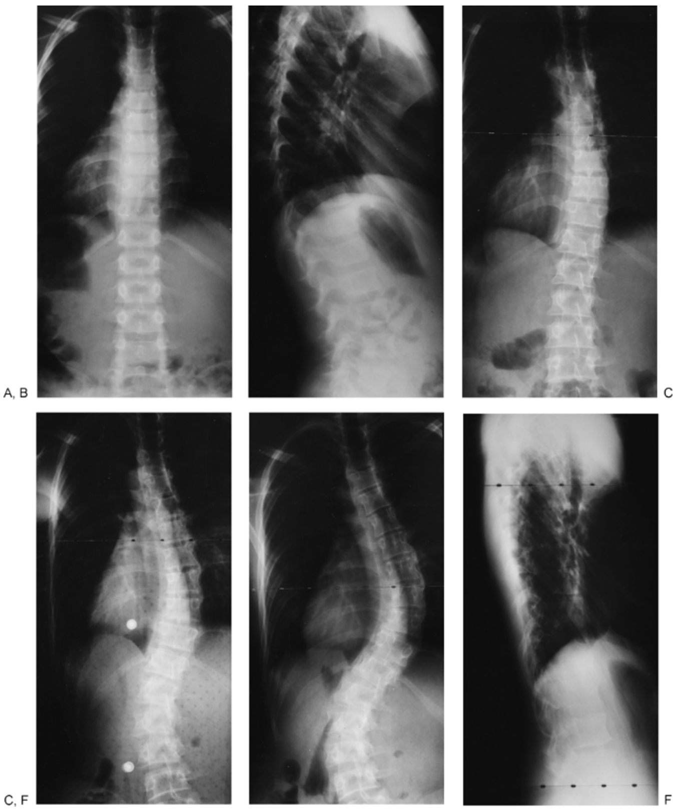

FIGURE 1. Anteroposterior **(A)** and lateral **(B)** radiographs of a 4-year-old girl with Marfan syndrome show no scoliosis and normal sagittal alignment. **C:** At age 12 years, there is a right thoracic curve of 17 degrees, and the patient was placed in a Wilmington jacket. **D:** At age 13 years, the right thoracic curve has progressed to 29 degrees despite compliant use of the brace. There is now a left lumbar curve of 30 degrees. Anteroposterior **(E)** and lateral **(F)** radiographs at the age of 14 years show a right thoracic curve of 62 degrees, a left lumbar curve of 52 degrees, and loss of thoracic kyphosis and lumbar lordosis.

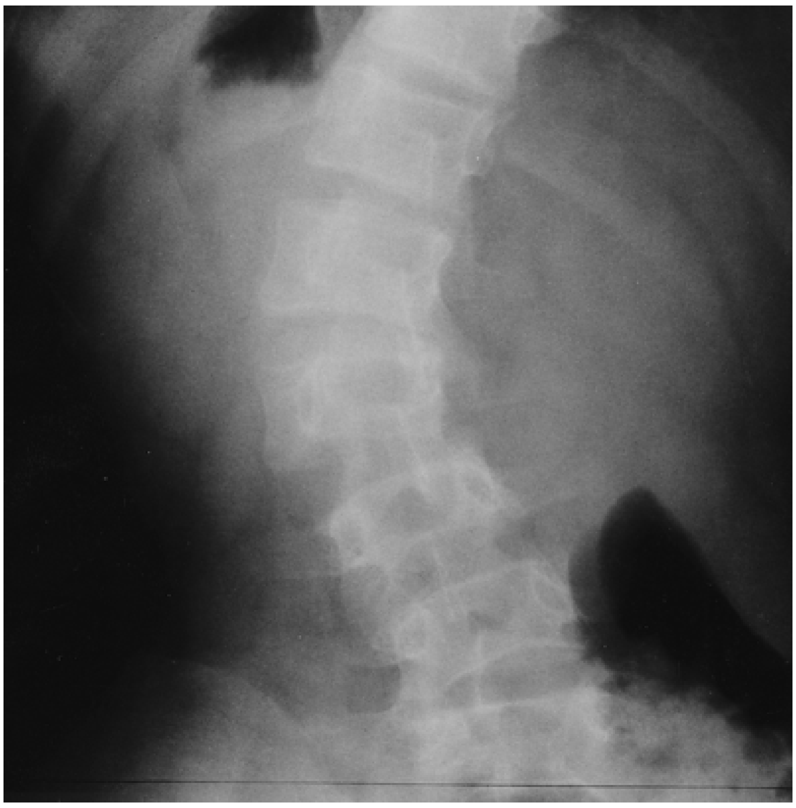

FIGURE 2. Anteroposterior radiograph shows dysplasia, subluxation, and marked rotation of the lumbar vertebrae. This situation can be exacerbated if the distal extent of the fusion ends amid these vertebrae or if a derotation maneuver is performed.

Patients with Marfan Habitus

Natural History

The prevalence of scoliosis among persons with Marfan habitus ranges from 34% to 88% (12 ,20 ,28 ,43 ,52).

Age at Onset

The age at onset of scoliosis among patients with Marfan habitus is similar to that among patients with the true syndrome. In this group, the average age at presentation ranges from 8.7 years to 10.5 years (43 ,52). In one series the scoliosis of seven of eight patients became apparent in the adolescent age period (43).

Presentation

No patient with the Marfan habitus in the series of Makin et al. (28) had back pain. In the series of Robins et al. (43), eight of 19 patients (42%) had scoliosis, and five of these had back pain. Fixed pelvic obliquity has not been reported among these patients.

Curve Types

Whereas double curves appear to predominate among patients with Marfan syndrome, patients with Marfan habitus appear to have a predominance of single curve patterns, especially right thoracic and thoracolumbar curves.

Curve Magnitude and Progression

The average curve at presentation (average age, 11.3 years) was 53.6 degrees in the series of Taneja and Manning (52), who also found curve progression (average, 10.5 degrees per year) to be slightly more rapid among patients with Marfan habitus than among those with Marfan syndrome. On the contrary, the patients with Marfan habitus in the report of Joseph et al. (20) appeared to have less rapid progression.

Treatment Recommendations

Nonoperative

Although it is generally accepted that the scoliosis associated with Marfan syndrome is probably recalcitrant to treatment with orthotic devices, an initial attempt should be made to manage the curves with an appropriate brace. We believe that once the curve reaches 20 degrees, consideration should be given to fitting a brace. Many patients experience difficulty in brace wear because of their asthenic body type or the presence of anterior chest wall deformities (52). Many authors believe that bracing is effective in holding in place a curve in a younger child until spinal fusion can be performed at an older age (35 ,43 ,44 ,52). Most researchers, however, have come to the conclusion that brace treatment is generally ineffective in preventing the need for spinal fusion.

Operative

Posterior spinal fusion should be considered once a curve reaches a magnitude greater than 40 degrees or if there is a rapid or documented progression of curve magnitude. Savini et al. (44) suggested fusion for curves greater than 50 degrees. There appears to be a higher than normal occurrence of mechanical problems with instrumentation and of pseudarthrosis (1 ,4 ,5 ,43 ,44), although this issue is debatable (52 ,60). For concomitant kyphosis, most authors recommend the addition of an anterior procedure (1 ,4 ,5 ,44). Most of these patients can safely undergo the rigors of spinal surgery if a thorough preoperative evaluation is performed.

Preoperative Considerations

Preoperative cardiac and pulmonary examinations should be meticulously performed and the results carefully weighed. Hemodynamic changes usually are poorly tolerated by patients with mitral and aortic regurgitation or aortic aneurysm. Goldberg (15) mentioned the theoretical possibility that overdistraction of the spine may transmit forces to the mediastinum and an intrinsically weak aortic root. Curve correction should not exceed the correction observed on preoperative side-bending radiographs. Patients with concomitant thoracic lordosis and pectus excavatum may encounter respiratory insufficiency at the time of the operation because of the compromise in chest space. Most surgeons agree, however, that the presence of cardiovascular abnormalities is not an absolute contraindication to spinal surgery. Mesrobian and Epps (33) believe that the preoperative evaluation should include elicitation for a history of dyspnea in various positions, a review of the tracheal air column on preoperative radiographs, and pulmonary function tests with flow volume loops in standing, prone, and supine positions.

The blood needs of these patients can be met safely with the use of predeposited autologous blood and meticulous hemostasis. MacEwen et al. (27) showed that the blood needs of patients weighing even less than 45 kg can be met by an autologous blood program without a concomitant increase in morbidity. Loder et al. (25) published an article concerning the use of somatosensory evoked potentials in operations on patients with nonidiopathic scoliosis. In their series, three patients had scoliosis associated with Marfan syndrome. In every instance, a somatosensory evoked potential was elicited. Thus this intraoperative monitoring modality should be used in operations on patients with Marfan syndrome in a manner comparable with its use in operations on patients with idiopathic scoliosis along with the monitoring of motor-evoked potentials. A wake-up test should be performed in the absence of motor-evoked potentials.

Surgical Options

Posterior spinal fusion with autogenous iliac crest bone graft and instrumentation is the mainstay in the treatment of scoliosis. Many studies report the use of no instrumentation or of Harrington distraction rods with good results (43 ,44 ,52 ,57). Isolated reports have appeared concerning the use of segmental fixation and multihook systems. Sublaminar wires, whether used in conjunction with Harrington rods or standard Luque or Unit rod instrumentation, have the advantage of restoring kyphosis to the hyperlordotic thoracic spine in selected patients. Wisconsin wiring can be used in conjunction with Harrington rods for added stability. Because these curves often are quite rigid, the effectiveness of the derotation maneuver with the Cotrel-Dubousset technique is not certain. Fusion to the sacrum has not been reported and is probably rarely indicated. Rigid curves may require anterior release and fusion before the posterior procedure, however, no patient in our series needed an anterior procedure. Preoperative traction is rarely effective and is not used. Side-bending radiographs should be used to determine curve flexibility and fusion levels. We disagree with Donaldson and Brown (11), who recommend using the same guidelines for choosing fusion levels as for patients with idiopathic scoliosis. It is mandatory that all curves, including compensatory curves, be fused. Use of the criteria set forth by King et al. (21) for the selection of fusion levels is not applicable to the patient population with Marfan syndrome (Fig. 3).

The role of subcutaneous Harrington instrumentation in the care of very young children with much growth potential is debatable. Joseph et al. (20) described a 4-year-old girl with a 90-degree curve that had progressed despite bracing. The girl was treated with limited posterior fusion and a subcutaneous Harrington rod. Fifty percent correction was achieved, but the patient still had complications. Sponseller et al. (47) treated three patients with a Harrington rod without fusion at a mean age of 3 years. The curves ranged from 60 to 80 degrees before surgery, and the treatment lasted an average of 30 months. Two cases of inferior rod dislodgment occurred.

Postoperative Management

Important considerations should be given to the postoperative management of these patients. Although the guidelines are essentially the same as those for any operation of this magnitude, careful attention should be given to the type of immobilization used. Hook displacement and dislodgment and pseudarthrosis have been reported among patients who received inadequate or no postoperative immobilization (1 ,62). Even patients who have supplemental sublaminar wires or multihook systems should have some form of postoperative immobilization.

Complications

There is debate whether patients with Marfan syndrome have a higher incidence of complications after spinal surgery than do other patients (5 ,60). It is important to analyze whether the complications are caused by extraneous factors, such as the type of instrumentation, or whether intrinsic factors of the syndrome are responsible for the complications.

Mechanical problems with instrumentation have been reported, although these may be related to the type of instrumentation and lack of postoperative immobilization rather than the patient's condition.

Amis and Herring (1) reported a case of iatrogenic kyphosis following operative correction of 50-degree right lumbar scoliosis managed with Harrington compression and distraction rods from T10 to L5. Forceful distraction caused dislocation of the facet joint and disruption of the disc space, which caused severe progressive kyphosis. The curve had corrected completely, which was 25 degrees more than that achieved on the side-bending radiographs. The patient was immobilized postoperatively with a Jewett brace. A postoperative lateral radiograph showed iatrogenic kyphosis with posterior wedging of the disc space between T11 and T12, facet joint distraction, and an avulsed fragment from the body of T11. Eighteen months later the kyphosis measured 70 degrees. The instrumentation was removed, and anterior discectomy with rib strut grafting was performed. Two weeks later posterior spinal fusion was performed with with Harrington instrumentation and autogenous iliac crest bone grafting. Two pseudarthroses were found at the operation. The authors speculated that if a body cast had been used, the pseudarthroses might not have developed. They concluded that in the care of patients with ligamentous laxity, compression instrumentation should extend through the uppermost instrumented vertebra, excessive distraction forces should not be used, and the degree of correction should not exceed that obtained on the preoperative side-bending radiographs.

Winter and Anderson (62) reported that one patient with Marfan syndrome underwent posterior spinal fusion with a Harrington distraction rod and sublaminar wires. The curve had been corrected to 2 degrees. No postoperative immobilization was used, and the patient subsequently dislodged the inferior hook, lost the curve correction, and had pseudarthrosis. These authors suggested wiring the two most distal spinous processes together to prevent this complication.

Taneja and Manning (52) had a patient in whom the upper Harrington hook cut through the facet joint. Savini et al. (44) treated four patients who had rotation of the upper Harrington hook and three who had dislodgment of the lower hook, two of which dislodged after rupture of the laminae due to pseudarthrosis. Savini et al. concluded that Harrington instrumentation is useful but that vertebral dysplasia causes a higher frequency of mechanical problems.

Hutchinson and Bassett (18) reported a case of superior mesenteric artery syndrome in a girl with Marfan syndrome who underwent posterior spinal fusion in situ. The girl was in the eightieth percentile for height and the seventh percentile for weight. One week after the operation, the patient was placed in

a body cast, which corrected the curve to 35 degrees. The patient was treated with intravenous fluids and nasogastric suctioning, and the cast was removed, thus resolving the symptoms.

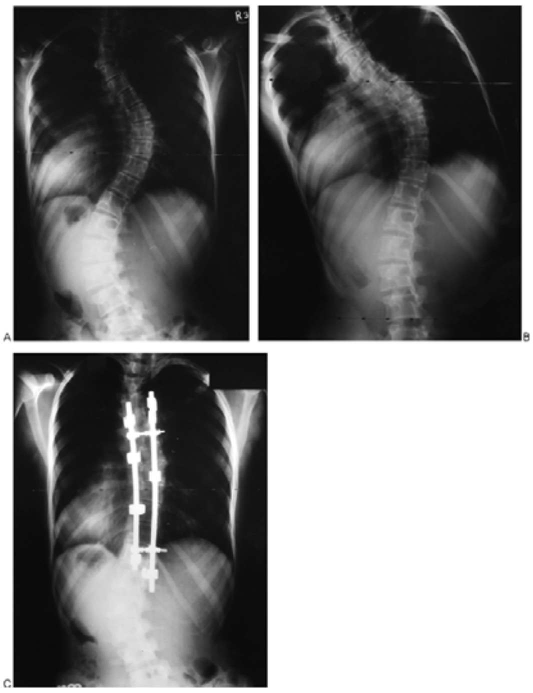

FIGURE 3. A: Anteroposterior radiograph of a 14-year-old girl with a 40-degree left cervicothoracic curve, 62-degree right thoracic curve, and 56-degree left lumbar curve. **B:** Preoperative side-bending radiographs show correction of the lumbar curve to 22 degrees. **C:** Two years postoperatively the lumbar curve has progressed to 44 degrees. Fusion should have been performed at the beginning.

It is a commonly held belief that patients with Marfan syndrome tend to have a higher incidence of pseudarthrosis than do other patients. Although pseudarthrosis has been reported in many series, the true incidence remains unknown. Birch and Herring (5) were able to achieve only three solid fusions in nine patients who underwent posterior spinal fusion. The rest of the patients had pseudarthrosis and complications. Five patients with pseudarthrosis occurred in the series of Robins et al. (43), even though the surgeons had used meticulous technique and autogenous bone graft. Makin et al. (28) and Taneja and Manning (52) each described one patient with this complication. Winter (57) had treated three patients who had pseudarthrosis; all patients had double curves. In the series of Savini et al. (44), two patients treated with bank bone had pseudarthrosis. Amis and Herring (1) attributed the two cases of pseudarthrosis that occurred in their patient to the lack of adequate postoperative immobilization. Winter and Anderson (62) also treated a patient who had no postoperative immobilization and who had multiple pseudarthroses. Sponseller et al. (48) had only one young patient who had pseudarthrosis. There was no case of pseudarthrosis or hardware failure in our series. We attributed this to meticulous exposure and decortication with facet fusion and the use of autogenous iliac crest bone and postoperative immobilization in an underarm orthosis (Fig. 4).

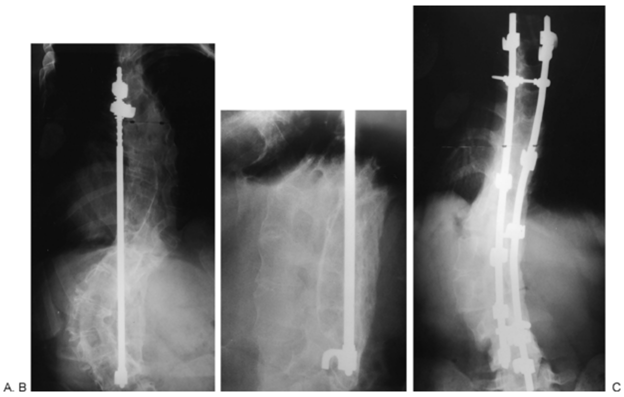

FIGURE 4. Anteroposterior **(A)** and lateral **(B)** radiographs of Harrington instrumentation. **C:** Anteroposterior radiograph of Cotrel-Dubousset instrumentation. Solid fusion mass is present in both cases, regardless of the type of instrumentation, with no hardware failure or pseudarthrosis at long-term follow-up evaluation.

Respiratory failure caused by kyphoscoliosis led to cor pulmonale in a patient with scoliosis greater than 100 degrees, kyphosis greater than 20 degrees, and a vital capacity less than 1 L (54). This was therefore not a complication of the operation but of the patient's condition. Mesrobian and Epps (33) reported a midthoracic tracheal obstruction caused by Harrington rod displacement in a boy who underwent posterior spinal fusion with Harrington compression and distraction rods for severe scoliosis. Preoperative radiographs revealed that the patient had thoracic lordosis with close approximation of the sternum and thoracic vertebrae at the level of the thoracic outlet. A postoperative radiograph showed complete loss of the tracheal air column at the same level. The authors speculated that the combination of structural weakness of the cartilaginous sternochondral junction and trachea, dilatation of the aortic root, and abnormal vertebral curvature contributed to this problem.

Results Obtained or to Be Expected

In the report of Taneja and Manning (52), the average correction obtained was 38.2%, the final curve showing an average loss of 9.9 degrees of correction. Robins et al. (43) reported an overall average correction of 41%, which they believed to be comparable with that seen in idiopathic scoliosis. The patient of Makin et al. (28) had an average 44% correction, whereas correction ranged from 10% to 81% in the series of Joseph et al. (20). Winter (57) reported almost no loss of postoperative correction at follow-up evaluations in his series. Winter and Anderson (62) reported the results of posterior spinal fusion with sublaminar wiring for 100 patients, five of whom had Marfan syndrome. The average preoperative curve among these patients was 52 degrees, and the average curve at follow-up evaluations was 29 degrees, representing an average curve correction of 33 degrees. Sponseller et al. (48) reported the results for nine children who underwent surgery at a mean age of 6.6 years. The mean immediate postoperative correction was 51%; however, after a mean follow-up period of 4 years, this correction was only 20%. The five patients treated with segmental fixation and Luque rods had a mean correction of 29%, whereas those treated with Harrington rod instrumentation had a mean correction of only 3%.

Miscellaneous Deformities

Sinclair et al. (45) reported the skeletal manifestations in 40 Marfan patients according to those thought to be caused by tissue and ligamentous laxity and those that were incidental findings. These included loss of normal lordosis in the cervical spine; thoracic kyphosis, scoliosis, rotation, “slipping” of vertebrae, compression fractures, and osteochondral dystrophy; and lumbar spondylolisthesis and vertebral dysplasia. Incidental findings included cervical spina bifida and congenital fusion, thoracic epiphysitis, and lumbar spina bifida. Seven patients had back pain. Additional problems listed included sacroiliac sclerosis, lumbar scoliosis, congenital fusion of sacroiliac joints, flattening of the thoracic vertebrae, and osteochondritis of the thoracic and lumbar vertebrae. There was no mention of treatment or subsequent outcome. Tallroth et al. (51) reported an 18% prevalence of lumbosacral transitional vertebra in their series (4% to 6% in the normal population) as well as the appearance of biconcave vertebral bodies, also known as *codfish vertebra.*

Thoracic Lordosis

Patients with Marfan syndrome may have a reversal of the normal sagittal alignment of the spine (Fig. 5). Thoracic lordosis or lumbar kyphosis occurs in some of these patients. Thoracic lordosis, especially in combination with pectus excavatum, can cause respiratory difficulty because of the narrowed anteroposterior (sternovertebral) diameter of the chest. The thoracic lordosis usually is associated with concomitant loss of normal lumbar lordosis (Fig. 6). Approximately two thirds of patients with Marfan syndrome have thoracic lordosis, regardless of the presence of scoliosis (15). Sponseller et al. (47) reported five variations in the sagittal alignment of the spine among these patients. Winter (61) reported the results of treatment of two patients for thoracic lordoscoliosis. The operative technique entailed the use of paired, square-ended Harrington distraction rods, square-ended hooks, and sublaminar wires. In no instance did wire cut through the laminae or did postoperative wire breakage occur.

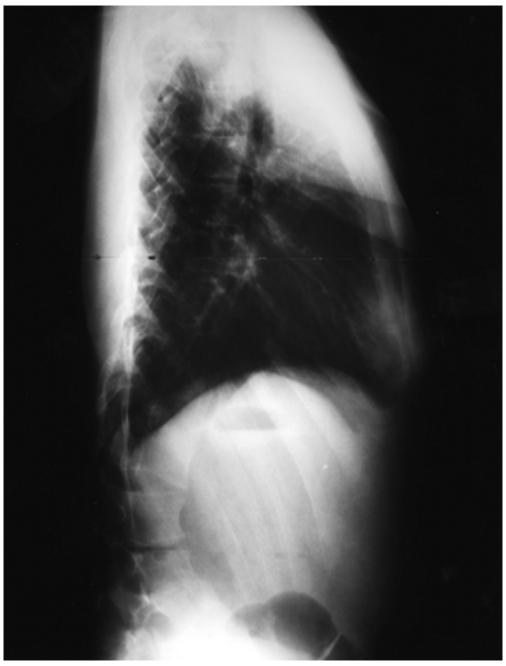

FIGURE 5. Lateral radiograph shows reversal of normal sagittal alignment, thoracic lordosis, and lumbar kyphosis.

Thoracic and Thoracolumbar Kyphosis

Approximately 10% of patients with Marfan syndrome have thoracic and thoracolumbar kyphosis, which usually manifests late in infancy or early in childhood and is most obvious when the child is sitting. Exercises to improve muscle tone often result in improvement, but many cases persist and progress during adolescence (15). Radiographically this deformity can mimic Scheuermann disease in that end plate irregularities often are noticed; Scheuermann disease, however, rarely occurs in the thoracolumbar spine.

Kyphosis of the thoracic spine has been reported among patients with Marfan syndrome, although Winter stated that it is rare (57). Sponseller et al. (47) reported that 41% of their patients had kyphosis greater than 50 degrees. It is usually part of the scoliotic deformity, causing kyphoscoliosis. Taneja and Manning (52) found a 45% incidence of “marked” kyphosis among their patients with Marfan syndrome and 11% among the patients with Marfan habitus. Savini et al. (44) had three patients with kyphosis that ranged from 50 to 100 degrees. Makin et al. (28) and Joseph et al. (20) each had three patients with kyphosis. Concomitant kyphosis can cause difficulties in treatment, as evidenced by the cases of Amis and Herring (1) and Birch and Herring (5). In the report of Birch and Herring, Luque instrumentation failed in one patient with thoracolumbar kyphosis, leading to pseudarthrosis. They suggested anterior and posterior fusion for kyphosis. However, this method of treatment was not without problems; four patients with pseudarthrosis and kyphosis who had anterior and posterior operations had a total of 19 procedures, leading the surgeons to recommend segmental fixation with massive amounts of bone graft.

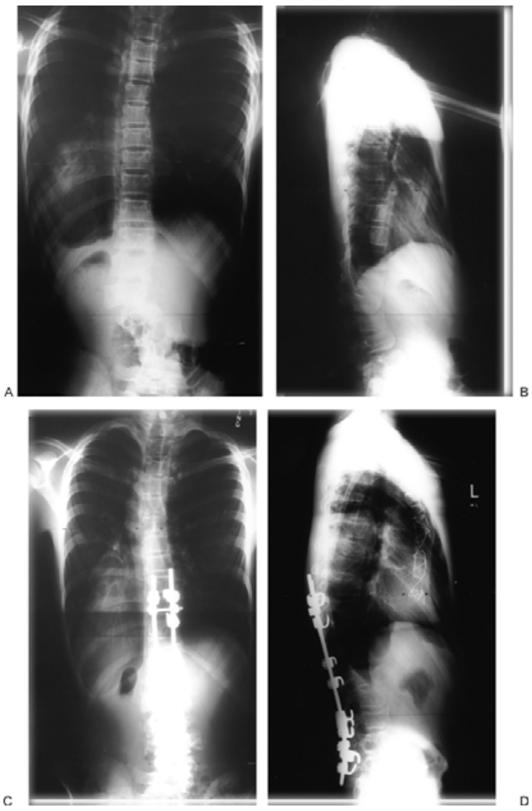

FIGURE 6. A 14-year-old boy with Marfan syndrome and progressive lumbar kyphosis and scoliosis. **A:** Anteroposterior view shows marked rotation in the lumbar curve with translatory shifts of L2 on L3 and L3 on L4. **B:** Marked lumbar kyphosis is visible with posture subluxation of L3 on L4 and secondary adaptive changes in vertebral shape. **C, D:** The patient was successfully treated by posterior spinal fusion and instrumentation. Cervical Spine Deformities

Levander et al. (24) reported the case of a woman with Marfan syndrome who had exaggerated deep tendon reflexes and paresthesia and weakness in all extremities when her head was flexed. Functional stenosis with flexion was found to be the cause of the neurologic symptoms, and occipitocervical stabilization relieved the symptoms. Nelson (38) reported the case of a patient with vertebral dysplasia in the cervical spine. The bodies of C3, C4, and C5 were tall and narrow with posterior scalloping, the importance of which was not discussed. Sinclair et al. (45) also described anomalies in the cervical spine. Yajnik et al. (63) reported the case of a patient with basilar impression. Hobbs et al. (17) reported a prevalence of focal kyphosis of 16%, and 35% of the patients had a loss of normal cervical lordosis. Hobbs et al. also found increased atlantoaxial translation in 54% of the patients and basilar impression in 36%. There was no increased frequency of developmental spinal stenosis or neck pain.

Congenital Spine Deformities

There is no report in the literature that deals solely with the topic of congenital spinal deformity in association with Marfan syndrome. It would seem that the appearance of scoliosis with congenital dysplasia of the vertebrae is incidental.

Spondylolisthesis

Spondylolisthesis has been reported infrequently among patients with Marfan syndrome (Fig. 7). Taylor (53) speculated that it is a result of the ligamentous laxity and poor musculature that occurs among these patients. In most reported cases, the deformity is described as severe (44 ,53 ,58). Makin et al. (28) described four patients who had either spondylolisthesis or spondylolysis; however, these authors did not differentiate between patients with true Marfan syndrome and those with Marfan habitus, nor did they comment on treatment or outcome. In the report by Sinclair et al. (45), spondylolisthesis is mentioned; one patient was found to have posterior slipping of L2 on L3. Sponseller et al. (47) reported a prevalence of spondylolisthesis of 6% among patients with Marfan syndrome, compared with 3% among the general population. The average slip was 30%, compared with 15% among otherwise healthy patients. Patients with the typical findings of lumbosacral step-off, flat buttocks, tight hamstrings (limited straight leg raising), and radicular pain in the backs of the legs should have undergo additional studies to delineate the cause. We believe that among children, posterolateral fusion in situ with autogenous iliac crest bone graft yields satisfactory results without the associated risk of neurologic injury from reduction maneuvers or instrumentation. Patients should be immobilized postoperatively for at least 4 months in a pantaloon spica cast.

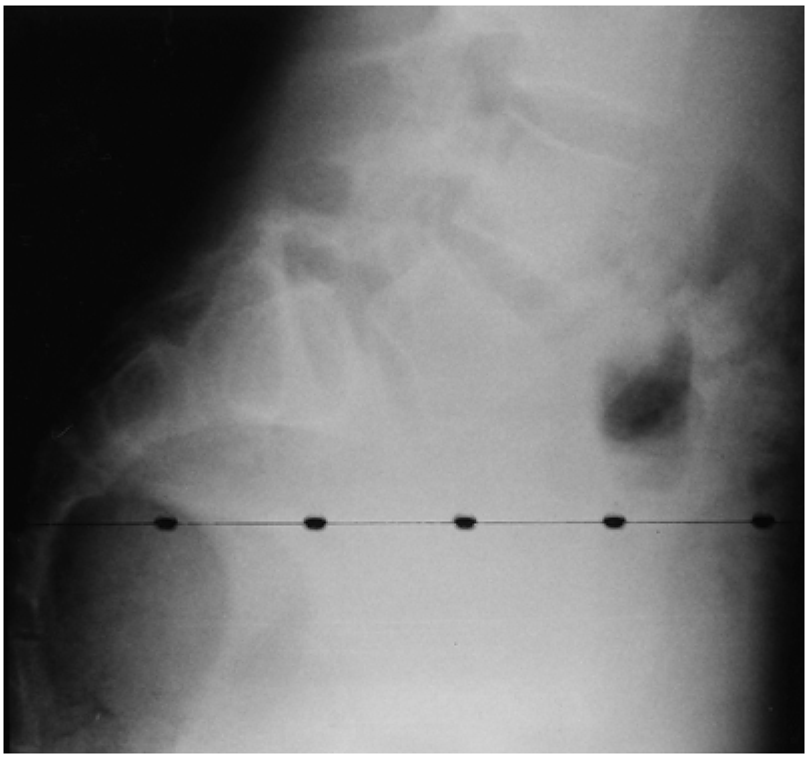

FIGURE 7. Lateral radiograph of a 15-year-old boy with a grade II spondylolisthesis.

Scheuermann Disease

Makin et al. (28) and Sinclair et al. (45) described patients with Scheuermann disease, but no details were given concerning its importance, characteristics, or treatment.

Scoliosis and Chest Wall Deformity

Waters et al. (55) conducted a study to define the incidence and characteristics of scoliosis among patients with pectus carinatum and pectus excavatum. They found that there is an association between Marfan syndrome, scoliosis, and anterior chest wall deformity. Of the patients with pectus excavatum, three had Marfan syndrome. Of the patients with pectus carinatum, two had Marfan syndrome. Waters et al. concluded that the presence of pectus deformities and scoliosis is a risk factor for Marfan syndrome.

Dural Ectasia and Meningocele

Dural ectasia, or widening of the spinal canal, appears to be a relatively common finding among patients with Marfan syndrome (49). Pyeritz et al. (41) found that 33 of 51 patients who underwent computed tomography had dural ectasia in the lower lumbar and sacral areas. The cause is thought to be an abnormality in the dura, which stretches with cerebrospinal fluid pressure. Intrasacral meningocele has been reported to occur in a few patients (2 ,13 ,16 ,34 ,50). Although most reports in the literature concern adult patients, it is worth mentioning this condition should a patient have low back pain or radicular pain. We prefer magnetic resonance imaging over myelography in the diagnosis of sacral meningocele because of its better resolution and noninvasive nature.

Summary

The disorder of connective tissue first described by the French pediatrician Marfan in 1896 is still an enigma. There is no way to reverse its effects on various systems, and treatment is mainly symptomatic. Until strict diagnostic criteria are used by researchers writing on the subject, exact details concerning the syndrome and its variants will remain elusive. Although the lifelong prognosis differs for patients with true Marfan syndrome and for those with Marfan habitus, management of spinal deformities for either group is relatively consistent. Scoliosis among patients with Marfan syndrome should be detected early and controlled by means of bracing. Although bracing may not be totally effective in preventing an operation, it can help postpone surgery until the child's condition is medically stable or the child is closer to skeletal maturity. All patients need a thorough preoperative cardiovascular evaluation. All curves should be fused, because the criteria of King et al., set forth for patients with idiopathic scoliosis, are not applicable to the patient population with Marfan syndrome or habitus. Standard posterior spinal fusion with rigid internal fixation should be performed. The value of derotational maneuvers is questionable and may even exacerbate the deformity. Copious amounts of autogenous iliac crest bone graft should be harvested. Postoperative immobilization in an underarm orthosis should be used until the fusion mass is solid. In spite of the pessimism in the literature regarding results of the operative management of scoliosis, with proper attention to details in the technique, selection of proper fusion levels, and appropriate instrumentation, good results can be obtained.

The emphasis of this chapter is on the clinical aspects and management of Chiari malformations, syringomyelia, and tethered spinal cord. Although traditionally considered products of dysembryogenesis, all three of these entities can be acquired as well, through inflammatory, infectious, neoplastic, or iatrogenic mechanisms. At times two or three of these entities occur simultaneously as part of a constellation of malformations or as interrelated pathophysiologic processes (17). This interrelationship makes dividing a chapter neatly into three components each addressing a single entity somewhat artificial. For the sake of discussion however, we address each entity separately and highlight any associations between or among Chiari malformations, syringomyelia, and tethered spinal cord.

Chiari Malformations

Although four types of Chiari malformations have been described, types I and II account for 99% of the clinical cases. Chiari I malformation involves descent of the cerebellar tonsils below the plane of the foramen magnum (Fig. 1). The cerebellar tonsils can be situated below the foramen magnum as a normal finding called *cerebellar ectopia.* This tends to occur more commonly between 5 and 15 years of age. The presence of up to 5 mm of cerebellar ectopia in this age group is considered by many investigators to fall within the normal range (10). The distinction between innocent cerebellar ectopia and true symptomatic Chiari malformation can be difficult in evaluations of a children. Chiari I malformations are not associated with myelomeningocele but infrequently may be associated with occult spinal dysraphism, such as spinal lipoma. Chiari II malformations are hindbrain hernias associated with myelomeningocele. In Chiari II malformation, the descent cerebellar vermis may be associated with caudal displacement of the medulla and the lower pons (Fig. 2). Often there is caudal displacement of the fourth ventricle and of the inferior cerebellar vermis into the upper cervical spinal canal and sometimes as low as the level of T4. Chiari III malformations are herniation of the posterior fossa contents through a bifid upper cervical canal. Chiari IV malformations involve agenesis of the cerebellum and no herniation of structures. Chiari IV malformation is not a surgical entity.

Etiology

Chiari I

The pathologic changes and the disordered anatomic features that occur among patients with Chiari malformation encompass an imaging and clinical spectrum from asymptomatic mild tonsillar ectopia to profound crowding of the foramen magnum and upper cervical canal with life-threatening symptoms and signs. During a surgical procedure the tonsils can be recognized readily because of the vertical orientation of their folia. The tonsillar loop of the posterior inferior cerebellar artery usually accompanies the cerebellum in its caudal descent. With long-standing compression, the tips of the tonsils may lose their fine pial vascularity and foliar pattern and appear pale. The tips of the tonsils can be tough and histologically gliotic. In Chiari I malformation, the denticulate ligaments, cervical nerve roots, fourth ventricle, and brain stem are in their normal positions. There are multiple mechanisms by which tonsillar descent can cause Chiari I malformation. Increased intracranial pressure from a supratentorial tumor or hydrocephalus gradually can lead to tonsillar herniation and the clinical signs and symptoms of Chiari malformation (Fig. 3). The presence of a lumboperitoneal shunt inserted to manage hydrocephalus can cause symptomatic tonsillar herniation (Fig. 4), especially among children (14 ,15 ,60).

These first two mechanisms clearly show that abnormal pressure gradients over time can cause Chiari I malformation. Multiple studies have addressed the possibility that the posterior fossa cranial volume can be relatively small for its contents, hence growth of the neural tissue follows the path of least resistance out the foramen magnum. In multisuture craniosynostosis when both lambdoid sutures have premature synostosis there is a high likelihood of tonsillar herniation. It is presumed that synostosis of the lambdoids does not allow adequate bony expansion of the posterior fossa to accommodate the neural contents (16). Acquired malformations of the skull base that reduce posterior fossa volume from progressive basilar invagination, such as osteogenesis imperfecta, can be associated with Chiari I malformation. The infrequent but real association of Chiari I malformation with occult spinal dysraphism suggests an embryologic event or condition that leads to tonsillar herniation. There are clearly multiple causes of Chiari I malformation. Determining which one is operative for an individual patient however, may not be obvious.

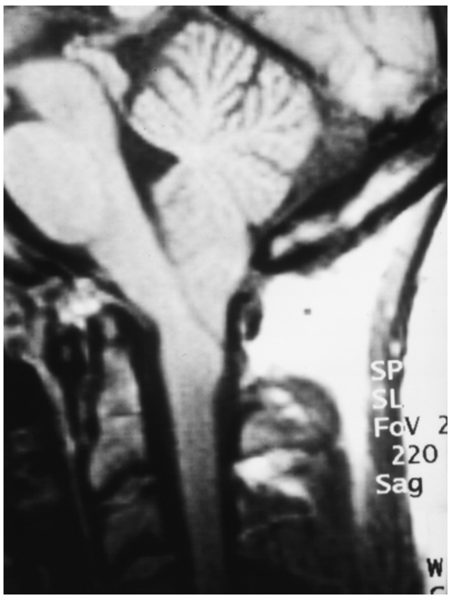

FIGURE 1. Sagittal, T1-weighted magnetic resonance image shows a typical Chiari I malformation. Crowded foramen magnum and cerebellar tonsil tips at the lower border of C1 are evident.

Chiari II

Whereas Chiari I malformation can have multiple causes, Chiari II malformation is almost exclusively associated with myelomeningocele. The mechanism of formation, however, remains disputed. The degree of neural malformation usually is much greater with Chiari II malformation because much of the posterior fossa contents, such as the brain stem, fourth ventricle, and vermis, are situated caudally. The caudal shift of the medulla may distort and compress the fourth ventricle and obstruct the flow of cerebrospinal fluid (CSF) through the foramina of Magendie and Luschka into the subarachnoid space. The choroid plexus may be outside the fourth ventricle. The descended vermis may appear yellow and gliotic with or without loss of the normal horizontal foliar pattern over its caudal portion. The dorsal surface of the displaced vermis may be hypovascular or hypervascular. The course of the upper cervical nerve roots can be upward or horizontal, and the denticulate ligaments can be taut and angled upward. The entire upper cervical spine usually appears crowded. A posterior extradural band may greatly constrict the neural structures under the arch of C1. This band usually corresponds to the periosteum of C1. The foramen magnum is often enlarged. Within the posterior fossa, the transverse sinuses and the torcular herophili (confluence of the sinuses) may be displaced downward. They may be displaced to such a degree as to lie at the foramen magnum, making operative exposure of the posterior fossa potentially hazardous. The upper portion of the cerebellar vermis may rise through the enlarged tentorial notch. Fusion of the superior and the inferior colliculi on both sides into a single beaked structure is common (1). The petrous ridges and the clivus are concave, again emphasizing the reduced volume of the bony posterior fossa in relation to its crowded neural contents.

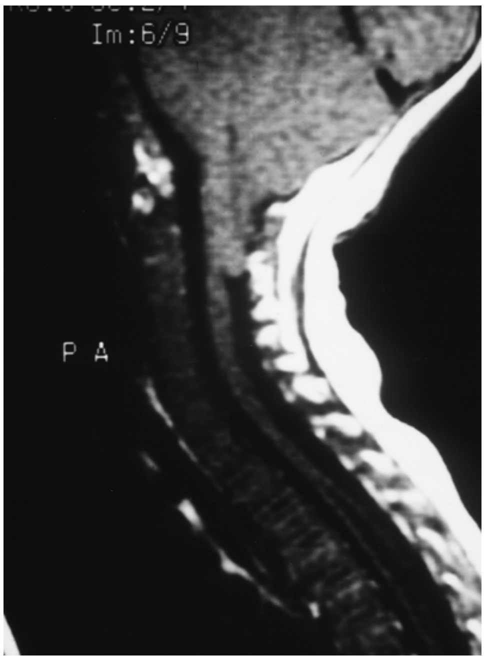

FIGURE 2. Sagittal, T1-weighted magnetic resonance image shows a typical Chiari II malformation. The entire posterior fossa is crowded, and the fourth ventricle is compressed and caudally situated. The caudal end of the pons is at the level of the basion, and the medulla is in the upper cervical canal.

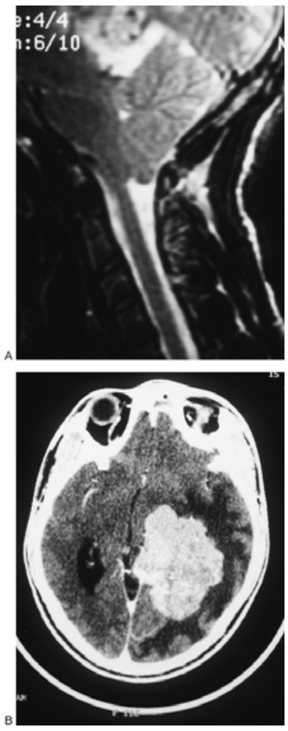

FIGURE 3. Sagittal, T2-weighted magnetic resonance image shows tonsillar herniation in a child with severe neck pain **(A)**. A contrasted computed tomographic scan of the head shows a huge intracranial tumor as the cause of elevated intrcranial pressure and tonsillar herniation **(B)**.

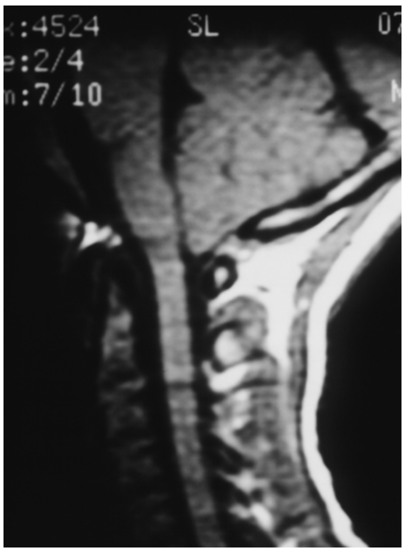

FIGURE 4. Sagittal, T1-weighted magnetic resonance image shows pointed tonsils below the foramen magnum in an 11-year-old child with neck pain and diplopia who had a lumboperitoneal shunt placed at 3 years of age.

Hydrodynamic Theory

Chiari proposed that the herniation of the posterior fossa contents was the result of supratentorial hydrocephalus (13). Gardner has been the major proponent of the hydrodynamic theory (26). He suggested that the foramina of Magendie and Luschka are either delayed in embryonic opening or remain functionally closed. Thus the pulsatile flow of CSF from the fourth ventricle is obstructed, and a water hammer pulse effect is generated. The pulsatility of the anterior choroid plexus in the lateral ventricles may push the tentorium too far inferiorly, diminish the size of the posterior fossa, extrude the cerebellum and the hindbrain, kink the cervicomedullary junction, and further aggravate the embryonic hydrocephalus. Progression of the hydrocephalus may then cause other supratentorial and infratentorial abnormalities.

Patients with Chiari I malformation have a high incidence of traumatic delivery and presumed subarachnoid hemorrhage and cerebral compression (52 ,72). This is thought to result in the development of subarachnoid adhesions that restrict equilibration of intracranial and intraspinal CSF pressures associated with Valsalva maneuvers. This results in impaction of cerebellar tonsils and further aggravates the difficulty of achieving pressure equilibration. Evidence against this theory comes from animal studies in which arachnoiditis and subarachnoid adhesions were caused by intracisternal injection of contrast agents and kaolin (77). In this model, cord cavities, which were in communication with the central canal or the fourth ventricle, were observed, but no hindbrain herniation was seen. Patients with basilar meningitis (Fig. 5) likewise may go on to have syringomyelia without Chiari malformation (5). Further support for the differential pressure theory has come from observations of progressive herniation of the well-developed cerebellar tonsils through the foramen magnum, which occurs years after insertion of a lumboperitoneal shunt (14 ,15 ,60).

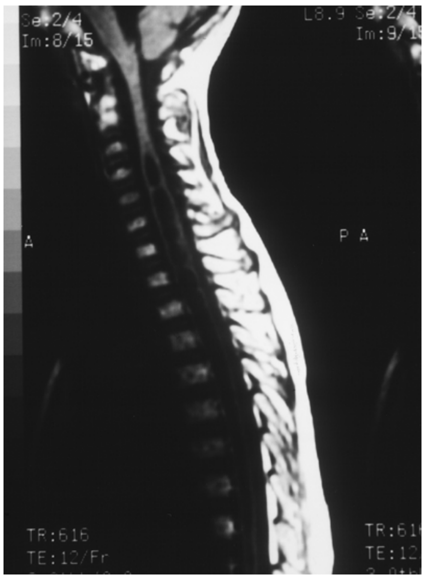

FIGURE 5. Sagittal, T1-weighted magnetic resonance image shows syringomyelia and an enlarged fourth ventricle in a child with a functioning ventriculoperitoneal shunt and a history of meningitis.

Developmental Theories

Marin-Padilla and Marin-Padilla (42) proposed a small posterior fossa theory based on the concept of primary paraxial mesodermal insufficiency as a cause of Chiari II malformation. They observed that among in hamsters treated with vitamin A, underdevelopment of the occipital bone resulted in a small, short posterior fossa. The overall consequence is that the cerebellum must grow toward the foramen magnum, the pontine flexure is reduced, and the angle of the cervical flexure is increased. No experimental embryo, however, had displacement of the posterior fossa elements below the foramen magnum, and there were no other manifestations of Chiari malformation. Nishikawa et al. (53) measured posterior fossa volume (osseous-dural confines) and posterior fossa content volume (neural elements) in adults with Chiari I malformation. They did not find any significant differences in these measurements compared with measurements of controls. When a ratio of neural content volume to osseous-dural defined volume was calculated, however, a difference was detected. This finding suggested that the patients with Chiari I malformation had relative overcrowding of the posterior fossa. Milhorat et al. (49) did find evidence of small posterior fossa volumes, reduced CSF volumes, and normal brain volumes in the posterior fossae of 364 patients with symptomatic Chiari I malformation.

McLone et al. (44 ,46) put forward a unified theory of Chiari II malformation based on their observations of genetic mutant mice with a sacral neural tube defect. The authors suggested that abnormal neurulation is an a priori feature of Chiari II malformation. Failure of correct timing of apposition and transient occlusion of spinal neuroceles lead to failure to maintain distention of the primitive ventricular system with CSF. Lack of distention of the rhombencephalic vesicles alters the inductive effect of pressure on the surrounding mesenchyma and endochondral bone formation and results in a small posterior fossa. Consequently, development of the cerebellum and the brain stem within the small posterior fossa leads to upward herniation, which produces an enlarged incisural opening and a dysplastic tentorium; downward herniation, which produces a large foramen magnum; and cerebellar vermis and brain stem displacement into the cervical spine. Hydrocephalus is caused by maldevelopment of the CSF pathways in the posterior fossa. This theory, supported with an animal model, seems the most compelling for explaining the pathogenesis of Chiari II malformation.

Clinical Features

The clinical signs and symptoms of Chiari malformation are truly protean and correlate with age at presentation (20 ,49 ,54 ,59). The symptoms can best be understood by remembering the anatomic structures that pass through the foramen magnum and upper cervical spine. There also may be symptoms referable to the accompanying syringomyelia and, in the case of the Chiari II malformation, the accompanying supratentorial anomalies, hydrocephalus, or myelomeningocele.

In a review of 39 patients with symptomatic Chiari I malformation, 30 of whom were younger than 19 years (54), there was a diversity of symptoms and signs (Tables 1 , 2). The most common symptom was pain, and the most common site of pain was the occiput or neck. In a number of patients, the pain was exacerbated by laughing, coughing, running, or, in one case, by heading the ball while playing soccer. These episodic exacerbations are often electric shock–like in nature. The other sites of pain include the shoulder, back, and upper or lower extremities. Such pain is typically not dermatomal in distribution but is deep and usually burning. Movement of the neck also may elicit pain, and because the pain is not dermatomal, the initial symptoms are easily cast aside. Other common symptoms are attributable to lower cranial nerve dysfunction. The most common signs were those of motor and sensory deficit. Two patients had been labeled as having cerebral palsy at birth. One of the two had fisting of both hands, and the other had varus deformity of both feet. The nystagmus that is characteristic among these patients is downbeat on down gaze and rotatory on lateral gaze. Esotropia without abducens paresis is a reversible deficit among this patient population (41).

TABLE 1. Symptoms among 39 Patients with Chiari I Malformation

Symptom	Number (%)
Pain	27 (69)
Weakness	29 (74)
Upper extremity	12 (31)
Lower extremity	7 (18)
Hemiparesis	7 (18)
Quadriparesis	3 (8)
Sensory changes	20 (50)
Numbness	17 (44)
Painless ulcers and fractures	5 (13)
Paresthesia	6 (15)
Clumsiness	6 (15)
Respiratory dysrhythmia	4 (10)
Dysphagia	4 (10)
Dysarthria	2 (5)
Hoarseness	3 (8)
Facial numbness	3 (8)
Hiccups	3 (8)
Severe snoring	2 (5)
Drop attacks	2 (5)
Urinary incontinence	2 (5)

Chiari II malformation is associated almost invariably with myelomeningocele, so most of these patients come to medical attention at birth for closure of their back lesions. However, only 20% of children with myelomeningocele have symptoms of Chiari II malformation (59). The symptoms and signs are more likely to be attributable to brain stem dysfunction with Chiari II malformation than they are with type I malformation.

TABLE 2. Clinical Signs among 39 Patients with Chiari I Malformation

Sign	Number (%)
Weakness	36 (92)
Upper extremity	20 (51)
Lower extremity	6 (15)
Hemiparesis	7 (18)
Quadriparesis	3 (8)
Atrophy	5 (13)
Sensory loss	29 (74)
Fewer than three dermatomes	7 (18)
More than three dermatomes	22 (56)
Posterior columns	9 (23)
Charcot joints	2 (5)
Hyporeflexia	15 (38)
Upper extremity	13 (33)
Lower extremity	2 (5)
Hyperreflexia	17 (44)
Lower-extremity clonus	7 (18)
Babinski response	11 (28)
Ataxia	9 (23)
Nystagmus	9 (23)
Absence of gag reflex	8 (20)
Facial sensory loss	5 (13)
Tongue atrophy	3 (8)
Vocal cord palsy	3 (8)

A typical sequence of events in an infant with myelomeningocele and Chiari II malformation may be as follows. The spinal lesion is repaired in the neonatal period, and a ventriculoperitoneal shunt is inserted to manage progressive hydrocephalus. On the return visit, at 4 to 6 weeks of age, the mother reports that the infant is feeding poorly and is episodically arching the head backward. Nasal regurgitation of milk or formula may occur as evidence of palatal dysfunction. Neurogenic dysphagia should be considered an urgent problem and addressed promptly (63 ,64). When angered or agitated, the infant may develop an inspiratory wheeze or stridor, sometimes described as *crowing*, which may develop into actual periods of apnea and anoxic seizure (34). On examination, the infant may have coarse downbeat or lateral gaze nystagmus, a diminished gag reflex, or fixed retrocollis. Examination of the vocal cords may show abductor paralysis with intact adduction (34). Long tract signs may develop.

No stereotypical development of symptoms and signs has been recognized to allow the determination of the importance of any single symptom. What is important to remember is that patients with myelodysplasia have a stable neurologic lesion and, on the whole, do not have new symptoms that are not attributable to either raised intracranial pressure or local complications from their spinal lesions. New symptoms attributable to either brain stem or long tract dysfunction among children with myelodysplasia of any age should alert the clinician to the possibility that Chiari II malformation can become symptomatic. It is of great importance to ensure the shunt is functioning because control of hydrocephalus reverses the symptoms of a Chiari II malformation for many of these children.

In addition to the signs and symptoms attributable to the Chiari malformation, patients may have symptoms of the associated syringomyelia (see later). Relapse and remission and diffuse involvement of the motor and sensory systems may lead to the diagnosis, particularly in adolescents and young adults, of demyelinating disease. If the motor symptoms and signs predominate and there is a paucity of sensory dysfunction, the patient may be thought to have motoneuron disease. Thus the protean manifestations of Chiari malformation and syringomyelia can confuse even an astute clinician.

Management

Diagnostic Evaluation

With the advent of magnetic resonance imaging (MRI), previous methods of diagnosing Chiari malformation, such as angiography, air myelography, and computed tomography (CT) with water-soluble contrast medium, rarely are necessary. MRI should be the initial investigation in the care of patients with suspected Chiari malformation (Figs. 2 , 3) (27 ,54). Both the brain and the spinal cord can be easily imaged in multiple planes. In addition to its high sensitivity and specificity, MRI is noninvasive in nature. This imaging modality also is useful for follow-up evaluations. Because MRI accurately delineates the size of the syrinx cavity, it can easily be used to monitor treatment failure as evidenced by increasing or lack of reduction in syrinx size. Other associated features such as syringomyelia, tethered cord, lipomyelomeningocele, and craniocervical junction abnormalities are easily seen at MRI. Infants and small children however, must be sedated so that they will lie still while the information is acquired to construct the images.

It occasionally is necessary to perform cisternography on patients who have syringomyelia with questionable hindbrain anomalies (6). In these cases, the cause of syringomyelia can be a CSF block caused by arachnoid adhesions at the foramen of Magendie. Conventional metrizamide myelography combined with delayed CT has been useful in defining anatomic details and in appreciating the dynamics of CSF flow in the region. There is no role for CT without subarachnoid contrast enhancement to exclude the presence of Chiari malformation. CSF flow studies performed with MRI are a noninvasive way of obtaining similar information (35). The reliability of this new technology, however, is yet to be proved.

As experience accumulates, gradations in the caudal descent of the cerebellar tonsils are becoming increasingly clear. Caudal descent of the tonsils more than 5 mm below the plane of the foramen magnum is considered by almost all authors to be pathologic. Caudal descent between 0 and 5 mm must be put in the perspective of the individual patient. Marginal caudal descent in conjunction with syringomyelia without another cause may well prove to be clinically significant. Minor degrees of cerebellar ectopia among patients without symptoms, however, usually warrant simple observation.

Treatment

Once the initial suspicion of a Chiari malformation has been confirmed, the question is what therapeutic alternatives are available and would be best suited to the patient's needs. Because these are structural abnormalities, no medical treatment is available for correction. All the therapeutic options consist of surgical intervention. If the patient has symptoms, clinical observation may be an option. It must be kept in mind, however, that the course of syringomyelia is progressive loss of neurologic function over years or decades (4). Some patients with asymptomatic Chiari I or Chiari II malformation experience sudden brain stem dysfunction and die without warning (70 ,83).

Patients with no symptoms referable to the craniocervical junction and 2 to 3 mm of caudal displacement of the cerebellar tonsils are being recognized with increasing frequency (Fig. 4). In general, this special group of patients without syringomyelia should simply be observed. At the other end of the spectrum are elderly patients with severe disabilities who have little chance of improvement after surgical intervention. Supportive measures may be provided to this group. In most instances, however, therapeutic intervention is indicated (Fig. 5). Patients with symptomatic Chiari I malformation and especially those with Chiari II malformation must have evidence of normal intracranial pressure before surgical decompression of the posterior fossa can be considered. Shunt revision or insertion is a much more appropriate therapeutic option for patients with increased intracranial pressure.

A number of studies have analyzed the effect of surgical treatment of patients with Chiari I malformation and syringomyelia (19 ,20 ,40 ,54). A direct comparison of studies is difficult because of the different clinical features emphasized and the varied operative procedures performed. Most patients, however, have improvement or stabilization of symptoms after decompressive surgery (54). The improvement is more marked in symptoms such as head and neck pain, cranial nerve dysfunction, and long tract signs. There usually is a stabilization of sensory and motor symptoms, but there is rarely a return of lost tendon reflexes, muscle wasting, or sensory loss. A retrospective study showed that there was either stabilization or improvement for 70% of patients with Chiari I malformation after decompression of the posterior fossa, but there was rarely complete resolution (54). Among patients who also had syringomyelia, there was a positive correlation between clinical improvement and improvement in the extent of the syrinx cavity (Fig. 6). Several authors showed improvement or stabilization of progressive scoliosis after surgical treatment of patients with Chiari I malformation and syringomyelia (50).

In contrast are neonates or infants with myelomeningocele, an adequately functioning shunt, and difficulty with respiration or swallowing. Despite operative intervention, this group continues to have a grave prognosis for survival (63 ,64). Chiari II malformation continues to be the leading cause of death among treated patients with myelodysplasia.

Operative Technique

Once the decision has been made to surgically treat a patient with a Chiari I malformation, a range of posterior decompressive procedures are used by various surgeons. Simple bony decompression of the occipital bone and upper cervical canal can be done. Intraoperative ultrasonography is used to document normal tonsillar motion. If there is not normal tonsillar motion, dural decompression is performed. Some surgeons open the dura without opening the arachnoid so as to avoid contamination of the CSF with blood. At the more aggressive end of the spectrum is opening of the arachnoid followed by microsurgical dissection of the tonsils and fourth ventricular outlet. To further lower any resistance to fourth ventricular outflow of CSF, the surgeon can coagulate and shrink the medial aspect of one cerebellar tonsil with bipolar cautery. In 95% of Chiari I decompressions, removal of the foramen magnum–occipital bone and C1 is adequate bony removal. In only 5% of our patients has removal of C2 been necessary for an adequate decompression. Restricting the bony removal to the foramen magnum and posterior arch of C1 decreases postoperative pain and increases the patient's long-term spinal stability. We have found that restricting the opening to this area has not led to any substantial spinal deformity. When the decompression needs to be caudal to the upper margin of C2, the surgeon can undercut the lamina and spinous process with rongeurs while leaving the C2 elements intact. Plugging of the obex and fourth ventricular stents are not only passe but also carry an unjustified high morbidity in the care of this patient population.

A small number of patients with Chiari I malformation have ventral brain stem compression from extradural osseous and soft-tissue anomalies that should be addressed before any posterior decompression is performed (Fig. 7) (27). The excepted approach to substantial ventral compression is to attempt reduction with halo traction. If the traction is successful, posterior decompression and fusion with internal fixation are performed. If the traction is not successful, then the ventral vector must be removed before any dorsal procedure is performed. This ventral decompression often is performed through the transoral route.

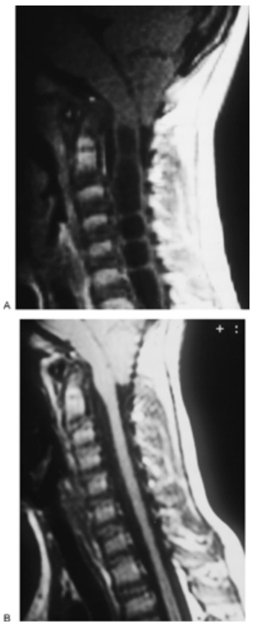

FIGURE 6. Preoperative sagittal, T1-weighted magnetic resonance image shows Chiari I malformation and cervical syringomyelia **(A)**. After posterior fossa decompression, the syringomyelia resolved **(B)**.

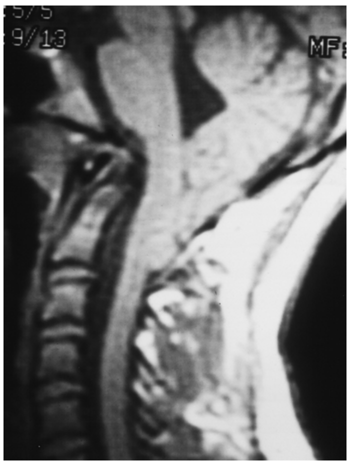

FIGURE 7. Sagittal, T1-weighted magnetic resonance image shows a Chiari I malformation with ventral brain stem compression even though there is no basilar invagination.

We routinely observe patients in a monitored setting the night of the operation and then transfer them to a regular floor the following day. Complications are infrequent but are severe when they occur. Intraoperative bleeding from an uncontrolled venous sinus is the most feared intraoperative complication. A small child can quickly exsanguinate from an uncontrolled venous sinus. Suturing of the dural leaves or approximating them with titanium hemostatic clips is at times invaluable when it is necessary to open a vascular dura. Lower cranial nerve dysfunction following posterior decompression in the face of ventral compression can occur when ventral compression has not been adequately addressed (27). Vertebral artery injury from craniocervical instability can cause thromboembolic complications among these patients. Leakage of CSF and meningitis can occur when increased intracranial pressure from hydrocephalus has not been controlled. Cerebellar slump can occur when a large posterior decompression is performed and the cerebellum sags into the decompression to produce traction on the brain stem or cranial nerves or recurrent crowding of the cervicomedullary junction. These mechanisms cause cranial neuropathy, brain stem dysfunction, or syringomyelia. One of our patients had postoperative bilateral posterior fossa subdural fluid collections that produced a mass effect and caused obstructive hydrocephalus (Fig. 8). “Expected” morbidity is neck pain and some nausea, which usually clears quickly.

For Chiari II decompression the most important preoperative information is the relation between the torcular herophili and the foramen magnum. Because the torcular can be situated at the foramen magnum, removal of the foramen magnum in these cases (a) usually does nothing to relieve the compression and (b) can cause catastrophic bleeding (Fig. 9). Usually the maximal compression is at the level of the cervicomedullary kink, which often is situated anywhere from the rostral cervical to rostral thoracic spinal canal. Therefore, unlike Chiari I malformation, for which a very stereotypical procedure often is performed, Chiari II malformation necessitates customization that depends on the MRI and intraoperative findings. Most Chiari II malformation are most effectively managed with multilevel laminectomy centered over the medullary kink and little if any foramen magnum decompression. This decompression should include the laminae over the caudally descended brain stem and fourth ventricle. There are little advantage and much risk in being too aggressive in the extent of this laminectomy. The medullary kink usually can be differentiated from the distal fourth ventricle and vermis. The laminectomy need not extend below the caudal fourth ventricle. In the presence of a large syrinx and an extensive laminectomy, there exists a real risk of development of severe kyphosis (swan-neck deformity). Restricting the bony opening to the smallest area necessary to allow a dural opening and to reestablish the foramen of Magendie lessens this risk.

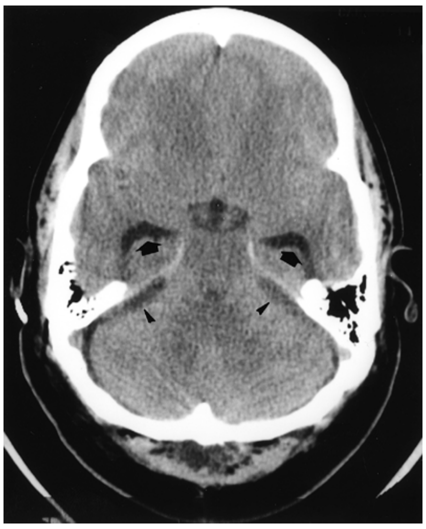

FIGURE 8. Axial computed tomographic scan of the head shows posterior fossa subdural hygromas (*arrowheads*) causing obstructive hydrocephalus (*arrows* show dilated temporal horns) 10 days after uneventful posterior decompression for Chiari I malformation.

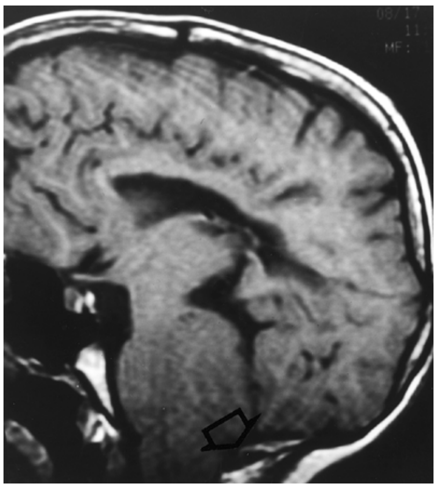

FIGURE 9. Sagittal T1-weighted magnetic resonance image of a child with a Chiari II malformation shows the torcular herophili (confluence of sinuses) situated at the foramen magnum.

Syringomyelia

Accumulation of CSF within the spinal cord has multiple causes. The most common is Chiari malformation followed by posttraumatic syringes and intramedullary spinal cord tumors. Syringes also occur in association with basilar meningitis and tethered spinal cord without Chiari malformation. There have been many theories as to how CSF accumulates within the spinal cord to cause syringomyelia. The underlying unifying pathogenesis seems to relate to a disturbance of CSF circulation in the subarachnoid space at either the foramen magnum or within the spinal canal.

Spinal cord cavitations traditionally have been considered hydromyelia if they are ependyma-lined dilatations of the central canal and considered syringomyelia if the cavitation is not ependyma-lined. The clinical practicality of this differentiation may be moot given the necessity of histopathologic examination to make the differentiation. We simply refer to all cavities as *syringomyelia.* Autopsy studies have shown that communication of the syrinx with the rostral central canal occurs almost exclusively among young children with myelodysplasia or other congenital anomalies. In the setting of Chiari I malformation and syringomyelia, there is more often a segment of cord without a patent central canal between the fourth ventricle and syrinx. This noncommunicating form of syringomyelia usually is associated with Chiari I malformation, trauma, intramedullary spinal cord tumor, or arachnoiditis. Among humans without syringomyelia, autopsy studies have shown a patent central canal in 97% of infants, 12% of adolescents and young adults, 4% of middle-aged adults, and 0% of adults older than 65 years (49).

The hydrodynamic theory proposed by Gardner (26) is that because the physiologic outlets of the fourth ventricle are obstructed, the CSF pulsations transmit down the central canal through a persistent communication between the fourth ventricle and the central canal and cause the canal to dilate. This theory may be operative among infants or fetuses with a Chiari II malformation. This situation is further exacerbated by the cranial spinal pressure dissociation theory proposed by Williams (75 ,76). Williams suggested that with a Valsalva maneuver, the intraspinal pressure increases owing to engorgement of the epidural veins. This causes displacement of CSF into the intracranial subarachnoid space. When spinal venous pressure returns to normal, the reverse occurs, and there is flow out of the intracranial cavity. If this equilibrium is delayed by adhesions or tissue in the foramen magnum, a pressure differential is produced between the intracranial and the intraspinal compartments, and alternative pathways of decompression are encouraged. One such pathway that allows reduction of pressure is through a patent rostral central canal; the result is dilatation of the central canal of the spinal cord. The other pathway is progressive caudal displacement of the posterior fossa tissue; the result is worsening of the Chiari malformation. Williams refers to this as the *suck hypothesis.* He provided support for this hypothesis by measuring CSF pressures simultaneously within the cranial cavity and the spinal canal of subjects with and those without Chiari malformation (75 ,76).

We have successfully treated patients with syringomyelia and no Chiari malformation with posterior fossa decompression. Our theory is that a disturbance of CSF flow at the foramen magnum despite no history of meningitis or trauma was the cause of the syringomyelia (35). This suggests that an anatomic abnormality need not be obviously present at MRI to cause the pathophysiologic features of Chiari malformation.

A cause of noncommunicating syringomyelia is intrinsic spinal cord tumor. Proteinaceous fluid may be secreted by the tumor cells. As the fluid accumulates, it dissects the spinal cord tissue at the pole of the neoplasm. With increasing accumulation the cavity enlarges, and the clinical worsening can be explained by expansion under pressure. But expansion of the syringomyelic cavity may be caused by other mechanisms. One such explanation is that CSF can dissect along the arteries and the Virchow-Robin spaces (7); macroscopic and microscopic openings provide the connections to fill the cyst with fluid. Evidence of such a mechanism came from studies in which water-soluble contrast medium injected into the subarachnoid space commonly opacified the syringomyelic cavity on delayed scanning (6). This suggests that obstruction of normal bulk flow of CSF by either a hydrodynamic mechanism or extramedullary compression can lead to syringomyelia. Bulk flow of CSF in the spinal canal goes from the spinal subarachnoid space into the central canal and then flows rostrally.

Another explanation for expansion of noncommunicating syringomyelia is provided by Williams and is once again based on the theory of differential pressures (75 ,76). In this instance, the differential pressure is within the spinal subarachnoid space. As before, a Valsalva maneuver causes engorgement of epidural veins and compression of a focal area of subarachnoid space. The change in pressure is dissipated throughout the subarachnoid space and causes a sudden upward surge within the cyst cavity. The cavity returns to the pre-Valsalva position because of the elastic properties of the cord tissue. Such a “sloshing” of the fluid within the spinal cord cavity may dissect additional portions of the spinal cord during this surge. This concept is clinically supported by the fact that patients with known syringomyelia can have sudden neurologic worsening during attacks of coughing or sneezing. Such a dynamic process may explain why more than one cyst may run in parallel within the spinal cord or why there may be several transverse septations within one syringomyelic cavity (75 ,76).

The incidence of syringomyelia among patients with posttraumatic paraplegia is between 2% and 8% (78). Posttraumatic syringomyelia can develop after severe or moderate spinal cord injury. The clinical symptoms can develop years or even decades after the injury. An intramedullary hematoma or hematomyelia can develop at the site of trauma. The spinal cord can become fixed by arachnoid adhesions, which reduce the mobility of the CSF around the cord. Such adhesions and reduced mobility can contribute to delayed ischemia of the cord. Both posttraumatic and delayed ischemia can cause myelomalacia and cyst formation (65). These cysts may move during a Valsalva maneuver. Pathologic examination shows that the area around the syringomyelic cavity can be affected by mild reactive gliosis, but typically there is no evidence of acute inflammation or vascular compromise.

Clinical Features

There is extreme variation in the clinical presentation and objective signs of syringomyelia, and the progression is relentless but protracted (22 ,32 ,75 ,80). In the past, it was because of this long interval of progression that syringomyelia was categorized as a chronic neurodegenerative disease (47). Syringomyelia associated with hindbrain herniation is the form of spinal cord cavitation most frequently seen by clinicians. It can be difficult to differentiate the symptoms caused by the cyst from those caused by the Chiari malformation, particularly among patients who may have cephalic dissection of the syrinx into the brain stem, which causes syringobulbia.

Well-recognized clinical features of syringomyelia include suspended and dissociated sensory loss, cervical and occipital pain, lower motoneuron weakness of the upper extremities, and neurogenic arthropathy (Charcot joints). Although prominently discussed, painless joint destruction occurs among only 5% to 7% of patients with syringomyelia. Numbness frequently is the initial symptom; the sensory disturbance usually is in the upper extremities and may be asymmetric. Typically there is loss of pain and temperature sensation with preservation of touch and proprioception. Dysesthesia and disturbance of proprioception may occur with advanced disease. The pain may be radicular in distribution or be more diffuse. Headache and posterior cervical pain are thought to be caused by distortion of the descending fibers of the trigeminal nerve or upper cervical nerve roots or by distortion of the C2 sensory roots by the caudal tonsils. The pain may be exacerbated or caused by coughing or sneezing. A Valsalva maneuver can alter neurologic findings among patients with syringomyelia of any cause. The disturbance in motor function is manifested by difficulty in performing motor tasks with the upper extremities. This may be followed by atrophy in both distal and proximal muscle groups. There may be fasciculations in the affected muscles, and deep tendon reflexes may be diminished or absent in the arms. The lower extremities can become spastic with ankle clonus and extensor plantar responses. A lower motoneuron syndrome in the lower extremities occasionally occurs. Bowel and bladder function usually is normal, and complete or partial Horner syndrome may be present. If there has been cephalic dissection of the syrinx into the brain stem, there may be cranial nerve and brain stem dysfunction.

The causal relation between syringomyelia and scoliosis is well recognized (61). Twenty percent to 25% of patients with syringomyelia have scoliosis. Scoliosis among this patient population is atypical in that it is midthoracic and convex to the left, unlike idiopathic scoliosis, which is more often convex to the right and involves the lower thoracic or lumbar region. In a series of 43 patients with Chiari I malformation, 50% of patients without scoliosis had syringomyelia, but syringomyelia was present in 95% of patients with scoliosis (54). Williams (75 ,76) and Foster (22) analyzed the clinical features of large numbers of patients with syringomyelia (Table 3).

The prognosis of syringomyelia is determined by the cause of the fluid accumulation. Patients with syringomyelia from a spinal cord neoplasm or arteriovenous malformation are best served with therapy for the underlying cause of the fluid accumulation and not the cyst itself. In general, for patients with spinal arachnoiditis or trauma, it is most effective to drain the cyst into the pleural or peritoneal cavity and not the subarachnoid space—this opinion is not universal.

Improvement after shunting for posttraumatic syringomyelia is seldom dramatic. Major neurologic deficits usually are permanent; however, there often is lasting improvement in pain. When considering surgery in the care of patients with posttraumatic syringomyelia, it is worth remembering that the course of the disease is progressive deterioration among about 50% to 70% of the patients. Barbaro (9) analyzed the results of various published reports and concluded that at least 50% of patients who underwent surgical treatment had signs of improvement and that an additional 30% had stabilization. In view of the course of this entity and the encouraging results, surgical intervention for posttraumatic syringomyelia is indicated when patients have symptoms or when there is MRI evidence of progressive enlargement of the syrinx.

TABLE 3. Clinical Symptoms and Signs Among 100 Patients with Syringomyelia

Symptom	No. of Cases	Sign	No. of Cases
Stiffness of the legs	42	Scoliosis	22
Hand numbness	28	Hydrosyringomyelia	78
Neck pain	24	Spastic paraparesis	58
Arm pain	16	Hydrocephalus	11
Headache	14	Brain stem signs	29
Oscillopsia	6	Proprioceptive loss	20
Diplopia	4	Neurogenic arthropathy	7
Vertigo	3	Horner syndrome	5
Drop attacks	2		

Management

Diagnostic Evaluation

MRI is the ideal means of detecting and evaluating syringomyelia. Not only is it a noninvasive means of defining a syrinx, but also it adequately delineates most associated entities, such as Chiari malformation, intraspinal tumor, and occult spinal dysraphism. It occasionally is necessary to perform cisternography for patients who have syringomyelia with questionable hindbrain anomalies (6). In these cases, the cause of syringomyelia may be CSF block caused by arachnoid adhesions at the foramen magnum. Conventional metrizamide myelography combined with delayed CT has been useful in defining anatomy details and in appreciating the dynamics of CSF flow in the region. MRI can be used to generate CSF flow studies. Standardization of these noninvasive techniques is in evolution. Whether the specificity and sensitivity are as good as those of CT cisternography remains a question.

Treatment

When syringomyelia is detected, the clinician must determine the cause of the syrinx. It usually is most appropriate to direct treatment at the cause of the syrinx rather than to conduct a direct attack on the syrinx. If the patient has symptoms, clinical observation may be an option. It must be kept in mind, however, that the course of syringomyelia is progressive loss of neurologic function over years or decades (4).

More than 90% of syringes associated with Chiari I malformation shrink after posterior fossa decompression alone. Establishment of normal CSF circulation at the foramen magnum resolves the syringomyelia. Among patients with myelomeningocele, inadequate function of a CSF shunt can cause syringomyelia. It is of great importance, therefore, to ensure adequate shunt function. If syringomyelia continues to be a problem for a patient with Chiari II malformation a functioning shunt, posterior fossa decompression alone is unlikely to resolve the syringomyelia. For these patients, arachnoidal scarring in association with tethered spinal cord or Chiari II malformation may be important factors (Fig. 10). We perform Chiari II decompression in concert with some form of syrinx shunt (usually syringopleural) with good success. Syringes associated with tumors or vascular malformations are addressed by treating the tumor or vascular malformation. Syringes associated with trauma probably are caused by a cavitating cord injury and arachnoidal scarring from hemorrhage. Therefore aggressive release of arachnoidal scarring along with a shunt from the syrinx to an extraarachnoidal site is the preferred treatment.

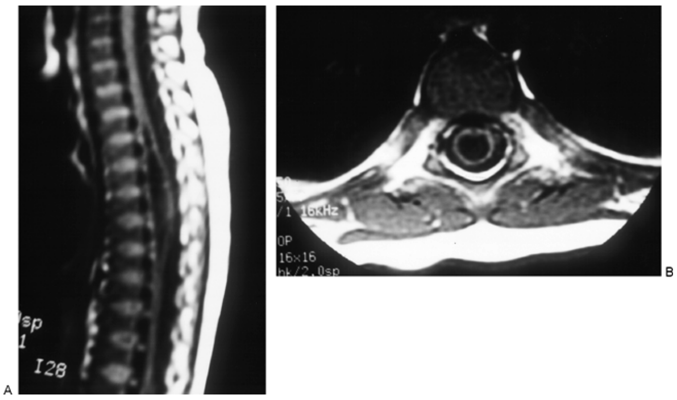

FIGURE 10. Sagittal **(A)** and axial **(B)** T1-weighted magnetic resonance images show syringomyelia of the thoracic cord in association with spina bifida.

Tethered Cord Syndrome

The term *tethered cord syndrome* has been used to describe a constellation of symptoms and signs thought to be caused by traction on the conus medullaris. This tension or traction usually causes caudal displacement of the conus. One can still have a functionally tethered spinal cord with the conus at a normal position. The cause of the tethering may be a variety of intradural congenital anomalies or previous surgical procedures. The tethering can be caused by a thickened or tight filum terminale; intradural lipoma, which usually extends into the subcutaneous tissues; intradural fibrous adhesions; split cord malformation; dermal sinus tract; occult meningocele; or previous myelomeningocele closure. Until recently, tethered cord syndrome usually referred to the lumbosacral cord exclusively, but a number of cases of tethered cervical cord have now been described (18 ,21 ,56 ,57 ,81).

Embryology and Pathophysiology

Congenital tethered cord syndrome is considered to be a form of occult spinal dysraphism. To understand the pathophysiology, it is important to review the development of the normal spinal cord. There are multiple reviews on this subject and we only briefly highlight the stages of spinal development (43 ,56). The vertebral column and spinal cord match segment for segment, and the spinal nerve roots exit through the intervertebral foramina directly opposite the point of origin until 9 weeks of gestation. Thereafter, the neural tube "ascends" within the vertebral column. Two processes are involved in this ascension of the spinal cord and the associated development of the cauda equina and filum terminale (38). The first process is regression or dedifferentiation of already formed structures. This causes the distal portions of the neural tube, formed by canalization, to undergo cellular necrosis between 40 to 48 days of gestation and form the future filum terminale.

The central canal immediately cephalic to the area of necrosis dilates to form the ventriculus terminalis. This lies at the entry zone of the fifth sacral nerve root and marks the junction of the future conus medullaris and the filum terminale. The distal end of the future filum terminale is attached to the posterior aspect of the fifth coccygeal vertebral segment. The second process involved in the ascension of the spinal cord is differential growth of the vertebral column and neural tube. Because the cephalic portion of the neural tube is fixed in position, relative cephalic migration of the caudal cord occurs. The lumbosacral nerves are attached to the spinal cord and lengthen to form the cauda equina. The filum terminale lengthens because of the growth of its fibrous components and mechanical stretching. Between 9 and 17 weeks of gestation, the conus ascends from the midcoccygeal level to the fourth lumbar level. After this the ascent is slow. The conus reaches the third lumbar vertebral body by term and the adult level of the L1–2 intervertebral disc space by 2 months of postnatal development.

Thus it is possible that during this complicated process, several errors can occur that lead to tethering of the lower part of the spinal cord (23). Tethering by a lipoma may be the result of inclusion of adipose tissue within the dural sac during early development, similar to the formation of more complex lumbosacral lipoma. An abnormality of canalization or regression may cause abnormalities in the filum terminale. The errors in closure of other midline structures, such as dura, vertebral body, or skin, may cause adhesion or fibrous bands and interfere with ascension of the cord. The result is tethering.

Breig (11) studied the biomechanics of the central nervous system in human cadavers. He established the dynamics of the spinal cord and described elongation of the cervical cord in flexion and slackening in extension. He showed that in the neutral position the cord folds as does an accordion and is under slight tension. During flexion the spinal cord first unfolds then undergoes elastic deformation near full flexion. Conversely, during extension, it simply folds and undergoes elastic compression. The change in length measured on the dorsal aspect in flexion and extension was 1.8 to 2.8 cm for the cervical cord, 0.9 to 1.3 cm for the thoracic cord, and 1 to 2 cm for the lumbar cord. Thus any interference with the mobility of the spinal cord can cause imbalance of traction forces and changes in blood supply.

Reigel (66) demonstrated attenuation of the spinal cord exacerbated by pelvic flexion. This observation suggested that intermittent stretch may occur with sitting, standing, and other daily activities. It also was found that the spinal cord vasculature often was attenuated and linear. This suggested that any process leading to lengthening or stretching of the spinal cord may cause intermittent or progressive ischemia and spinal cord dysfunction. The slow rate of progression of symptoms may further support vascular insufficiency as an etiologic factor in tethered cord syndrome. Experimental traction on the spinal cords of cats decreases local blood flow and impairs oxidative metabolism (82). It also increases the vulnerability of the spinal cord to compressive injuries (24). Among patients with tethered cord syndrome, oxidative metabolism improved after untethering (82). Vulnerability of spinal cord gray matter to ischemia during experimental tethering in animals was further confirmed in horseradish peroxidase studies (25).

Clinical Syndrome

Swift and Carmel (69) analyzed data from a number of studies and drew up a table of common causes of spinal cord tethering (Table 4). Pang and Wilberger (58) compared tethering lesions found at operation in the adult population with those found by Anderson (3) in children. There also are an increasing number of reports of tethering of the cervical cord, which may be associated with cervical cutaneous lesions (81), cervical split cord malformation (56 ,57), or cervical dermal sinus (21).

TABLE 4. Causes of Spinal Cord Tethering

Cause	No. of Cases
Thickened filum terminale	8
Lumbosacral lipoma	34

From Swift DM, Carmel PW (69).

Cutaneous manifestations (Fig. 6) are present among 54% of patients with tethered cord syndrome of congenital origin: 22% have hypertrichosis; 15% have subcutaneous lipoma; and 17% have hemangiomatous discoloration, congenital dermal sinus, or multiple manifestations (23). The converse has not been analyzed; thus the incidence of spinal cord tethering among the population with minor midline cutaneous lesions, such as hemangiomatous discoloration, is not known. Because of the availability of noninvasive imaging of the spinal cord (MRI), there is increasing awareness of the association between tethered cord and midline cutaneous lesions (2).

The incidence of tethered cord in the overall incidence of occult spinal dysraphism is unknown. There is a 2:1 female preponderance. The symptoms of tethered cord syndrome vary considerably in time and mode of presentation and generally suggest progressive myelopathy. French (23) analyzed a number of published reports of tethered cord syndrome and suggested that most patients are younger than 20 years at the time of initial presentation. He found that 31% came to medical attention between birth and 5 years of age, 21% between 6 and 10 years, 42% between 11 and 20 years, and 6% after 21 years of age.

Hoffman et al. (30 ,31) commented on the “protean manifestations” of tethered spinal cord among children. The most common presentation in their population was progressive motor dysfunction with hyperreflexia and a positive Babinski sign. Other features included orthopaedic deformities of the feet and legs and bladder and bowel dysfunction and scoliosis. Pain at presentation is uncommon among children with tethered cord syndrome. In contrast, back pain was the most common presenting symptom among the adult population (58). Analysis of data from many studies showed that 93% of patients had gait difficulty, 63% having possible muscle atrophy, a short limb, or ankle deformity. Sensory deficit was present among 70%, and bladder dysfunction in 40% of patients. Only 4% of patients had bladder dysfunction in the absence of motor, sensory, or skeletal abnormalities. Most of these patients with bladder dysfunction alone were children (37). Pain in the back or leg or in the arches of the feet occurred among 37% of patients.

Pang and Wilberger (58) compared the presentation of tethered cord syndrome among children with that among adults. The study also suggested a clear-cut precipitating factor for presentation among 6% of the adult population. Among the pediatric population, tethered cord syndrome may become apparent during periods of growth spurt (39), but repetitive trauma associated with spinal flexion is a more reasonable explanation for progressive symptoms.

Among adults the pain of tethered cord syndrome is dramatic and often is localized to the anal, perineal, or medial gluteal region (58). It occasionally is diffuse over one or both lower extremities. Shocklike sensations (Lhermitte sign) are characteristic of dorsal column demyelination. Urinary symptoms include urgency, frequency, dribbling, or stress incontinence (58). Urodynamic abnormalities include detrusor hyperactivity, low-compliance bladder, and sphincter detrusor dyssynergia (37 ,84). Orthopaedic deformities include kyphoscoliosis, leg length discrepancies, and foot deformities (31 ,66). The common sensory deficit is saddle anesthesia (58) or hyperesthesia with variable involvement of the feet.

Patients with tethering of the cervical spinal cord may have progressive cervical myelopathy (21). There may be progressive loss of fine motor skills in the hands, increasing clumsiness, and intermittent sensory symptoms in the upper and lower extremities. These patients usually do not have bladder dysfunction, and pain may be absent. On occasion, arm symptoms may be caused by lumbar spinal cord tethering. Although somewhat controversial, this phenomenon has clearly appeared in our practice both from myelomeningocele tethering and from a thickening of the filum terminale. These arm symptoms may be modestly reversible after untethering.

Management

Diagnostic Evaluation

In view of the protean manifestations of tethered cord syndrome, the patient be brought to a pediatrician, dermatologist, orthopedist, neurologist, or in rare instances directly to a neurosurgeon. Such patients need a multidisciplinary evaluation to ascertain the anatomic cause of tethering and the extent of the functional deficits. A detailed neurologic examination is the cornerstone of such an evaluation.

Radiologic assessment should begin with plain radiographs of the spine. In a series of 30 patients with surgically confirmed tethered cord (48), 28 were found to have open lumbar or sacral vertebral arches (Fig. 7), seven had fused arches, three block vertebra, one butterfly vertebra, five bony spurs, 11 sacral hypoplasia, nine scalloping of the vertebra, and eight scoliosis. MRI has revolutionized imaging of the spinal cord. The imaging features that suggest tethered cord include low position of the conus (68 ,79), thickened filum terminale (68), fatty infiltration of the filum terminale (Fig. 11) (55), split cord malformation (Fig. 12) (48 ,56), asymmetric location of the cord (48), intraspinal lipoma (Fig. 13), dorsal location of the cord (68), and abnormal movement of the cord from prone to supine position (68). Scatliff et al. (68), using metrizamide myelography with CT, showed that among 14 patients with tethered cord, 12 had an abnormally low conus medullaris, nine had thickened filum terminale (ranging from 1.5 to 4 mm in transverse diameter at L5), and all (including the two with normal position of the conus) had a decrease in movement of the cord as the myelographic position changed from prone to supine (normal movement is thought to be 5 mm or greater).

The normal position of the conus medullaris continues to be debated. In a study using MRI, Wilson and Prince (79) concluded that a conus level of L2–3 or above is normal at any age. A conus level at L3 is indeterminate, because it is possible for a normal or tethered conus to be located at this level. Merx et al. (48) analyzed several features seen at metrizamide myelography with CT of 30 patients who had surgically proven tethered cords. The authors estimated the sensitivity, specificity, and predictive value of these features. On the basis of the data, they suggested that contrast myelography with CT be used as a standard of reference for preoperative evaluation for tethered cord syndrome. The main limitations of myelography, however, are its invasive nature and the amount of ionizing radiation needed to complete the study. Because of the noninvasive nature of MRI and its availability, it should be the first line of investigation for patients who may have tethered cord syndrome. A number of studies have emphasized the specificity and sensitivity of spinal MRI (29). Ultrasonography has been proposed as a useful tool to screen infants for low conus, but use of this modality is limited to patients with incomplete posterior elements of the spine and to infants (51). The availability of an acoustic window in the developing lumbar spine usually is limited to the first 6 months of life. When available, ultrasonography can give clear visualization of the important anatomic features and add dynamic information concerning spinal cord mobility.

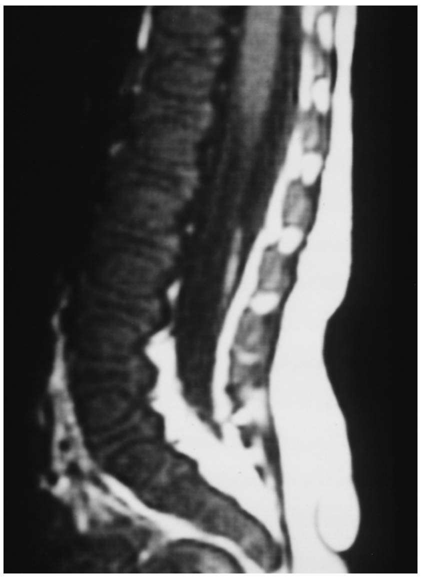

FIGURE 11. Sagittal T1-weighted magnetic resonance image of an infant with cutaneous dermal sinus shows lipomatous elements in a thickened filum terminale.

Children with tethered cord syndrome may come to medical attention with bladder dysfunction (37 ,84). Zoller et al. (84) performed urodynamic studies for 14 children with tethered cord syndrome. Seven of these 14 children did not have any clinical signs of bladder dysfunction. Urodynamic studies, however, showed neurogenic bladder in three of the seven children. The studies showed overactive detrusor function in two children and reflexic detrusor function in the third. Other authors have emphasized the high incidence of bladder dysfunction among children with tethered cord syndrome (31 ,66). It is therefore generally recommended that all children with tethered cord syndrome undergo preoperative urodynamic evaluation.

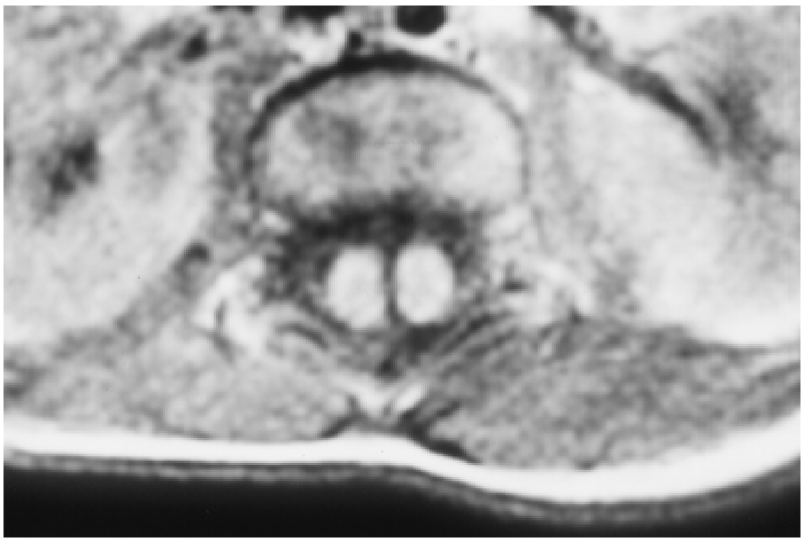

FIGURE 12. Axial, T2-weighted magnetic resonance image of an infant with a pronounced hairy patch in the lumbar region shows split cord malformation.

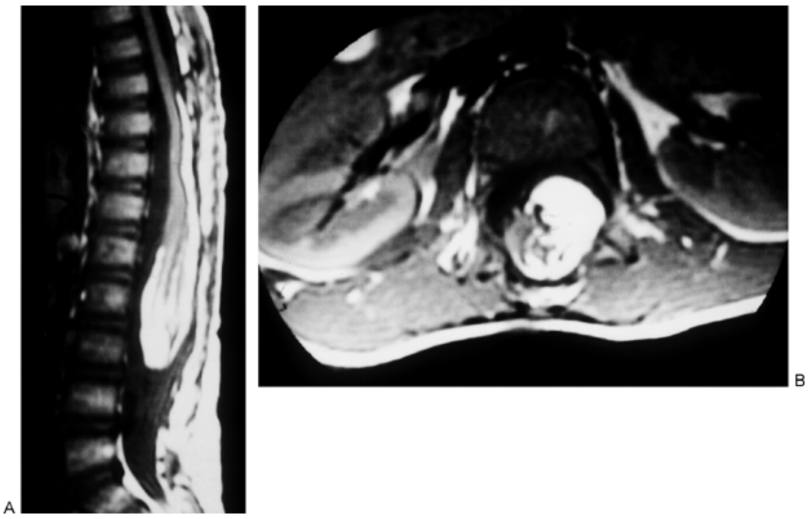

FIGURE 13. Sagittal **(A)** and axial **(B)** T1-weighted magnetic resonance images show large lipomyelomeningocele. Axial image shows how the conus and nerve roots are completely engulfed by lipoma, making simple debulking a treacherous undertaking.

The usefulness of electrophysiologic studies (somatosensory evoked potentials) in evaluating patients with tethered cord syndrome is not fully established. Kang et al. (36) studied sensory evoked potentials and regional spinal cord blood flow in an experimental model of the tethered spinal cord in growing cats. They showed that tethering caused reduction in blood flow and suppression of early components of sensory evoked potentials. They suggested that early untethering can normalize sensory evoked potentials and improve blood flow. Similarly, Roy et al. (67) were able to show that somatosensory evoked potentials from the lower extremity were altered among patients with tethered cord syndrome. Roy et al. (67) also showed a significant correlation ($r = 0.81$) between the severity of neurologic impairment and the extent of the abnormality of posterior tibial somatosensory evoked potential. Electrophysiologic studies alone should not be used to evaluate for the presence of tethered cord syndrome.

Treatment

Operative intervention should be considered for patients with spinal cord fixation from split cord malformation or from thickened filum terminale and symptoms attributable to that level of the spinal cord. The purpose of operation is to release the cord from its point of fixation. This would include resection of bony or cartilaginous septum with its dural sleeve or section of the filum terminale. In operations on patients without clear evidence of progressive dysfunction, the risks of operative intervention must be contrasted with the risks of the course of the condition. Guthkelch (28) provided a classic natural historical study in which 37 cases were diagnosed with myelography and followed. The conditions of 83% of the patients worsened in the 15 years of follow-up study. Continued observation of patients who have undergone surgical treatment shows them to have a high likelihood of remaining in neurologically stable condition after adequate surgical intervention. With this simple analysis, there appears little justification for a conservative approach to infants and children with these conditions.

A more difficult problem exists in the care of patients with symptoms referable to the conus medullaris and fat in the filum terminale but a distal conus only over the lower border of L2. We conducted an analysis with a group of 14 patients who had evidence of appropriate symptoms and associated findings of congenital malformation in which the conus could be considered in the lower limits of the normal position (71). Our view is that in a risk-benefit analysis, this select group of patients should be considered for operation if the clinical and radiographic evidence is strong.

TABLE 5. Results of Untethering of the Spinal Cord

Author	Year	No. of Patients Operated On	No. Improved	No. Unchanged	No. Worse
Anderson	1975	69	50	17	2
Hoffman et al.	1976	31	26	3	2
Pang and Wilberger	1982	23	15	7	1
Reigel	1983	102	60	29	13
Hendrick et al.	1983	86	64	22	0
Pierre-Kahn et al.	1986	64	14	48	2
McLone and Neidich	1986	50	20	27	3
Khoury et al.	1990	31	21	10	0
Zoller et al.	1991	14	3	10	1
Total		470	273 (58%)	173 (37%)	24 (5%)

Early operative intervention also should be considered for patients with lipomyelomeningocele. For decades, neurosurgeons shunned this group of children, thinking that if the condition remained clinically stable or if the lesion did progress, an operation would have little chance of altering the process. Within the past 15 years, inevitable progressive neurologic decline has been accepted as the natural course of these lesions, and operative intervention to release the cord and remove most of the infiltrating adipose tissue has become markedly safer (12 ,62). A large number (approximately 10%) of patients with this lesion, however, have recurrence of the cord fixation symptoms over several years. Operative intervention improves on the course of the lesions but can be associated with adhesions at the operative site, which secondarily cause cord fixation.

Tethered cord syndrome caused by closure of myelomeningocele is much more controversial. It is recognized that patients in this group are at risk of deterioration with respect to progressive weakness, scoliosis, pain, and bladder dysfunction. Even upper-extremity dysfunction has been attributed to caudal tension. The problem is not recognition of symptoms but the risk of the operative procedure to release the cord and the ability of any untethering procedure to keep the patient's condition neurologically stable for a long time. The results of untethering procedures among this population are still under study, and no general recommendation can be made at this time. For a large number of these patients, the intradural soft tissues are densely adherent. Surgically releasing these tissues without undue damage appears problematic, much less maintaining these tissues in a free state within a restricted and scarred dura. It seems logical at this point to reserve surgical treatment for the group of patients with documented progressive loss of neurologic function (8).

With regard to outcome (Table 5), numerous authors have documented their results. It appears that fixed deficits in children older than 4 years are unlikely to improve (33). Back pain is very likely to improve. Motor recovery improves among 40% and urinary continence among only 12% of patients (45). With this limited improvement in urinary dysfunction, early intervention appears justified if the operative risks are sufficiently low and the likelihood of long-term neurologic stability after the operation is high.

The Cell Biology of Spinal Cord Injury

Vincent J. Caiozzo

V.J. Caiozzo: Neuromuscular Research Laboratory, Department of Orthopaedics, College of Medicine, University of California, Irvine, California 92717.

One of the key concepts underlying cell physiology is the concept of cellular homeostasis. In essence, this principle states that the survival of a cell depends on its ability to maintain a constant internal environment. From a mechanistic perspective, the cell is isolated from its external environment by the cell membrane, which is composed of a lipid bilayer that contains many different kinds or classes of proteins. The physical-chemical properties of the lipid bilayer and associated membrane proteins are essential in maintaining a homeostatic environment. If the function of these different systems becomes impaired, then the very ability of the cell to regulate its internal environment becomes compromised. The result is consequential cell injury or death. As shown in Fig. 1 , the major components of the cell membrane responsible for maintaining the precarious balance between intracellular and extracellular compartments include (a) the phospholipids that provide the backbone of the cell membrane; (b) receptor-gated ion channels; (c) voltage-gated ion channels; (d) Na^+-Ca^{2+} exchangers; and (e) pumps such as the Na^+-K^+-ATPase pump and Ca^{2+}-ATPase pump.

When the functions of these different components become disrupted, there seem to be two major pathways by which cellular injury or death may occur. The first of these pathways is elevation in intracellular calcium concentration. As shown in Fig. 1 , elevated concentrations of calcium ion are known to overactivate a number of key enzymes that produce hydrolysis of the cell membrane, degradation of key cytoskeletal proteins, digestion of deoxyribonucleic acid (DNA), and evolution of free radicals. The second pathway involves lysis of the cell by unregulated influx of sodium and chloride ions.

Over the past 5 years, a great amount of attention has been devoted to studying programmed cell death, that is *apoptosis*. The concept of programmed cell death is thought to be in stark contrast to that of necrosis. It is entirely possible, however, that there may be hybrid forms of cell death that share features of apoptosis and necrosis. Hence, the first part of this chapter contrasts the morphologic, biochemical, and molecular features associated with apoptosis and necrosis. This is especially appropriate given the tremendous amount of scientific interest in apoptosis that has occurred during the past 5 years. This is followed by a discussion on the role of calcium, sodium, and chloride ions and free radicals in the cell death of neurons of the spinal cord. Efficacious management of spinal cord injury requires a molecular model of the cellular components involved in promoting spinal cord injury and paralysis. This review is intended to provide an overview of current knowledge regarding the cellular and molecular events involved in spinal cord injury and to introduce various animal models developed to address these issues.

Programmed Cell Death (Apoptosis) and Necrosis

Cell death is a fundamental biologic process that occurs under a variety of conditions, such as development, the adult steady-state condition, and disease. Programmed cell death occurs continuously during the adult state. It is well known to occur, for instance, where there is slow or rapid proliferation of cells, as in the intestine.

Many years ago it was suggested that physiologic cell death was much different from that which occurs after trauma or disease. At least two different terms—*apoptosis* and *necrosis*—were developed to differentiate these types of cell death from one another. Apoptosis has received much attention over the past 5 to 10 years and is thought to have a signature distinct from that of necrosis that varies in morphologic, biochemical, and molecular features. Physiologic cell death often is referred to as *apoptosis* and is mediated by active intrinsic factors. In contrast, pathologic cell death resulting from trauma or disease results in extrinsic insults to cells. For example, the insult can be osmotic, traumatic, toxic, or thermal in nature. Features of cell necrosis include disruption of cell membrane integrity, uncontrolled influx of calcium ion and water, and lysis and dissolution of the cell.

The foregoing scheme suggests that there are only two forms of cell death. However, there are forms of cell death that clearly share properties of both apoptosis and cellular necrosis. Hence, differentiating one form of cell death from another may not always be a simple task. It has been suggested that there can be an apoptosis-necrosis continuum based on the findings that excitotoxic neuronal cell death has features common to both apoptosis and necrosis. Other schemes of classifying the various types of cell death differentiate on the basis of nuclear or cytoplasmic degeneration.

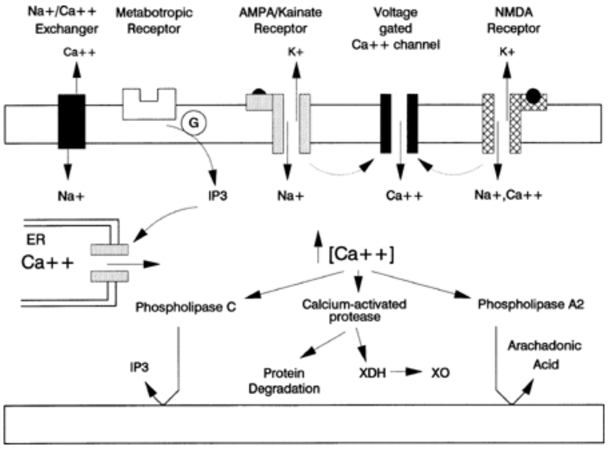

FIGURE 1. Mechanisms proposed as responsible for elevated intracellular Ca^{2+} concentration after injury and the possible pathways by which elevated intracellular Ca^{2+} concentration may produce cell injury or death. *G*, G protein; *XDH*, xanthine dehydrogenase; *XO*, xanthine oxidase.

Morphologic Features of Apoptosis and Cellular Necrosis

From a morphologic perspective, the phenotype of apoptosis is distinctive. The earliest phenotypic alteration typically occurs in the nucleus (43 ,44). Nuclear alterations include condensation of chromatin that abuts the nuclear envelope. Nucleolar dissolution occurs concomitantly with condensation of the chromatin. A number of alterations occur within the cytoplasm. The cytoplasm is known to condense with a consequential shrinkage in cell size. The mitochondria appear normal during this period, and it is thought that they are essential for apoptosis to continue. Subsequently, the nuclear and cellular membranes become convoluted in such a manner that it often is described as *budding*. So-called apoptotic bodies are then formed. Apoptotic bodies are membrane bound and can contain rough endoplasmic reticulum and mitochondria (42 ,115). The cellular debris then undergoes phagocytosis by neighboring cells without an inflammatory response. Hence, one of the key features of apoptosis is that infiltration of neutrophils does not occur (115). This is in contrast to cellular necrosis.

Unlike apoptosis, cellular necrosis usually occurs when there is a rapid departure from steady-state conditions, as can occur during anoxic-ischemic or traumatic events. The causal events that initiate cellular necrosis typically occur before the morphologic features of cell injury and death are detected. Perturbations that alter cell-volume homeostasis and mitochondrial function typically culminate in cellular necrosis (15 ,48 ,49 ,61). Such perturbations typically affect the integrity of the cell membrane and alter the ability to regulate the movement of ions. Perturbations that produce cellular necrosis affect oxidative phosphorylation and deplete high-energy phosphates. During apoptosis, there appears to be well-organized dismantling of the cell. In contrast, during cellular necrosis, cellular dysfunction appears to occur at many different nuclear and cytoplasmic levels. With respect to ultrastructural changes, clumping of chromatin, swelling and degeneration of organelles, and destruction of membrane integrity are key events. The progression of cellular necrosis contracts the mitochondria and condenses the inner membrane. Ribosomes are known to disengage from the rough endoplasmic reticulum and become dispersed throughout the cytoplasm. Unlike apoptosis, cellular necrosis culminates in the release of antigenic cellular debris that produces an inflammatory response characterized by leukocytic infiltration, edema, and a gross change in the histologic appearance of the tissue.

Dna Fragmentation During Apoptosis and Cellular Necrosis

One of the key approaches developed for classifying cellular death has been the so-called DNA ladder. During the process of cellular death, Ca^{2+}-Mg^{2+} endonucleases are known to be activated, and this phenomenon leads to digestion of DNA. The process of DNA digestion signifies an irreversible stage of cell death (3 ,109 ,115). It is generally believed that activation of endonucleases produces digestion of DNA that yields fragments that are uniform in length (180 bp). One of the proteins involved in the digestion of DNA during apoptosis is DNA fragmentation factor 45. This protein functions downstream of caspase-3 and causes internucleosomal DNA digestion during apoptosis (55). This type of digestion produces the DNA ladder, which can be identified with gel electrophoresis. In contrast, the digestion of DNA that occurs during cellular necrosis is much less uniform and produces a smear pattern (115). There are exceptions to these general rules. For example, internucleosomal DNA fragmentation occurs in ischemic liver necrosis and *N*-methyl D-aspartate (NMDA)–induced excitotoxicity.

DNA fragmentation can be detected in situ with several different techniques involving the end-labeling of either single-strand or double-strand DNA breaks (28 ,112). In the in situ nick translation technique DNA polymerase is used to catalyze the transfer of deoxyuridine triphosphate, which is conjugated with a reporter molecule. The TUNEL technique derives its name from the fact that it involves terminal transferase-mediated D-uridine triphosphate nick end labeling. Both techniques are highly sensitive to identifying nicked DNA. However, DNA repair might also lead to end labeling. Neither of these techniques can be used to differentiate apoptotic from necrotic cell death.

Molecular Aspects of Apoptosis

Two major gene families are believed to play critical roles in mediating apoptosis. The caspases are one of these families and belong to a group of so-called cysteine proteases. To date, at least ten different caspases have been identified. The caspases are proenzymes that undergo proteolytic cleavage and rearrangement of subunits to produce active enzymes that interact with substrates at the nuclear level, the cytoskeletal level, and the inflammatory level. A second group of apoptotic regulatory genes is the *bcl*-2 protooncogene family. Within this family *bcl*-2, *bcl*-xl, and *mcl*-1 are antiapoptotic. Other members of this family are proapoptotic and include *bax, bcl*-xs, *bad, bak*, and *bik*.

A number of lines of evidence indicate that the mitochondria play a key role in the apoptotic process. For example, it has been shown that during apoptosis the mitochondria remain intact and that *bcl*–2 localizes on the outer membrane of the mitochondria (52). Additionally, it has been shown that the mitochondria of *Xenopus* eggs contain a dense organelle essential for apoptosis. Cytochrome *c* also has been shown (51 ,54) to be an essential component of the apoptotic program. The suggestion is that the mitochondria release cytochrome *c* during apoptosis. One model (51) is used to propose that cytochrome *c*, also called apoptotic protease activating factor 2, is a potent activator of caspases. Subsequent involvement of caspases leads to cleavage of a protein with deoxyribonuclease activity, which causes internucleosomal fragmentation of genomic DNA. The antiapoptotic proteins *bcl*–2 and *bcl*-xl are thought to prevent release of cytochrome *c* from the mitochondria. This prevents activation of caspase-3. The role of *bcl*–2 and *bcl*-xl in preventing the release of cytochrome *c* from the mitochondria may involve inhibition of *b*ax-related channels, proapoptotic activity of the outer membrane of the mitochondria, or the regulation of mitochondrial membrane potential.

Calcium Paradox

Large differences in ion concentration exist across the cell membrane. For example, the extracellular concentration of sodium ion is approximately tenfold greater than the intracellular concentration. In contrast, the extracellular concentration of potassium is approximately 30-fold less than the intracellular concentration. Of all the main ions, however, the 10,000-fold concentration difference for calcium is the most prominent. Although the cytoplasmic concentration of calcium ion is regulated at very low concentrations, calcium is an extremely important ion that is essential for normal cellular function.

The role of intracellular calcium was first elucidated in 1883 by Sidney Ringer, who showed that calcium is essential for the contraction of cardiac muscle. The role of calcium in modulating neurotransmitter release was elucidated by Bernard Katz during the 1950s and 1960s. We now know that calcium ions play a key role in regulating a vast array of cellular processes under normal physiologic conditions. It plays a key role in regulating actin-myosin interaction, which is essential for locomotion, breathing, and cardiac function. It serves a pivotal role in regulating the release of neurotransmitters from synaptic vesicles. It plays an important role in the allosteric regulation of calmodulin, and calcium serves a key function in exocytosis.

As shown in Fig. 1 , the intracellular concentration of calcium is normally regulated by a variety of systems, which include plasma membrane proteins such as the Ca^{2+}-ATPase pump, Na^{+}-Ca^{2+} ion exchanger, voltage-gated calcium ion channels, receptor-gated ion channels, and second-messenger systems. Within the cell, organelles such as the endoplasmic reticulum and mitochondria play a key role in maintaining calcium ion concentration at micromolar levels (68).

Under conditions of anoxia or toxicity, each of these systems potentially represents a failure point that can disturb the homeostasis of intracellular calcium ion (68). Evidence of the involvement of calcium ion in promoting cell injury and death has come from the study a number of different cell types. For example, Dayton et al. (14) showed that calcium ion plays a central role in the dissolution of Z lines in skeletal muscle. Schanne et al. (84) examined the effects of ten different toxins on hepatocyte viability. In each instance, the investigators concluded that calcium ion is essential for promoting cell death induced by the toxins. In the presence of these ten different toxins but in the absence of calcium ion, almost all hepatocytes survived. These investigators concluded that cell injury or death occurs in a two-step process. The first phase is disruption of the integrity of the cell membrane; the second is influx of extracellular calcium ion into the cytoplasm of the cell. The latter phase was described as the final common pathway for cell death.

With respect to neurons, Schlaepfer et al. (85 ,86 ,87 ,88 ,89 ,90 ,91 ,92) as early as 1973 reported that degeneration of axons depends on a calcium-mediated process. Schlaepfer et al. (85 ,86 ,87 ,88 ,89 ,90 ,91 ,92) later identified this degenerative process as degradation of microtubules and the neurofilament triplet. The neurofilament triplet is composed of three subunits with molecular weights of 200 kd (heavy subunit), 150 kd (medium subunit), and 68 kd (light subunit). Using the calcium ionophore A23187, Schlaepfer (85) showed that peripheral nerves exposed to the ionophore in the absence of calcium exhibited little degradation of the neurofilaments. When calcium was added to the bathing medium, degradation of the neurofilament triplet was substantial.

With respect to spinal cord injury, Young (117) reported that impact trauma causes the extracellular concentration of calcium ion to decrease from a normal value greater than 1 mmol to less than 0.001 mmol. The marked decrease in extracellular calcium ion concentration is the result of cellular injury, which allows calcium ion to flow into the cytoplasm in an unregulated manner. Consistent with these findings was the finding by Happel et al. (31) that spinal cord intracellular calcium levels are elevated as early as approximately 30 minutes after injury induced by the weight-drop technique. Regan and Choi (77) explored the importance of calcium ion in promoting cellular injury. These investigators used spinal cord cultures and found that the cellular damage induced by high concentrations of glutamate (see later) depends on the presence of calcium. When calcium was not included in the bathing medium, the rate of cellular injury decreased by approximately 80%. Banik et al. (4) reported that at the protein level neurofilament degradation in the spinal cord was evident as early as 15 minutes after injury. Degradation of neurofilaments is a calcium-dependent process. The observation that neurofilament degradation occurs very early during injury demonstrates that unregulated calcium influx occurs early in the evolution of spinal cord injury. My colleagues and I (25) found that 4 hours of anoxia was sufficient to decrease the neurofilament triplet content of the spinal cord approximately 60%.

As shown in Fig. 1 , uncontrolled influx of calcium ion can mediate cellular injury through a number of pathways. These include overactivation of (a) calcium-activated neutral proteases, (b) phospholipase C, (c) phospholipase A_2, and (d) endonucleases. This represents the *calcium paradox*. Under normal conditions, calcium ions play key roles in regulating a number of important biochemical pathways. However, if the intracellular homeostasis of calcium ion becomes disrupted, cell death is a likely consequence.

The pivotal role of calcium ion in mediating cellular injury has stimulated investigators to examine a number of potential pathways by which extracellular calcium ion enters neurons during episodes of anoxia or ischemia.

Role of Excitatory Amino Acid Receptors in Promoting Spinal Cord Injury

Excitatory Amino Acids As Neurotransmitters

Excitatory amino acids such as glutamate and aspartate are major neurotransmitters within the central nervous system. These excitatory amino acids are normally released from the axon terminal of a neuron and bind to excitatory amino acid receptors on the postsynaptic membrane, producing depolarization of the postsynaptic neuron. Under normal conditions, excitatory amino acids play important roles in processes such as synaptogenesis, neuronal plasticity, learning, memory, and central pattern generators (9 ,21 ,101 ,102).

Paradoxically, under conditions of anoxia, extracellular calcium ion may leak into the axon terminals of presynaptic neurons and cause glutamate to be released in large, uncontrolled quantities. Under these conditions, the glutamate concentration in the synaptic cleft may reach concentrations approaching 10 mmol, a concentration two orders of magnitude greater than that needed to cause extensive neuronal damage (12). The ensuing neuronal damage is thought to be caused by the unregulated release of these excitatory amino acids, which overactivates the respective receptors on the postsynaptic cell. This process of overactivation has been called *excitotoxicity*. Olney and Rothman (67 ,81) initially developed the concept of excitotoxicity, which is that exposure of neurons to excitatory amino acids such as glutamate produces excess depolarization. This excessive depolarization was hypothesized to produce altered ionic flux across the cell membrane. This hypothesis was supported further when it was shown that excitatory amino acids induce swelling of the cell bodies and dendrites, regions of the neurons that have high concentrations of excitatory amino acid receptors (60). The swelling that accompanied exposure to excitatory amino acids was later shown to be related to the uncontrolled influx of sodium and chloride ions. When these ions were replaced with impermeable ions, the swelling that accompanied exposure to excitatory amino acids was abolished.

A cornerstone to the concept that spinal cord injury may be mediated by the unregulated release of excitatory amino acids is the observation that spinal cord injury does produce elevations in extracellular concentrations of glutamate and aspartate, two of the major excitatory amino acids in the spinal cord (19 ,53 ,74). Panter et al. (74) reported that the concentrations of glutamate and aspartate were markedly (approximately 300%) elevated above baseline values immediately after impact trauma. Liu et al. (53) found large increases in the extracellular concentrations of glutamate and aspartate after impact trauma. In both studies, the increases in extracellular concentrations of excitatory amino acids were rapid (within several minutes after trauma) and remained at toxic levels for several hours after impact trauma. These two key studies showed that trauma to the spinal cord can produce toxic concentrations of excitatory amino acids.

Major Classes of Excitatory Amino Acid Receptors

Four major classes of excitatory amino acid receptors have been identified. Each of these receptors can play a role in promulgating spinal cord injury. The four excitatory amino acid receptors are the NMDA receptor, the *a*-amino-3-hydroxy-5-methyl-4-isoxazole propionate receptor (AMPA), the kainate receptor, and the metabotropic receptor. The NMDA, AMPA, and kainate receptors have been classified as ionotropic receptors because they are associated with an ion channel. The ion channels associated with each of these three kinds of excitatory amino acid receptors are typified by different permeabilities to sodium, potassium, and calcium ions (21 ,60 ,64).

Nmda Receptor and its Possible Role in Spinal Cord Injury

The NMDA receptor is a macromolecular complex that contains a transmitter-binding site, a modulatory site that binds the allosteric activator glycine, and an ion channel permeable to sodium, potassium, and calcium ions (21 ,59 ,60 ,64). It has been hypothesized that during ischemic or anoxic episodes, the NMDA receptor may become overactivated by means of unregulated release of the neurotransmitter glutamate from presynaptic vesicles or by means of impaired uptake of glutamate by glial cells. Both of these mechanisms are attractive because they can account for the pathways by which calcium and sodium ions may gain access to the cytoplasm after events that induce spinal cord injury.

Overactivation of the NMDA receptor provides a secondary pathway by which calcium ion homeostasis can be disturbed. Overaction of the NMDA receptor is known to depolarize the cell. As a consequence, the voltage-gated calcium ion channels become activated and allow calcium ion to enter through this additional pathway.

The spinal cord is known to contain NMDA receptors. Studies by Jansen et al. (39), Mitchell and Anderson (62), Monaghan et al. (64), and Shaw et al. (95) have shown the existence of NMDA receptors in the spinal cords of cats, rats, and humans. Shaw et al. (95) found that the greatest density of NMDA receptors occurs in the lumbar and sacral segments of the spinal cord. With respect to the distribution of NMDA receptors in the gray matter, Mitchell and Anderson (62) and Shaw et al. (95) found that the greatest density of NMDA receptors occurs in the dorsal horns. Shaw et al. (95) found that the density of NMDA receptors in the substantia gelatinosa was approximately twofold greater than throughout the rest of the gray matter. The remaining regions of gray matter appear to have a uniform density of

NMDA receptors. Shaw et al. (95) also found focal areas of high concentration of NMDA receptors in the ventral horn. These focal areas had NMDA receptor concentrations twofold greater than the substantia gelatinosa. Shaw et al. (95) suggested that the distribution and size of these foci were similar to those of the cell bodies of motor neurons.

The potential role of NMDA receptors in promoting cellular injury in the central nervous system was highlighted by the finding that NMDA antagonists protect the hippocampal region of the brain from ischemic insult (100). Simon et al. (100) induced ischemic brain damage by occluding the carotid arteries for 30 minutes. They found that the NMDA antagonist 2-amino-phosphonoheptanoic acid (APH) markedly attenuated ischemia-induced injury. The NMDA antagonist was found to be so effective that some of the APH-protected hippocampal regions appeared normal. The findings of Simon et al. (100) provided a strong stimulus for examining the potential role of the NMDA receptor in promoting spinal cord injury.

Faden and Simon (19) were one of the first groups of investigators to examine the role of excitotoxicity in spinal cord injury. Using a weight drop model of inducing spinal cord injury, these investigators examined the extent of spinal cord injury in animals that were treated with an NMDA antagonist, MK-801, or a control solution of saline. Faden and Simon (19) found that the NMDA antagonist was effective in minimizing the extent of spinal cord injury. Four weeks after the initial injury, 45% of animals treated with MK-801 had regained the ability to walk; 20% of the animals used as controls had the same result. Gomez-Pinilla et al. (29) found that MK-801 provided a moderate neuroprotective effect after injury induced with a weight-drop technique.

Yum and Faden (118) examined the efficacy of using MK-801 after spinal cord ischemia induced with a catheter balloon. As did earlier investigators, these investigators found that administration of MK-801 was followed by motor scores and a greater survival rate of neurons within the ventral horn of the spinal cord.

Regan and Choi (77) showed that the NMDA receptor can play a powerful role in promoting cellular injury and death. Using cultured neurons obtained from the spinal cords of mice, these investigators found that high concentrations of glutamate markedly elevated the lactate dehydrogenase (LDH) concentration of the bathing medium. When the noncompetitive NMDA receptor antagonist dextrorphan was added to the bathing medium containing high concentrations of glutamate, the LDH concentration in the bathing medium was markedly reduced. These investigators also found that high levels of glutamate in the absence of calcium ion in the bathing medium produced little cellular injury. This finding in combination with those observed with dextrorphan suggests that high concentrations of glutamate induce death of spinal cord neurons by means of excessive calcium influx.

Gardner et al. (25) showed that at the protein level, neurofilament degradation in anoxic spinal cords can be amplified when the spinal cord is bathed in a medium containing high concentrations of glutamate or NMDA. When ketamine, an NMDA receptor antagonist, is included in the bathing medium, the extent of neurofilament degradation decreases.

The Nmda Paradox: its Role in the Neurogenesis of Locomotion

It is ironic that although the NMDA receptor can play such powerful role in promoting cell injury within the spinal cord under abnormal conditions, it is essential for the neurogenesis of locomotion under normal conditions—hence the NMDA paradox. In studies of the spinal cords of lampreys, Brodin and Grillner (9) showed that when the spinal cord was exposed to NMDA receptor agonists a rhythmic swimming motion was initiated. Smith et al. (101 ,102), using a neonatal rat model, found that all forms of locomotion depended on activation of the NMDA receptor. Locomotion initiated by activating the command center in the brain stem can be blocked with application of a competitive inhibitor of the NMDA receptor, AP5, to the solution bathing the spinal cord. Smith et al. also showed that the application of AP5 to the bathing solution abolished locomotion initiated by sensorimotor circuits. They (102) concluded that all locomotor activity ultimately depends on activation of the NMDA receptors in the spinal cord.

Potential Role of the Ampa Excitatory Amino Acid Receptor in Spinal Cord Injury

As shown in Fig. 1 , the AMPA receptor is permeable to sodium and potassium ions (21 ,64). As with the NMDA receptor, during episodes of spinal cord trauma, elevated toxic levels of glutamate may occur. Overactivation of this receptor consequently depolarizes spinal cord neurons. This depolarization causes the voltage-gated calcium ion channels to open and allows unregulated influx of calcium ions. In this scenario, the AMPA receptor is thought to be capable of inducing cell death through overactivation of calcium-mediated pathways as well as through cellular swelling and lysis.

The investigations of Jansen et al. (39) and Mitchell and Anderson (62) indicated that the greatest density of AMPA receptors is within lamina II region of the dorsal horn. Using a quantitative radiographic technique, Mitchell and Anderson (62) found that the lamina III-V region of the dorsal horn has a receptor density approximately 70% of that in the lamina II region. In the ventral horn, AMPA receptor density was approximately 50% of that in lamina II.

The presence of AMPA receptors and their potential for mediating neuronal injury by means of unregulated influx of sodium ions and activation of voltage-gated calcium ion channels raises the possibility that these receptors might be involved in promoting spinal cord injury. We do not know of any studies examining the role of the AMPA receptor in promoting spinal cord damage after anoxic insult or trauma after weight drop. However, the AMPA receptor has been implicated in promoting motor neuron death associated with human neurolathyrism. Neurolathyrism is characterized by irreversible spastic paralysis of the lower limbs (8 ,80 ,103). Neurolathyrism occurs as a result of excessive consumption of seeds (*Lathyrus sativus*, the chickling pea) that contain the neurotoxin *β-N*-oxalylamino-L-alanine L-BOAA). L-BOAA is a very potent excitotoxic glutamate analogue. Spencer et al. (103) found that subconvulsive doses of L-BOAA produced motor deficits among other primates similar to those among humans. Ross et al. (80) later showed that the excitotoxic effect of L-BOAA can be attenuated by antagonists of the AMPA receptor.

Neurolathyrism provides an important model to establish the potential role of the AMPA receptor in spinal cord injury. However, no studies have directly examined the role of this excitatory amino acid receptor in the promulgation of spinal cord injury. This issue needs to be specifically addressed as does the mechanism by which overactivation of this receptor induces cellular injury (cellular swelling through influx of sodium ions, unregulated influx of calcium ion).

Recent studies have showed that the extent of cellular injury in the brain after an ischemic insult can be minimized with AMPA antagonists. For example, Buchan et al. (10) used a four-vessel occlusion rat model to produce severe forebrain ischemia. The AMPA antagonist reduced the amount of cellular injury from a control value of approximately 75% down to approximately 25% of the CA1 cells examined. A similar effect was found by Sheardown et al. (96). In both studies, investigators used the AMPA antagonist 2,3-dihydroxy-6-nitro-7-sulfamoyl-benzo-(f)-quinoxaline (NBQX). These studies provide encouraging possibilities with respect to the potential involvement of AMPA receptors in promoting spinal cord injury.

Although the AMPA receptor may play a role in the pathogenesis of spinal cord injury, the findings of Regan and Choi (77) suggest that the NMDA receptor plays the central role among excitatory amino acid receptors in promoting this process. Regan and Choi (77) found that spinal cord neurons in culture are extensively damaged when incubated with a high concentration of glutamate and physiologic concentration of calcium ion. When the NMDA receptor antagonist dextrorphan was included in the bathing medium, the extent of cellular damage was reduced by approximately 80%, as indicated by LDH levels. Because of this finding, it would appear as if most of the cellular injury induced by elevated levels of glutamate occurs through the NMDA receptor and that at most the combined effect of the AMPA and kainate receptors can account for only approximately 20% of cell damage.

Possible Involvement of Kainate Receptors in Promoting Spinal Cord Injury

Like the AMPA receptor, the kainate receptor is believed to be permeable to both sodium and potassium ions (21 ,64). Overactivation of this receptor consequently can produce excitotoxicity by allowing excessive influx of sodium ion and producing cellular swelling and lysis. Elevation of the resting membrane potential caused by influx of sodium ions through the kainate receptor may act through a secondary pathway, that is, voltage-gated calcium ion channels. As with the NMDA and AMPA receptors, the kainate receptor is capable of promoting cellular injury and death by two different pathways.

The spinal cord has been shown to contain a large number of kainate receptors. Monaghan et al. (64), Jansen et al. (39), and Mitchell and Anderson (62) have consistently found that the greatest density of kainate receptors occurs in the dorsal horn of the spinal cord. In a quantitative study, Mitchell and Anderson (62) found that the greatest density occurred in lamina I-II with the lowest density occurring in the ventral horn. The general pattern of receptor density is similar to that of the NMDA and AMPA receptors.

Regan and Choi (77) have provided strong evidence that in the presence of elevated concentrations of glutamate, the NMDA receptor plays a key role in modulating the extent of neuronal injury in the spinal cord. However, Urca and Urca (111) showed that intrathecal injection of high concentrations of kainate (the preferred agonist of the kainate receptor) were capable of producing nonselective destruction of neurons in the lumbar region of the spinal cord. However, when low doses of kainate were intrathecally injected there was limited damage to motor neurons and little motor deficit.

Most studies examining the importance of excitatory amino acid receptors in the pathogenesis of spinal cord injury have been focused on the NMDA receptor. More work is needed to better define the role of AMPA and kainate receptors in this process.

Potential of the Metabotropic Receptor for Promoting Spinal Cord Injury

As shown in Fig. 1 , the endoplasmic reticulum is known to sequester calcium. Therefore the concentration of calcium ion within the endoplasmic reticulum is much higher than the cytosol concentration. The endoplasmic reticulum is known to regulate the content of calcium through the interaction of two endoplasmic reticulum membrane proteins, the Ca^{2+}-ATPase pump and a calcium ion release channel. The Ca^{2+}-ATPase pump moves calcium ions against a large concentration gradient into the endoplasmic reticulum. In contrast, the open calcium ion release channel allows calcium ion to diffuse from the endoplasmic reticulum compartment into the cytoplasm. The endoplasmic reticulum calcium ion release channel is known to be activated by a second messenger, inositol triphosphate. Elevation of inositol triphosphate level during ischemic or anoxic events can cause the endoplasmic reticulum to release a large amount of calcium ion into the cytoplasm of the affected neuron.

As shown in Fig. 1 , overaction of the metabotropic receptor because of the presence of elevated concentrations of glutamate may play a role in promoting spinal cord injury by producing abnormal levels of inositol triphosphate. We know of no studies, however, in which investigators have attempted to examine the role of the metabotropic receptor in spinal cord injury. The findings of Madden et al. (57) and Regan and Choi (77) seem to indicate that the disruption of calcium ion homeostasis that occurs during anoxia or elevated glutamate exposure occurs as a result of overaction of the NMDA receptor. Although the metabotropic receptor does have the potential for disrupting calcium ion homeostasis, it would seem to play a minor role at best.

Na^+-Ca^{2+} Exchanger

Overactivation of excitatory amino acid receptor potential may alter calcium ion homeostasis by acting on the Na^+-Ca^{2+} exchanger. Under normal conditions, the high concentration gradient for sodium ion that exists causes sodium ions to move inward through this membrane protein. In exchange, calcium ions move from the intracellular to the extracellular compartment, thereby maintaining intracellular concentration of calcium ion at a low level. The high concentrations of intracellular sodium ion that accompany exposure to elevated levels of glutamate, however, can reduce the concentration gradient for sodium ion and may actually cause the Na^+-Ca^{2+} exchanger to work in a reverse direction, moving extracellular calcium ions into the intracellular compartment.

Potential Role of Voltage-Gated Calcium Ion Channels in Promoting Spinal Cord Injury

As shown in Fig. 1 , voltage-gated calcium channels have been postulated to play a role in the pathogenesis of spinal cord injury. Any mechanism capable of elevating the resting membrane potential of a spinal cord neuron is thought to be capable of activating the voltage-gated calcium channels and producing an unregulated influx of calcium ions. It has been proposed that overactivation of the NMDA, AMPA, and kainate receptors may play a role in this process.

Voltage-gated calcium ion channels normally play a vital part in intracellular calcium homeostasis. These calcium ion channels, which open in response to membrane depolarization, have been found to be ubiquitous among vertebrates. With the aid of pharmacologic tools such as dihydropyridines and natural toxins, it has been possible to identify a number of subtypes of voltage-gated calcium ion channels. At least three different kinds of voltage-gated calcium ion channels are present in neurons. These have been classified as the L (long lasting), T (transient), and N (neither L or T) types (97). The N type is thought to be specific to neurons, whereas the L type has been found in a number of other excitable tissues, such as skeletal and cardiac muscle (97). These channels differ from one another with respect to conduction properties and activation-inactivation properties. The L-type channel is located on the cell bodies and dendrites of neurons in the spinal cord (97). The N type of voltage-gated calcium ion channel is believed to be predominately located in the axon terminal that corresponds to sites where neurotransmitter release is known to occur. The different locations of the L (postsynaptic) and N (presynaptic) types of channels suggest different roles for these subtypes of voltage-gated calcium ion channels. It has been proposed that the location of the N-type channel on the presynaptic membrane indicates that this type of channel plays a key role in regulating neurotransmitter release (97). In contrast, the postsynaptic localization of the L type has been suggested to reflect its role in a number of activities specific to the cell body, such as cytoskeletal organization and gene expression.

A small peptide has been isolated from the venom of a marine snail (*Conus geographus*) and has been shown to be a potent and highly specific inhibitor of the N-type voltage-gated calcium ion channel. Madden et al. (57) used this peptide to explore the role of the N-type channel in pathogenesis of spinal cord injury. They found that when the N-type channel was blocked with this peptide, there was a small effect on the calcium accumulation that occurred under hypoxic conditions. They also found that blockade of the N-type channel had little effect on calcium accumulation when neurons were exposed to high concentrations of glutamate. When ketamine was added to the bathing medium, however, it was found that all of the glutamate-induced calcium accumulation could be prevented. The findings of this study are important in two respects. First, they suggest that the N-type voltage-gated calcium ion channel does not have an important role under injurious conditions such as hypoxia or high levels of glutamate. Second, the investigators found that all of the calcium accumulation during exposures to high glutamate concentrations could be prevented when cells were bathed with the NMDA receptor antagonist ketamine. This is powerful evidence that the AMPA and kainate receptors have a much less important role in the pathogenesis of spinal cord injury than does the NMDA receptor. However, the N-type channel is thought to be located in the region of the axon terminal that might preclude the N-type channel from playing an important role in neuronal death. It might be possible that the L-type channels more proximal to the cell body play a greater role in the pathogenesis of spinal cord injury.

Some studies of the L-type channel (98) have shown that antagonists of this channel can be effective in minimizing the extent of cerebral damage after ischemia. However, results of these studies seem to indicate that antagonists such as nimodipine exert influence by acting on the blood vessels and producing vasodilatation rather than preventing an unregulated influx of calcium ion through L-type channels. These findings are consistent with those of Regan and Choi (77) and Madden et al. (57). The combination of the latter two studies strongly suggest that the large influx of calcium ion associated with hypoxia or elevated levels of glutamate occurs through the NMDA receptor (11). At most, it appears as if 20% of the calcium ion influx can be explained by the involvement of voltage-gated calcium ion channels.

Calcium-Mediated Cell Death: the Final Common Pathway

Calcium may act in a variety of ways to produce cell death. The different pathways include activation of calcium-activated proteases I and II (calpains I and II), phospholipase A_2, phospholipase C, or endonucleases.

Calcium-Activated Neutral Proteases (Calpains)

As early as 1964, Guroff (30) described a calcium-activated neutral protease responsible for degrading a number of proteins in the cytoplasm of neurons. Dayton et al. (14) later were able to develop a purified preparation of calcium-activated neutral proteases. They showed that these proteases were capable of degrading cytoskeletal proteins such as α-actinin, which makes up the Z line in skeletal muscle. These calcium-activated neutral proteases are now called *calpains*.

Calpains are calcium ion–activated cysteine proteases. At least two isoforms exist. These have been classified as calpain I and calpain II. Calpain I is known to be activated at micromolar concentrations of calcium ion. Calpain II requires millimolar concentrations of calcium ion to become activated. Both calpain I and II are heterodimers composed of a heavy catalytic subunit (approximately 80 kd) and a light regulatory subunit (approximately 30 kd). The heavy subunits of calpains I and II each contain four domains. The first domain represents the N terminus and is composed of 79 residues. The second domain (240 residues) has a high degree of homology with papain. The third domain is also approximately 240 residues long. The fourth domain has a calmodulin-like sequence (145 residues long) and binds calcium ions.

In contrast to the heavy chain, the light chain contains two subunits. The first subunit comprises the N terminus, whereas the second subunit contains a calmodulin-like sequence at the C terminus. Site-directed mutagenesis has shown that the first domain is not essential for the catalytic activity of the 80-kd subunit. However, the second subunit of the light chain seems to play an essential role in the activation of the 80 kd catalytic subunit.

The common properties of calpains are that (a) activation requires calcium ion and a sulfhydryl reducing agent, (b) these substances are principally located in the cytosol, (c) molecular weight is approximately 110,000 composed of two subunits with molecular weights of 72 to 82 kd and 25 to 30 kd, respectively, (d) these substances are specifically inactivated by endogenase inhibitor calpastatin and microbial inhibitor leupeptin, and (e) the optimum pH is 7.0 to 8.5. The active site is known to be located within the heavy subunit. Calpains and their endogenous inhibitor are present in a wide variety of cell types, including neurons, cardiac and skeletal muscle, hepatocytes, and erythrocytes.

As shown in Fig. 1 , calpains are known to play an important role in promoting cell death. Overactivation of calpain has been shown to degrade a number of proteins essential for normal cellular function and possibly to promote production of superoxide free radicals by means of activation of xanthine dehydrogenase.

Membrane-Associated Protein Substrates of Calpain

Calpains have been shown to act on a number of membrane-associated proteins. These include spectrin, fodrin, ankyrin, Ca^{2+}-ATPase, *α*-adrenergic receptors, and the phospholipid-binding protein lipocortin (33 ,35). Spectrin is known to be a major calpain substrate. Spectrin is of particular interest because it seems to play an important role in the cytoskeletal architecture of neurons, providing a link between proteins such as actin and neurofilaments (22 ,23). Spectrin is known to be composed of two large subunits classified as alpha and beta (22 ,23). Specifically, the *β* subunit has been shown to contain binding sites for both actin and neurofilaments (22). Both the *α* and *β* subunits are known to be degraded by calpain (33 ,94). Overactivation of calpain by an unregulated influx of calcium ions has the potential for disrupting the cytoskeletal architecture of neurons. Seubert et al. (94) found that the spectrin meshwork is essential for maintaining membrane lipid bilayer asymmetry and that loss of this asymmetry has been shown to result in engulfment of erythrocytes by macrophages. Seubert et al. (94) suggested that a similar scenario may occur in neurons.

Cytoskeletal Substrates of Calpain

Overaction of the calpain system is capable of disrupting the normal cytoskeletal architecture not only by acting on spectrin but also by degrading important cytoskeletal proteins, such as neurofilaments, microtubule-associated proteins, tubulin, and vimentin. Neurofilaments are known to be located in axons and are thought to play a role in axonal transport of key molecules. The neurofilament is known to be composed of three subunits. These have been identified as the heavy (200 kd), medium (160 kd), and light (68 kd) subunits. Schlaepfer et al. (85 ,86 ,87 ,88 ,89 ,90 ,91 ,92) initially described the susceptibility of the three neurofilament subunits to calcium-mediated protein degradation. The initial studies were performed on peripheral nerve. These investigators later were able to confirm similar findings in the spinal cord. The neurofilaments were shown to be selectively degraded by calcium-activated neutral proteases (38 ,71 ,72 ,73).

Tsujinaka et al. (110) synthesized an inhibitor of calcium-activated proteases that they called *calpeptin*. The strategy of these investigators was twofold: (a) to develop an inhibitor directed at the active site of calpain and thus very specific and (b) to chemically modify such an inhibitor to enhance its permeability. Following this scheme, Gardner et al. (26) synthesized calpeptin in a similar manner. Using this inhibitor, Gardner et al. (26) examined the role of calpain in producing the neurofilament degradation that accompanies anoxic events in the spinal cord. These investigators used three different indexes to assess the effectiveness of calpeptin. These were total neurofilament pellet weight, total protein, and quantitative assessment of each of the individual neurofilament triplets. By every account, calpeptin proved to be extremely effective in preventing loss of the neurofilament triplet. For example, the heavy, medium, and light subunits were reduced by only 24%, 23%, and 16%, respectively, which compares with losses of 92%, 92%, and 86% under conditions in which the spinal cords was exposed to an anoxic calcium ion solution.

In addition to the neurofilament, calpain also has been shown to degrade microtubule-associated protein 2 (MAP2). The *α* and *β* tubulins form the structural backbone of mircrotubules. Microtubules are long, unbranched macromolecules. The presence of microtubules and neurofilaments in the axon suggests that these macromolecules play a role in axonal transport. MAPs are thought to play a role in determining the polymerization of tubulins, their association with other cytoskeletal proteins, and the treadmill-like activity associated with microtubules. MAP2 is thought to be restricted to the dendritic and cell body regions of neurons, where it plays an important role in morphogenesis. Inuzuka et al. (35) used a calpain inhibitor, E-64c, to examine the degradation of MAP2 after cerebral ischemia. These investigators found that ischemia reduced the MAP2 content approximately 70%. When E-64c was injected into the animals before the ischemic episode, loss of MAP2 decreased, demonstrating the potential role of calpain in mediating disassembly of microtubules after ischemic insult.

Role of Phospholipases in Producing Membrane Dysfunction

Although elevated levels of intracellular calcium ion are capable of producing cell injury by acting on calcium-activated neutral proteases, the elevation of intracellular calcium ion concentrations can produce extensive membrane damage by acting on two key enzymes, phospholipase A^2 and phospholipase C. Phospholipases are known to catalyze hydrolysis of the phospholipids that make up the cell membrane (62). The membrane plays a key role in maintaining intracellular homeostasis. Activation of these two enzymes has the potential for disrupting normal membrane function.

Phospholipase A^2 and the Arachidonic Acid Cascade

As shown in Fig. 2 , activation of phospholipase A^2 catalyzes a reaction that splits arachidonic acid off from the phospholipids of the cell membrane. Once formed, arachidonic acid is converted by one of two enzymes, cyclooxygenase or lipoxygenase, into a class of chemical messengers known as *eicosanoids*. As shown in Fig. 2 , cyclooxygenase converts arachidonic acid into one of three classes of cyclic endoperoxides. These are prostaglandins, thromboxanes, and prostacyclin. In contrast, lipoxygenase converts arachidonic acid into leukotrienes. Arachidonic acid and its metabolic by-products have been shown to play key roles in such neuronal processes as modulating ion channel activity, modulating ligand binding, modulating neurotransmitter release, and interacting with other cellular messenger systems (79). Under normal conditions, the concentration of arachidonic acid is relatively low (99). However, under conditions that produce cellular injury, it has been observed that the intracellular concentration of arachidonic acid increases rapidly. Prostaglandins, thromboxanes, and leukotrienes are known mediators of inflammatory reactions. More important, it is known that the synthesis of prostaglandins from the precursor arachidonic acid produces oxygen free radicals (46).

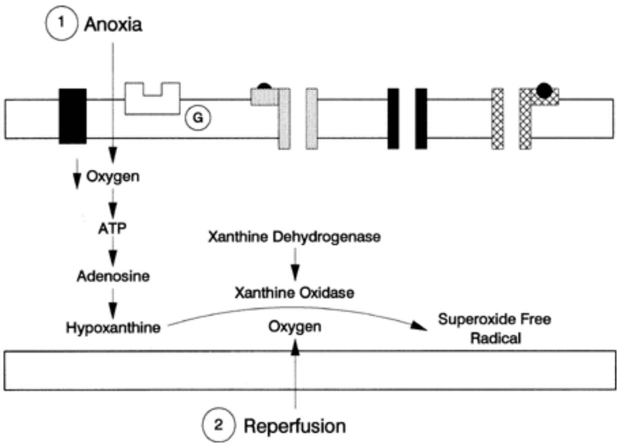

FIGURE 2. Pathway by which superoxide free radical may be formed after anoxia (*1*) and subsequent reperfusion (2). (Modified from McCord JM (1987): Oxygen-derived radicals: a link between reperfusion injury and inflammation. *Fed Proc* 46:2402–2406 with permission.)

Phospholipase A^2 and the Arachidonic Acid Cascade

The role of phospholipase A^2 in promoting neuronal damage was first described by Bazan (5) who found that arachidonic acid levels were markedly elevated after ischemia of the brain. At that time, however, it was not clear which phospholipases played key roles. Over the past several years, it has been shown that the activity of phospholipase A^2 increases dramatically with cerebral contusion or ischemia. Shohami et al. (99) found that phospholipase A^2 activity was elevated 175% 15 minutes after cerebral contusion. These investigators also found an increase of approximately 100% in prostaglandin E levels. Rordorf et al. (79) induced 10 minutes of cerebral ischemia by occluding the common carotid arteries; they found 10 minutes later that the activity of phospholipase A^2 was elevated approximately 60%. Rordorf et al. (79) identified three different phospholipase A^2 isoforms, which they classified as cytosolic, mitochondrial, and microsomal. The activity of each of these forms of phospholipase A^2 was elevated after the induction of ischemia. These investigators found that the mitochondrial membranes are rich with unsaturated fatty acids, which are good substrates for phospholipase A_2. They also found that mitochondrial phospholipase A^2 acts on cardiolipin, which plays an important role in the electron transport chain.

Phospholipase C and Disruption of Normal Membrane Function

The role of phospholipase C in promoting spinal cord injury has not been studied. However, results of studies of the role of phospholipase C in myocardial ischemia suggest that this enzyme may be involved in the pathogenesis of spinal cord injury. Prasad et al. (75) showed that phospholipase C is capable of converting phosphatidylinositol, a membrane phospholipid, into inositol triphosphate and diacylglycerol. The overactivation of phospholipase C can further elevate intracellular levels of calcium ion by acting on the calcium ion release channel of the endoplasmic reticulum through the action of inositol triphosphate. This causes the calcium ion sequestered within the endoplasmic reticulum to be emptied into the cytoplasm.

Free Radicals

Formation of highly reactive molecules containing oxygen is a normal consequence of a number of biochemical pathways. If such a molecule contains one or more unpaired electrons, the molecule is called a *free radical*. The intracellular production of free radicals evolves from the activity of cyclooxygenases, lipoxygenases, dehydrogenases, oxidases, and peroxidases (37). Sources of free radicals include the lipid bilayer of the cell, mitochondria, endoplasmic reticulum, peroxisomes, and the nucleus. It has been proposed that during ischemic events, the catabolism of adenosine triphosphate (ATP) increases the level of hypoxanthine. Xanthine oxidase then acts on hypoxanthine in the presence of molecular oxygen to produce the superoxide free radical (Fig. 3).

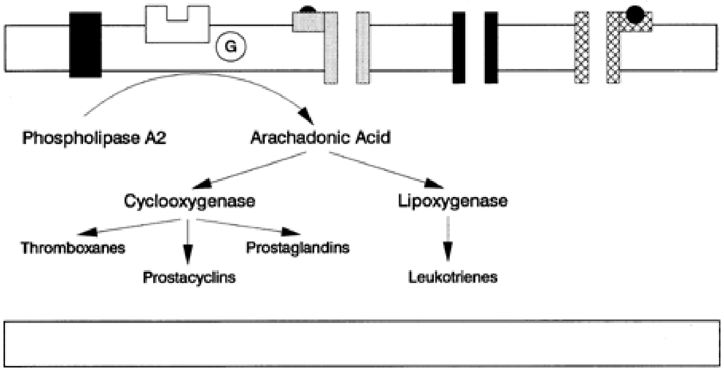

FIGURE 3. Arachidonic acid cascade.

The prime targets of free radicals include the unsaturated bonds in membrane lipids (64). Free radicals thereby disturb the fluid mosaic motif of membranes by altering the fluidity of membranes and altering the alignment of proteins within these membranes. Free radicals also can cause tissue damage by means of cross-linking and denaturation of proteins.

McCord (58) proposed that elevated intracellular concentrations of calcium ion can increase superoxide formation by activating calcium-activated proteases. These proteases were hypothesized to convert xanthine dehydrogenase to xanthine oxidase. Xanthine oxidase then would generate the superoxide radical by means of univalent reduction of molecular oxygen. Given the potential role of free radicals in exacerbating the extent of spinal cord injury, free radical scavengers may play an important role in inhibiting the production of free radicals.

Xu et al. (116) found that the activity of xanthine oxidase was elevated by approximately 100% 4 hours after spinal cord injury induced with the weight-drop model. These investigators showed that the increase in xanthine oxidase activity could be prevented with allopurinol, a strong xanthine oxidase inhibitor. The scavenging enzyme superoxide dismutase also is known to inhibit xanthine oxidase and as a consequence has been shown to be effective in preventing injury that would usually occur as a result of this cascade. Agee et al. (1) attempted to induce paraplegia by occluding the abdominal aorta. Paralysis developed in 30% of animals given superoxide dismutase. In contrast, 90% of the control animals had paralysis.

Animal Models

A tremendous amount of research has accumulated on the subject of the experimental management of spinal cord injury. The basic premise for this research has been mounting evidence of a reversible component of neuronal injury caused by a derangement in the metabolic cascade (4). Because of lack of standardization of animal models, results of most of these pharmacologic studies claiming success of treatment cannot be verified or compared. This flaw in basic clinical research is becoming more obstructive as a host of new and mechanism-specific agents are being evaluated for use in the treatment of patients with spinal cord injuries. From neurotransmitter antagonism to proteolytic enzyme inhibition, the mechanism of these compounds have been developed through painstaking neuroscientific research with molecular biologic techniques. The ability of the agent to reduce neuronal injury in vitro usually is well established. However, the ability to diminish spinal cord damage after traumatic injury may be difficult to evaluate given the present status of animal models as screening studies for these compounds. The ideal model should mimic the human condition of spinal cord trauma, be reproducible, and allow precise biochemical and physiologic quantification of the degree of residual spinal cord damage. Recognizing the limitations of each model in achieving this ideal goal may provide useful information to clinicians struggling with the decision to treat pharmacologically a patient with spinal cord injury. This section describes the various techniques for studying experimental spinal cord injury and points out the shortcomings and advantages of each model.

General Considerations

Until the last decade, most spinal cord research was performed with large animals, such as dogs, cats, or monkeys (56). Because of protests from increasingly powerful animal rights groups, experimental spinal cord injury research is currently performed with rabbits, mice, or especially laboratory rats as the animal model. Strict attention to the guidelines of the animal studies committee at each institution is imperative in this work. General nursing care for paraplegic animals can be time consuming and frustrating; all the complications that occur among humans with spinal cord injury can occur with experimental spinal cord injury. Surgical technique should be meticulous and blood loss compulsively controlled. Blood pressure is an extremely important variable and should be kept normal during the procedure. Hypotension has been shown to produce detrimental effects on the porcine cauda equina during compression studies (27). In addition to physiologic monitoring, in vivo studies can be affected by the type of anesthetic. Halothane is recommended over pentobarbital or nitrous oxide (82). Ketamine may have protective effects owing to its NMDA antagonist properties (see earlier).

Surviving animals usually are evaluated at regular intervals with a series of standard motor tasks described first by Tarlov et al. (106 ,107). A limitation of the Tarlov scoring system is the difficulty in reproducing consistent data between laboratories. The inclined-plane test of Rivlin and Tator (78) is less subjective, but only one complex motor function can be analyzed. Gale et al. (24) developed a complex system that combines evaluation of both sensory and motor function with multiple behavioral tests. This combined behavioral score is more consistent and predictive of functional deficits.

In addition to behavioral analysis, histologic examination of the spinal cord is performed. Central necrosis is the hallmark of impact studies and of most other forms of experimental spinal cord injury. Quantification of necrosis with analysis of cross-sectional area makes it difficult to depend on intraobserver variability for comparison of data.

Electrodiagnostic studies have been used to assess the severity of trauma after graded spinal cord impact. Somatosensory evoked potential area and amplitude reduction 4 weeks after injury have been found to correlate with the combined behavioral score (76). No correlation between latency and injury was found. In another study evoked potentials returned among animals sustaining only petechial hemorrhages but not those with central cavitation (13).

Impact Studies

Initially described by Allen (2) with various modification since (7 ,16 ,17 ,41 ,47 ,56 ,63 ,66 ,70 ,113), impact or contusive spinal cord injury classically is produced with a weight of a specific mass in grams dropped down a cylinder or over a metal shaft from a specific height in centimeters onto an exposed posterior spinal cord (usually thoracic). This standardized load is calculated as the product of the mass and height or gram-centimeter force.

This technique appears sound at first glance. It is believed that the main advantage of the impact model of Allen is its similarity to human spinal cord injury. However, the posterior spinal cord is injured in the model, and human spinal cords are most often injured anteriorly. Using high-speed scintigraphy, Koozekanani et al. (47) found that a single weight drop produces several collisions between spinal cord and impounder and that the impounder weight varies between studies. Dohrmann et al. (16 ,17) and Molt et al. (63) showed that the actual trauma dose can vary widely even when the products of various gram-centimeter combinations are equal. Dohrman et al. (16 ,17) concluded that calculated injury values consisting of impulse, energy, and velocity of deformation correlate more closely with the response to injury than the gram-centimeter product. A wide variability of the effects of various gram-centimeter forces between different animal species also is evident. Hashemi et al. (32) showed that the amount of cord compression varies inversely with the square root of cord stiffness; therefore, a smaller cord will suffer a greater degree of compression than a larger cord for a given drop-mass energy with all other factors being equal. This may explain the relative resistance to spinal cord injury among large animals (400 g-cm required energy for dogs verses 25 to 100 g-cm for rats). That is out of proportion to the difference in size of the animals. Other difficulties involved with this test are the importance of controlling vertebral motion during impact (73) and difficulty controlling rate and amount of compression (17).

Difficulty with the weight-drop test has led investigation into other forms of spinal cord impaction. Models of anterior injury have been developed but used sporadically. Kearney et al. (40) developed a model that allows independent control of rate depth and duration variables. The velocity of impact and duration are controlled with a pneumatic impactor, thus allowing for a situation of constant velocity and compression.

Compression Studies

Ability to control the rate of cord displacement has intrigued investigators since Tarlov's first report of a compression model with dogs (6 ,34 ,36 ,93 ,108). An implantable inflatable balloon was attached to a movable guide, and the dog was allowed to walk in the cage during spinal cord compression. The dog was examined while awake for acute effects of compression. This ingenious device would be difficult to reproduce because of the present state of animal rights activities on most university campuses.

A compression models of a circumferential balloon in monkeys was described by Tator (108). This technique involved passing a polymeric silicone cuff around the spinal cord and then rapidly filling the cuff. The pressure in the cuff was recorded with a Taylor aneroid sphygmomanometer. This technique was thought to represent a more clinically applicable model because spinal cord injury usually produces impingement of both posterior and anterior structures. However, the degree of dissection and the possibility of surgical injury to the cord have discouraged wide use of this model.

A number of investigators have used slow, graded compression. Each technique is a modification of a template that slowly compresses the posterior thoracic spine. Hukuda and Wilson (34), however, used a screw to transmit force to the anterior cervical spine. These techniques provide more precise control over the force applied to the cord but lack clinical correlation to acute spinal cord injury. Use of these techniques for the neuropathologic study of neoplastic or other slower compressive states and the investigation of cord recovery with varying rates is a promising area for this model.

Various orthopaedic laboratories have used cauda equina compression with a plastic band. In these studies, rapid circumferential restriction was used to simulate acute cauda equina syndrome. Elaborate modifications of these studies with cystometrographic analysis have shown a potential for nerve root recovery even with late decompression. Other models of spinal cord injury using “pinch” technique are rarely used and are not described herein.

Distraction Studies

Of most importance to pediatric spinal surgeons are distraction studies that presumably mimic scoliosis surgery. Dolan et al. (18) described use of a distraction device in a cat model. Circumferential clamps were used around adjacent vertebral bodies, and a central screw moved a clamp along a threaded rod. This technique produced considerable displacement of the vertebrae, and thus spinal cord distraction. Spinal cord blood flow and evoked potentials were recorded. The authors believed their data supported the view of spinal cord ischemia as the mechanism of cord injury. The results of spinal cord blood flow and histologic studies were not conclusive, however.

Perhaps the ideal model for studying the effects of spinal distraction on a scoliotic spine and cord was described by Salzman et al. (82). They initially produced scoliotic deformities in Sprague-Dawley rats by suturing the scapula to the pelvis. After 8 weeks of tethering, permanent kyphoscoliosis had developed. The mean scoliotic curves of 51 rats was 31.7 degrees. The rats were then subjected to incremental (5.0 mm over 2.5 minutes) distraction with a modified Harrington distraction device until the upper laminae separated. Twenty-nine rats with kyphoscoliosis were used in this experiment. Twenty-four sustained complete hindlimb paralysis, and five severe paraparesis. A strain gauge was used to measure the force on the upper hook, and force to failure was similar for all rats. The authors performed this experiment to assay for concentrations of serotonin and its metabolite 5HIAA at various sites in the spinal cord. Their results showed an increase in serotonin concentration at the level of distraction and long-term depletion of serotonin below the site of injury. An elaborate hypothesis for serotonin-induced spinal cord injury involving platelet-derived serotonin and the raphe-spinal tract was hypothesized. The hypothesis of serotonin-induced cellular injury requires more validation. However, the model for distraction and the attempt at quantifying the degree of neuronal injury with a molecular marker represent an important step in the study of iatrogenic spinal cord injury. This model may prove useful in examining the integrity of the cytoskeleton (neurofilament composition) and the role of excitotoxicity.

Occlusion Studies

Because the incidence of paraplegia after operations on the thoracic or thoracoabdominal aorta ranges from 2.2% to 24% (45), much of the work using arterial occlusion spinal cord injury models has been performed in vascular surgery laboratories (50). Various animal species have been studied. Apparently, because of the variability of the spinal cord blood supply in rats, dogs, and nonhuman primates, models with these species have produced only inconsistent spinal cord ischemia. Rabbits are the most widely used species and their unique vascular anatomic features allow infrarenal aortic cross-clamping to produce paraplegia (119). However, the behavioral repertoire of rabbits is extremely limited. Large animals are more easily examined behaviorally, but long-term maintenance of paretic dogs or primates is extremely difficult. Rats have been subjected to cord ischemia by means of a median sternotomy incision for cross clamping of the descending aorta.

In Vitro Spinal Cord Model

Although each of these models has yielded interesting and valuable results, our ability to understand and intercede in the events that lead to paralysis after spinal cord injury would be facilitated by a model that allows the cellular and molecular mechanisms responsible for both normal locomotion and pathologic damage to be studied in the same preparation. In this respect, an isolated in vitro spinal cord preparation may offer several advantages because (a) cord function can be directly assessed before, during, and after a variety of insults; (b) the environment surrounding the cord can be carefully regulated and easily modified; and (c) the cord is readily available for rapid biochemical analysis. Considerable progress has been made in the development of in vitro spinal cord preparations and in the elucidation of the transmitter systems that participate in the generation of locomotion (9). Several studies have identified the excitatory amino acid systems, the NMDA receptor in particular, as the primary transmitter system involved in locomotion. It has been established that in addition to participating in normal function, under pathologic conditions the NMDA receptor can contribute to neuronal damage and loss through the process of excitotoxin-mediated cell death (11 ,12).

The presence of NMDA receptors in the spinal cord and their role in locomotion and excitotoxicity raise several questions regarding the potential involvement of the NMDA receptor in pathologic conditions of the spinal cord. We (105) are attempting to answer these questions with a modification of the model developed by Smith et al. (101 ,102). Twenty-two neonatal rats ages 0 to 4 days were used in four series of experiments. The experiments were performed by means of dissecting the brain stem–spinal cord and hindlimbs of each animal and perfusing the preparations with physiologic solution and bubbled oxygen. These preparations were viable for up to 8 hours with the ability to generate locomotion (coordinated hindlimb movement that can be observed, videotaped, and neurodiagnostically monitored with electromyography and lumbar spine peripheral nerve condition). Experimental conditions such as hypoxia also can be produced, and the ability of the preparation to withstand these conditions with various pharmacologic agents can be tested. Mechanical conditions can be produced that provide compression or distraction.

Our preliminary results with this model have shown that excitatory amino acids can cause excitotoxic damage in neonatal spinal cords. We view the advantages of this model as follows: (a) the neural circuitry in the brain stem motor command center, in the spinal cord central pattern generators, and in the sensorimotor circuits can be selectively activated; (b) the conditions of the medium bathing the spinal cord can be selectively controlled; (c) hindlimb movement represents a powerful functional bioassay that provides important information about the integrity of the neural circuits responsible for generating locomotion; (d) the preparation can be partitioned so that injury can be induced at any level of the brain stem–spinal cord; (e) diffusional limitations are minor, and consequently the preparation is robust; (f) the model is ideally suited for studying issues related to injury and the developmental state; (g) anoxic injury can be carefully controlled; (h) the preparation can be easily adapted for distraction or compression studies, yet the conditions of the bathing medium can be controlled; (i) the model can be easily adapted for impact studies; and (j) this preparation is one of the few spinal cord models ideally suited for examining issues related to excitotoxicity.

Limitations of this model are that (a) the brain stem–spinal cord–hindlimb preparation cannot be used to examine issues related to long-term recovery; and (b) the applicability of this preparation to the adult condition is yet to be determined. It may be that there are substantial ontogenic differences between neonates and adults that limit the applicability of this preparation to the adult condition.

Summary

Injury to and death of neurons in the spinal cord occur when these cells lose the ability to regulate their internal environment. Although calcium ion plays a critical role in regulating the molecular events of neurons within the spinal cord under normal conditions, it also has become apparent over the past 10 to 15 years that calcium ion paradoxically plays a central role in promoting cellular injury to and death of these neurons. Because of the involvement of calcium ion in this process, investigators have focused on the cell membrane and various receptors, ion channels, and second-messenger systems. It appears as if excitatory amino acid receptors may play a major role in regulating the influx of calcium ion during periods of hypoxia and anoxia. Of the four kinds of excitatory amino acid receptors (NMDA, AMPA, kainate, metabotropic), studies indicate that the NMDA receptor can play a prominent role in facilitating the influx of calcium ion under injurious conditions such as hypoxia and anoxia. Therefore, damage to the spinal cord and ensuing paralysis appears to involve not only the calcium paradox but also the NMDA paradox. Under normal conditions, the NMDA receptor seems to play a key role in the neurogenesis of locomotion. More complete understanding of the events involved in spinal cord injury will evolve as understanding of molecular events continues to progress. Good experimental models are needed to facilitate this understanding. We believe that in vitro spinal cord models capable of generating locomotion will play a key role in this process.

Cervical Spine Injuries in Children

Nathan H. Lebwohl

Frank J. Eismont

N.H. Lebwohl and F.J. Eismont: Department of Orthopaedics and Rehabilitation, University of Miami School of Medicine, Miami, Florida 33101.

Injuries to the cervical spines of children are relatively uncommon. There are few large series reported in the literature, and most major medical centers treat only one or two patients each year. Despite this, the need to evaluate children for possible injury to the cervical spine is common. In the care of very young children, this task is complicated by the inability to obtain a complete history and by the radiographic appearance of the vertebral column, which changes during development. The delay in diagnosis commonly cited in reports of treatment of series of patients attests to these difficulties. Familiarity with the developmental anatomy of the spine and with the usual patterns of injury should help the physicians confidently arrive at an accurate diagnosis.

Epidemiology

In 1969, Melzak (65) reported that only 2% of patients admitted to a spinal cord injury center in Great Britain were children. Burke (19) found only 29 children with spinal cord injury admitted to Rancho Los Amigos Hospital over an 18-year period; 13 of those had a injury to the cervical spine. Kewalramani and Tori (50) reviewed admissions to the Institute for Rehabilitation Research in Houston. They found that 13.2% of all patients with spinal cord injury were younger than 16 years. Two thirds of the injuries were to the cervical spinal cord. In a study spanning 41 years at the Mayo Clinic, McGrory et al. (63) estimated the incidence of injury to the cervical spine among patients living in Olmsted County, Minnesota, to be 1.19 per 100,000 for children younger than 11 years. For children between 11 and 15 years of age the incidence was 13.24 per 100,000. In this series, 62 of 143 patients (43%) had neurologic injury, and there was no difference in frequency between the younger and older groups.

Motor vehicle accidents are responsible for most injuries to cervical spine among children (58). These are followed by falls, athletic injuries, and gunshot wounds in most series (Fig. 1). Among the youngest patients, falls are the most common cause of injury (44,83). Diving is the sport most commonly associated with injury to the cervical spine. Gymnastics, football, wrestling, rugby, and trampoline also are common causes (38).

The incidence of birth injury to the spinal cord is not known. In the past, most such injuries were associated with breech delivery. From 5% to 25% of breech deliveries are associated with spinal cord injury (1,3,14). Injury also can occur with cephalic presentations (89). The use of forceps has been associated with an increased incidence of spinal cord injury. Evidence of spinal cord injury has been identified in as many as 50% of neonatal deaths (1,4).

Child abuse is another important cause of pediatric injury to the cervical spine. Once again, the true incidence is not known. An infant's large head, combined with poor control of cervical musculature predisposes the cervical spine to injury from violent shaking. Vigilance for associated musculoskeletal injuries should help identify abuse among these children (23,51,100).

Early Management

Whenever a spinal injury is suspected, the patient must be immediately immobilized and transported carefully to avoid neurologic injury. Injury to the cervical spine should be considered whenever a patient is unconscious after trauma or reports numbness, weakness, or neck pain. Even transient neurologic symptoms after trauma warrant immobilization until instability is ruled out.

Because young children have a large head in comparison with the rest of the body, positioning on a standard backboard forces the cervical spine into relative kyphosis. Herzenberg et al. (46) described ten patients with unstable cervical spine injuries in whom the kyphotic deformity increased with positioning on a standard backboard. They recommended use of a double mattress pad to raise the chest or use of a recess for the occiput (Fig. 2). This discrepancy between the circumference of the head and the circumference of the chest exists until 8 years of age, when the chest attains 50% of its adult size (91). Ogden (69) advocates placing a small support under the lumbar spine to maintain normal lordosis and to prevent malalignment.

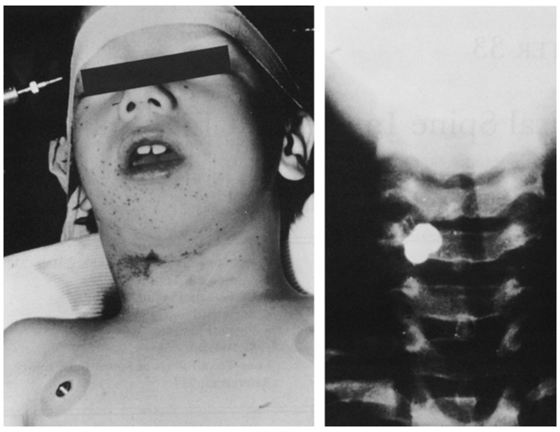

FIGURE 1. Gunshot wounds are an increasingly common cause of pediatric spinal cord injury in inner cities in the United States.

Athletic injuries are a common cause of injuries to the cervical spine among older pediatric patients. Spine boards always should be present at playing fields and gymnasiums where high-risk sports such as football and gymnastics take place. The combination of tape and sandbags provides much more effective immobilization of the head and neck than does use of a hard collar. In helmeted sports, the face mask should be cut away to provide access to the airway. The patient should be transported with the helmet in place, because it is difficult to remove the helmet without causing neck flexion. Removal of the helmet usually is best accomplished when the patient arrives in the emergency department. The helmet is spread open and pulled off while the head is manually stabilized (105).

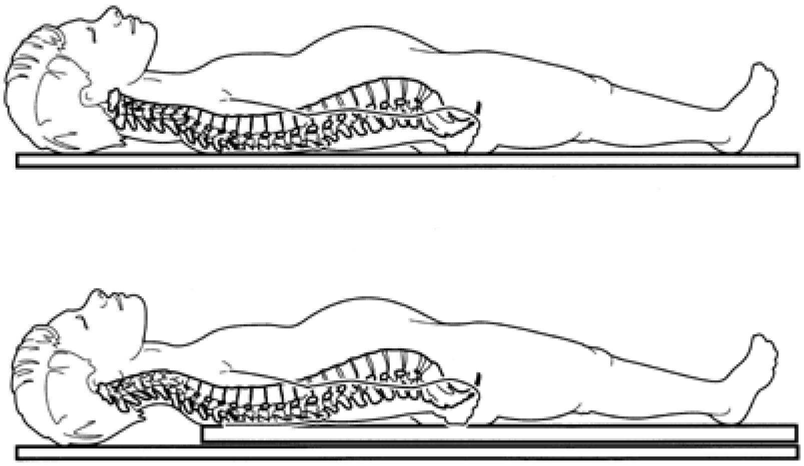

FIGURE 2. Because a child's head is large in proportion to its chest, immobilization on a standard backboard pushes the cervical spine into kyphosis. This may increase fracture deformity among patients with unstable spines. The use of a double mattress pad allows the head to fall backward and allows the spine to assume a more normal lordosis.

As in all emergency care, initial attention must be given to the airway, breathing, and circulation. Children with injury to the cervical cord commonly have compromised respiratory function and need endotracheal intubation. There is controversy about the safety of various techniques to establish an airway. Aprahamian et al. (5), in a radiographic study of cadavers, found that cervical collars did not immobilize the spine during orotracheal intubation. Nasotracheal intubation, however, caused minimal motion of the spine. Majernick et al. (57) likewise found that cervical collars did not adequately immobilize the spine during orotracheal intubation. In-line traction, however, minimized spinal motion during intubation. In contrast, Bivins et al. (12), Turner (103), and Joyce (49) argued against the use of in-line traction during intubation because of the danger of overdistraction of a highly unstable injury. In combined clinical series of 136 patients with fractures of the cervical spine who underwent oral intubation and 143 patients who underwent nasal intubation, Holley and Jorden (47) and Suderman et al. (97) found no patients with neurologic deterioration attributable to intubation technique. In the series described by Suderman et al., 83 of the patients underwent intubation after induction of general anesthesia.

Other techniques that have been advocated for airway management in the care of patients with injuries to the cervical spine include fiberoptics-guided intubation and intubation over a wire placed percutaneously through the cricothyroid membrane and guided retrograde into the mouth (8). None of these studies has specifically addressed airway management in the care of injured pediatric patients.

Physical Assessment

An unresponsive child with a head injury always should be considered to have a spinal injury until proved otherwise. The presence of clonus in a child with a brain injury without the finding of decerebrate rigidity strongly suggests spinal cord injury (90). Facial abrasions and scalp wounds also should direct attention to the cervical spine and suggest the direction of forces that could have caused injury (10,55). Palpation of a gap between the spinous processes implies severe ligamentous disruption and a highly unstable injury. A history of cardiopulmonary arrest after trauma should alert the physician to the possibility of an injury to the upper part of the cervical spine (13).

Evaluation of an awake child who is unable or unwilling to cooperate with an examination can be difficult. Determining the extent of paralysis, or even determining its presence for an infant, is challenging. A child with paralysis may have reflex mass flexion withdrawal movements in response to stimulation. These movements may be indistinguishable from the normal movements of an infant. In examinations of older, cooperative patients, absence of voluntary movement in the extremities, or sensory deficit, makes the diagnosis of spinal cord injury obvious. It is important, however, to elicit a history of transient neurologic deficit for children who appear to have normal findings. These patients may have occult instability, identification of which can make the difference between no injury and neurologic catastrophe.

Tenderness to palpation of the neck, muscle guarding, cervical rigidity, and torticollis all suggest injury to the cervical spine. Injured children may support their heads with their hands. Seimon (86) described two children with fractures of the odontoid process whose only symptom was neck pain when changing from a lying to a sitting position. Missed and delayed diagnosis is commonly reported in series of pediatric spinal fractures, and a conservative approach to management with immobilization and reexamination is prudent.

Pattern of Injury

Although injuries to adolescents are similar to those to adults, injuries to young children are distinctly different. Allen and Ferguson (2) classified pediatric injuries into three groups: infantile, young juvenile, and old juvenile.

Infantile injuries are those that occur before the development of good head control. These children lack adequate voluntary muscle strength and cannot protect their spines from external forces. They are susceptible to traction and torsion injuries during birth and to flexion and extension injuries inflicted by parental shaking (20). Radiographs are commonly unrevealing, perhaps because of the large proportion of the infantile spine that is cartilaginous and therefore difficult to evaluate radiographically (35) or because of the elasticity of the infant's spinal column, which can be deformed or stretched. The stretching allows injury to the less elastic spinal cord, which is tethered by exiting nerve roots and the dentate ligaments. In the laboratory, the infantile spinal column can be stretched more than 2 inches (5 cm) without injury, although the adult spinal cord ruptures when stretched more than $^1/_4$ inch (6.25 mm) (29,54). Stretching and disruption of the vertebral arteries also may be important in fatal neurologic injuries owing to distraction of the cervical spine and craniospinal junction (24,110).

Young juvenile injuries are classified as those occurring after the development of good head control until about 8 years of age. Unlike injuries in older age groups, most injuries to these children occur in the upper cervical spine, above C4 (11). The fulcrum of normal cervical spinal motion among children younger than 8 years is at the C2–3 interspace rather than at C5–6 (67). This is attributed in part to the disproportionate largeness of the heads of young children but also to the relatively horizontal orientation of the upper cervical facet joints of children, which allows hypermobility of the upper cervical spine (98). Ligamentous laxity also contributes to the hypermobility of the juvenile spine. Some authors have identified the anteriorly wedged appearance of the normal child's cervical vertebral bodies as a contributing factor in cervical instability (95); however, this is merely a radiographic finding caused by the pattern of vertebral ossification. The vertebral body itself is not wedged.

In the lower cervical spines of young children, the joints of Luschka are incompletely developed. The absence of a well-developed uncinate process may predispose children in this age group to separation of the vertebral end plate, an injury that may play an important role in the syndrome of spinal cord injury without radiographic abnormality.

After the age of 8 years, a child's spine begins to take on a more adult appearance, and the pattern of injuries is similar to that of adults. Injuries in the midcervical spine become more frequent. The proportion of head size to torso size decreases. The cervical facet joints become more vertical and reach the adult shape by the age of 10 years. These changes combine to reduce the hypermobility of the upper cervical spine and move the fulcrum of spinal motion down toward the midcervical spine. By the age of 8 years, all of the ossification centers have appeared and fused, with the exception of the apical odontoid epiphysis and the ring apophysis and other secondary ossification centers at the tips of the spinous, transverse, and mammillary processes, which appear in puberty. Thus Salter-Harris type I physeal separations (84) of the synchondroses or the basilar odontoid growth cartilage can no longer occur. In this age group, sports injuries become a more frequent cause of spinal injury than they are younger children.

Specific Injuries

Occipitoatlantal Dislocation

Traumatic dislocation of the occiput from the atlas occurs commonly in fatal craniospinal injuries (Fig. 3). Bucholz and Burkhead et al. (17,18) reported an incidence of 8% among victims of fatal traffic accidents, making it the single most common injury encountered. The injury was more than twice as frequent among infants and children (15%) as it was among adults (6%). This finding is consistent with the higher incidence of injuries to the upper cervical spine among children than among adults.

Occipitoatlantal dislocation with survival is rare. This is because of the neurologic deficits caused by injury to the upper cervical cord, brain stem, and cranial nerves. Dislocation usually is the result of high-energy trauma, commonly involving a motor vehicle. Severe associated injury is common. Survival is being reported with increasing frequency, in part because better emergency care results in early cardiopulmonary resuscitation and ventilatory support of these patients, who previously would not have lived.

The degree of neurologic injury to patients who survive occipitoatlantal dislocation varies. In rare instances, patients have normal neurologic findings or minimal deficit. In a series described by Montane et al. (66), two patients had minor weakness and hyperreflexia, and one patient had a more severe neurologic injury, retaining only unilateral antigravity strength in her extremities. The latter patient also had several episodes of heart block and respiratory arrest, suggesting injury to the cardiorespiratory centers in the brain stem. A fourth patient, who did not live, had complete cord transection at C1 and severe head injury. The patient described by Zigler et al. (112) lived with complete paralysis at the C1 level and palsy of the spinal accessory nerve. This resulted in a flail neck, which necessitated fusion from the occiput to the thoracic spine to avoid the need for external support. The patient also needed tracheostomy because he was ventilator dependent. Ogden (69) described a 6-year-old girl with irregular pulse and respiration, which resolved with extension of the neck. Page et al. (72) described a patient with C5 quadriplegia and palsy of the tenth and twelfth cranial nerves at initial presentation with ascent to a C2 level. Przybylski et al. (80) summarized the findings in the published reports of 79 patients who survived atlantooccipital dislocation: 18% had normal neurologic findings, 10% had isolated cranial nerve deficits, 34% had unilateral limb deficits, and 38% had quadriparesis or quadriplegia.

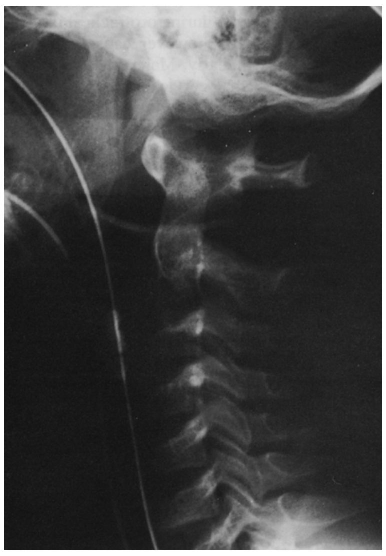

FIGURE 3. Occipitoatlantal dislocation in a child after a motor vehicle accident. This usually is a fatal injury because of the associated trauma to the high cervical spinal cord.

The radiographic diagnosis of occipitoatlantal dislocation may not be apparent until traction is applied to the skull. It is important to examine a lateral radiograph of the cervical spine immediately after applying traction to avoid overdistraction of this or other ligamentous injuries. Wholey et al. (108) studied the relation between the basion and the dens on 600 lateral radiographs of the cervical spine. They found that that the distance between the basion and the dens should not exceed 5 mm in adults and 10 mm in children. The greater distance in children was attributed to incomplete ossification of the dens. Powers et al. (78), however, found that in a randomly selected population of 100 adults and 50 children, the dens-basion distance exceeded those values in 85% of patients. Powers et al. devised a ratio based on two simple measurements: the distance between the basion (*B*, the anterior margin of the foramen magnum) and the posterior arch (*C*) of the atlas divided by the distance between the opisthion (*O*, the posterior margin of the foramen magnum) and the anterior arch (*A*) of the atlas. Values greater than 1.0 are definitely abnormal, values less than 0.9 are definitely normal (Fig. 4). The advantage of this ratio is that it is dimensionless and thus unaffected by magnification of the radiograph. If the landmarks are not easily identified on a lateral radiograph of the cervical spine, they can be measured on a midline sagittal reconstruction of a computed tomographic (CT) scan. The ratio is sensitive to anterior occipitoatlantal dislocation because one line, *BC*, parallels the direction of dislocation, and the second, *OA*, is almost perpendicular to it. The Powers ratio may be insensitive to posterior occipitoatlantal dislocation, as described by Eismont and Bohlman (31) and is not valid if there is a fracture of the atlas or congenital anomaly of the foramen magnum (22,79).

Another measurement that can be used to evaluate the stability of the occipitoatlantal joint is horizontal translation on flexion and extension. The basion should not translate more than 1 mm relative to the odontoid process. This value has only been established for adults, however, and has not been validated for children (106). This measurement should not be made if there is evidence of spinal instability on the plain radiographs or if the patient is not able to cooperate. Flexion-extension radiographs never should be obtained when the patient is comatose or otherwise unresponsive.

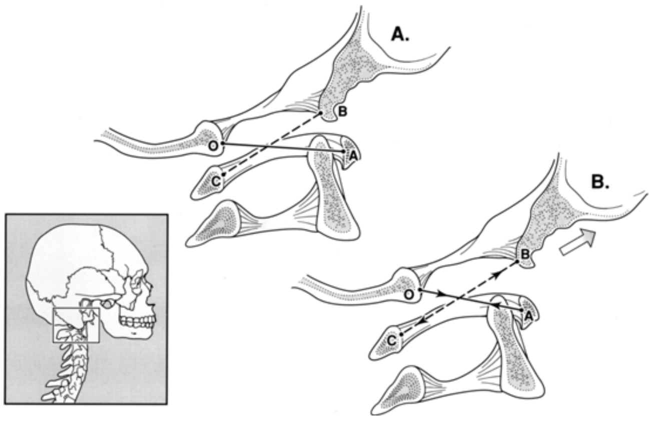

FIGURE 4. The Powers ratio is determined by means of drawing a line from the basion (*B*) to the posterior arch of the atlas (*C*) and a second line from the opisthion (*O*) to the anterior arch of the atlas (*A*). The length of the line *BC* is divided by the length of line *OA.* **A:** Values less than 0.9 are definitely normal. **B:** A ratio greater than 1.0 confirms the diagnosis of anterior occipitoatlantal dislocation.

There is controversy regarding management of occipitoatlantal dislocation. Some authors have advocated immobilization in a halo or Minerva cast. Most recent authors advocate operative treatment with posterior occipitocervical fusion. Because traction can distract the occipitocervical junction, halo immobilization is recommended as soon as this injury is identified. This device provides the most secure stabilization and should be placed preoperatively.

Atlas Fractures

Burst fractures of the C1 ring can occur among children (70,102), although they are infrequently described. The mechanism of injury is believed to be similar to that for adults. A blow to the head transmits an axial compressive force. The occipital condyles push down onto the lateral masses of the atlas, which are displaced centripetally (69). If the force is severe enough, the transverse ligament ruptures or is avulsed at its point of attachment. Among young children, the fracture can occur through neurocentral synchondroses (42), which may remain unfused until 7 years of age (7). CT scanning usually is the most helpful diagnostic study. It is important not to confuse normal synchondroses with fractures. In addition, anomalous ossification centers of the anterior arch are common and should not be confused. Ogden (69) recommends treatment in a Minerva cast for 6 months followed by a brace. Sponseller and Herzenberg advocate treatment in a less restrictive cervical orthosis (92). Allen and Ferguson (2) advocate an initial 4- to 6-week period in traction if more than 4 mm lateral displacement of the lateral masses is present. After treatment, stability of the atlantoaxial articulation should be confirmed on flexion-extension radiographs.

Atlantoaxial Instability

Traumatic atlantoaxial subluxation due to rupture of the transverse ligament of the atlas among children may be more common than previously believed. McGrory et al. (63) reported an incidence of 10% in their large series of injuries to the cervical spine. DeBeer et al. (26) reported that rupture of the transverse ligament was the second most common type of injury to the cervical spine. Among young children, one would expect the synchondrosis at the base of the dens to fail, rather than the transverse ligament. An atlantodens interval measuring more than 5 mm on a lateral radiograph after trauma suggests the diagnosis of rupture of the transverse ligament (Fig. 5). An atlantodens interval up to 4 mm is normal for children (56). Fielding (35) recommends 8 to 12 weeks of immobilization for management of acute traumatic rupture of the transverse ligament. DeBeer reported excellent results for all 3 patients treated in this way in his series. In contrast, Floman et al. (39) reported that immobilization did not adequately reduce subluxation and argued that atlantoaxial arthrodesis is the treatment of choice.

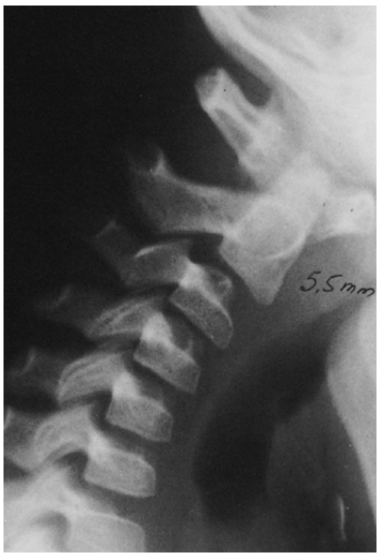

FIGURE 5. An atlantodens interval greater than 5.0 mm suggests rupture of the transverse ligament in a child injured in a motor vehicle accident.

Atlantoaxial Rotatory Subluxation

Rotatory instability of the atlantoaxial joint is probably the most fascinating abnormality of the pediatric cervical spine. Although it can occur as the result of minor or major trauma, its cause is commonly atraumatic. Most cases not involving trauma follow upper respiratory infections (28). Other predisposing conditions include rheumatoid arthritis and a history of head or neck surgery. A small number of patients have no obvious predisposing factor. Sir Charles Bell is credited with first describing this condition, in 1830 (33). Grisel in 1930 described two cases of torticollis following pharyngeal inflammation (43). In the same year an additional case was reported by Desfosses with the description *maladie de Grisel.* Since that time, the eponym *Grisel syndrome* has been used.

Parke et al. (74) described a venous plexus, the pharyngovertebral veins, which drain the posterosuperior nasopharynx and anastomose with the epidural plexus and periodontoidal plexus. Lymphatic vessels from the nasopharynx enter directly into the pharyngovertebral veins. It is believed that inflammatory exudates can be transported via these veins to the ligaments that support the atlantoaxial complex, resulting in inflammation and secondary ligamentous laxity. Once ligamentous laxity exists, rotation of the neck can result in subluxation of the atlantoaxial joints. A combination of muscle spasm and infolding with interposition of swollen capsular and synovial tissue are believed to be responsible for blocking reduction of the subluxation.

Patients have painful torticollis, and neurologic deficit is uncommon. Conventional radiographs can be used to confirm the diagnosis, but interpretation is difficult. Dynamic CT scanning with the head turned to the right and the left is the best examination; evidence of loss of normal rotation between C1 and C2 confirms the diagnosis (Figs. 6, 7).

When the injury is diagnosed early, most patients respond well to a simple treatment program. Once other injuries have been ruled out, treatment protocols are the same whether or not the onset was traumatic or atraumatic. Immobilization in a collar and bed rest may be adequate to allow resolution of muscle spasm and torticollis. If symptoms persist for more than 1 week, cervical traction with a head halter or tongs should be used until the spasm resolves and the subluxation is reduced. Fielding (35) recommended an arbitrary maximum weight of 6.8 kg for children. Once reduction is achieved, immobilization for 4 to 6 weeks is recommended. If subluxation reoccurs, the prognosis for successful nonoperative treatment is poor (96). If symptoms have been present for more than 1 month, reduction with traction is less likely (75), and operative treatment is appropriate. Manipulative reduction under general anesthesia is controversial because of the risk of spinal cord injury. El-Khoury et al. (32) described three children with more severe rotational abnormalities at C1–2 after trauma. They called this condition *atlantoaxial dislocation* and recommended immediate reduction with traction and manipulation. They found reduction easy to accomplish. Reduction was followed by immobilization for 10 to 16 weeks in a cervical orthosis with good results for all three patients treated.

Fielding and Hawkins (37) described a subgroup of patients with long-standing torticollis and irreducible atlantoaxial rotatory subluxation. They called this condition *rotatory fixation.* Among their patients, there was an average delay in diagnosis of more than 11 months, underscoring the importance of early recognition of this entity. Fielding and Hawkins recommended an initial period of traction followed by posterior cervical fusion. If reduction is not achieved, fusion in situ should be performed rather than reduction under general anesthesia, which can cause neurologic deficit.

Odontoid Fracture

Fractures of the odontoid process in young children always occur as epiphyseal separation of the growth plate at the base of the dens. Most cases are caused by severe falls or motor vehicle accidents, but separation of the growth plate can occur with minor trauma as well. Most authors report that neurologic deficit is uncommon. In the series reported by Sherk et al. (88), the only patients with neural deficit were those who had sustained concomitant head injury. In contrast, Odent et al. (68) reported neurologic involvement in eight of 15 patients; four of the eight had high thoracic paraplegia and three had quadriplegia. None of these patients had associated head injury. Fracture displacement of at least 50% was universal among the patients described by Sherk et al. If displacement is not present, identification of the fracture on radiographs can be difficult. Tomograms may show widening of the growth plate. Anterior angulation of the odontoid fragment is an almost constant finding and may help identify the nondisplaced fracture. As in other injuries to the upper cervical spine, occipital pain, muscle spasm, and resistance to movement are common symptoms and physical findings (Fig. 8).

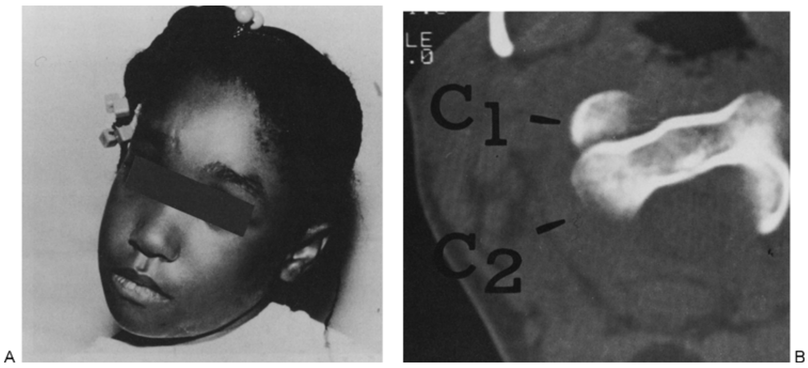

FIGURE 6. A: Cock robin appearance of a child with atlantoaxial rotatory subluxation. **B:** Computed tomographic scan through the C1–2 facet joint demonstrates subluxation. Diagnosis is confirmed if subluxation persists when scan is repeated with the head turned in the direction opposite the subluxation. (CT scan courtesy of Dr. Stephen Stricker. From Grobman LR, Stricker S (1990): Grisel's syndrome. *Ear Nose Throat J* 69:799–801, with permission.)

Postural reduction with cast or halo immobilization is the appropriate management of this injury, and 6 to 8 weeks of immobilization is required. When the patient is appropriately immobilized, nonunion is rare, as is avascular necrosis or growth disturbance of the odontoid fragment. Fractures of the odontoid process among older children after closure of the growth plate at the base of the dens are extremely uncommon. When they occur, such fractures follow the patterns seen among adults. It is important not to confuse the epiphyseal scar at the base of the odontoid process with a fracture.

Failure to recognize and immobilize an odontoid fracture in a child may be responsible for the clinical syndrome of os odontoideum. It once was believed that os odontoideum was a congenital anomaly caused by failed fusion of the odontoid process to the vertebral centrum (30,109). Several case reports in the literature, however, document os odontoideum or disappearance of the odontoid process after trauma to the cervical spine (36,41,45,48,85). In nine cases, radiographic documentation exists of a normal odontoid with the development of an os odontoideum after trauma. Fielding et al. (36,37) wrote that injury to the blood supply combined with retraction of the dens by the alar ligaments contributed to nonunion of the odontoid. Os odontoideum causes atlantoaxial instability because the odontoid can no longer function as a post with which the anterior atlas and the transverse ligament can articulate. When a patient has symptoms or a patient without symptoms has documented instability, treatment is by means of posterior cervical fusion.

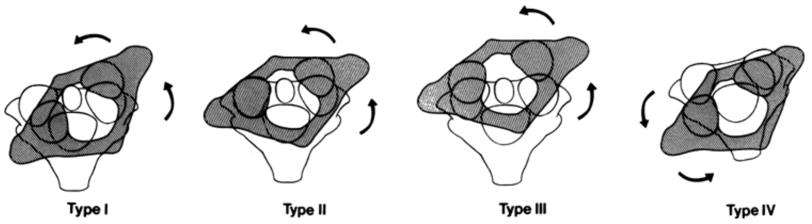

FIGURE 7. Fielding and Hawkins classification of C1–2 rotatory subluxation. **A:** Type 1 rotation without anterior displacement (transverse ligament intact). **B:** Type 2 rotation with 3 to 5 mm anterior displacement (transverse ligament deficient). **C:** Type 3 rotation with greater than 5 mm anterior displacement (transverse and secondary ligaments insufficient). **D:** Type 4 rotation with posterior displacement (odontoid deficiency). (From Grobman LR, Stricker S (1990): Grisel's syndrome. *Ear Nose Throat J* 69:799–801, with permission.)

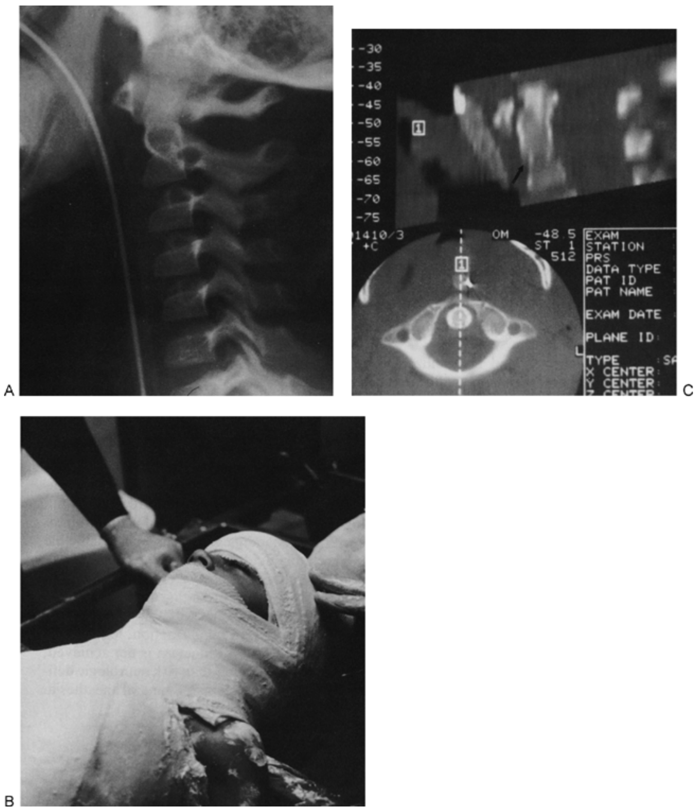

FIGURE 8. A: Fracture through basal growth plate of the odontoid process is appreciated only on computed tomographic sagittal reconstruction. **B:** Anterior displacement at the fracture site is evident. **C:** Application of Minerva cast to immobilize the patient.

C2 Pedicle Fracture

Fracture of the C2 pedicle, better known as *hangman's fracture*, has been reported in an infant as young as 7 weeks old (99).

No data exist regarding the mechanism of injury among children, but it is believed to be similar to that for adult hangman's fractures (40). In most reported cases, there is no associated neurologic deficit. Weiss and Kaufman (107) reported the case of a 12-month-old child with central cord syndrome, which had almost completely resolved after 1 year of follow-up evaluation. In the series of Pizzutillo et al. (76), only one of five patients had a neurologic deficit, which had resolved completely after 1-year of follow-up evaluation.

Radiographic evaluation of C2 pedicle fracture is complicated by two factors. The neurocentral synchondroses can mimic a fracture on oblique radiographic views (82) and may persist beyond the age of 7 years, by which time it usually is closed (59). The more difficult problem in radiographic evaluation is differentiating physiologic subluxation at C2–3 from pathologic subluxation caused by disruption of the pedicles of C2. Hypermobility at C2–3 is common among children up to about the age of 8 years (21). This is the result of ligamentous laxity and horizontal alignment of the facet joints. The posterior cervical line of Swischuk (101) is useful in evaluating hypermobility at this level. The posterior laminar line is identified at the base of the spinous process at C1, C2, and C3. A line is drawn connecting this landmark at C1 and C3. The posterior laminar line of C2 should lie within 1 mm of this line. If it lies more than 1.5 mm posterior to the Swischuk line, a fracture may separate the anterior body and posterior lamina. If the distance is more than 2 mm, a fracture is almost certainly present. Anterior displacement greater than 2 mm implies pathologic subluxation without pedicle fracture. If the static view is normal, the same criteria should be applied to the flexion radiograph. A true lateral radiographic view is essential for this technique to be used reliably (Fig. 9).

Treatment of infants with hangman's fracture is similar to treatment of adult. If the body of C2 is not significantly displaced on C3, immobilization in a collar or custom-fabricated splint should be adequate. If there is more than 3-mm anterior displacement of C2 on C3, more rigid immobilization is indicated (2). A Minerva cast or a halo would be appropriate for 8 to 12 weeks.

Subaxial Injuries

Among children older than 8 years, most injuries occur below C2. Injury patterns are similar to those among adults. Flexion injuries predominate. Complete facet dislocations appear to be uncommon until late adolescence. Simple compression fracture is the most common injury. Residual kyphosis after flexion injury may be less well tolerated by growing children than by adults. Some authors advocate posterior fusion to prevent late disability (34,61). In contrast, Ogden (69) stated that surgical treatment rarely is necessary in the care of young children, even with ligamentous instability. He advocated reduction in traction followed by rigid immobilization for these injuries.

With the exception of burst fractures and other injuries in which anterior surgery is needed to remove bone fragments that compress the spinal cord (87), there is a relative contraindication to anterior fusion in a growing child. Anterior fusion destroys the anterior growth potential. Posterior growth continues, and a kyphotic deformity may result (94). If posterior fusion is needed, autogenous bone graft should be used. The use of allograft bone is associated with a high rate of pseudarthrosis (93). For posterior fusions, we routinely use iliac crest bone graft. We take care to minimize injury to the cartilaginous iliac apophysis. The use of rib graft has also been described, and the results have been good (64). The use of allograft bone in anterior fusion with instrumentation was reported to be successful in a small series (15). In posterior fusion, care must be taken to avoid exposure of levels not to be included in the arthrodesis to avoid spontaneous extension of the fusion. This occurred among 38% of patients described by McGrory and Klassen (62). (Figs. 10, 11).

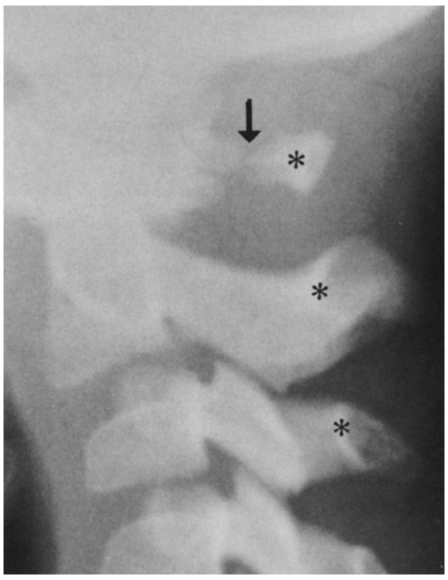

FIGURE 9. Pseudosubluxation of C2–3 is common among children younger than 8 years. *Asterisks* denote posterior laminar lines at C1, C2, and C3. The posterior laminar line of C2 should lie within 1 mm of a line drawn from C1–3, the posterior cervical line described by Swischuk. Greater than 2 mm posterior displacement of the C2 posterior laminar line implies C2 pedicle fracture. If anterior displacement is more than 2 mm, pathologic subluxation is implied. This patient also has incomplete ossification of the posterior arch of C1 (*arrow*), a common anomaly.

Physeal Injuries

One important type of subaxial injury does occur among young children. Separation of the vertebral end plate from the vertebral body can occur through the epiphysis; it is similar to a physeal injury to a long bone. Salter-Harris type I injuries occur among infants and young children; type III injuries occur among older adolescents as the physis begins to close (53). The true incidence of this injury is not known because it is difficult to identify on radiographs. The fracture may recoil after injury and return to normal alignment, making radiographic identification impossible. The most likely radiographic finding is widening of the intervertebral disc space. Physeal separation can play an important role in injuries in which neurologic deficit has occurred,

but no radiographic abnormality is seen. Aufdermaur (6) found this injury in 12% of juvenile autopsy specimens and then reproduced the injury by applying an extension force to the spines of cadavers. In the cervical spine, the injury usually involves the inferior end plate. This has been attributed to a protective effect of the uncinate process, which may stabilize the end plate (Fig. 12).

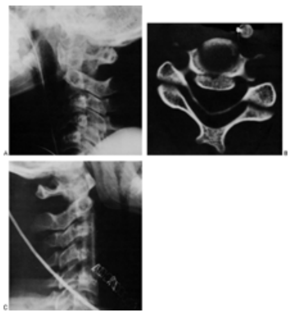

FIGURE 10. Subaxial injuries are more common among older than among young children. **A:** Image of a 16-year-old girl shows severe burst fracture of C4 with neurologic injury. **B:** Computed tomographic scan shows retopulsed bone in canal and posterior subluxation of the facet joint. **C:** Lateral radiograph obtained after anterior decompression and reconstruction with fibular allograft. (Courtesy of Barth Green, M.D.)

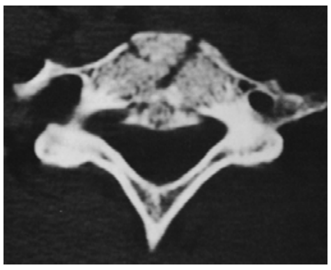

FIGURE 11. Burst fracture of C7 without neurologic injury. The 15-year-old boy was treated with initial traction followed by halo immobilization.

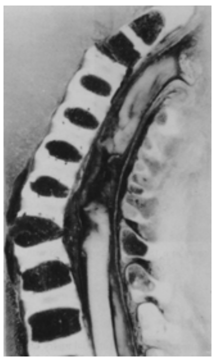

FIGURE 12. Cryosection of spine from infant victim of child abuse demonstrates end plate separation at C3–4, disruption of cord, and separation through vertebral body at T1. (Courtesy of Richard Bunge, M.D., and Bill Puckett, Miami Project to Cure Paralysis.)

Subaxial type I injuries are extremely unstable. If identified in a surviving child, Ogden (69) advocated operative stabilization. In contrast, type III injuries do not completely separate the physis from the vertebra. Therefore stability is maintained, and these injuries heal quickly if immobilized.

Sciwora

The syndrome of spinal cord injury without radiographic abnormality (SCIWORA) after trauma is the single most common severe injury to the pediatric spine among patients who survive. The incidence in various reports ranges from 4% to 66% of all children with spinal cord injury (27). The incidence among younger children is higher (71). In most series, injury at the cervical level is slightly more common than injury at the thoracic level. Incomplete neurologic injuries have a good prognosis for recovery of function. Complete neurologic injuries have a dismal prognosis. There is a trend to more severe injury among younger children. When myelography or magnetic resonance imaging has been performed, there has been no consistent finding to explain the neurologic injury. In some cases, no abnormality can be identified. Cord swelling, cord disruption, leak of myelographic contrast medium, and epidural hematoma all have been described (111). Normal findings are common, but magnetic resonance imaging was used infrequently in the reported series.

The mechanism of injury is not known. More than one mechanism is likely. Theories proposed include traction injury to the spinal column and cord, end plate separation, transient disc herniation, and vascular compromise with infarction of the cord (104). Because the mechanism is not known, all patients should be treated initially as if their spines are unstable. Routine immobilization is appropriate. Careful radiographic evaluation is essential with special attention to spinal stability and compressive lesions that can be removed. There is no place for routine laminectomy to decompress the cord unless a compressive lesion is identified.

One of the most important observations was that of Pang and Wilberger (73). These authors found that 52% of children with SCIWORA had delayed onset of paraplegia, up to 4 days after the injury. Most of these children recalled transient symptoms at the time of injury. If instability is the mechanism of injury, it is possible that progressive deficit can be prevented by means of immobilization. The physician must be vigilant to identify these patients, in the hope of preventing more severe injury. Pollack et al. (77) advocate rigid cervical immobilization for 3 months for all of these patients, even if there is no radiographic evidence of instability. This recommendation is made on the basis of their finding that recurrent cord injury occurred among eight of 42 patients within 2 months after the initial injury. A clearly defined traumatic episode, usually trivial, was identified in seven of these eight cases. The incidence of SCIWORA after spinal cord concussion, as occurs among athletes, is not known (81). The role of steroids in preventing progressive deficit has not been studied.

Long-Term Effects of Spinal Cord Injury

Children who sustain spinal cord injuries share all the problems of their adult counterparts. Sphincter dysfunction, pulmonary insufficiency, autonomic dysreflexia, joint contractures, pressure sores, and spasticity are just a few of the chronic complications of spinal cord injury. In addition, children with spinal cord injury commonly have spinal deformity at or below the level of the injury. Age at injury is the single most important factor in the development of scoliosis (52). Among patients injured before the onset of the adolescent growth spurt, the development of severe deformity is almost universal. Deformity may progress more rapidly among patients with high cord lesions, but a low thoracic lesion does not exempt the patient from the development of deformity (60). Bracing delays the progression of deformity, but the use of bracing must be weighed against limitation of mobility (16,25).

Paraplegic and quadriplegic patients with scoliosis are predisposed to ischial pressure sores because of uneven weight bearing while sitting. Correction of the deformity is required once it exceeds 40 degrees. If a curve progresses rapidly, the cord should be screened for the development of a posttraumatic syrinx. If surgery is needed, limited fusion is not successful. Fusion must extend into the upper thoracic spine to prevent the development of late kyphosis above the instrumentation. The lower end of fusion is subject to much controversy. Most authors advocate extending the fusion to the sacrum and anchoring the instrumentation in the pelvis. This is to prevent the progression of pelvic obliquity. Some authors describe stopping at L5 to maintain lumbosacral mobility and avoid pseudarthrosis. At present there have been no results of a prospective series large enough to guide this decision.

Thoracic, Lumbar, and Sacral Spine Fractures and Dislocations

Henry G. Chambers

Behrooz A. Akbarnia

H. G. Chambers and B. A. Akbarnia: Department of Orthopaedic Surgery, University of California, San Diego, California.

Fractures of the thoracic, lumbar, and sacral spine are rare in children. Fractures that are significant in adults may be less so in children, who have more elastic soft tissue, the potential for remodeling, and normal mineralization of their bones. Certain injuries are unique to children, including posterior limbus injuries, most cases of spinal cord injury without radiographic abnormalities (SCIWORA), and, unfortunately, child abuse. This chapter discusses the anatomy, pathomechanics, clinical presentation, and treatment of injuries of the thoracic, lumbar, and sacral spine in children.

Incidence

The true incidence of thoracic and lumbar fractures in children is difficult to ascertain. Because of biases inherent in reporting methods, data collection systems, and classifications, the number of fractures is underreported and underestimated (21). Most of the literature on this subject is related to traumatic quadriplegia or paraplegia in childhood, and many articles include cases of cervical spine injuries (8,15,21,30,46). Twenty-six to 75% of all spine fractures in children are in the thoracic or lumbar spine (15,36). Our experience is that about 50% of pediatric spine fractures are in this region. These are relatively infrequent fractures, constituting only 2% to 3% of all injuries in children. The incidence of pediatric spine injuries peaks in two age groups: children 5 years old or younger, and children older than 10 years of age (15,41,42).

The most common cause of spinal injury in children is motor vehicle accidents in which they are either passengers or pedestrians (8). Other common causes of spine fractures are falls from heights (46), sports-related activities, and child abuse (2,5,54). Spinal cord injuries are common in accidents involving motorcycles and all-terrain vehicles (53). Boys and girls have an equal incidence of nonosseous injury, but boys have a greater incidence of bony involvement (59). There are other associated injuries in about half of patients, and 20% of those who have a spinal fracture have an associated neurologic injury (7).

Anatomy

The differences in the anatomy between adult's and children's bone determine the different manifestations of trauma to the thoracic and lumbar spine. Children have a greater capacity for growth and remodeling and are much more resilient to trauma. The osseous, ligamentous, cartilaginous, and neurologic anatomy must be completely understood before interpreting clinical, radiographic, and other imaging studies (see Chapter 1 .)

Clinical Presentation

The force necessary to create a spinal fracture is considerable and is often dissipated throughout the body, involving not only adjacent neural elements and ligamentous structures but also chest and abdominal organs. Half of patients with spinal fractures have associated injuries, and 20% to 30% have neurologic injuries (7,59).

The history should determine the mechanism of injury. Automobile accidents, crush injuries, and sports injuries involve much higher energy than a fall from a chair. Child abuse must be contemplated when the history given does not correlate with the clinical picture. Flexion-distraction spinal injuries and abdominal injuries are common in patients wearing seat belts in automobile accidents.

Examination of the spine often demonstrates posterior tenderness of both the spinous processes and the paravertebral musculature. There may or may not be a palpable step-off. Crepitus may be elicited in spinous process fractures. The neurologic examination is extremely important. A complete examination must be performed initially and at frequent intervals, even in neurologically normal children, because delayed neurologic deterioration may occur (47). The neurologic examination is difficult in small children, but every attempt to perform a complete examination should be made. A rectal examination should be performed in all patients. In those who have neurologic involvement, the bulbocavernosus test must be performed to determine the presence of spinal shock. All patients with a significant spinal injury should have evaluation of their bladder function, usually by a postvoid straight catheterization.

Associated injuries, such as cardiac contusion, pneumothorax, hemothorax, aortic injury, abdominal visceral ruptures, and renal and bladder injuries, are all life-threatening insults that may present with spinal injuries. These associated injuries may not manifest on the initial trauma evaluation but may present later. Awareness and prompt treatment of such associated injuries may save the child's life.

Imaging of Spinal Fractures

Crawford (15) believes that there are three “must know” categories in the management of spinal injuries: alignment, displacement, and extent of canal compromise. There are six major imaging studies to ascertain this information: plain radiography, computed tomography (CT) with or without contrast and with or without three-dimensional reconstruction, tomography, magnetic resonance imaging (MRI), myelography, and technetium bone scan.

Plain radiography permits a good evaluation of fractures, overall alignment, and displacement (33). Because of the complex anatomy of the vertebra, this two-dimensional image may not completely demonstrate the extent of the injury. In many severe injuries, especially SCIWORA (by definition), the plain radiographs are normal.

The CT scan should be used when bony injuries are suspected or known to exist to help determine the extent of canal impingement. Vertebral end plate fractures are imaged better by this modality than by any other (16). The addition of contrast, either intravenously or myelographically, can often enhance the lesion (bone or end plate) impinging on the canal or neuroforamina. Cystic lesions may be seen in the cord. The addition of computer software enables CT images to be converted to a three-dimensional reconstruction, which is extremely helpful in the planning of both surgical and nonsurgical treatment.

Plain tomography, although not as readily available as previously, can be helpful in determining the extent of canal compromise. The widespread availability of CT scans with sagittal reconstruction makes this modality less useful. However, it may still be the best imaging modality in flexion-distraction (seat-belt) injuries.

MRI is best used when soft tissue injuries are suspected; these include herniated disc, neuroforaminal encroachment, hematoma, spinal cord edema, or posttraumatic spinal cord cyst (25). The MRI may help find a lesion when the clinical presentation does not match the radiographic examination. A soft tissue or cord injury at a level different from that of the bony lesion may be present. Therefore, every child who has a neurologic deficit should have an MRI in addition to other imaging modalities. Myelography has a limited role in children's thoracic and lumbar fractures and should not be used if MRI is available.

Radionuclide imaging using technetium-99m phosphate can be helpful in diagnosing stress fractures of the spine, especially in spondylolysis of the pars intraarticularis. It may also be helpful, when combined with laboratory studies and the clinical presentation, in differentiating trauma from other entities that might present as back pain, such as infection or tumor. It has been used successfully to evaluate children who have been abused. The single-photon emission computed tomography (SPECT) scan is an important adjunct to the diagnosis of stress fractures, especially of the pars intraarticularis, because it may have positive results even in the presence of “normal” bone scans.

The clinical examination and knowledge of the pathophysiology of thoracic and lumbar trauma determine which imaging modality is used. Because of the inherent elasticity of the soft tissue in children's spines, trauma can cause damage that will not be evident on plain radiography. Other factors, such as the need for anesthesia for MRIs in young children, exposure to radiation, and the judicious use of financial resources must also be considered when imaging thoracic and lumbar spine injuries. The determination of alignment, displacement, and extent of canal compromise must occur with the fewest possible tests.

Differential Diagnosis

Children can sometimes sustain spinal fractures—usually anterior compression fractures—with seemingly minor trauma, such as falling out of bed. The radiographic appearance may suggest a fracture, but several other diagnoses must be entertained before beginning treatment.

Congenital Hemivertebra

Although congenital hemivertebra is typically not painful, generalized back pain with an anterior wedge hemivertebra (congenital kyphosis) could be confused with acute trauma. Other vertebrae are often involved to a lesser or greater degree. There are often abnormalities of the end plate and disc. There would not be localized tenderness over the paravertebral musculature. The bone scan would be normal to confirm the diagnosis of a congenital problem.

Infection

Occasionally, a pathologic fracture can occur through an osteoporotic infected vertebral body. Wedging can also occur in adjacent vertebrae as a result of discitis (56). The plain radiographs often demonstrate narrowing. Patients with vertebral osteomyelitis are usually very ill, but this is not always the case. The cause of this pathologic fracture may be trauma, but other pertinent information from the history, such as fever, antecedent back pain, and a concurrent infection, should raise suspicion. There is often fever, leukocytosis, and an increased erythrocyte sedimentation rate. A blood culture is often positive. Bone scan may not differentiate among fracture, tumor, or infection. MRI may show replacement or edema of the marrow elements. Occasionally, biopsy may be necessary to obtain a correct diagnosis.

Neoplasm

Primary tumors, both benign and malignant, involve the thoracic and lumbar spine. As the marrow and cancellous bone become replaced by tumor, pathologic fractures can occur. Metastatic tumor may occur in the vertebral body, leading to weakened bone and subsequent fracture. Biopsy is often necessary to confirm these diagnoses. Treatment is dependent on the tumor: some can be treated by support and observation (e.g., eosinophilic granuloma); others may require radiation therapy or even excision. Often, the spine needs to be supported while treatment is underway (e.g., for leukemia) (31).

Metabolic Disease

Any of the metabolic diseases that lead to osteopenia significantly weaken the vertebrae, so that minor trauma can lead to a pathologic fracture. Osteogenesis imperfecta patients often have spine fractures at different levels. The mucopolysaccharidoses often involve the spine; Morquio syndrome is characterized by involvement of all the vertebrae. The radiographic appearance is similar to that of spondyloepiphyseal dysplasia with platyspondia (44). A careful history and physical examination, as well as laboratory investigations, usually help make the diagnosis of metabolic bone disease.

Scheuermann Disease

Scheuermann disease is characterized by wedging of multiple thoracic vertebrae. These patients have a characteristic round back deformity with chronic thoracic spine pain and a rigid kyphoses. The radiographic picture is one of narrowed disc space, increased anteroposterior diameter of the apical thoracic vertebra, loss of normal height of the involved vertebrae, and end plate irregularity (14). Schmorl nodules may be present, but their presence is not necessary to make the diagnosis. Classically, the wedging is described as three consecutive vertebrae with wedging of at least 5 degrees (58). The clinical and radiographic presentation of Scheuermann disease usually eliminates trauma as a cause of the wedging of the vertebrae.

When evaluating a child with vertebral wedging, all the diagnoses described previously must be considered. The reader is referred to other chapters in this text discussing these entities in greater detail. Trauma, albeit minor, may be involved in the occurrence of pathologic fractures.

Evaluation and Treatment of Major Spinal Fractures

Evaluation

In an effort to describe the biomechanics of the spine and the pathomechanics of spine fractures, Holdsworth (34) developed the two-column theory of the spine. This theory allows for the understanding of many spine injuries but does not describe canal impingement, which is the most devastating aspect of spinal fractures. Denis (17,18) described the three-column spine, which has proved more useful in understanding spinal fractures. Although developed for the adult spine, this system can be extrapolated to children and adolescents with adjustments for anatomic and biomechanical differences. The pediatric spine has most of the adult radiographic features by 8 years of age, although juvenile features occasionally persist until 11 or 12 years of age (51). The physis may continue to grow even after damage, and restoration of the height of the vertebral body may occur in young children whose physes are not damaged (36).

The posterior column consists of the posterior laminar arch, supraspinous ligament, interspinous ligament, posterior lateral capsule, and ligamentum flavum. The middle column includes the posterior longitudinal ligament, posterior annulus fibrosis, and posterior wall of the vertebral body. The anterior column consists of the anterior vertebral body, anterior annulus fibrosis, and anterior longitudinal ligament (17) (Fig. 1).

The three-column system permits injuries to be divided into four major types: *a compression fracture*, which is a failure of the anterior column with an intact middle column; *a burst fracture*, which is a failure under compression (usually axial) of both the anterior and middle columns; *a seat-belt fracture*, which is a compression injury of the anterior column, with distraction of the middle and posterior columns through either bony or ligamentous elements; and a *fracture-dislocation*, in which all three columns fail in compression, with rotation and shear of the anterior column, distraction with shear of the middle column, and distraction with rotation and shear of the posterior column (15,17,18). Spinal stability has many definitions, but Denis (18) groups instability into three main types: *first-degree instability*, which is a mechanical instability with risk for kyphosis; *second-degree instability*, which is a neurologic instability, such as a collapsing "stable" burst fracture; and *third-degree instability*, which is both mechanical and neurologic instability, such as an unstable burst fracture or a fracture-dislocation.

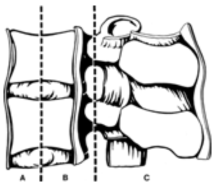

FIGURE 1. The three-column concept. *A*, Anterior column. *B*, Middle column. *C*, Posterior column.

Another way to group fractures in terms of stability is acute versus chronic. Those fractures in which there is either bony instability or progression of neurologic deficit are labeled *acute instabilities.* Fractures in which there will be a predictable increase in angulation (kyphosis or scoliosis) and a potential for late neurologic compromise are *chronic instabilities.*

General Principles of Treatment

The goal of operative treatment of spine fractures is threefold: to provide an environment for maximal neurologic recovery, to preserve maximal spinal mobility, and to provide long-term stability in a balanced spine.

Management of thoracic and lumbar spine fractures in children is not significantly different from that in adults. However, there are some aspects of childhood fractures of the spine that differ. There is immature muscle development, and the support of the posterior ligamentous complex is often lost. If a kyphotic deformity is allowed to remain after treatment of spine fractures, it may spontaneously progress. This is more likely when there has been crushing of the vertebral body and epiphyseal plate, similar to postlaminectomy kyphosis. On the positive side, the growth potential may help remodeling and reconstitution of the deformity (48). This is often seen in compression fractures. Spinal canal compromise seen in burst fractures has more potential for remodeling in a child than in an adult. If the fragments have not caused neurologic deficit, they may often be left alone; further remodeling can be expected if the spine is otherwise stable.

The alternatives in surgical management of spine fractures in children are reduction, fusion, decompression, and instrumentation. The assessment of a child's spine fracture should include evaluation of spinal alignment, spinal stability, and degree of canal compromise (15). If initial imaging studies show that the alignment of the spine is satisfactory, there is no displacement at the fracture site, and the spinal canal has not been violated by bony or disc fragments, no reduction is necessary. The need for surgical stabilization depends on the degree of stability after reduction. In cases of neurologic deficit, the spinal canal should be evaluated by imaging studies such as MRI or CT contrast. Patients with complete neurologic deficits who have no apparent spinal fractures (e.g., those with SCIWORA) or whose spines are aligned and stable do not require surgical intervention. Patients with incomplete neurologic deficits and spinal canal compromise and patients who are worsening neurologically are candidates for spinal canal decompression.

In the thoracic spine, the arthrodesis and instrumentation can be extended a few levels above and below the fracture. Longer posterior instrumentation may be necessary to correct and maintain kyphosis in this region. In addition, mobility of the thoracic spine is not significantly affected by longer instrumentation and fusion.

In the lumbar spine, shorter instrumentation is desirable to preserve maximum mobility. Fixation must be secure. A pedicle screw system may be of benefit for the lumbar spine (3). Thoracolumbar fractures (T12 to L2), especially when associated with increased kyphosis and neurologic deficit, may be approached with anterior decompression, grafting, and instrumentation, or posteriorly by posterolateral decompression, posterior interbody grafting, and posterior instrumentation. If the loss of anterior vertebral height is significant, anterior strut grafting is preferable to posterolateral interbody fusion. In the case of burst fractures, decompression can be done anteriorly or posterolaterally (13,39).

The surgical approach and the choice of instrumentation depend on the type of fracture, location, neurologic deficit, and surgeon's experience.

Flexion (Compression) Fractures

Compression fractures of the thoracic spine are relatively common. Fractures in the thoracolumbar region occur more frequently than those in the thoracic or lumbar spine. The compression is usually 20% or less and may occur over several levels. This results from the strong normal disc and end plates. There is an additional support from the rib cage, which prevents excessive translational movements during trauma.

The elasticity of the entire segment permits compression of only the anterior column. The end plates may be involved in fractures, with a superior end plate sustaining injury twice as often as an inferior end plate (24). Even in those fractures with 50% compression, the posterior elements are often not involved. Although there may be pain and tenderness in the posterior spine, there is usually no palpable defect of the interspinous ligament.

The wedge, if in the sagittal plane, usually reconstitutes the vertebral height, especially if the child is younger than 10 years of age (Fig. 2). Frontal plane wedges do not correct as well. If the end plates are fractured, there is usually no correction. Slight axial deviations are corrected by growth of adjacent vertebral bodies.

Compression fractures that do not have posterior involvement or apophyseal ring fractures are usually stable, both mechanically and neurologically. If there is any middle or posterior column involvement, there is some potential for instability.

Most compression fractures—except for some severe compressions and multiple fractures in the thoracic spine—can be treated conservatively. Compression fractures heal quickly and do not tend to progress. If the compression is mild, the patient can be treated symptomatically by bed rest and immobilization with or without external support. Children are usually symptom free within 1 or 2 weeks. Posterior tenderness at the level of fracture may continue for several weeks but often responds to symptomatic treatment. If there is an end plate fracture or disc herniation, symptoms may persist a little longer. The outcome of conservative treatment with casting and bed rest has been satisfactory (35). Compression fractures with less than 50% loss of anterior body height are good candidates for nonoperative treatment. Increase in kyphosis is rare after 3 months (32). Patients with multiple compression fractures should be watched closely because further deformity—in both the coronal and the sagittal planes—can develop.

When there is more than 50% loss of anterior height or there are multiple compression fractures leading to an increased kyphosis, posterior instrumentation may be necessary. Contoured (to the sagittal alignment) Harrington rods or any of the newer rod-hook systems may be used (6). Instrumentation should be long enough in the thoracic spine to encompass the kyphosis and apply compression force by multiple anchors.

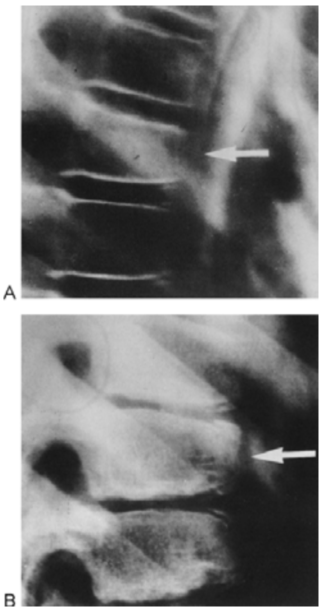

FIGURE 2. A: Mild compression fracture *(arrow)* of a thoracic vertebra. **B:** Appearance one year later; reconstitution of the anterior height is beginning.

Axial (Burst) Fractures

Holdsworth (34) introduced the concept of "burst" fractures in 1970. When a vertical (axial) compression force is applied, the vertebral end plate fractures and the nucleus of the disc are forced into the vertebral body, which explodes and shatters. Burst fractures usually occur in the lower thoracic region, thoracolumbar junction, and lumbar region, where axial loading is possible. Holdsworth stated that these are stable but painful injuries.

Some of these burst fractures are both mechanically unstable—with collapse and painful kyphosis—and neurologically unstable—both acutely and chronically, with a retropulsed middle column into the spinal canal and neural foramina (45). Those fractures in which the end plate is damaged are prone to physeal damage and may progress to kyphosis with further growth. The extent of bursting cannot always be appreciated on plain radiography. CT scanning has proved invaluable in the evaluation of burst fractures, both as an aid to diagnosis and as a guide to further treatment (20,45,57).

"Stable" burst fractures may be treated conservatively if the kyphosis is less than 20 degrees (23). If the fracture is deemed "unstable," surgical treatment is necessary. For a burst fracture in the thoracic spine, the length of the instrumentation may be similar to that used for compression fractures, without compression force. Contouring the rods and using three-point fixation help the reduction and restore spinal alignment. In the lumbar region, instrumentation can be short, using pedicle fixation (pedicle screw fixation in children has not been approved by the U.S. Food and Drug Administration) or hooks. After reduction, if there is a significant loss of anterior body height (more than 60%), anterior grafting—from either a posterior or an anterior approach—may be required.

It is often possible to use one screw at the fracture level in one pedicle. This adds to the strength of the construct. If required, decompression, especially in the lower lumbar spine, can be accomplished through one pedicle, including anterior interbody grafting (4) (Fig. 3). Pedicle screw devices are usually extended one level above and one level below the fracture. Harrington instrumentation can be used for longer instrumentation levels to reduce the fractures, with contoured rods and application of three-point fixation, distraction, and short (two-disc and even one-disc) fusion to preserve mobility. Rods are usually removed 6 months after surgery (6,18,22).

At the thoracolumbar junction, in fractures with severe anterior angulation of the vertebral body, anterior instrumentation with the Kaneda device or other similar instrumentation allows reconstitution of vertebral height and a short fusion (one vertebra above and one vertebra below) (39). In cases of neurologic deficit, anterior decompression is possible at the same time (13,38) (Fig. 4).

Flexion-Distraction (Seat-Belt) Injuries

Chance (12) described three fractures of the lumbar spine in which the fracture went through the vertebral bodies, exiting through the neural arches and the pedicle. He thought that the fracture was secondary to a flexion injury, but Smith and Kaufer (52), and later Rennie and Mitchell (50), described what is now the accepted pathomechanics of flexion and distraction as the cause of the fraction (Figs. 5, 6, and 7).

Gumley and colleagues (29) suggested a classification based on the location of the fracture in the posterior elements of the vertebra. Type I extends through the spinous process and travels symmetrically forward through all the posterior bony elements to emerge in a variable position in the vertebral body. Type II is identical, except that the fracture line traverses the posterior elements between the spinous processes. Type III is asymmetric, involving the posterior elements more on one side than the other, which is possibly associated with a rotational force occurring around a seat-belt strap (27,29).

Gertzbein and Court-Brown (27) extended this classification to describe the trauma to the anterior vertebral column, the posterior elements, and the resulting axially loaded spine (Fig. 8). The anterior lesion may be a fracture or a combination of soft tissue injury and bony injury. Type A injuries, involving the disc, may not heal sufficiently to restabilize the spinal segment. Similarly, type C injuries involve only a small area of bone as

the injury proceeds through the end plate. Type B injuries through the vertebral body, compression fractures (type D), and burst injuries (type E) are all associated with major bony trauma and usually heal with little surgical intervention. Classification of these injuries allows one to identify the degree of soft tissue involvement and thereby plan for management, either surgical or nonoperative (27).

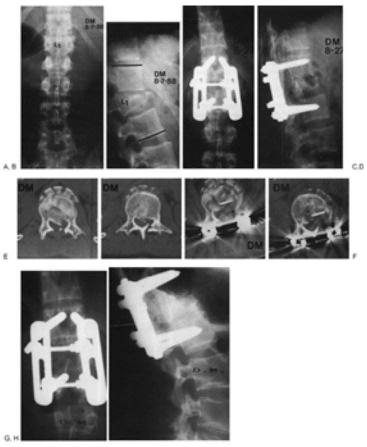

FIGURE 3. Seventeen-year-old girl with a burst fracture of L1, severe anterior height loss, and significant spinal canal compromise. She had posterior instrumentation with pedicle fixation and VSP plate. **A and B:** Preoperative anteroposterior and lateral radiographs showing anterior body loss and kyphosis at the thoracolumbar junction and increased interpedicular distance. **C and D:** Postoperative anteroposterior and lateral radiographs show correction of kyphosis and anterior body height loss. Patient had posterior interbody fusion through the pedicle approach at the time of decompression. **E and F:** Computed tomography scan before **(E)** and after **(F)** surgery showing adequate spinal canal decompression postoperatively. Note the anterior graft; this is not the posterior cortex of the vertebral body but the new corticocancellous graft placed anteriorly through the pedicle. **G and H:** Anteroposterior and lateral follow-up radiographs showing maintenance of correction and solid fusion. One year after surgery, the patient had no neurologic deficit.

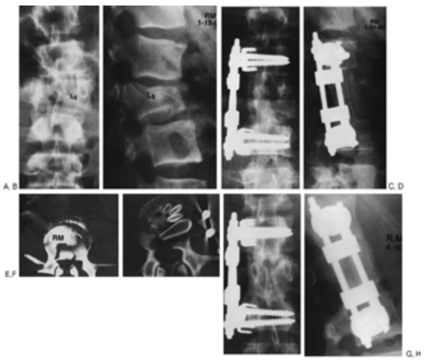

FIGURE 4. Fifteen-year-old boy with an L3 burst fracture and incomplete neurologic deficit. **A, B:** Preoperative anteroposterior and lateral radiographs. **C, D:** Immediate postoperative radiographs showing restoration of alignment following vertebrectomy, grafting, and Kaneda instrumentation. **E, F:** Preoperative **(E)** and postoperative **(F)** Computed tomography scans showing anterior decompression and grafting. **G, H:** Anteroposterior **(G)** and lateral **(H)** radiographs 2 years after surgery showing the maintenance of alignment and solid fusion. The patient had incomplete neurologic recovery.

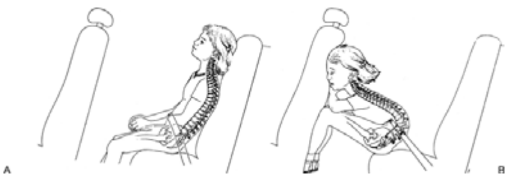

FIGURE 5. **A:** A child with typical slouched posture; note poorly developed anterosuperior iliac spine. **B:** Frontal collision; lap belt slips over iliac crests to focus bending force in the midlumbar region.

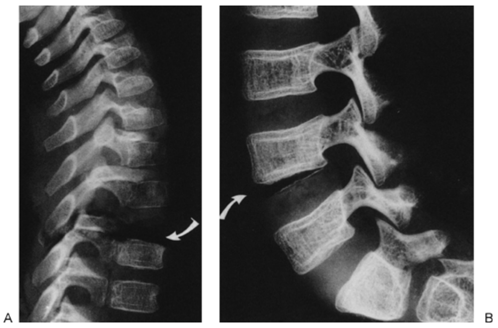

FIGURE 6. Experimental flexion-distraction injuries of immature spines. **A:** Thoracic. **B:** Lumbar.

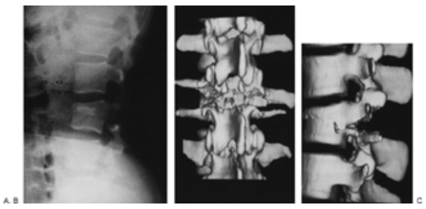

FIGURE 7. Seventeen-year-old girl who sustained an L3 flexion-distraction injury. **A:** Lateral radiograph. **B:** Anteroposterior three-dimensional reconstruction. **C:** Lateral three-dimensional reconstruction.

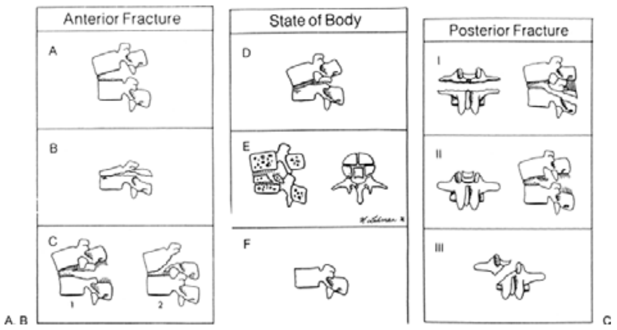

FIGURE 8. Classification of flexion-distraction injuries. **A:** Anterior disruption. **B:** State of the vertebral body. **C:** Injuries of the posterior elements. (From Gertzbein S, Court-Brown C (1988): Flexion-distraction injuries of the lumbar spine: mechanisms of injury and classification. *Clin Orthop* 227:52–60.).

Many state laws require that children use seat-belt restraints while traveling in automobiles. None of these laws requires the use of shoulder belts, which would decrease the incidence of lap belt injuries but might increase neck injuries in severe crashes. Children are particularly susceptible to the seat-belt injury because they have a large head relative to their body length, a high center of gravity compared with that of adults, poor protection of thoracic and abdominal organs by the chest and abdominal wall, and underdevelopment of the anterior iliac crests, which serve to anchor the body to the seat belt (11). The National Transportation Safety Board suggested that the use of seat belts may be more harmful than no seat belt because “in many cases the lap belts induce severe to fatal injuries that would not have occurred if the lap belt had not been worn” (28). Therefore, the seat belt must be worn correctly.

Agran and associates (1) reported on 191 patients who were wearing seat belts when they were involved in motor vehicle accidents in the Los Angeles area. This study represented only 12% of the 1,642 patients who were involved in motor vehicle accidents. The children were divided into the following groups:

Infants and toddlers (0 to 3 years). These children have proportionally larger heads and a higher center of gravity than older children. Internal chest and abdominal organs are less protected by overlying bony structures and muscles. In motor vehicle crashes, these children tend to undergo rotational movement, become airborne more easily, and move head-first toward the side of impact. Child safety seats are designed for children in this age group.

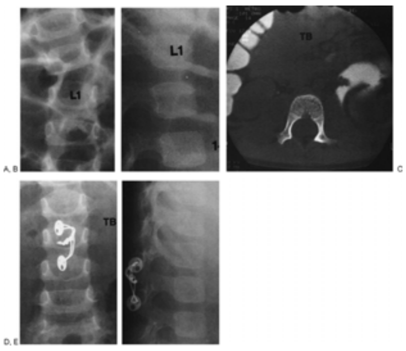

FIGURE 9. Three-year-old child with seat-belt fracture (flexion-distraction) that is mostly posterolateral, with obvious separation at L1 to L2. **A, B:** Injury radiograph showing the separation between L1 and L2. **C:** Computed tomography scan showing the "naked facet sign" (absence of articulating facet), indicating facet dislocation. **D, E:** Radiograph showing internal fixation with Wisconsin wires in compression correcting the deformity. At surgery, the facets were found to be dislocated. No fracture was found. There was leakage of cerebrospinal fluid.

School-aged children (4 to 9 years). During these growth years, the center of gravity moves toward the umbilicus, thus reducing the top-heaviness evident in the younger group. Nonetheless, the iliac crests are not adequately developed at this age to serve as a lap-belt anchor point. Also, proper upright seated posture is difficult to maintain because of lordosis in this age group. The seat belt tends to slide up and lie over the abdomen. Although these children have outgrown child safety seats, a booster seat is available to be used in conjunction with the seat belt to assure proper positioning of the belt on the child's body.

Adolescents (10 to 14 years). The physical characteristics of this age group are more like those of an adult. By 10 years of age, the anterior iliac crests are adequately developed to serve as anchor points for the lap portion of the belt. In addition, an upright seated position can be maintained.

Johnson and Falci (37) described nine patients who had lumbar spine injuries caused by rear lap seat belts. Four of the nine had associated severe abdominal injuries. One had a skull fracture caused by the forward thrust of the unrestrained upper body against the poorly padded interior of the car. There is also a possibility of a bony injury at one level and a disc injury at another level. This must be thoroughly evaluated with MRI.

Seat-belt fractures can be treated nonoperatively if satisfactory reduction can be obtained and maintained in a cast or a rigid orthosis. Conservative treatment appears to be more efficient when the fracture crosses through the bone. In burst fractures, if the lesion involves the end plates, progressive deformity may result; children should be observed carefully for this complication. Spontaneous interbody fusion seldom occurs and should not be depended on to provide long-term stability (36). Satisfactory results in burst fractures with or without neurologic deficit have been reported after nonoperative treatment, with excellent long-term functional results (49,55). Children who are treated nonoperatively for their spine fractures should be followed longer to make sure no subsequent deformity develops.

If reduction is not achieved by nonoperative methods of casting or postural reduction, surgery may be indicated. A posterior compression force is required to reduce the fracture. This can be achieved by wiring in small children or by pedicle screws in older patients. Instrumentation is usually extended one level above and one level below the level of injury using hooks (18,27) (Fig. 9).

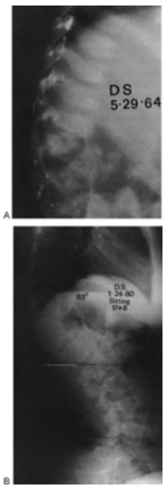

FIGURE 10. Fracture-dislocation of the spine in a 2-year-old abused child who became paraplegic. **A:** Injury. **B:** Sixteen-year follow-up. (Courtesy of Robert Winter M.D., Twin Cities Scoliosis Spine Center, Minneapolis, Minnesota.)

Fracture-Dislocation Injuries

These rare fractures usually occur at the thoracolumbar junction. There are often associated neurologic injuries of either the conus medullaris or nerve roots. This injury is always unstable, requiring operative stabilization (and decompression) as dictated by the individual patient's clinical presentation (10) (Fig. 10).

Fracture-dislocation injuries are unstable and require rigid fixation with long instrumentation levels and multiple anchors, starting close to the fracture level. Long instrumentation ensures increased stability. In addition, if the patient has complete neurologic deficit, longer fusion and instrumentation may help prevent subsequent paralytic deformity (Fig. 11). If short segmental

instrumentation is used, it should be extended at least two levels above and two levels below, with postoperative bracing.

Fifteen-year-old boy with a burst fracture of T5. **A:** Lateral injury radiograph. **B, C:** Preoperative computed tomography scans showing significant canal compromise. **D:** Radiograph after posterior spinal fusion and Cotrel-Dubousset instrumentation throughout the kyphosis. No decompression was performed. **E and F:** Computed tomography scans 1 year after injury showing excellent remodeling and restoration of the spinal canal.

The Role of Spinal Decompression

The indications for decompression in patients with spine fractures who are neurologically intact are controversial. There is a significant potential for remodeling of the spinal canal in children (40). Therefore, decompression in neurologically intact patients who have spinal canal compromise may not always be necessary. If patients require anterior grafting for correction of kyphosis, decompression can be done at the same time (Fig. 12).

Patients who have incomplete return of neurologic function and have no change in this status or are getting worse are candidates for decompression. There is evidence that early anterior decompression may lead to an improved neurologic recovery (13).

Posterolateral decompression includes removal of the entire pedicle at the fracture level and the disc superior to the level of the fracture; it also includes an “eggshell” procedure of the vertebral body to allow room for fragments to reduce. Special instruments are necessary to accomplish this goal (Fig. 13).

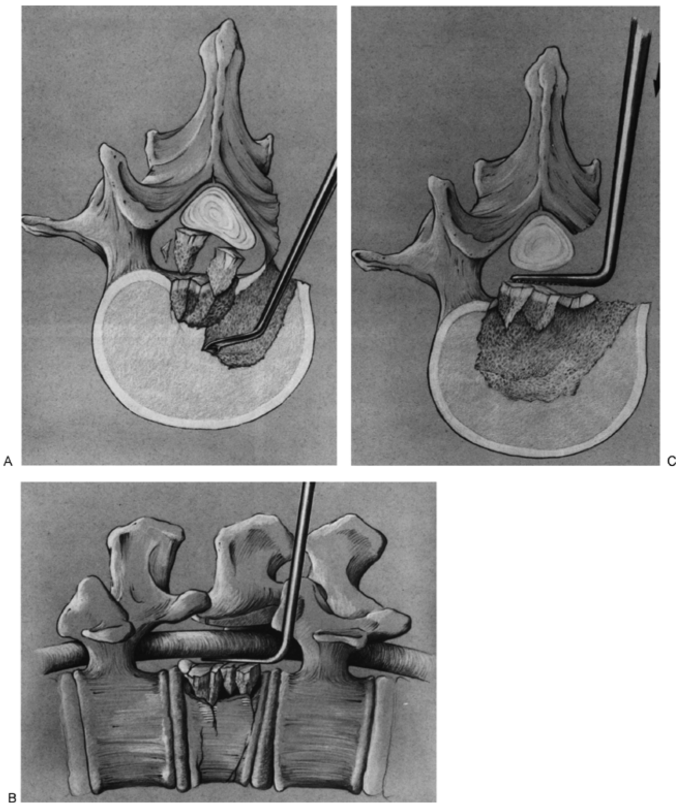

FIGURE 13. The technique of posterolateral decompression. **A:** Removal of the pedicle and lateral cortex, leaving the medial cortex intact to protect the dura while special currettes are used to “eggshell” the vertebral body. **B:** Removal of medial cortex of the pedicle and beginning of impaction. **C:** Impaction of the protruded fragments into the vertebral body. Interbody grafting can be done after disc removal if necessary.

Minor Spinal Fractures

Fractures of the spinous and transverse processes are often encountered with blunt trauma to the back. Although the fractures themselves may be minor, the associated injuries may be severe. Transverse process fractures of the thoracic region may be associated with significant pleural cavity trauma; those in the thoracolumbar region may be associated with renal damage; and those in the lower lumbar region may have an accompanying unstable pelvic fracture. Associated injuries must be thoroughly investigated before these “minor” injuries are treated symptomatically.

Fractures Resulting from Child Abuse

The true incidence of spinal injuries as a result of child abuse is not known, but it ranges from 0% to 3% in large series (2,5,7,26). One of the reasons for this discrepancy may be the lack of consistency in obtaining a skeletal survey among different institutions. Most radiology departments include an anteroposterior radiograph of the entire spine in a skeletal series, but the lateral radiograph is often not included. Furthermore, abused children with spinal injuries occasionally show mild kyphosis, but most patients do not have significant clinical findings referable to their spine. It is not unusual that many of these injuries go unrecognized, and they may be more common than is reported in the literature. Because these injuries are likely to be silent but associated with extremely violent assaults, routine evaluation of the spine is mandatory.

The average age reported by Kleinman (43) of 45 children with 85 spinal fractures was 22 months. Most spine fractures caused by abuse involve vertebral bodies. Posterior elements are involved only occasionally. Varying degrees of anterior compression are seen. There may be anterior notching of the vertebral body near the superior end plate (54). There may be decreased disc space caused by disc herniation.

Severe injuries, such as fracture-dislocations with or without neurologic deficit, have also been reported. Spinal cord injury or hematoma may be seen without bony involvement. Significant fracture-dislocations, especially those not associated with neurologic deficit, may go unrecognized and result in significant spinal deformity later in life (Fig. 10).

The mechanism of injury in most cases is hyperflexion, extension, or a combination of the two. Multiple compression fractures are not unusual findings. Fractures of the upper extremities may be seen in association with spine fractures. For example, children are held above a table or counter and their buttocks are slammed down, they use their outstretched arms to break the impact, causing fractures of the upper extremities. Most fractures are in the region of the thoracolumbar and lumbar spine. However, fractures and fracture-dislocations of the cervical region are also seen.

In evaluating the changes in vertebral bodies and the disc space in child abuse, one should consider developmental changes or infection. Disc space narrowing caused by infection is usually more severe than that caused by trauma and disc herniation. The value of the bone scan in detecting spinal injuries in child abuse is not clear, and it is generally believed that the standard radiographic studies are the primary method of detecting spinal trauma in child abuse.

According to Kleinman (43), vertebral body fractures and subluxations are fractures with moderate specificity for child abuse, but if the history of trauma is absent or inconsistent with the injuries, they become high-specificity lesions. After child abuse is detected, the principles of diagnosis and treatment of victims should be followed (2,5).

Sacral Fractures

Sacral fractures are usually associated with pelvic injuries and are not common in children. They may also occur in association with more obvious thoracolumbar spinal fractures and as such they are frequently underdiagnosed.

Fractures of the sacrum may involve the sacral nerve roots and cause neurologic deficit. Higher-level sacral injuries (S1 to S2 or S2 to S3) are more likely to cause bladder paralysis than lower injuries, such as S4 to S5. The foraminal entrapment of S3 and S4 is less likely than that of S1 and S2 because of the size of the nerve root relative to the foramen at these levels (19). If sacral fractures are undiagnosed and untreated, they may result in neurologic symptoms and deficits in the lower extremities and in urinary, rectal, and sexual dysfunction. These neurologic problems often remain the major chronic sequelae after the more obvious pelvic trauma has healed (19).

Denis and colleagues (19) studied 236 patients with sacral fractures in a series of 776 patients with pelvic injuries (30.4%) and introduced a new classification system. Previous classifications did not provide a simple anatomic-clinical correlation, particularly for bladder involvement (9). Denis divided the sacral fractures into three zones (Fig. 14). A zone I (alar zone) fracture, by definition, involves a fracture through the ala without any damage to either the foramina or the central sacral canal. A zone II (foraminal zone) fracture involves one or several foramina. It may also go through the ala without impinging on the central sacral canal. A zone III (central zone) fracture involves primarily the central sacral canal. The fracture line may involve two zones or, in the case of a transverse fracture, all three zones. Any fracture involving multiple zones and the central canal is considered a zone III fracture because the central canal is the most significant component of the injury. Most sacral fractures are not associated with neurologic deficit.

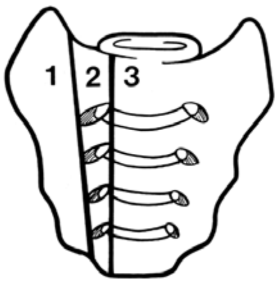

FIGURE 14. Classification of sacral fractures: the region of the ala (zone I); the region of the foramina (zone II); the central sacral canal region (zone III) (From Denis F, Davis S, Comfort T (1988): Sacral fractures: an important problem. Retrospective analysis of 236 cases. *Clin Orthop* 227:67–81, with permission.)

Zone I fractures are rarely associated with neurologic deficit resulting from sacral nerve root entrapment, although they may occasionally involve the L5 nerve root or the sciatic nerve. Vertical shear-type fractures may compress the L5 nerve root between the ala and the transverse process of L5. Initial traction may be helpful in reducing the compression, but if displacement and neurologic deficit continue, open reduction may be necessary. When the sacral fracture has been displaced vertically by 2 cm or more for more than 72 hours, it is difficult to reduce because the paravertebral musculature has contracted.

Zone II fractures may involve one or several foramina. Neurologic injuries are found in 28% of these fractures; they may include bowel and bladder dysfunction and L5, S1, S2, and nerve injuries. If the CT scan shows reduction of the sacral foraminal size by at least 50%, early surgical decompression may be indicated. In the case of unstable fractures, open reduction posteriorly in conjunction with anterior pelvic external fixation may be required.

Zone III fractures involve primarily the central sacral canal. Neurologic damage occurs in more than half of these cases and involves the bowel and bladder in most cases. It may also involve L5 and S1 nerve roots independently or in combination. Transverse sacral fractures may be associated with thoracolumbar burst fractures. Treatment of zone III fractures without neurologic deficit is aimed at pelvic stabilization. Neurologically involved patients require careful evaluation, including CT scans with thin cuts and tilted gantry and reconstruction. Three-dimensional CT programs are invaluable for this purpose. Cystometrograms are also helpful in determining bladder function before and after surgery.

Decompression of sacral roots in the acute phase may be necessary to improve neurologic function. Delayed decompressions are often difficult and may not lead to significant recovery.

Spinal Cord Injury and Posttraumatic Deformities

Thomas S. Renshaw

T. S. Renshaw: Department of Orthopaedics, Yale University School of Medicine, New Haven, Connecticut 06510.

Up to 10,000 spinal cord injuries (SCIs) occur in the United States each year, or almost 40 cases per 1 million people (22,47,81,87). Perhaps half again those many do not survive the trauma and are not included in occurrence figures (88). An estimated 200,000 Americans are alive with their SCI. The mean age at the time of injury is about 30 years, with only 3% to 5% of SCIs occurring in children younger than 15 years of age (59,69,88).

Spinal cord injured children who initially survive the trauma and are hospitalized have an overall mortality risk of 5% to 10% during the first year, with most early deaths occurring in the first 2 weeks after the injury as the result of cardiac or pulmonary complications (33). Fatalities from cervical spine injuries in children correlate directly with the level of the lesion: the more cephalad the injury, the worse the prognosis. Most atlantoaxial injuries result in death, and injury levels of C1, C2, C3, and C4 had fatality rates of 17%, 9%, 4.3%, and 3.7%, respectively, in a study of 227 treated children (62). This study also showed that the younger the child, the more cephalad the cervical injury.

The causes of SCI in children vary with the age of the child and where he or she lives. Among the most common causes are falls and automobile-related injuries (46,72,85). Falls are a particularly frequent cause in younger children (less than age 6 years); even falls from low heights (less than 5 feet) can result in C1 to C2 subluxation, odontoid fracture, and C2 fracture (75). Motor vehicle accidents most commonly involve occupants of automobiles or pedestrians and bicyclists struck by automobiles. Airbags and seat belts, although major advances in saving lives, may nevertheless produce SCI when used improperly (31,34). Gunshot wounds account for a disproportionate share of SCIs in some cities (3), and other acts of violence and sports-related injuries, particularly diving accidents, each account for a double digit percentage in most series. Much less common are sports injuries related to football, wrestling, and horseback riding (6,24,59,60). Other uncommon causes are shaken baby syndrome (76), birth trauma, industrial and agricultural accidents, infections, and vascular episodes.

Older boys are more likely to be injured than older girls (60,72,85), but under 3 years of age, the sex incidence is nearly equal (88). SCIs occur more commonly in the summer months and near the end of the week or on weekends (88). Resultant incomplete neurologic lesions are more common in most reports (72,85), but in some, complete and incomplete lesions are about equal in frequency (33,60). High-velocity injuries have a worse prognosis than low-velocity injuries; open fractures do worse than closed fractures; higher levels of paralysis have more complications than lower levels; and older patients have a poorer outcome than younger patients.

Considering all injuries to children's spines, the cervical region is the most commonly injured and most dangerous site. Fractures here carry a risk of neurologic injury of up to 53%, compared with a 15% to 20% risk in the thoracolumbar region (9,24,60). Children 10 years of age and younger have a predominance of ligamentous injuries in the cephalic portion of the cervical spine. Those 11 years of age and older are likely to have a more caudal cervical injury, with a pattern similar to that seen in adult trauma (3,59).

Whenever the spine is fractured, it is essential to look for more than one lesion. A report on more than 800 patients includes a 6.4% incidence of noncontiguous spine fractures (45); another report lists noncontiguous abnormalities and spinal cord injury without radiographic abnormality (SCIWORA) as the most common injuries in very young patients (53). Contiguous and noncontiguous injuries can occur in 15% to 24% of spine trauma patients (20,33,37,49).

Anatomy and Pathophysiology

The spinal cord occupies about half of the space in the bony spinal canal, except at the level of C1, where it fills one third of the cross-sectional area. The cord expands in the cervical and lumbar regions because of the concentration of nerve roots to the extremities, but this expansion is accompanied by widening of the canal. Cervical nerve roots arise from the cord opposite their corresponding vertebrae and exit through foramina above those vertebral bodies. Because there are seven cervical vertebrae and eight cervical nerve roots, the C8 nerves exit between C7 and T1. The thoracic roots originate from segments of spinal cord about one level cephalad to the corresponding numbered vertebral body and exit through the foramina just caudal to the corresponding vertebra (9). The lumbar and sacral nerve roots originate from the cord between the levels of T10 and L1, the conus medullaris. The spinal cord normally ends at the level of the L1 to L2 intervertebral disc. Caudal to the conus is the cauda equina. This group of free nerve roots has ample space in the spinal canal and, therefore, is less susceptible to injury than is the spinal cord.

Most SCIs in children are the result of crushing, contusion, or stretching of the cord, often with hemorrhage, rather than complete disruption. The injury sets off a cascade of events, including ischemia, hypoxia, edema, and necrosis (38). Experimental evidence has shown that spinal cord distraction can generate cord tissue pressures that could cause a spinal cord compartment syndrome and thus impair spinal cord blood flow (42).

In the initial minutes after SCI, neurogenic shock may be present. It has been reported to occur in 69% of cervical spine injured patients (77) and is characterized by hypotension and bradycardia. The magnitude of neurogenic shock is directly proportional to the magnitude of the SCI (67). It is believed to be the result of unopposed vagal parasympathetic activity that is manifest because sympathetic function from the thoracic and lumbar spinal cord has been interrupted (36).

Spinal shock is different from neurogenic shock but also occurs directly after SCI. It is a physiologic phenomenon that almost always lasts less than 24 hours (78). Rarely, it can persist for as long as a few weeks (92). It is characterized by flaccid paralysis and areflexia and is thought to result from interruption of descending inhibitory fibers of the caudatospinal, reticulospinal, cerebelloreticular, and corticobulboreticular pathways (81). After spinal shock resolves, the upper motor neuron lesion findings of hypertonia, hyperreflexia, and clonus can be elicited through stimulation of monosynaptic reflex pathways in the intact spinal cord caudal to the lesion. Other reflexes, such as the bulbocavernosus, cremasteric, and anal wink, also return.

Care of the Spinal Cord Injured Patient

Prehospital Management

The mortality and morbidity of SCI in children can depend on the patient's management at the scene of the accident. At the accident site, the ABCs (airway, breathing, circulation) of trauma management begin. Assessment of the airway must include careful handling of the cervical spine, the assumption being that there is an unstable injury. Respiratory and cardiovascular evaluation and resuscitation, if necessary, are done simultaneously with immobilization of the spine in the neutral supine position on a spine board or rigid stretcher. It must be remembered that before 6 years of age, a child's head size is relatively greater than his or her chest size, so that immobilization on a flat board can produce flexion or anterior translation of an unstable cervical injury and cause further spinal cord damage. This is avoided by using a child-specific spine board with a cutout for the occipital area or by placing a folded sheet or blanket under the chest so that the top-center area of the shoulders is horizontally level with the external auditory meatus (39).

Sterile dressings are placed on open wounds, fractures are splinted in a position of function, and a screening motor and sensory examination is done and recorded. If a cervical injury is suspected, the head should be taped to sandbags or towels and then to the backboard, or an appropriate pediatric cervical orthosis should be applied and then the head taped to the backboard. To avoid distracting an unstable spine and further injuring the spinal cord, cervical traction should never be applied during transportation.

Venous access should be established with two large lines. Next, a Foley catheter is placed in the bladder and a nasogastric tube is carefully inserted, taking great care not to move the neck from the neutral position. Hypovolemic shock is a frequent occurrence and is treated with volume replacement. Neurogenic shock is initially treated with volume replacement; if bradycardia and hypotension persist, vasopressors should be given. It is important to remember that in patients with neurogenic shock, further vagal stimulation, caused by endotracheal intubation or suctioning, may produce cardiac arrest. Overhydration in patients with neurogenic shock can precipitate pulmonary edema. Continued monitoring and resuscitation occur during transport to the emergency department.

Patients with SCI may be equally safely transported by ground or air. The distance and the extent of associated injuries should dictate the means of transport. Using standard methods of stabilization, it is exceptionally rare for an ascending level of injury to result from the transfer (13).

Emergency Department Treatment

While pulmonary and cardiovascular management and spinal immobilization continue, more sophisticated monitoring equipment is applied. A rapid but detailed history is obtained from the patient (if possible), the emergency medical technicians, and any eyewitnesses to the accident who may provide information about the type or direction of forces involved. Thorough general physical, neurologic, and musculoskeletal examinations are performed and recorded. Venus blood and arterial oxygen samples are obtained, and a urinalysis is collected. At this time, prevention of hypoxia and hypotension may be critical in preserving spinal cord function. When an SCI is confirmed, the steroid protocol discussed later in this chapter should be immediately initiated (11). Although acute life-threatening injuries have priority over spinal cord trauma, it is ideal to manage all problems simultaneously.

Meaningful data on specific associated injuries in other systems in children are few, but such injuries have been reported in up to 31% of spine trauma cases and are more common in older children (24,58,77). A study of associated injuries in 508 consecutive spinal injury admissions, mostly adults, showed that 47% of patients had such injuries, the most common being head, chest, and long bone trauma. Single associated injuries occurred in 22%; 15% had two associated injuries; and 10% had three or more. These injuries were more common with thoracic and lumbar fractures, and patients with associated injuries were surprisingly less likely to have a neural deficit (73).

Neuromusculoskeletal examination begins with observation of voluntary or spontaneous extremity motion, particularly in unconscious or intoxicated patients. With the spine immobilized, the patient should be rolled to one side and the entire spine inspected for deformity and obvious traumatic lesions. The spinous processes are palpated to detect any tenderness, widening, or step-off between them.

TABLE 1. Grading System for Voluntary Muscle Strength

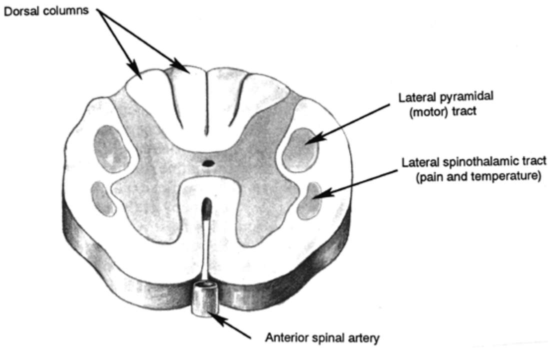
Grade	Description
0	Complete paralysis
1	The least detectable voluntary contraction; only a flicker
2	More than a flicker but less than antigravity strength
3	Able to maintain position against gravity
4	Stronger than antigravity, but less than full strength[a]
5	Full strength

[a] Grade 4 is a wide range and may be separated into 4^- and 4^+.

A conscious patient can relate the location of any pain and voluntarily cooperate with motor and sensory examinations. Motor evaluation should assess all major extremity muscle groups using the universal grading system of grades 0 to 5 (Table 1). Keep in mind that children are not as strong as adults.

Sensory evaluation should include both dorsal and lateral column assessments. The lateral columns, which carry pain and temperature perception, are of greater prognostic value regarding the return of motor function than are the dorsal columns, which carry touch, vibration, and position sense (32) (Fig. 1). The sensory examination should test dermatomal patterns (Fig. 2), and the findings should be recorded on a time-oriented flow sheet.

Rectal examination is part of the neurologic evaluation of all SCI patients. Voluntary motor sparing, as indicated by sphincter contraction and perianal sensation to pinprick, indicates an incomplete lesion with implications for treatment and prognosis.



Dorsal columns
Lateral pyramidal (motor) tract
Lateral spinothalamic tract (pain and temperature)
Anterior spinal artery

FIGURE 1. This cross-section of the spinal cord shows the major descending and ascending motor and sensory tracts.

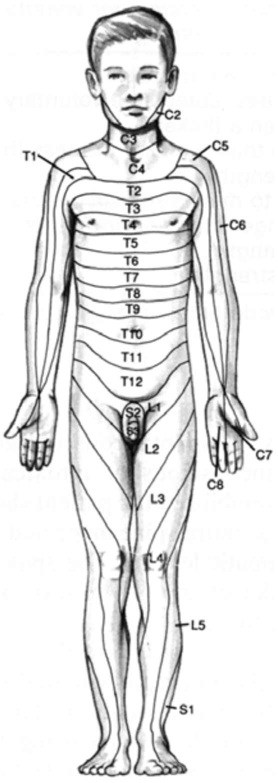


FIGURE 2. A chart of the sensory dermatome segments is invaluable for recording sensory function. This should be done during the initial evaluation and then periodically, as indicated, throughout the treatment process.

It is important to differentiate voluntary motor function from reflex withdrawal. Evaluation of stretch reflexes is important but is less reliable than motor and sensory examinations. Spinal shock may obliterate all reflexes for up to 24 hours or more. The absence of stretch reflexes in an unconscious patient suggests either spinal shock or a lower motor neuron injury; exaggerated stretch reflexes imply an intracranial or other upper motor neuron lesion.

Other reflexes are important as indicators of the status of spinal shock. Continued paralysis in the presence of intact caudal reflex arcs implies a poor prognosis. The bulbocavernosus reflex produces contraction of the anal sphincter and reflects the integrity of the third and fourth sacral roots. It is dependent on a horizontal sensory-motor reflex arc and is, therefore, independent of a cord lesion at a higher level. A similar contraction of the anal sphincter, the anal wink, is elicited by stroking the skin of the perianal area. This reflex tests roots S2 through S4. The cremasteric reflex is elicited by stroking the proximal medial thigh with an instrument and eliciting elevation of the scrotal sac by cremasteric muscle contraction. This tests roots T12 and L1.

Radiographic Evaluation

Plain radiographs most often provide the definitive diagnostic information regarding injuries to the vertebral column. It is essential to obtain anteroposterior and lateral images of the entire spine. This helps detect spinal injuries at multiple levels. If the lower cervical vertebrae are not seen on standard views, a swimmer's view or plain tomogram or a computed tomography (CT) scan may be obtained.

To interpret cervical radiographs correctly in children, knowledge of the normal cervical anatomy, ossification process, and normal variants is essential. The following are some important considerations:

Anterior soft tissue spaces: Increase in the prevertebral space between the anterior vertebral body of C3 and the laryngeal air column may not be a useful marker in children. Although the distance is increased with bleeding, infection, or edema, the normal space varies with neck flexion, extension, and respiration, and baseline values are lacking (49). On the other hand, the normal amount of retropharyngeal soft tissue space between the air column and the anterior body of C2 has been reported as great as 7 mm in children. The retrotracheal space anterior to the body of C6 is normally as wide as 14 mm (9).

Atlas-odontoid interval: An interval of more than 5 mm on a lateral flexion radiograph indicates instability. In extension, 20% of normal children have riding up of the anterior arch of the atlas to the top of the odontoid (15).

Space available for the cord: The space from the posterior odontoid cortex to the anterior cortex of posterior arch of C1 should be greater than 13 mm in older children. In young children, it should be equal to or greater than the width of the odontoid.

Facet joints: The planes of the facet surfaces change with growth, becoming more vertical. Upper facets (C2 to C4) change from 30 to 70 degrees and lower facets from 55 to 70 degrees (63).

C2 to C3 and C3 to C4 displacement: Until middle childhood, substantial anterior displacement of C2 on C3 and C3 on C4 can normally occur in flexion. The Swischuk line is helpful in delineating pathologic displacement (82). The C3 and C4 vertebral bodies are commonly wedged anteriorly in childhood, and their facets are more horizontal, contributing to the hypermobility.

Sagittal cervical contours: Angulation at a single interspace, absence of normal cervical lordosis, and absence of cervical kyphosis from C2 to C7 on maximal flexion can be normal in 14% to 16% of children (15). Widening of more than 10 mm between the spinous processes of C1 to C2 on a neutral lateral radiograph should alert the physician to the potential for cervical SCI (2).

Ossification variants: Spina bifida occulta can occur throughout the cervical spine, especially in the lower levels. It is also seen at C1, where multiple ossification centers may be present and are differentiated from fractures by their smooth cortical margins (49). The dens has its major ossification centers joined by the dentocentral synchondrosis and has another small center at the apical epiphysis of the odontoid. Fusion of these centers can occur at any time over a span from at least 3 to 11 years. The spinous processes of a vertebra may have secondary ossification centers that can be confused with fractures and are differentiated by lack of focal tenderness (49).

When assessing the spine by radiograph, it is important to remember that substantial soft tissue injury with resultant instability can be masked by spontaneous reduction, protective myospasm, or immobilization devices. Subtle signs, such as reversal of normal cervical, thoracic, or lumbar sagittal curves and evidence of soft tissue swelling, may indicate significant ligamentous disruption. If cervical spine instability is strongly suspected but is not seen on routine still radiographic views, careful, gentle, slow active flexion and extension lateral radiographs or fluoroscopy of the neck may reveal an unstable lesion. This must only be done with the patient awake, alert, and cooperative and must be stopped immediately if any symptoms of spinal cord impingement occur. Anteroposterior and lateral radiographs are usually adequate for the thoracic and lumbar spine.

Cervical immobilization must be carefully monitored at all times when the patient is in the radiology department. A soft collar does not provide adequate immobilization; the cervical spine should be immobilized using a rigid collar or a four-poster or other cervicothoracic orthosis or by taping the forehead to bilateral sandbags and a spine board. Most physicians believe that the spine board provides adequate immobilization for the thoracic, thoracolumbar, and lumbar spine.

Other imaging techniques can be invaluable when plain radiographs do not clearly define a spinal injury. Plain tomography allows visualization of the cervicothoracic junction, the occiput, C1, and C2, including the odontoid, unilateral cervical facet dislocations, and subtle fractures elsewhere in the spine. A CT scan is valuable for identifying these injuries as well as lesions of the facets and posterior elements, defining burst fractures of vertebral bodies, and assessing the spinal canal. Reconstructed CT scans in the coronal, sagittal, or oblique planes can also be helpful.

Magnetic resonance imaging (MRI) is the technique of choice for imaging soft tissues, particularly the spinal cord. Accurate assessment of spinal cord parenchymal lesions improves the accuracy of prognostication. An MRI study can also demonstrate extrinsic cord compression from bony fragments, vertebral canal malalignment, and disc extrusion. Studies have shown that early MRI findings correlate well with outcome in SCI (49). Spinal cord transection is presently irreversible, and cord hemorrhage is nearly so; however, patients with edema have potential for recovery of neurologic function. Contusion is often associated with an incomplete lesion, whereas compression patterns are likely to be associated with either complete paralysis or an incomplete lesion with little likelihood of improvement (68). When MRI is not available or cannot be done, myelography with water-soluble contrast material may be helpful in assessing extrinsic cord compression, particularly in patients with incomplete lesions.

Evoked Potentials

Another prognostic technique that is sometimes useful in SCI is the early assessment of evoked motor and sensory potentials. Good correlations have been noted between the severity of the cord injury and sensory evoked potential grading. For motor potentials, the assessment of intercostal responses to cervical and cortical stimulation is a good prognostic indicator. In incomplete lesions, both types of potentials can be found in areas that are clinically deficient. Patients with complete lesions and absent sensory and motor responses have a poor outcome (17).

Mitigating Spinal Cord Damage

Directly after an acute mechanical SCI, secondary chemical changes take place in the cord. Oxidative enzymes produce further necrosis, and neurotoxicity results from excitatory amino acids and free radicals (8). There is much research emphasis on attempts to reverse or prevent this chemical neurologic damage, and some positive beneficial interventions have been established.

A multicenter study showed that for patients with acute SCI, treatment with methylprednisolone in the early hours after injury improves neurologic recovery. The dose given is 30 mg/kg in a 15-minute bolus infusion, followed by a 45-minute pause, and then a maintenance infusion of 5.4 mg/kg per hour for either 24 or 48 hours (11). Patients who receive methylprednisolone within 3 hours of injury should be maintained on the treatment regimen for 24 hours. When methylprednisolone is initiated 3 to 8 hours after injury, patients should be maintained on the regimen for 48 hours (11). The steroid regimen is based on studies of patients aged 14 years and older, but until a pediatric age group can be studied, it seems prudent to extrapolate the beneficial results to children (54).

Another study showed an increase in neurologic return by giving the ganglioside GM-1 within 72 hours of injury (30). The use of methylprednisolone, however, may negate the effects of ganglioside (18). Hyperbaric oxygen has been shown to accelerate peroxide formation and the generation of free radicals. This should increase the secondary injury and, therefore, is not indicated in SCI (8). Ongoing research is evaluating hypothermia for reducing the production of excitatory amino acids and the activity of degradative enzymes (55).

Treatment Plan

If the initial radiographs suggest a cervical spine injury, a halo or tongs may be elected for stabilization. In children, these are applied under general anesthesia. A child's skull is smaller, thinner, and more elastic than an adult skull, and halo application is different. Skull thickness can vary substantially, even up to 10 years of age; therefore, a CT scan of the skull is wise before halo application (91). In young children, six or eight pins may be necessary, each tightened to 2 to 4 inches per pound of torque. In infants, 10 pins tightened to 2 inches per pound are appropriate (61). Later retightening of pins is not recommended in children, although this point is controversial (6). Proper cervical spine alignment in children is with the external auditory meatus centered over the midsagittal shoulder. This position should be confirmed radiographically. The child with a halo should be followed frequently, with special attention to pin loosening, infection, or increased pin penetration as well as to skin breakdown beneath the vest or cast. If the halo is not tolerated, use of a Minerva cast or Minerva cervicothoracolumbosacral orthosis (CTLSO) is the best alternative.

After emergency department evaluation is complete, the patient is transferred either to the operating room, the intensive care unit, or the ward. The absolute indications for emergency surgery in spinal injuries are documented deterioration of an incomplete neurologic lesion, open fractures or penetrating wounds of the spine, and life-threatening injuries to other systems. As a rule, those injuries with spinal column instability of a pure ligamentous nature that cannot be reduced or in which the reduction cannot be maintained, those with an overtly unstable fracture pattern, those with unreducible kyphosis, and those with associated neurologic or intraabdominal injury should undergo operative reduction and internal fixation with fusion (34). In patients with complete or incomplete but stable cord lesions, the spine must be initially immobilized and may be electively stabilized by surgical means within 7 to 10 days or, if appropriate, treated with orthoses or by other closed means. Regardless of the type of initial treatment, patients with SCI should have repeated neurologic evaluations performed and recorded on a flow sheet at appropriate intervals dependent on their neurologic status.

Long-term follow-up studies of acutely performed surgical fusion in children with SCI are few, but at least one has indicated that for cervical fractures and dislocations, lasting stability is established, the fusion mass remains intact, and deformity does not recur (57). Overall neck mobility does decrease, however, and significant osteoarthritic changes occur in the adjacent unfused segments as follow-up time increases. Spontaneous extension of the fusion mass was seen in 38% of cases (46).

Problems and Complications

After the acute phase of treatment, patients who have complete or severe incomplete spinal cord lesions may develop multiple problems related to the paralysis. Spinal deformity (discussed later in this chapter) and hip subluxation or dislocation are the most common orthopaedic problems in younger patients (23,70,94). Children with prolonged spasticity are at particular risk for progressive acetabular dysplasia, hip subluxation, or dislocation, either unilateral or bilateral (Fig. 3). The cause of the hip instability may be pelvic obliquity, asymmetric spasticity, flexion-adduction contracture, or flaccidity with a paralytic pattern. Despite this, it is rare for patients to have functional problems related to the hip abnormality. Soft tissue releases may be needed for spastic contractures with hip dysplasia to improve sitting or hygiene. Bony surgery or operative reductions are rarely necessary, even with subluxation or dislocation (70). Lower extremity osteopenia (44,71), low-energy fractures (27,86), hypercalcemia, joint contractures, and heterotopic bone formation, usually at the hip (29), can also occur.

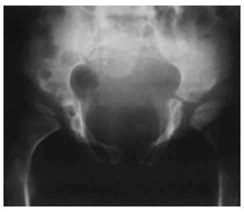

FIGURE 3. Anteroposterior radiograph of the pelvis of a child with long-standing thoracic paraplegia. There is severe bilateral acetabular dysplasia and hip subluxation.

Spasticity and pain have been reported by more than 25% of SCI survivors (43). In adolescents and adults, the continuous intrathecal infusion of baclofen has been effective in reducing spasticity and mitigating pain caused by cramps. Accommodation to the drug often occurs, so that increasingly larger doses may be necessary to maintain the clinical effect (7). The use of baclofen in children younger than 12 years of age has not been thoroughly studied. As an alternative, a shorter-term treatment of spasticity and pain by intramuscular injections of botulinum toxin, type A may be beneficial (1). Spasticity can be treated by surgical means, such as tendon lengthening, tenotomy, or rhizotomy. The use of implanted spinal cord stimulators has not been shown to be effective (8).

Chronic pain is a common, potentially devastating problem; it may be classified as central or neurogenic, musculoskeletal, or syringomyelic pain. Its quality and location suggest confirmatory studies that may reveal correctable causes (28).

Another important consideration is the development of a latex allergy, the likelihood of which increases with the time from injury. Latex allergy has been reported in 18% of children with SCI (90). Because of this, all children with SCI should be provided with a latex-free environment (8).

Common nonorthopaedic problems are discussed in Chapter 33 and have been well-reviewed (25,69,89). It is wise to reevaluate SCI patients periodically, looking for multisystem problems as well as the development of spinal deformity and hip problems.

Spinal Cord Injury Syndromes

SCI may produce complete neurologic loss or any of a wide variety of incomplete or transient patterns of neurologic deficit. Although “classic” patterns of incomplete injury are described here, it is unusual to see pure patterns. The most widely used classification of functional neurologic deficit is that of Frankel and colleagues (26) (Table 2).

Complete Lesions

Complete lesions show immediate and total loss of motor and sensory function caudal to the injury and, during spinal shock, absence of segmental reflex responses caudal to the lesion. With initially complete lesions, some functional motor recovery is seen in only 3% of patients during the first 24 hours and, thereafter, drops to virtually zero (3). Complete cervical injuries produce predictable motor involvement patterns in the upper extremities (Table 3).

After the resolution of spinal shock, which occurs within 24 hours in 99% of patients (35), caudal spinal cord reflexes return. Lack of neurologic function below the level of the injury after the return of such reflexes identifies a complete lesion. Nerve roots immediately proximal to the level of the SCI may be contused and initially appear nonfunctional. Recovery over a period of several months may occur, a phenomenon known as *root escape*.

If spinal cord and root impingement is demonstrated, late surgical decompression, even up to 24 months after injury, has been shown to afford some benefit in terms of root recovery in selected cases (10,84). Because the spinal cord ends at L1 to L2, lesions caudal to this level damage the cauda equina instead of the cord. Delayed recovery of these lower motor neuron lesions is more likely than when the conus medullaris or the spinal cord is injured.

TABLE 2. Frankel Classification of Functional Neurologic Deficit

Grade	Description
A	Absent motor and sensory function
B	Sensation present, motor absent
C	Sensation present, motor active but not useful
D	Sensation present, motor active and useful
E	Normal motor and sensory function

Incomplete Lesions

Incomplete lesions have a better prognosis than complete lesions, and greater functional motor return is often seen. These lesions are defined by patterns of partial neurologic loss. As a general rule, the more distal the lesion and the greater the function distal to the lesion, the more rapid the recovery and the better the prognosis (51). The following are the most common incomplete spinal cord lesions.

Brown-Séquard Syndrome

A Brown-Séquard syndrome results from a unilateral SCI and is characterized by unilateral weakness or paralysis and bilateral, but dissociated, sensory loss. The clinical picture, therefore, is ipsilateral motor loss, ipsilateral loss of posterior column position and vibratory sensation, often vasomotor changes, and contralateral loss of pain and temperature sensation (Fig. 4). Because light touch and pressure are conducted bilaterally, they are spared. The syndrome is most commonly seen in the cervical spinal cord and is usually not a pure lesion. Most patients demonstrate partial to complete recovery and maintain ambulatory ability and normal or near-normal bowel and bladder function (16,74,78).

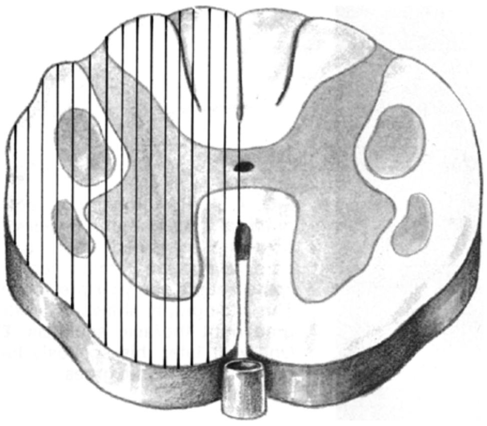

FIGURE 4. Brown-Séquard syndrome involving one side of the spinal cord. With this lesion, ipsilateral motor and position senses are compromised, as are contralateral pain and temperature perceptions.

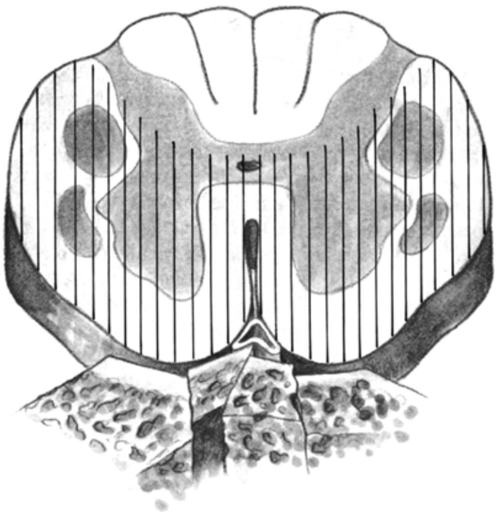

FIGURE 5. Anterior cord syndrome. This lesion is characterized by motor loss and interference with pain and temperature perception. Posterior column function is preserved.

Anterior Cord Syndrome

Anterior spinal cord damage is usually caused by cervical flexion injuries. It may also occur from vertebral body fracture or the acute posterior herniation of a disc (Fig. 5). The anterior part of the spinal cord (supplied by the anterior spinal artery) is involved, including motor neurons and the corticospinal and spinothalamic tracts. The patient shows caudal motor loss, usually with flaccid paralysis or weakness; atrophy; areflexia; and interference with pain and temperature sensation. Other sensations usually remain intact. Unless recovery begins within 24 hours of injury, this syndrome has a poor prognosis (74) (Fig. 6). Only about 10% of patients show functional motor recovery (79,81).

Central Cord Syndrome

Central cord syndrome is the most common incomplete neurologic injury (78). It almost always occurs in the cervical region and is seen after hyperextension injuries, although it may occur with any injury pattern (Fig. 7). Chiari I malformations, syringomyelia, and central spinal cord parenchymal tumors may be associated with this syndrome (80). The clinical presentation is substantial weakness of the arms with lesser paresis in the lower extremities, although almost complete quadriplegia can occur (78). Sacral sparing is the rule. This occurs because in the motor tracts, the sacral and lower-extremity fibers are most peripheral and cervical fibers most central. Because of edema and irregular parenchymal vascular damage, pure symmetric central lesions are unusual. Incomplete lesions with variable sensory loss have a reasonably good prognosis, with about 50% to 75% of patients showing functional motor recovery. Recovery begins with improvement of function in the lumbar-innervated structures. The likelihood of return of upper extremity function is remote, however (74,81).

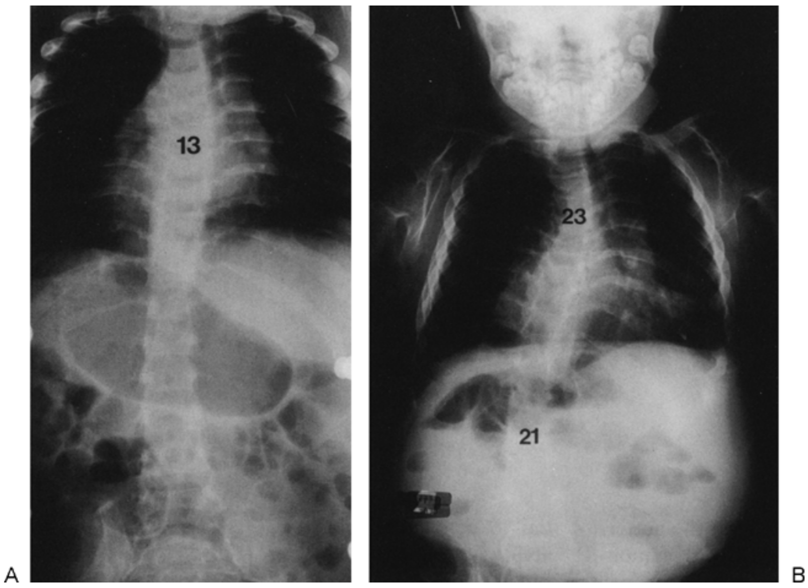

FIGURE 6. A: Posteroanterior radiograph of the spine of a 6-year-old boy who sustained an anterior cord syndrome from cervical spine trauma 1 year previously. The radiograph shows a 13-degree right thoracic scoliosis. **B:** One year later, his scoliosis has progressed to 23 degrees.

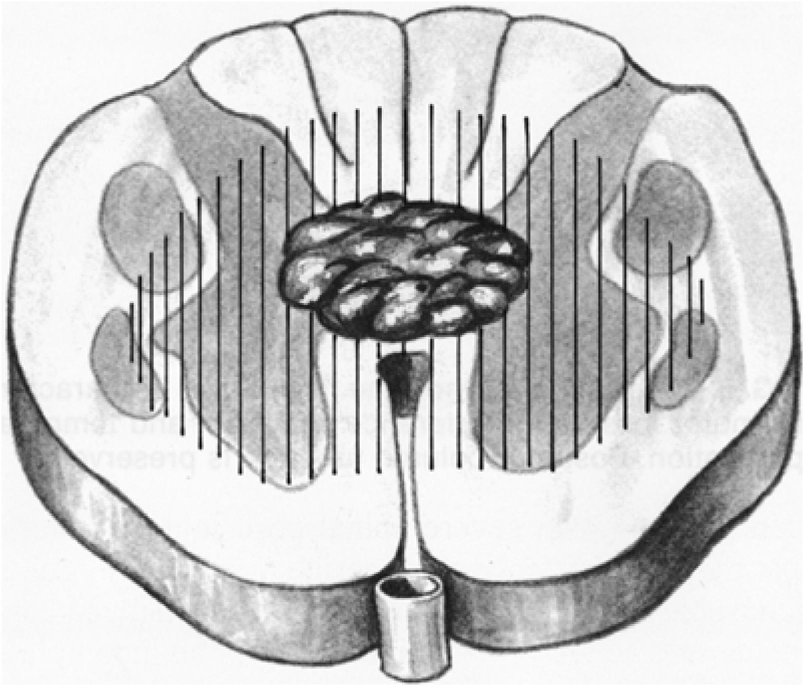

FIGURE 7. Central cord syndrome. This lesion produces bilateral involvement, with greater weakness of the upper extremities than the lower extremities.

Posterior Cord Syndrome

Posterior cord syndrome is a rare lesion, usually the result of a hyperextension cervical injury. Posterior column function is compromised, which results in loss of proprioception, deep pain, and deep pressure sensation (Fig. 8). Recovery is likely in most cases (33).

Cervical Cord Neurapraxia

Cervical cord neurapraxia is a transient phenomenon, characterized by paresthesias such as numbness, tingling, or burning in any distribution pattern, including quadrimelic. It is seen mostly during athletic activities such as football and wrestling and can last from seconds to several minutes. Congenital or degenerative narrowing of the sagittal diameter of the cervical spinal canal is the major contributing causative factor. Neurapraxia is then produced by excessive flexion, extension, compression or other combined motions. In a study of 110 cases, there were no instances of permanent neurologic injury, even with a recurrence rate of 56% in those who returned to contact sports. The smaller the canal, however, the greater the likelihood of recurrence (83).

Root Syndromes

Spinal nerve root injuries may occur as isolated phenomena but are more commonly associated with SCIs in the region. Unless the root is transected, partial or complete recovery is possible. Most lower cervical SCIs show recovery of at least one root level, and midcervical lesions have about a 60% chance of some root recovery. The prognosis is not as good with high cervical lesions (80).

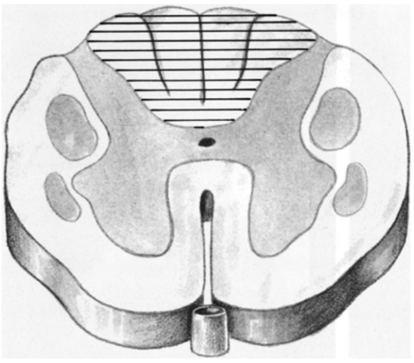

FIGURE 8. Posterior cord syndrome. Pain and temperature sensation and motor function are preserved in this lesion.

Conus Medullaris Injuries

The conus medullaris is the caudal end of the spinal cord, and an injury to this area usually is a sacral cord injury. This may produce an areflexic bladder and bowel. Lumbar roots may be injured at the same time, resulting in lower motor deficits in the lower extremities.

Cauda Equina Lesions

Cauda equina lesions interfere with function in lumbar and sacral innervated regions and may be overlooked if anal sphincter tone, perineal sensation, and distal lower-extremity motor function are not clinically assessed. The cauda equina is composed of peripheral nerves; thus, an injury produces a lower motor neuron type of flaccid paralysis. The lesion is usually patchy and may produce areflexia in the bowel and bladder and limb weakness or paralysis. Some roots can escape injury, resulting in asymmetric neurologic deficit in the lower extremities. Because the cauda equina consists of peripheral nerves, recovery is possible unless complete disruption has occurred.

Sacral Sparing

In patients with severe SCIs, sacral sparing with retention of perineal sensation, voluntary anal sphincter tone, and often flexor hallucis longus muscle activity is an indication of an incomplete lesion. This indicates that the peripheral white matter of the spinal cord remains intact and that further functional recovery may occur. Sacral sparing may be the only early indication of an incomplete lesion (6).

Spinal Cord Injury Without Radiographic Abnormality

In children younger than 10 years of age, the spine is considered biomechanically immature (4,40). The elasticity of the spinal column exceeds that of the spinal cord, and severe injury can overstretch the cord or impinge it on bony elements and produce substantial cord injury. Instantaneous reduction then occurs, preventing a radiographically recognizable lesion, referred to as SCIWORA (65,66). Flexion and extension are the most common causative mechanisms, not only in cases of single major trauma, but also with repetitive microtrauma, as seen in the shaken baby syndrome.

SCIWORA most often involves the cervical spinal cord, with the peak age at injury ranging from 3 to 6 years (64,66,73,93). Such injuries reportedly constitute 21% to 35% of SCIs in children. The likelihood of a complete neurologic lesion is about 40%, and children younger than 8 years of age are at greatest risk for severe neurologic injury (64,65,72). The younger the child, the more cephalad the level of injury. Thoracic, thoracolumbar, and lumbar SCIWORA can occur, usually in older children subjected to high-energy trauma. In these cases, there is a high incidence of associated trunk injuries.

It is important to realize that the onset of neurologic deficit or the increased deterioration of neurologic status can be delayed for up to several days (65,66). A history of transient neurologic symptoms or the presence of neck or other spine pain should raise one's awareness of this possibility.

The diagnosis is confirmed either by carefully supervised dynamic flexion and extension radiographs in a fully awake, alert, cooperative child or by MRI studies. The MRI findings, both neural and extraneural, are well reviewed by Pang (65). In some cases, evoked sensory and motor potentials can detect a lesion in an unconscious patient.

Treatment of the injury consists of immediate institution of the high-dose steroid protocol (11) and immobilization of the involved spinal region. Cervical immobilization is by means of an appropriate orthosis or a halo vest until adequate healing has occurred, as documented by stability on flexion and extension lateral radiographs. This requires a minimum of 3 months of immobilization. Recurrent SCIWORA has been reported in cases in which adequate healing did not occur (65). The indications for surgery to stabilize an unstable vertebral lesion in SCIWORA are the inability of an orthosis to maintain a stable reduction, and late instability after an adequate period of immobilization.

Posttraumatic Spinal Deformity

Spinal deformity in a paralyzed child may result from the following:

- Chronic instability with progressive deformity at the site of the vertebral trauma
- Muscle weakness with paralytic collapse of the column into scoliosis, kyphosis, or lordosis involving much larger segments of the spine
- Injury to the vertebral growth plates producing asymmetric growth arrest (41)
- Postlaminectomy deformity, especially after multilevel laminectomies at or above the thoracolumbar junction (5,92) (Fig. 9)
- Exacerbation of a preexisting idiopathic spinal deformity (Fig. 10)

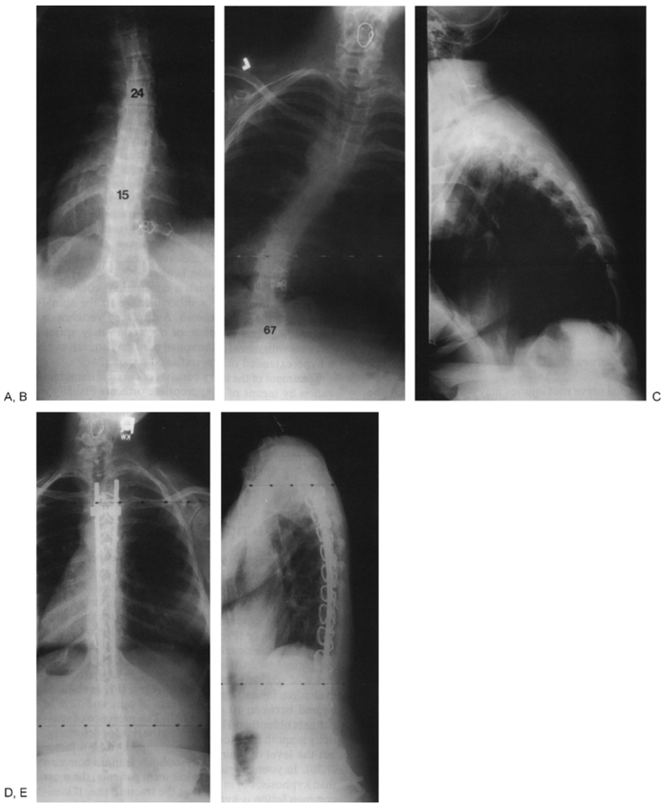

FIGURE 9. Exacerbation of preexisting idiopathic scoliosis in a skeletally mature adolescent after a complete traumatic cervical spinal cord lesion. **A:** Preinjury posteroanterior radiograph obtained at the time of discharge from the idiopathic scoliosis follow-up clinic. The patient is a 15-year-old girl with double thoracic scoliosis measuring 24 degrees and 15 degrees. **B:** Two years after injury, the left curve has progressed to 67 degrees. **C:** Lateral radiograph showing paralytic kyphosis. **D:** Postoperative radiograph showing stabilization of the scoliosis with a segmental fixation system from T4 to the pelvis. **E:** Lateral view showing restoration of the normal sagittal spinal contours.

The most significant factor influencing the development of scoliosis is the age of the patient when the paralysis occurs (69). The incidence of scoliosis has been reported to be up to 100% in children injured before 10 years of age, 19% in children injured between 10 and 16 years of age, and 12% in patients older than 17 years (48). Another study reports scoliosis developing in 97% of children with SCIs incurred before the adolescent growth spurt and in 52% of those injured after the growth spurt (19). The presence of spasticity is another factor increasing the risk for deformity, but the level of injury does not appear to be a factor (19,48). In younger patients, scoliosis is more common than kyphosis, but in postadolescent patients, the most common lesion is kyphosis at the fracture site. When laminectomy has been performed at or above the thoracolumbar junction, the risk for kyphosis is substantially increased (5,56) (Fig. 11). Older children with preexisting but static idiopathic scoliosis or kyphosis may experience significant curve progression when paralysis is superimposed (69).

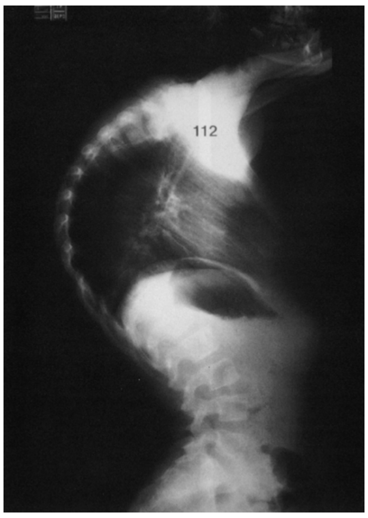

FIGURE 10. Lateral radiograph of the spine of a 7-year-old girl obtained 3 months after complete bilateral laminectomy from T3 to T9. Before surgery, her sagittal plane contour was normal.

TABLE 4. Etiologic Factors in Paralytic Spinal Deformity

Acquired neurologic lesions
Trunk muscle paralysis
Asymmetric fractures
Gravity
Osteopenia
Pelvic obliquity
↓
Loss of trunk muscle support
Loss of spinal column end support
Increased spinal flexibility
Increased spinal length with growth
Asymmetric growth
↓
Paralytic spinal deformity

The pathogenesis of paralytic spinal deformity in children is probably multifactorial (Table 4). Spasticity, particularly asymmetric spasticity, is likely a major factor. Deformity may relate to lack of spinal support because of muscle weakness or paralysis, the effect of gravity, asymmetric trunk muscle imbalance, fascial contractures, osteoporosis with loss of vertebral strength, and asymmetric growth based on the Heuter-Volkmann principle. Pelvic obliquity, pelvic rotation contractures, and hip flexion and adduction contractures may also predispose to the development of scoliosis. Conversely, progressive scoliosis may lead to suprapelvic obliquity and continue a vicious circle. Other etiologic factors include progressive neurologic lesions, such as syringomyelia and cord necrosis (35), and asymmetric fractures of vertebrae with imperfect reduction or malunion (52). Investigation of the cause of scoliosis in SCI continues, with emphasis on basic neurophysiology and neuropharmacology. A recent study suggested that in spinal cord injured experimental animals, clenbuterol, a B^{2}-adrenoceptor agonist, can retard loss of muscle contractility and bone mineralization caused by denervation and reduce the magnitude of resultant scoliosis (95).

Early Treatment

Children with paralysis caused by SCI should be assumed to be developing spinal deformities until proved otherwise. Periodic clinical and, if indicated, radiographic assessment is therefore advisable throughout childhood (Fig. 11). Prevention of deformity may not be possible; in fact, half or more of spinal cord injured preadolescent children require later spinal fusion surgery

(23,56). Nevertheless, perfect reduction of the initial vertebral injury is wise. Prevention of major lower extremity joint contractures and measures to reduce spasticity may also be helpful.

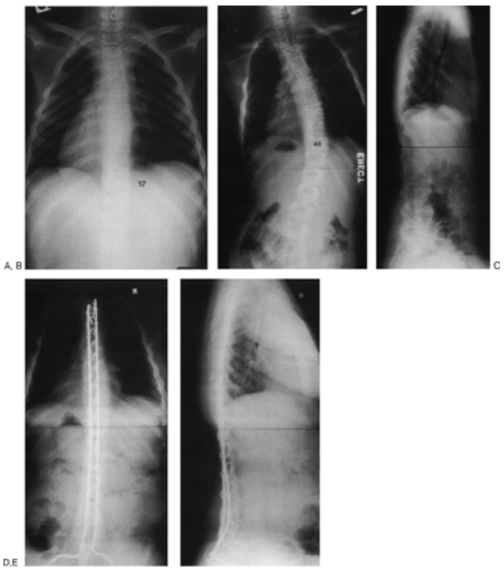

FIGURE 11. Progression of paralytic spinal deformity in a boy who sustained a traumatic cervical cord lesion at 12 years of age. **A:** Two years later, he had developed a 17-degree right thoracic scoliosis. **B:** Four years after injury, the curve had progressed to 48 degrees, and surgery was performed. **C:** Lateral radiograph of the spine showing a mild low thoracic kyphosis. **D:** Postoperative radiograph after posterior spinal fusion from the upper thoracic spine to the pelvis. **E:** Lateral radiograph after spinal fusion.

Although orthotic treatment of early spinal deformity is rarely successful in halting curve progression (19), it may help in slowing curve progression to “buy time” while further useful growth of the spine occurs. In this situation, treatment is usually initiated when the curve reaches 20 to 30 degrees, but there are no objective data to support this intervention. Most surgeons agree that by 10 years of age, the spinal growth is sufficient to proceed with the definitive spinal fusion surgery (50). A thoracolumbosacral orthosis (TLSO) can improve sitting balance and allow freer use of the arms and hands (14). If orthotic treatment is undertaken, attention to detail is necessary to prevent skin breakdown and thermoregulation problems. The orthosis should be easily removable, well padded, and perfectly fitted. Although Milwaukee brace treatment may be successful, most physicians prefer a total-contract TLSO. Children who are obese or who have rigid curves usually do not benefit from an orthosis but rather are uncomfortable and risk pressure ulcers of their skin.

Surgical Treatment

When paralytic scoliosis exceeds 45 to 50 degrees in a child older than about 10 years of age, surgical treatment is indicated. The treatment of choice is a long posterior spinal fusion with a segmental fixation system incorporating rigid rods that are cross-linked together and attached to the spine by sublaminar wires, multiple hooks, or vertebral body or sacral screws. Instrumentation from T2 to the pelvis is often appropriate (Fig. 12), but taking away the flexibility of the paralytic spine may hamper function in activities of daily living and transfers. Preserving motion by not fusing the entire lumbar spine is theoretically desirable but may only lead to increased pelvic obliquity with its attendant problems and is probably best reserved for those few patients with incomplete lesions who are able to walk. A particular challenge is the child, younger than 9 or 10 years of age, with a large and progressing curve not controllable by a TLSO. In this case, a short segment fusion may be preferred, with the knowledge that adding on will occur and extension of the fusion will be necessary years later when further beneficial spine growth has occurred.

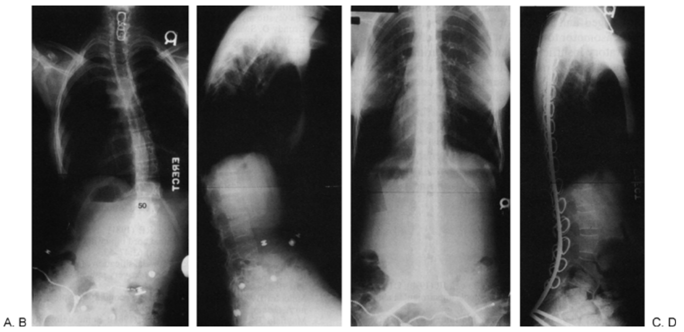

FIGURE 12. Surgical treatment of paralytic scoliosis after a cervical fracture-dislocation. **A:** Fifty-degree right thoracolumbar curve 2 years after a complete traumatic spinal cord lesion in the lower cervical region. **B:** Lateral radiograph showing paralytic kyphosis. **C:** Postoperative radiograph showing stabilization of the scoliosis. **D:** Lateral radiograph showing normal sagittal spinal contour.

Anterior surgery is indicated for correctability in rigid curves that are larger than about 60 degrees on a correction film, such as with bending or traction; in spines with deficient posterior elements, for example, after extensive laminectomy; and to prevent the crankshaft phenomenon in children younger than 10 years of age. Whether it also has a role in preserving lumbar segments is yet to be determined. Anterior fusion may also be required in treating pseudoarthroses and in cases in which previous spine surgery, often at the time of the injury, has been performed and subsequent deformity has developed.

Surgery may be indicated for a rigid paralytic kyphosis of greater than 70 or 80 degrees or for shorter angular kyphoses of lesser magnitudes, but this is a case-by-case consideration. In kyphosis, an anterior fusion is usually necessary in addition to a posterior procedure.

TABLE 5. Preoperative Considerations in Paralytic Spinal Deformity

- General condition
- Ambulatory status
- Pulmonary status
- Cardiac status
- Renal function
- Liver function
- Nutritional status
- Serum electrolytes
- Coagulation studies
- Pelvic obliquity
- Spinal flexibility
- Posterior versus circumferential fusion
- Extent of fusion
- Implants
- Postoperative management

The objectives of surgery are to halt progression of deformity, obtain correction, and balance the spine over a level pelvis in order to distribute the sitting skin pressure equally and to prevent or at least minimize the occurrence of pressure ulcers (21). Grafting allograft bone or bone-extender substances to augment the local autogenous bone is necessary to maximize the development of an adequate fusion mass. Preoperative considerations are numerous before such surgery (69) (Table 5).

Patients with SCI and spinal deformity are often nutritionally and metabolically disadvantaged and have poor muscle tone, osteopenia, poor vasomotor tone (so that bleeding is often profuse), respiratory insufficiency, and chronic urinary tract infections. Postoperative complications are more common in this population than in patients with most other neuromuscular disorders or in idiopathic scoliosis patients and include an increased risk for infection, pseudarthrosis formation, and delayed wound healing (12,56,69). Postoperatively, unless profound osteopenia has been encountered and the integrity of the internal fixation is questionable, external orthotic support is usually not necessary. Postoperative mobilization and rehabilitation should be rapid and vigorous.

Spinal Cord Injury Rehabilitation

Randal R. Betz

M. J. Mulcahey

R.R. Betz and M.J. Mulcahey: Shriners Hospitals for Children, Philadelphia, Pennsylvania 19140.

From an orthopaedic standpoint, the comprehensive care of a child with a spinal cord injury (SCI) is an ongoing process beginning at the time of injury and lasting not only through the rehabilitation and discharge phases but for the remainder of the patient's life. A common misconception held by many orthopaedists and neurosurgeons is that their role is an active one during only the acute phase, and then the child's care is turned over to rehabilitation specialists. But treatment and prevention of soft tissue contractures, pressure ulcers, spine deformity, hip dislocation, upper extremity pain, spinal cord tethering, syrinx formation, and so forth, as well as upper extremity reconstruction, must start immediately after injury and continue indefinitely, and the orthopaedist must continue to be a key member of the patient care team long after the acute phase has passed.

The concept of early rehabilitation has led to the development of hospitals and hospital units that specialize in treating patients with SCI. As a result of a patient's early transfer to one of these specialty units (preferably the day of the injury), the number of complications and days spent in the hospital are greatly reduced (46).

Discharge planning should begin immediately on a patient's admission to a hospital and must consist of more than a tentative plan for rehabilitation. Discharge planning must address both the human environment (people in the discharge setting) and the nonhuman environment (architectural and geographic barriers). Evaluation of the nonhuman environment should begin immediately so that arrangements can be made for proper equipment and modifications to the home, school, or workplace. Architectural evaluations and home visits should be scheduled throughout the rehabilitation period. Education for people in the child's discharge environment (family members, school personnel, and fellow students) should also begin immediately so that the stigmas and preconceptions that are often associated with disabilities are minimized as the child reenters the community.

If at all possible, a child or adolescent with an SCI should undergo rehabilitation in a pediatric rehabilitation facility, where health care providers are specifically trained to address their ever-changing needs. Adult rehabilitation centers provide for a population with a wide range of disabilities and ages, and it is difficult for a child to feel comfortable in a place where his or her needs and normal development are so different from those of most of the other patients. Also, peer interaction with other children with SCI allows a newly injured child or adolescent to talk to and model himself or herself after someone who has adjusted to a similar injury.

Family-centered care (24,146), which actively involves the family members in the care and rehabilitation of the child, should be employed.

Demographics

Prevalence

There are roughly 200,000 people living in the United States with some degree of spinal cord impairment resulting from trauma (47,74). It is estimated that there are 7,800 to 11,000 new cases of SCI each year (129) and that 4% to 14% of such injuries occur in patients younger than 15 years of age (30,64,83). Forty percent have tetraplegia, and 60% have paraplegia. Thirty to 40% have incomplete lesions.

Causes of pediatric SCI include motor vehicle accidents in about 40% of patients, diving in 13%, other sports in 24%, gunshot wounds in 8%, falls in 8%, transverse myelitis in 4% (49), and spinal cord tumors in 3% (147). Causes unique to the pediatric population include birth injury (1,68), child abuse, high cervical injuries secondary to skeletal dysplasias, Down syndrome, and juvenile rheumatoid arthritis. With improvements in medical technology, a child with paraplegia or tetraplegia may now survive through normal adulthood (22,45,48).

Brain injury concomitant with SCI occurs in 25% to 50% of patients (41,142). Careful history of the injury should be obtained because unrecognized brain injury can significantly affect the rehabilitation process. Patients with both brain injury and SCIs may have perceptual deficits, speech deficits, and other associated disabilities that may affect the rehabilitation course.

Unique to pediatrics is SCI without radiographic abnormalities (SCIWORA), which occurs in about 16% to 20% of children's injuries (133,169). Diagnosis is delayed for up to 4 days in about half of these patients (4). The neurologic level in most children with complete lesions and SCIWORA does not improve (4). Isolated examples of physeal injury have been reported (80,91,131). Magnetic resonance imaging (MRI) of the spine should still be done in children with SCIWORA to exclude a displaced ring apophysis (Fig. 1).

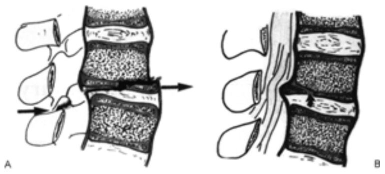

FIGURE 1. Schematic drawings of injury pattern of ring apophysis. **A:** Displaced anteriorly. **B:** Displaced posteriorly.

Classification of Injury

Most spinal cord lesions are initially described as complete or incomplete at a given bony level (the level of injury) of the spinal column. A system promoted by the American Spinal Injury Association (ASIA) to describe a patient's functional level of injury defines the level of function as that at which there is minimal muscle power of 3 and intact sensation to pinprick (2). The next proximal muscle must be grade 5. The muscles affected that are tested at each level of the spinal cord are listed in Table 1 . The use of this motor classification system allows for a total motor index, which then allows for accurate comparison of neurologic recovery from either natural history or surgical intervention (Table 2). In addition, patients are classified by the ASIA Impairment Scale A through E. This is similar to the old Frankel grading system but now to be classified as incomplete there must be evidence of sacral sparing either by perianal sensation or voluntary anal contraction. With the ASIA Impairment Scale, A is complete, B is sacral sparing plus preserved sensation only, C is sacral sparing plus motor preservation distal to the level of injury but nonfunctional, D is sacral sparing plus motor preservation and functional, and E is normal.

TABLE 1. Key Muscles for Motor Level Classification

Motor Level	Muscles
C5	Elbow flexors (biceps, brachialis, brachioradialis)
C6	Wrist extensors (extensor carpi radialis longus and brevis)
C7	Elbow extensors (triceps)
C8	Finger flexors (flexor digitorum profundus to the middle finger)
T1	Small finger abductors (abductor digiti minimi)
L2	Hip flexors (iliopsoas)
L3	Knee extensors (quadriceps)
L4	Ankle dorsiflexors (tibialis anterior)
L5	Long toe extensors (extensor hallucis longus)
S1	Ankle plantar flexors (gastrocnemius, soleus)

TABLE 2. Motor Examination: Required Elements

Grade	Description
0	Total paralysis
1	Palpable or visible contraction
2	Active movement, full range of motion (ROM) with gravity eliminated
3	Active movement, full ROM against gravity
4	Active movement, full ROM against moderate resistance
5	(Normal) active movement, full ROM against full resistance
NT	Not testable

Medical Problems

Deep-Vein Thrombosis

Kewalramani (82) noted a 50% risk for thrombosis in children but only a rare occurrence of pulmonary embolus. Most cases of DVT occur during the first 3 months after injury, but it should be considered a risk whenever a patient is kept on bed rest after plastic surgery for decubitus or for any subsequent spinal column surgery. Preventive measures include antiembolism stockings, compression boots, subcutaneous heparin (enoxaparin sodium [Lovenox]) or low-dose warfarin sodium (Coumadin).

Immobilization Hypercalcemia

Hypercalcemia is a risk for any patient who is immobilized but especially for children on bed rest after SCI (35,90). Nand and Goldschmidt (124) reported a 19.8% incidence of hypercalcemia as defined by a serum calcium level of greater than 10.6 mg%. Symptoms include nausea, vomiting, abdominal cramps (if the patient has sensation), and distinct personality changes. Diagnosis is confirmed with a high serum calcium level but must be differentiated from primary and secondary hyperparathyroidism by a parathyroid hormone assay. Treatment consists of intravenous hydration and early mobilization of the patient. Temporarily, a diet including less than 400 mg of calcium per day may also help. Additional treatment aimed at retarding any osteoclastic-mediated bone resorption includes biphosphates and calcitonin (135).

Autonomic Dysreflexia

Patients with injuries above T6 are at risk for autonomic dysreflexia as a result of the traumatic sympathectomy. Autonomic dysreflexia is triggered by noxious afferent stimuli to the skin and viscera below the level of the SCI. The sympathetic reaction cannot be modulated by higher levels of the central nervous system because the response is blocked at the level of the spinal cord lesion. The autonomic reflex through the lateral horn cells in the spinal cord below the level of injury remains intact and unchecked, causing reflex arteriolar spasm and blood pressure elevation. The hypertension is recognized by baroreceptors in the carotid sinus, aortic arch, and cerebral vessels. These receptors send impulses to the vasomotor center in the brain stem through the ninth and tenth cranial nerves. The vasomotor center sends efferent vagal stimulus to slow the heart rate and cause dilation of the skin vasculature, which can occur only above the level of injury (144) (Fig. 2).

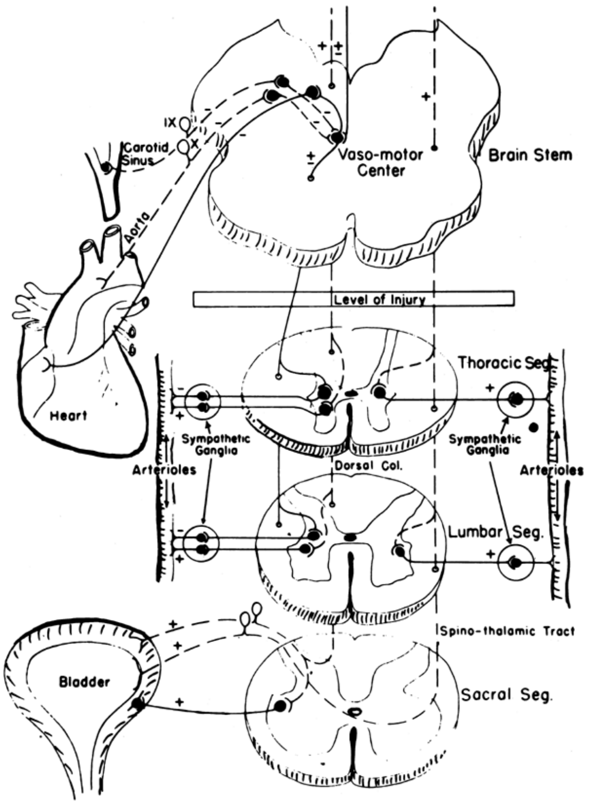

FIGURE 2. Diagram demonstrating the neuroanatomic pathways relevant to autonomic dysreflexia.

Signs and symptoms include hypertension, bradycardia, pounding headaches, vasodilation, flushing, blotching of the skin, and cold sweating above the level of the spinal cord lesion. The major differential diagnosis is anxiety. If the pulse is elevated instead of decreased, the episode is more likely an anxiety attack. If there is evidence of bradycardia, it is most likely autonomic dysreflexia.

Dysreflexia is a medical emergency. The initial step is to detect and eliminate the cause of the noxious stimuli. In general, the most common cause is an overfull bladder, and the second most common cause is fecal impaction (83). If the cause cannot be found and alleviated, medical treatment with an antihypertensive agent should be initiated. The treatment of choice is 10 to 20 mg of nifedipine in a bite-and-chew capsule or sublingually. If this fails and arterial blood pressure monitoring is available, a nitroprusside drip works well. If not, Arfonad (ganglionic blocker), hydralazine hydrochloride, or intrathecal tetracaine hydrochloride is an acceptable treatment option (52).

Respiratory Insufficiency

Depending on the level of injury, respiratory inefficiency of tetraplegia and high-level paraplegia can occur. Decreased inspiratory ventilation is the result of lost intercostal muscles. Decreased expiratory pressure occurs because the diaphragm cannot be passively pushed upward by the contracting abdominal muscles. These patients are at risk for aspiration pneumonia and bronchopneumonia. Prevention of respiratory infections, including pneumococcus and yearly influenza vaccines, is crucial. Postural maneuvers and breathing exercises are essential to train accessory muscles to assist in breathing and to help clear secretions.

Cardiovascular Problems

Bradycardia is the primary cardiac problem in patients with tetraplegia. It results from the loss of sympathetic control of the vagovagal reflex (33). In the acute setting, this can account for 66% of the mortality rate in adult patients with cervical SCI. The cardiovascular system readjusts itself within 3 to 5 weeks, and the patient does not require a pacemaker. If needed, vagolytic therapy with either atropine or propantheline is effective (165). Hypotension in patients with tetraplegia can occur when they attempt to sit. The use of an abdominal binder can decrease venous pooling and help control this.

Vertebral Artery Injury

Although rare, vertebral artery injury can occur with cervical spine trauma. Phenomena not ordinarily associated with cervical trauma, such as altered consciousness, nystagmus, swallowing difficulties, ataxia, and dysarthria, should arouse suspicion (98).

Urologic Problems

The major goals of urologic management of children with SCI are continence and the prevention of urogenital complications, primarily urinary tract infections, urolithiasis, and renal damage. A bladder management program must accommodate the physical and psychosocial development of children and should be convenient and economical, foster independence, and provide for adequate privacy.

During the acute phase of an SCI, an indwelling urinary catheter is usually used to monitor the patient closely. As soon as possible after the injury, an intermittent catheterization program should be implemented, which is initially performed by the hospital staff with sterile equipment and technique. If the neurologic level and developmental age permit, the patient is taught a clean intermittent self-catheterization program (89); otherwise, caregivers are instructed in the procedure. Some children can start to learn to catheterize themselves at about 5 years of age. A clean intermittent catheterization program results in complete emptying of the bladder, which is integral in preventing infections and consequent renal damage. The frequency of catheterization ranges from four to six times a day and is adjusted to maintain continence, maximize convenience, and prevent overdistention. Catheterized volumes approximate 100 to 150 mL in preschool-aged children, 200 to 250 mL in school-aged children, and 400 to 500 mL in adolescents (Vogel LC, personal communication).

To remain continent between catheterizations, some patients require pharmacologic intervention. Commonly used medications include parasympatholytics such as oxybutynin, which relax the bladder detrusor, and *α*-adrenergic agents such as ephedrine or pseudoephedrine, which increase bladder outlet resistance. Pharmacologic intervention is most effective after a urodynamic evaluation of the detrusor-sphincter dysfunction using a functional classification of the neuropathic bladder (99).

Management of bacteriuria with the use of prophylactic antibiotics is not recommended. Routine culturing of urine from symptom-free patients and treatment of asymptomatic bacteriuria in patients without any significant urologic abnormalities should probably be avoided (154).

Patients should have a baseline renal ultrasound, urodynamics, and follow-up renal ultrasound every 12 months.

Kidney and bladder stones are common in children because of the increased incidence of hypercalcemia and subsequent hypercalciuria, especially if there is a urinary tract infection. Stones are less common in patients who practice intermittent catheterization (157).

Adjunct surgical procedures are available for children with bladder management problems. Patients with incontinence associated with high bladder pressure or refractory to oral medication are candidates for augmentation cystoplasty. In this procedure, a piece of bowel is sewn into the bivalved bladder, which increases the bladder volume and lowers intravascular pressure (63,79,85,95,148). Problems reported with augmentation have included cases of acidosis secondary to absorption of urine across the bowel wall (which can be treated by oral alkalyzing agents) and a few isolated cases of colonic cancer in the bladder.

For some patients with cervical level injuries, clean intermittent catheterization still requires dependence on a caregiver. In these cases, a continent diversion can be an excellent option to facilitate independence. In the Mitrofanoff procedure (111), the appendix is implanted into the bladder and the other end brought out to the skin (most commonly near the umbilicus) to function as a continent, catheterizable stoma.

For patients with upper level tetraplegia who cannot independently cath because they cannot remove their clothing, reconstruction of the hands for grasp and pinch along with a continent diversion such as the Mitrofanoff can make them independent in bladder care.

Another option is a device recently approved by the U.S.

Food and Drug Administration called the Vocare system (NeuroControl, Inc., Cleveland, Ohio), which is a sacral root electrical stimulator. A dorsal root rhizotomy desensitizes the bladder, increasing bladder capacity and improving continence, thus allowing for electrically stimulated control of bladder contractions. The electrical leads from the sacral roots are channeled from the spine at the S1 to S3 laminectomy, subcutaneously around the trunk, to the implant on the abdominal wall. Through a radio frequency antenna, power and stimulus controls are transmitted to the implanted receiver, giving the patient control over bladder contractions. In a series by Egon and colleagues (50), continence was obtained in more than 90% of patients secondary to the rhizotomy, and bladder emptying occurred in 90% of the patients using the stimulator. Bowel programs are a secondary adjunct to this procedure, and bowel times are reduced by 50%.

TABLE 3. Differential Diagnosis of Fever of Unknown Origin

- **Most common possibilities**
  - Urinary tract infection
  - Upper respiratory infection
  - Atelectasis
  - Pneumonia
  - Deep-vein thrombosis
  - Extremity fracture
  - Early heterotopic ossification
  - Viral gastroenteritis
  - Grade III pressure ulcers
  - Otitis media
  - Wound infection
  - Thermoregulator insufficiency
- **Less common possibilities**
  - Drug fever
  - Hepatitis
  - Pancreatitis
  - Cholecystitis
  - Appendicitis
  - Perforated ulcer
  - Autonomic dysreflexia
  - Abscess

Fever of Unknown Origin

Fever is a common problem in children with SCI. Evaluation includes history (checking for recent urine culture and sensitivity or recent surgery), physical examination (routine thigh and calf measurements for swelling, crepitus in the extremity, skin lesions), laboratory studies (urinalysis, urine culture and sensitivity, complete blood count with differential, sedimentation rate, chest radiograph, bilirubin, liver enzymes, and sometimes amylase), and other studies (radiographs of extremities and abdomen, bone scan, and venous imaging study of the lower extremities). A sample differential diagnosis is listed in Table 3 .

Orthopaedic Problems

Halo Fixators

As with adults, proper halo ring application in children is crucial in preventing problems with pin loosening and infection. Anterior pins should be placed superior to the middle or lateral one third of the orbit (to avoid the supraorbital and supratrochlear nerves) and below the greatest circumference of the cranium (59). For the patient older than 12 years, pins should be torqued to 8 lb/in^2, which has been shown to reduce pin loosening and infection as compared with 5 to 6 lb/in^2 (21). If a pin starts to drain fluid, a culture should be obtained, antibiotics started, and the torque on the pin checked. The pin should tighten within three turns; if not, it should be removed and a new one inserted (59).

Children younger than 12 years of age present a unique problem with halo fixation. Multiple pins (10, as compared with 4 in adults) with low torque (2 lb/in^2) have been shown to be safe in infants (115) (Fig. 3). For children 2 to 12 years of age, the torque used may range from 4 to 6 lb/in^2. For children younger than 6 years of age, computed tomography (CT) scanning of the skull is recommended for pin placement because of the great variability in skull thickness (60,93). When halo fixation fails because of loosening or infection, a Minerva-type cervicothoracolumbosacral orthosis (CTLSO) is effective.

Use of Crutchfield tongs in patients younger than 12 years of age is associated with skull penetration and dural fluid leaks. Use of the halo ring for traction, using the principles outlined previously, can be an effective alternative.

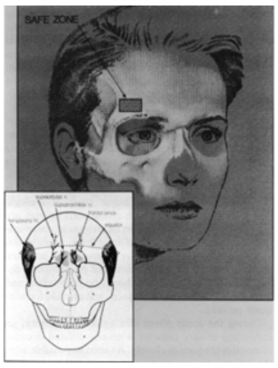

FIGURE 3. Schematic drawing of the ideal position for the anterior pins in the halo, avoiding the superorbital and supertrunclear nerves and the temporalis muscle.

TABLE 4. Rigid Conventional Braces that Provide the Best Control of Flexion and Extension at Different Levels of the Cervical Spine

Segmental Levels	Brace	Mean Motion Allowed (degrees)
C1–C2	Halo	3.4
C2–C3	Halo	2.4
	Four poster	3.7
	Cervicothoracic	3.8
Middle (C3–C5)	Cervicothoracic	4.6
Lower (C5–T1)	Cervicothoracic	4.0

From Johnson RM, Hart DL, Simmons EF, et al. (1977): Cervical orthoses: a study in comparing their effectiveness in restricting cervical motion in normal subjects. *J Bone Joint Surg Am* 59: 332–339.

Halo vests can cause severe pressure ulcers in a paralyzed patient. Frequent skin inspection beneath the entire halo vest by the nursing staff initially and then by the care provider at home is essential.

Bracing for Spinal Instability

Data on bracing the cervical spine are available for adults and extrapolated to children, but no actual pediatric data are available (78). Recommended bracing by level of injury reported by Johnson and colleagues (78) is reported in Table 4 . For thoracic and lumbar injuries, a custom thoracolumbosacral orthosis (TLSO) is the preferred choice for bracing.

Spasticity

Whenever an upper motor neuron SCI exists, spasticity is present. Spasticity is a condition of excessive reflex activity associated with involuntary movements and clonus accompanied by increased muscle tone. It becomes apparent about 6 weeks after injury and appears to plateau after 6 months. Unique to pediatrics is a higher incidence of patients with flaccid rather than spastic paralysis. In a review of 169 pediatric patients (147), only 74% had spasticity, with 26% being flaccid. Of adults with SCI, most (more than 90%) have spasticity. This may be due to a more severe SCI secondary to the flexible condition of a child's spinal column. Although spasticity may be annoying to the patient, it is thought to preserve muscle mass, which may aid in preventing pressure ulcers. Spasticity may increase with nociceptive complications such as a urinary tract infection, kidney stones, pressure ulcers, bowel impaction, tight clothes, or underinflated wheelchair cushions.

Treatment involves prevention of noxious stimuli and putting the paralyzed joints through a full range of motion. Drug treatment is the mainstay of therapy and includes diazepam (Valium), baclofen (Lioresal), tizanidine (Xanoflex), and dantrolene sodium (Dantrium). Dantrolene sodium is potentially toxic to the liver; therefore, liver function tests are necessary at regular intervals (109). It also causes muscle weakness. Patients for whom drug treatment is not effective may be candidates for a baclofen pump.

Heterotopic Ossification

Heterotopic ossification occurs in 16% to 53% of patients with SCI of all ages and is most commonly seen at the hips, knees, elbows, and shoulders (161). It usually develops during the first 14 months after injury in children, as compared with 6 months in adults (62), and is most common in patients with tetraplegia. Heterotopic ossification may present subtly as an inflammatory reaction of increased redness, warmth, swelling, and gradual loss of joint motion. In pediatrics, the only finding commonly seen is decreased range of motion (62). Several patients have presented with knee and hip joint effusions. Three-phase bone scans are often positive 4 to 6 weeks before there is evidence of ossification on plain radiographs (31). Treatment involves maintaining range of motion and indomethacin. Didronel (etidronate disodium) can be effective, but the dose must be 20 mg/kg per day (initially intravenously). Didronel should be used with caution in children because it may cause growth abnormalities (153). Radiation therapy has been effective in adults, but it is not used in children except for the second occurrence because of the risk for sarcomatous changes.

Heterotopic ossification can be a significant problem, especially at the hips, in that it can prevent a patient from sitting (Fig. 4). It appears to become mature after about 18 months, but maturity can be assessed by bone scan and alkaline phosphatase level. The timing of surgery is crucial. In the past, it was believed that an abnormal serum alkaline phosphatase level and an abnormal three-phase bone scan were predictors of recurrence (156). As a result, it used to be recommended that the bone scan and alkaline phosphatase level be repeated and surgery delayed until they returned to normal. Garland (61) strongly recommends resecting the heterotopic ossification 1.5 years after SCI. Waiting any longer for the bones scan and alkaline phosphatase to return to normal increases the risk for severe intraarticular fibrosis and femoral neck osteoporosis, which prevent return of hip motion or increase the risk for hip fracture during surgery.

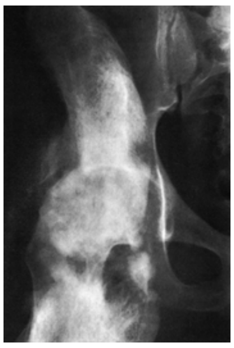

FIGURE 4. Anteroposterior radiograph of an 18-year-old patient with quadriplegia and severe heterotopic ossification of the right hip. The patient's hip was fixed in 20 degrees of flexion.

Spine Deformity

There is a high prevalence of spine deformity in children and adolescents with SCI. If a child is injured more than a year before reaching maturity, the child has a 98% chance of developing scoliosis and a 67% chance of requiring surgery (43,88,102). In contrast, if an adolescent is injured less than a year before reaching maturity, there is only a 20% chance that he or she will develop scoliosis, with a 5% risk of progressing to surgery (43).

Prophylactic bracing in the form of a lightweight TLSO may be effective in delaying surgery. In a comparison series reported by Lieberman and Betz (94), 24 patients who underwent prophylactic bracing showed an 80% success rate in maintaining their curvature versus a 20% failure rate, progressing over 50 degrees. In comparison, in a group of 5 patients who were never braced, scoliosis in 4 of the 5 (80%) progressed past 50 degrees and required surgery. In that study, further analysis of the data showed that starting a brace before the curve progressed to more than 20 degrees or before 1 year after injury had an excellent success rate in maintaining a curvature as compared with with later bracing, which had a much higher rate of progression.

For patients with tetraplegia, a brace can sometimes provide trunk support, which may help increase upper extremity work space but may cause problems in other areas, such as dressing and transfers. The child's and family's goals for rehabilitation may need to be redefined because of the TLSO, and expectations for independence in some activities may not be met. For example, it is self-defeating to train a child in dressing if the child is to be discharged in a TLSO because a primary requirement of independent dressing is trunk movement. In this case, rehabilitation may need to emphasize parent training in dressing as the patient verbally instructs the activity. When the TLSO is discontinued at skeletal maturity, the patient can then participate in a self-dressing and self-transfer rehabilitation program. For the long term, sacrificing a few years of independence while wearing a TLSO for the benefit of a flexible spine, versus a rigid, instrumented spine (T2 to sacrum) for a lifetime seems more appropriate.

Before reaching skeletal maturity, a child should be seen every 3 months for observation of paralytic spine deformities. For children older than 10 years of age, surgery is recommended when curves progress past 40 degrees. For those younger than 10 years of age, curves of up to 80 degrees are tolerated if they are somewhat flexible and temporarily decrease while in a brace; otherwise, surgery is recommended regardless of age.

Dislocated or Subluxated Hips

In an unpublished review of pediatric patients with SCI (136), there was a 43% prevalence of nonseptic subluxated or dislocated hips in growing children followed a minimum of 3 years. Age at injury correlated with hip deformities, with a 100% incidence of instability in those injured before 5 years of age and 83% of those injured before 10 years of age. It appears to be equally prevalent in patients with tetraplegia and paraplegia and in boys and girls (9). The onset of hip instability after SCI varies widely, from 7 months to 15 years after injury. Hip instability has been seen in patients with spastic and flaccid SCI. Several skeletally mature patients have been seen at our center with rapid onset of noninfected hip subluxation. Untreated, these hips can develop into a Charcot joint. As the hip dislocates and relocates with spasticity, a vicious circle is created; increased fragmentation of the joint results in further spasticity, until the hip socket is totally destroyed (Fig. 5).

In the past, the hips of children with SCI have not routinely been treated. One report of a small series notes no functional deficits in children with SCI with subluxated or dislocated hips (137), but diminution in sitting tolerance has been reported (6). With the development of functional neuromuscular stimulation for computerized standing and walking and the future potential for spinal cord regeneration, more aggressive treatment of hip deformities must be considered. Prophylactic abduction bracing starting at the onset of injury should be instituted in all patients younger than 5 years of age to help prevent subluxation or dislocation. No reports are yet available on this treatment.

Treatment of a patient with a subluxated or dislocated hip is complex. Spasticity needs to be addressed with medication, nerve blocks, a baclofen pump, or rhizotomies (either thermal or open). Soft-tissue contractures must be released. After the spasticity and contractures are addressed, bony stability should be achieved. The hip instability is usually posterior; therefore, a posterior capsulorrhaphy and an acetabular augmentation posteriorly (12) or a Chiari osteotomy should be considered.

Pain

Chronic pain after SCI can be disabling and can have negative effects on successful school, work, and social interactions (26). Pain can originate from the area of trauma, either in a radicular pattern (specifically from compression of the nerve root at the level of injury) or from mechanical instability of an unhealed fracture, or it can consist of central pain (also known as *spinal cord pain* or *dysesthesia*) (55).

Spinal cord dysesthesias constitute a perplexing problem involving numbness, tingling, burning, and pain felt below the level of injury, similar to phantom pain after amputation. The dysesthesias are diffuse and do not conform to a dermal distribution. The incidence of dysesthesias in patients with SCI ranges from 82% to 94% (42), and they are influenced by many factors, including depression, anxiety, weather, smoking, alcohol, exercise, and fatigue. Drugs are occasionally effective, including nonsteroidal antiinflammatory agents, amitriptyline (Elavil), carbamazepine (Tegretol), phenytoin (Dilantin), and gabapentin (Neurontin). A transcutaneous electrical nerve stimulation (TENS) unit can be helpful on occasion (55).

Upper extremity pain is common (31% to 55%) among patients with tetraplegia, especially at the C5 level (7,149). This can occur because of muscle deconditioning and shortening, overuse, or cervical radiculopathy. Treatment most often requires muscle strengthening and stretching (145) and alternative ways of performing functional tasks (149).

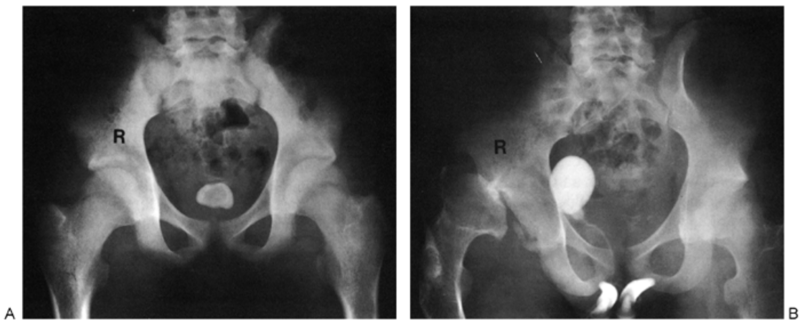

FIGURE 5. A: This 17-year-old boy with T8 complete paraplegia had severe flexor and adductor spasms. He was instructed to perform range-of-motion exercises, sleep prone with a pillow between the legs, and take antispasmodic medication. The patient refused to utilize the recommendations and did not follow-up. **B:** The patient was seen 9 months later with the right hip dislocated posteriorly and no evidence of sepsis. Fragmentation of the joint confirmed the diagnosis of a Charcot joint.

Reflex Sympathetic Dystrophy

Reflex sympathetic dystrophy has been seen in patients with tetraplegia who complain of diffuse pain, swelling, and stiffness in their upper extremity. A prospective series by Gellman and associates (67) showed a prevalence of 12% in adults. Three-phase bone scan is considered the most sensitive and specific diagnostic study (105), and the diagnosis is confirmed by a response to a stellate ganglion block.

Carpal Tunnel Syndrome

Gellman and colleagues (66) reported that 38 of 77 patients (49%) with paraplegia whose level of injury was at or caudad to the second thoracic vertebra were found to have signs and symptoms of carpal tunnel syndrome.

Osteopenia

Osteopenia occurs in all patients with SCI. It starts immediately and appears to plateau between 6 months and 1 year after injury. Children and adolescents with SCI appear to have bone density that is about 60% of that in normal age- and gender-matched controls (14).

Fractures Secondary to Osteopenia

The prevalence of pathologic fractures occurring secondary to osteopenia in patients with SCI ranges from 10% to 20% (37,107,130,158). In a review of 176 children and adolescents with SCI (147), 25 patients had 54 pathologic fractures. The etiology in 40% included gait training, range-of-motion exercises, and minor trauma. Sixty percent presented with no etiology, and presentation included fever of unknown origin or redness and swelling around the lower extremities. The most frequent locations of fracture were the supracondylar region of the femur and the proximal tibia. Fractures also occurred at the hip and the ankle.

Treatment of pathologic fractures is usually best managed by soft dressings and splints because of the high prevalence of decubitus ulcers beneath casts (51,106). If casts are essential, they should be foam padded over all bony prominences, and spasticity must be controlled. Because the bone is osteoporotic, long bones typically do not hold internal or external fixation very well. Surgical fixation may be necessary to obtain or maintain bony alignment, but supplemental immobilization may also be needed. For fractures around the hip, internal fixation is necessary and has been reported to be successful (103). If internal fixation of long bone fractures is needed, intramedullary fixation should be used. Fortunately, exuberant callus is generated within 3 to 4 weeks, at which time the splinting and soft tissue dressing can be minimized and general range of motion resumed. Generally, ambulation in braces must be delayed for 6 to 8 weeks after any fracture.

Posttraumatic Syrinx

Posttraumatic syrinx after SCI has been reported (5,138). In the past, the prevalence was thought to be very low (2% to 3%), and diagnosis by CT myelography was required (138). However, recent studies with MRI report an incidence averaging 50% (5). Therefore, because the cysts are extremely common, it is essential that a patient's symptoms be established and related to a progressive cyst before decompression is considered. Symptoms that may necessitate decompression of a cyst include ascending neurologic level, increasing pain, increased spasticity, and change in bladder management and hyperhidrosis. Surgical treatment may include aspirations or shunting through a catheter into either the intrapleural or the intraperitoneal cavity (138). Detethering the scarred area with dural patching has been helpful (54).

Brachial Plexus Palsy

A brachial plexus injury may be seen concomitant with SCI (71). The clinical features suggesting an associated brachial plexus palsy include lower motor neuron paralysis, absent reflexes, variable sensory changes, and occasionally Horner syndrome.

Anesthesia Issues

Surgical procedures are relatively common in patients with SCI, including children. Genitourinary tract procedures, such as removal of calculi, repair of urinary fistulae, or procedures for bladder emptying, are most common. Plastic and orthopaedic procedures for decubitus and spine and extremity deformities are also common.

It should not be assumed that because a patient with SCI has no sensation distal to the level of the injury there is no need for anesthesia when performing surgical procedures (27). Autonomic dysreflexia is a life-threatening situation that can occur intraoperatively as a result of a noxious stimulus, especially in patients with injury levels above T6. Severe hypertension may result in fatal cerebrovascular hemorrhage (44). It is probably best to assume that the patient is at risk for autonomic dysreflexia and that an invasive procedure should be performed under controlled general or spinal anesthesia.

Schonwald and colleagues (141) documented the reliability of halothane and enflurane in preventing autonomic dysreflexia. Succinylcholine has been associated with acute cardiac arrest secondary to massive release of potassium from the muscle after induction of muscle relaxation in patients with SCI (125).

The Rehabilitation Process

Establishment of Realistic Goals

Traditionally, goals for rehabilitation of children with SCI have been based on charts of adult function with complete SCI (97,164). These functional level charts should be considered indicators of minimal levels of function as opposed to the traditional perspective of maximal levels of function for the following reasons: About half of SCIs are incomplete lesions (170), suggesting increased potential for independence. Also, there is a great deal of anatomic variation regarding what muscles are innervated and denervated at specific injury levels, and children, because of their size, weight, flexibility, and apparent resiliency, may excel beyond established levels of adult outcome. In addition, with improved acute management, increased technical developments, advances in orthoses, functional electrical stimulation (FES), biofeedback, environmental modifications, and public laws, previously unobtainable functional levels are now possible for some patients (166,167,168). In the past, most discussions of rehabilitation focused on adults, but there is an emerging body of literature on children (3,8,11,118,120,132,141,151,155,162). Although discussions of most of these issues are beyond the scope of this chapter, we review several pertinent topics related to pediatric SCI rehabilitation.

Prevention of Deformity

The primary goal is to obtain pain-free functional range and mobility in all affected joints, including those of the rib cage and spinal column. All children and adolescents with paraplegia should be able to range both lower extremities independently. Problems such as the hip flexors can be addressed not only by daily ranging but also by prone positioning when sleeping or lying prone for part of the day. Patients who cannot perform range-of-motion exercises themselves should be taught to instruct others in this task. The shoulders also need to be ranged, especially while the patient is in a halo.

Traditional approaches of SCI rehabilitation have encouraged specific patterns of joint limitation because they actually enhance function. The most prevalent example concerns the intentional tightening of the finger flexors in patients with C5 or C6 tetraplegia. With tightening of the long finger flexors, when the wrist is flexed by means of gravity, the fingers passively extend for hand opening. With voluntary wrist extension, the fingers pull into the palm, creating a passive pinch. This tenodesis action (Fig. 6) enables the patient to grasp and release small, light objects and, with the assistance of a wrist-driven flexor hinge orthosis, control the thumb and strengthen the pinch (Fig. 7). Although encouragement of tight finger flexors has been the traditional standard of care for the hands of patients with a C5- or C6-level injury, the contractures prove to be a difficult obstacle to overcome in the event that FES or tendon transfers are desirable. Splinting the hand in an intrinsic-plus posture at night prevents flexion contractures and preserves the hand for future FES or tendon transfers.

Return to Vertical Positioning

Tolerance of vertical sitting and, when appropriate, standing, should be considered soon after an injury but may not always be achieved during the early stages, especially when patients have undergone spine surgery. One barrier to obtaining a vertical position soon after injury is postural hypotension, which is manifested by decreased blood pressure, increased pulse, pallor, and dizziness. Initially, this can be managed by a reclining wheelchair, and most patients respond to progressive attempts to sit or stand. On occasion, pressure-gradient stockings or abdominal binders are necessary.

Prevention of Pressure Ulcers

Patients with paralysis resulting in insensate areas must understand the importance of skin care, safety, hygiene, skin checks, and pressure reliefs. With advances in technology, sophisticated pressure mapping and monitoring can aid in decisions concerning appropriate seating systems and prevention of shearing forces. In the event of a pressure ulcer, a program consisting of progressive sitting or weight bearing should be implemented.

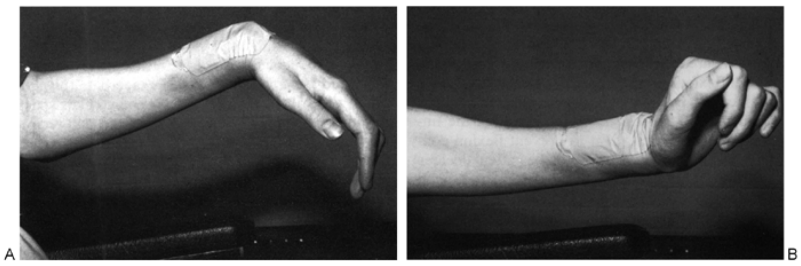

FIGURE 6. Tenodesis action of the fingers with wrist flexion and extension. **A:** With passive flexion of the wrist, the fingers extend. **B:** With active extension of the wrist, because of the contractures of the flexor digitorum superficialis and profundus, the fingers are pulled into the palm, enabling the patient to grasp and release small, light objects. Usually, the thumb pinch is weak, requiring either a tenodesis orthosis or a flexor pollicis longus (FPL) tenodesis to the distal radius.

Prevention of pressure ulcers is of utmost importance and involves pressure relief skills, frequent skin inspections, and avoidance of trauma while transferring. The patient also needs to be taught to protect the skin from extreme heat or cold. Burns can easily occur during bathing or from cigarettes, heating pads, or car heaters.

Respiratory and Cardiovascular Function

Rehabilitation goals include training in more efficient coordinated breathing patterns, maintaining chest mobility, and bronchial hygiene. Use of an incentive spirometer and group games, including sipping through straws and blowing bubbles, are helpful. Specific training of the diaphragm and the secondary accessory muscles, such as the sternocleidomastoid, trapezius, levator scapula, and scalene muscles, can also improve function. An elastic abdominal binder may also assist with respiratory function. Maintenance or improvement of chest mobility should be attempted with counterrotation trunk exercises. Patients should be taught assisted coughing, postural drainage, and deep-breathing exercises.

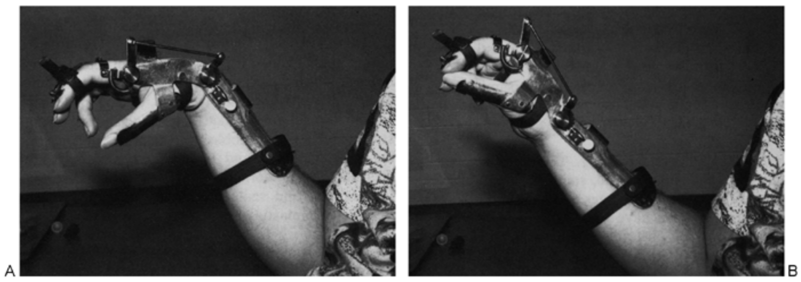

FIGURE 7. Tenodesis orthosis. With the tenodesis action, the orthosis controls the thumb, index finger, middle finger. **A:** With passive flexion of the wrist, the thumb is abducted out of the palm. **B:** With active extension of the wrist, the fingers and thumb are drawn together, producing a pinch.

Tendon Transfers for Volitional Arm and Hand Function

Static and dynamic splints and a variety of orthoses are available to improve hand function of patients with tetraplegia (87), even for children (117). Typically, however, splints and orthoses are abandoned after discharge because of the cosmesis, the added stigma, and the burden of carrying equipment to and from different settings. Many children and adolescents with tetraplegia could benefit from surgical restoration of hand function by means of tendon transfers. Although the literature is extensive with regard to results and procedures for adults (75,104,112), literature describing the results of tendon transfers in children and adolescents with SCI is just recently emerging (116,121).

TABLE 5. International Classification of Hand Surgery in Tetraplegia

Group	Characteristics[a]	Function
0	No muscle below elbow suitable for transfer	—
1	Brachioradialis	Flexion and supination of the elbow
2	Extensor carpi radialis longus	Extension of the wrist (weak or strong)
3[b]	Extensor carpi radialis brevis	Extension of the wrist
4	Pronator teres	Extension and pronation of the wrist
5	Flexor carpi radialis	Flexion of the wrist
6	Finger extensors	Extrinsic extension of fingers (partial or complete)
7	Thumb extensor	Extrinsic extension of the thumb
8	Partial digital flexors	Extrinsic flexion of the fingers (weak)
9	Lacks only intrinsics	Extrinsic flexion of the fingers
×	Exceptions	Extrinsic flexion of the fingers

[a] Key muscles must be tested as grade 4. Note that this is different from the ASIA functional level, in which muscles are tested as grade 3. A sensory prefix is also needed: O, ocular intact; Cu, sensation <10 mm on two-point discrimination in thumb and index finger.

[b] It is not possible to determine strength of the extensor carpi radialis brevis without surgical exposure.

Candidates for upper extremity reconstruction are evaluated based on the International Classification System for Surgery of the Hand in Tetraplegia (104). As shown in Table 5, surgical reconstruction of the upper extremity in tetraplegia has been performed to restore elbow extension (29,34,75), wrist extension (57,108), finger flexion (53,58,75,81), and thumb pinch (75,76). Restoration of these functions is made possible by transferring the tendons of muscles under voluntary control to the tendons of muscles that are paralyzed. Often, other procedures, such as an arthrodesis, tenodesis, or the New Zealand flexor pollicis longus split tendon transfer (113), are performed in conjunction to enhance hand function.

Functional Electrical Stimulation of the Upper Extremities

Functional electrical stimulation (FES) applications have concentrated on restoration of grasp and release in adults and adolescents with C5 and weak C6 function who do not meet the criteria for reconstructive surgery according to the international classification (122,134).

The success with the research-grade percutaneous systems (13,118,134,150) has led to development and market approval of the Freehand System, an eight-channel hand stimulation system with totally implantable electrodes. The Freehand system involves implantation of electrodes onto select muscles of the arm and hand. The electrode leads are tunneled subcutaneously to the stimulator that is sutured onto the subcutaneous fascia in the chest. Control of stimulated grasp and release is achieved with a sensor that is typically mounted onto the contralateral shoulder. Outcomes data on the Freehand system with both adults (84) and adolescents (116) show increased independence in activities and improved satisfaction level of activity performance.

Applications of FES in patients with high-level tetraplegia (C4) are also under investigation (13,73,123,126,127,128). Restoration of elbow flexion and grasp and release by means of FES has enabled one adolescent with a C4-level injury to feed himself and drink with minimal assistance and little external bracing (13). Although patients with high-level tetraplegia will always require some level of attendant care, FES may provide a higher degree of independence and autonomy.

Standing and Ambulation

Most children and adolescents with SCI desire to stand and walk. The importance of standing as a component of the rehabilitation process, especially with children, cannot be overemphasized. The following physiologic benefits of standing have been described (28,40,56,92,160):

- Maintenance of range of motion in both lower extremities
- Reduction of hypercalciuria and osteoporosis of the long bones
- Improvement of organ position and bowel and bladder function
- Improvement in skin condition as a result of pressure relief of pelvic bony prominences
- Improvement in regulation of orthostatic circulation
- Reduction in spasticity

In very young children with a SCI, standing also has developmental significance for perceptual, cognitive, and emotional growth (114,160). In the past, patients with injury levels of T10 or below were routinely fitted with some form of standing brace (139). In children and adolescents, there are few guidelines for upright mobility (11).

Methods for providing standing and walking ability fall into five categories: orthoses, standing frames, specialized wheelchairs, FES, and hybrid systems. The general advantages and disadvantages of each method are considered elsewhere (39,77). The most frequently prescribed method of standing is the knee-ankle-foot orthosis (KAFO). Several studies of adults with SCI addressed the long-term use of KAFOs after discharge from rehabilitation (38,110). In all these studies, most adults had abandoned their orthoses for a variety of reasons, including time spent donning and doffing, pressure problems related to extended wear, impracticality, energy expenditure, inability to rise independently, and poor cosmesis.

A survey of young patients with SCIs assessed their attitudes about standing (36). One hundred five individuals responded, with 48 responses coming from patients with T4- to T12-level paraplegia. In this subgroup, 85% reported that they used a lightweight sport wheelchair—50% without armrests and 35% with. Sixty percent of the subgroup reported that they had KAFOs, but only half reported using their KAFOs more than 3 days a week for exercise, standing, or ambulation. When asked to rank the most important reasons for standing, 39% chose getting an object stored out of reach; 35% chose being eye to eye with another person; and 27% chose transferring more easily.

The fact that more than one third of the respondents chose being eye to eye with another person as the most important reason to stand is testimony to the powerful psychological benefit associated with standing. An assistive device is necessary to achieve standing with all portable standing methods, and the preference for lightweight sport wheelchairs dictates careful consideration of an appropriate device. In adolescents, choosing to convert from upright mobility to wheeled mobility should be viewed as a transition rather than a failure.

For young children, one alternative to KAFOs is the parapodium, which allows sitting and standing. For a child with tetraplegia, a swivel walker may allow standing and ambulation for a short distance in the home, but the time necessary to don and doff the orthosis typically makes it impractical for daily and spontaneous use. Other common orthoses include the hip-knee-ankle-foot orthosis (HKAFO) and the reciprocating gait orthosis (RGO), which are described in detail elsewhere (39).

Functional electrical stimulation for standing and walking has been under investigation for several decades (40,100,101,119,152). The Parastep I (Sigmedics, Inc., Northfield, IL) (86), a surface stimulation system, is available on the market and provides short-distance walking ability to persons with mid-thoracic injuries. In our study of an investigational device (114), adolescents used FES to stand at home between two and four times a week. Common activities while standing included reaching high places, accessing environments, and exercise.

In another study (19), we showed that FES was comparable or better than braces in facilitating independence and that FES was preferred over braces for most activities. Research is underway on totally implantable FES devices for upright mobility (10).

Denervation of lower extremity muscles excludes 23% of patients from FES (159) because only upper motor neuron innervated muscles can be stimulated. This problem could be overcome by transferring spastic muscles, which can then be stimulated, as has been done in the upper extremity (163). Orthopaedic problems, such as hip dislocation, severe scoliosis, and muscle flaps for pressure ulcers, will continue to affect future FES candidates and should be addressed prophylactically.

Research

It is important that the care provider organizing a patient's rehabilitation be up to date on research being conducted on SCIs. Patients and parents are likely to ask about the status of research regarding a cure. Current research strategies are focused on protection, enhancement, and regeneration.

A large portion of research is working toward minimizing the trauma at the time of the acute injury. Trauma alone causes the anatomic transection of the spinal cord in less than 15% of cases (18). The neurologic deficits caused by microscopic physical disruption of the axons transversing the injury site are compounded by local infarction, microhemorrhages, or edema. Laboratory studies of chronically injured spinal cords indicate that even a few remaining intact axons (5% to 18%) can support functional recovery (15,16). Although axons remain, they may be dysfunctional, and demyelination is probably responsible for most of this dysfunction (17).

To minimize this secondary damage after trauma, high-dose methylprednisolone (30 mg/kg of body weight followed by an infusion of 5.4 mg/kg per hour for 23 hours started within 8 hours of injury) is used (23). No patients under 13 years of age have been studied. Gangliosides (Sygen) present in central nervous system cell membranes augment neurite outgrowth in vitro and induce regeneration and sprouting of neurons (69,70). Melsher and associates (65) reported results of a randomized, prospective study of Sygen in about 1,000 patients. They showed no change in patients classified as ASIA A, but there was improvement in patients classified as ASIA B and earlier recovery in those classified as ASIA C and D.

Research in regeneration of injured spinal cords has focused on ways to stimulate axonal growth. Brain-derived neurotrophic factor and Schwann cells from peripheral nerves in tissue culture have been found to stimulate neurite outgrowth in a rat model (72). The axonal proteins that appear to inhibit regeneration of the spinal cord, in contrast to peripheral nerve regeneration, have been identified (32,143). Attempts in laboratories to modulate these protein productions have been through immunologic manipulation (140) and enzymatic alteration, both of which appear to be promising. In animal studies, electrical stimulation of regenerating axons has been performed (20), as has embryonic transfer of fetal tissue (25,96).

Even when regeneration of the spinal cord becomes possible, there will be patients with SCI whose injury is either so severe or of such a nature that regeneration will never be possible. Such injuries include gunshot wounds that completely destroy the spinal cord, massive infections that leave the spinal cord completely necrotic, and severe trauma with documented total transection of the spinal cord. These patients will need other means to restore them to more functional lives. Functional neuromuscular stimulation of both the upper and lower extremities will probably be the most promising treatment for these patients.

Pyogenic Infectious Spondylitis in Children

Dennis R. Wenger

David Ring

Gregory V. Hahn

D. R. Wenger: Department of Pediatric Orthopedics, Children's Hospital San Diego, San Diego, California 92123.

D. R. Ring: Department of Orthopaedic Surgery, Massachusetts General Hospital and Harvard Combined Orthopaedic Program, Boston, Massachusetts 02114.

G. V. Hahn: Department of Orthopaedic Surgery, All Children's Hospital, St. Petersburg, Florida 33701.

Infections involving the spinal column in children produce confusing symptoms and findings, which historically have led to delay in diagnosis. The evolution to current understanding of this condition is outlined in Table 1 . Modern imaging techniques have blurred the distinction between infection of the disc space and vertebral osteomyelitis. Pyogenic infections in patients of all ages characteristically involve a single disc and both adjacent vertebral bodies. The persistent belief in alternative etiologies for what has been termed “discitis” in children is puzzling when one considers that the insidious onset, disc space narrowing, magnetic resonance imaging appearance, and difficulty isolating the causative organism observed in pediatric infectious spondylitis are almost identical to the clinical situation encountered in adults. The unusual feature of pediatric spinal infections is that, in many cases, the infection resolves without specific antibiotic therapy and with few long-term sequelae. Nonetheless, treatment with antibiotics rapidly diminishes symptoms, decreases the risk for recurrence, and may limit the potential for development of psoas or epidural abscesses.

Etiology and Pathophysiology

Anatomy

The distinction between disc space infection in children and vertebral osteomyelitis in adults has long been reinforced by observations of a vascular supply to the intervertebral disc that is present in children but disappears after adolescence; however, the vascular anatomy of the intervertebral disc is disputed. The published experiments claiming to demonstrate either the presence or the absence of a vascular supply to the intervertebral disc in children are consistent in that they demonstrate vascular channels in the hyaline cartilage of the vertebral end plate in children, but not in adults (10 ,22 ,33 ,42 ,46 ,59 ,60) (Fig. 1).

They differ simply on the anatomic definition of the intervertebral disc, with those authors who include the hyaline cartilage of the end plate as an anatomic portion of the disc claiming that the disc is vascular in children (10 ,22 ,33 ,46) and those who restrict the definition of the intervertebral disc to the annulus fibrosus and the nucleus pulposus claiming that the disc is avascular throughout development (42 ,59). They also differ on the estimated age at which the vascular supply to the hyaline cartilage of the vertebral end plate is lost.

Modern imaging modalities have demonstrated early involvement of the intervertebral disc in pyogenic infections at all ages, making considerations of vascular anatomy less important (3 ,13 ,16 ,17 ,23 ,34 ,43 ,44 ,45 ,52 ,57) (Fig. 2). Current pathophysiologic theories propose that, in both children and adults, hematogenous bacterial emboli lodge in either the subchondral bone or the hyaline cartilage of the vertebral end plate and spread rapidly to the intervertebral disc and the opposite vertebral end plate (42 ,54 ,59) (Fig. 3). The mechanism of such progression is speculative but most likely involves direct spread through the disc, facilitated by bacterial or inflammatory enzymes or perforations in the vertebral end plate (25 ,37).

The differences between the usual course of such infections in children and adults remains incompletely explained. It has been suggested that differences in the vascularity of the vertebrae (which may influence the spread of septic thromboses) are important (54 ,59). Other important factors may include differences in the source of bacteremia (believed to be small, transient, and incidental in the context of cuts, abrasions, or pharyngitis in otherwise healthy children as opposed to more substantial, repeated episodes in intravenous drug–abusing adults and the debilitated elderly) and the overall health of the patient. A third unexplained subgroup occurs in bacteremic neonates, in whom pyogenic infectious spondylitis can be quite destructive (15).

Bacteriology

Because many cases of spondylitis have been treated successfully without antibiotics, some authors have proposed that the disc narrowing and adjacent reactive bony changes are a result of some other developmental or reactive process (11 ,27 ,50 ,55). A careful consideration of alternative causes of symptomatic disc narrowing in children, however, finds little support for any other process as a cause of the radiographic changes seen in infectious spondylitis. A number of authors have cited the large percentage of negative cultures as further support for a nonbacterial etiology in many cases of disc space narrowing in children. Among the numerous small case series that comprise the existing literature documenting pyogenic infections of the spine in children, the reported rate of successful isolation of a causative organism has ranged from 27% to 88% (average, 60%) (8 ,11 ,12 ,13 ,26 ,32 ,35 ,48 ,50 ,55 ,58).

TABLE 1. The Evolution of Understanding Pyogenic Infectious Spondylitis

Date	Event	Results
c. 1880	Koch's experiments with the anthrax bacillus establish the germ theory of disease. Koch also discovers tubercle bacillus.	Vertebral caries are understood to represent tuberculous osteomyelitis
	Pasteur isolates *Staphylococcus* species from a superficially draining spinal abscess in the setting of an acute febrile illness.	Pyogenic vertebral osteomyelitis distinguished from tuberculous osteomyelitis
c. 1896	Roentgen and advent of radiography	Increased recognition of infectious spondylitis before death and autopsy
c. 1900–1960	Improved clinical recognition of infectious spondylitis	Description of “benign” forms of vertebral osteomyelitis
		In 1940, Ghormley and colleagues (19) proposed the concept of intervertebral disc infection
		The concept of discitis in children gains in popularity.
c. 1940	Development of antibiotics	Minimal influence on vertebral osteomyelitis noted initially, mainstay of treatment remains prolonged brace immobilization and surgery when necessary.
c. 1950–1980	High percentage of sterile cultures of direct biopsy specimens noted in many musculoskeletal infections	As an explanation of this observation in discitis, alternative, nonbacterial causes are proposed.
c. 1970	Improved treatment of musculoskeletal infections with parenteral antibiotics	Vertebral osteomyelitis in adults becomes a medically treated disease for which prolonged immobilization and operative intervention are rarely required. Traditional treatments (immobilization) are still advocated for discitis in children.
c. 1980	Computed tomography	Substantial bone and soft issue involvement are noted in so-called “discitis.”
c. 1985	Magnetic resonance imaging	The appearance of pyogenic infections of the spine in adults and children is noted to be essentially identical.

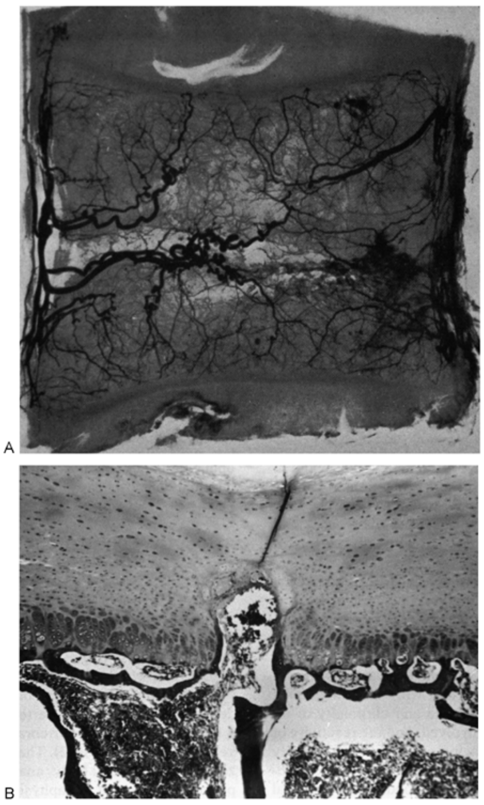

FIGURE 1. A: Blood supply of a vertebral body and adjacent discs above and below. **B:** Vertebral end plate (cartilage), adjacent disc, and cancellous bone of the vertebral body in an autopsy histologic specimen from a child. Note the vascular channel traversing the end plate. Such channels allow bacterial infection to involve the disc. (**A** from Menelaus MB (1964): Discitis: an inflammation affecting the intervertebral discs in children. *J Bone Joint Surg Br* 46:16–23, with permission.)

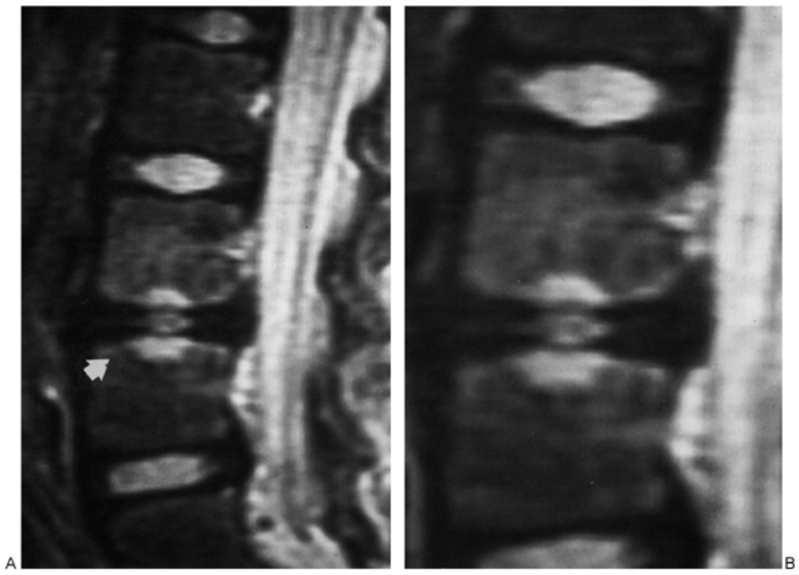

FIGURE 2. A: Magnetic resonance imaging study in a 4-year-old with *Staphylococcus aureus* spondylitis (later proved by biopsy). Note asymmetric involvement of the end plates of the affected disc *(arrow)*. **B:** Close-up view. The end plate below the disc appears to be more involved.

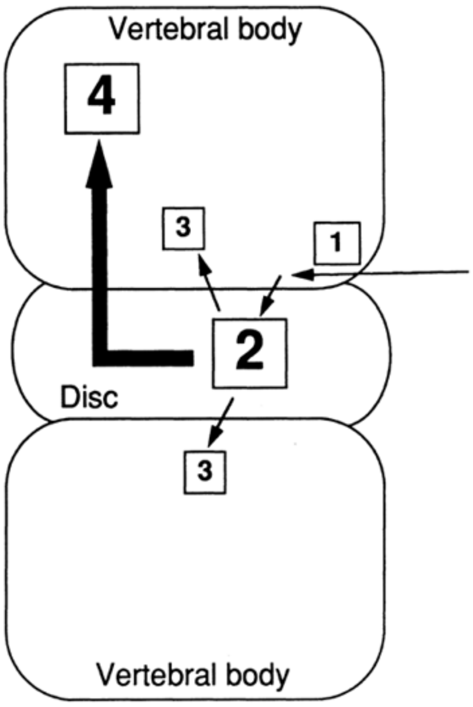

FIGURE 3. Proposed sequence of intervertebral disc infection and evolution to osteomyelitis: (*1*) microabscess in "metaphysis" (adjacent to end plate), (*2*) disc colonized and infected, (*3*) reactive process (or low-grade infection of opposite end plate), (*4*) diagnosis and treatment delayed—development of vertebral osteomyelitis.

The bacteriologic data from the Toronto study (58) is one of the most comprehensive available. Biopsy was performed in nine patients in an attempt to establish an accurate diagnosis. There were four needle and five open biopsies. Six of the nine biopsy specimens were positive for *Staphylococcus aureus*, and one of the six also grew *a*-hemolytic *Streptococcus* species. The other three biopsy specimens showed no growth. Histologic examination showed acute inflammation in a few cases, with subacute and chronic inflammation in the remainder. Blood specimens were cultured for 22 patients. Positive cultures for *S. aureus* were obtained in nine patients and for diphtheroids in one. The diphtheroid culture was considered a probable contaminant. One patient had both a positive blood culture and a positive culture from biopsy material. Few patients had cultures of both blood and biopsy tissue. Most of the biopsies performed were in patients in the early years of the study, when only occasional blood specimens were drawn for culture; in more recent years, when blood was cultured in most patients, few patients underwent biopsy. Organisms were identified in 14 of the 28 patients (50%) who had cultures of blood or biopsy material.

In considering all of the bacteriologic data, one must keep in mind that direct biopsy material for culture and organism isolation has rarely been sought in cases of inflammatory disc narrowing in children. The organism has most often been identified from blood cultures. Such difficulty with organism isolation is typical of other pyogenic musculoskeletal infections (48 ,56). Therefore, alternative, nonbacterial, etiologies such as viral infection, trauma, or a nonspecific inflammatory disorder are unlikely (1 ,4 ,5 ,11 ,14 ,26 ,31 ,35 ,47 ,53 ,55).

Imaging

In children, the appearance of pyogenic infectious spondylitis on standard radiographs rarely progresses beyond disc space narrowing with erosion or sclerosis of the adjacent vertebral end plates (Fig. 4).

The radiology literature on pyogenic infectious spondylitis affirms the usefulness of computed tomography (CT) and magnetic resonance imaging (MRI) in both managing and understanding this disease. Studies have confirmed the findings of Crawford and colleagues (11) and Szalay and associates (57) that MRI and CT are more sensitive than bone scan for diagnosing infectious spondylitis (13 ,49 ,54). The extent of the inflammatory process is also better depicted, with frequent demonstration of paravertebral inflammatory masses, intraspinal soft tissue extension, psoas involvement with abscess formation, and advanced bony destruction. In a review of the CT scans of seven patients with spondylitis, paravertebral masses were present in all seven, intraspinal extension was noted in six of seven, and a psoas abscess was appreciated in one, demonstrating that the inflammatory process may be more extensive than demonstrated by conventional radiographic studies and thus more consistent with an infectious etiology (49).

The MRI findings recognized as characteristic of vertebral osteomyelitis in adult patients (diffusely decreased signal in adjacent vertebral bodies, with loss of distinction of the intervertebral disc, on T1-weighted images; increased signal in the disc and loss of the intranuclear cleft on T2-weighted images; and increased signal in the adjacent vertebral body end plates on T2-weighted images) have also been found to be characteristic of infectious spondylitis in children (13 ,54 ,57). In fact, it is difficult to distinguish between the imaging appearance of pyogenic infectious spondylitis in children and adults (29) (Fig. 5). As a result, the concept of a noninfectious inflammatory disc space narrowing in children has become less appealing.

Clinical Observations

Despite the fact that a large percentage of cases of inflammatory disc space narrowing in children have been proved to be of bacterial etiology, the process resolves spontaneously in many children (9 ,14 ,19 ,21 ,26 ,30 ,32 ,40). This is an interesting observation of the ability of the immune response in young patients to resolve a pyogenic skeletal infection, but not a reason to suggest alternative, nonbacterial etiologies. Denying a bacterial etiology may be risky because some children with pyogenic infectious spondylitis occasionally develop an abscess requiring operative drainage (24 ,31 ,49 ,51).

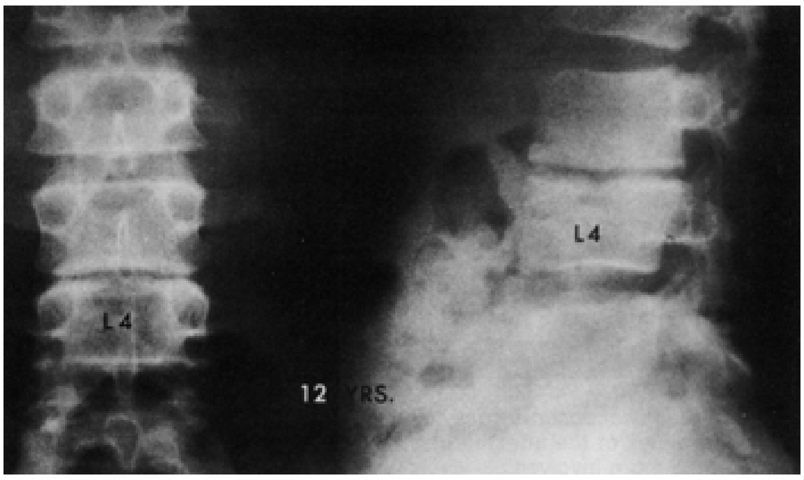

FIGURE 4. Classic pyogenic infectious spondylitis changes. The child had onset at 4 years of age and is now 12 years of age. Note the disc narrowing and vertebra magna but absence of vertebral wedging.

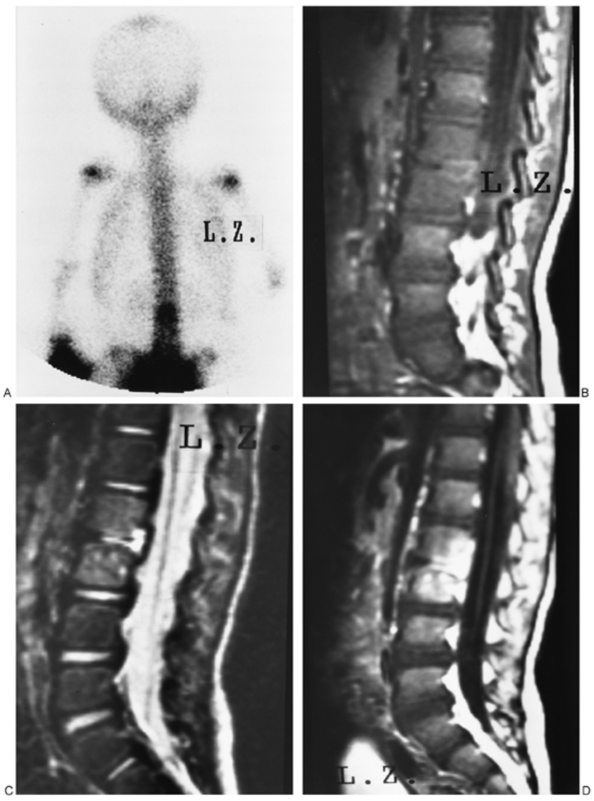

FIGURE 5. A 17-month-old girl presented with a 3-day history of refusal to ambulate and was found to have an increased erythrocyte sedimentation rate. A lateral radiograph demonstrated narrowing of the disc space between the second and third lumbar vertebral bodies (not shown). **A:** Technetium-99m methylene diphosphonate bone scan demonstrates increased uptake in the second and third vertebral bodies. **B:** T1-weighted image demonstrates decreased signal throughout the second and third lumbar vertebra-disc-vertebra unit. **C:** T2-weighted image demonstrates narrowing of the intervertebral disc between the second and third lumbar vertebral bodies with increased signal in the adjacent end plates and posterior soft tissues. **D:** Gadolinium-enhanced T1-weighted image demonstrates high-intensity signal in areas corresponding to those enhancing on T2-weighted images. The patient was ambulating normally within 48 hours of the initiation of treatment with parenteral cefazolin.

Diagnosis

History

Young children cannot communicate their symptoms, and often the presentation is nonspecific. The clinical subgroups described by Puig Guri continue to be useful (41 ,58).

Failure to Walk Syndrome

Children younger than 3 years of age who cannot accurately verbalize their complaints often present with apparent dysfunction of the lower extremities or failure to walk. The alarming chronology of a previously normal child suddenly being unable to walk often led to an extensive, misguided workup in the era before bone scans. Occasionally, the child was admitted to the neurology service because of a fear of impending paraplegia, and studies such as myelograms were performed. The series of clinical, radiographic, and even exploratory abdominal procedures used to evaluate these patients is, in retrospect, quite remarkable.

Abdominal Pain Syndrome

Somewhat older children (3 to 8 years of age) often have pain referred to the abdomen, particularly with low thoracic lesions. In the past, these children underwent a variety of complex studies including upper and lower gastrointestinal studies, intravenous pyelograms, even inferior venacavograms (Fig. 6). Occasionally, these patients had exploratory laparotomies for a suspected inflamed retrocecal appendix or psoas abscess (58). The prevalence of psoas inflammation noted on MRI may explain, in part, the presentation with abdominal symptoms.

Back Pain Syndrome

Teenagers with spondylitis are more likely to have specific back pain, but those with lumbar involvement often present with a "disc pattern," with discomfort radiating into the legs.

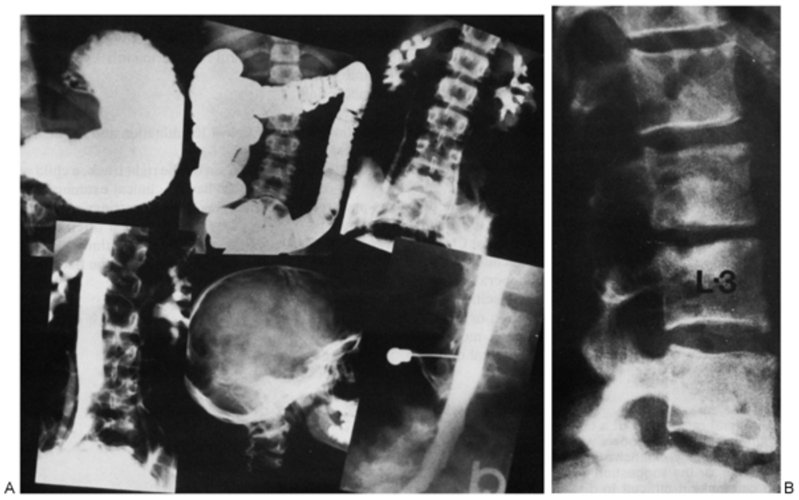

FIGURE 6. A: Multiple studies (including an inferior venacavogram) ordered in a 10-year-old with abdominal pain in the era before bone scanning. **B:** The patient was later found to have L2 to L3 pyogenic infectious spondylitis.

Physical Examination

A child with possible pyogenic infectious spondylitis should have a clinical examination, which often demonstrates tight hamstrings or positive straight-leg raising test (Fig. 7). The child often has a characteristic loss of normal “spinal rhythm.” When the child is asked to pick up a toy from the floor, the back is held in an abnormally stiff posture rather than the usually smooth flexion and extension.

Diagnostic Tests

Although younger children often present with a nonspecific presentation, the possibility of a skeletal infection is usually considered, particularly if the erythrocyte sedimentation rate or C-reactive protein level is elevated. If symptoms or signs can be localized to the spine, radiographs should be ordered; however, during the early stages of the illness, the process may not be apparent (Fig. 8).

This nonspecific presentation makes a bone scan the best choice for diagnostic imaging (Fig. 9). MRI is more specific, may be more sensitive, and can define the extent of the process, but it should not be obtained before the bone scan unless the process can be clearly localized to the spine by history or examination.

It is important to draw blood cultures because they may isolate the causative organism in many patients. A direct biopsy is probably not necessary on a routine basis because most of the organisms known to cause pyogenic infectious spondylitis in children are sensitive to first-generation cephalosporins. In areas with a large percentage of cases of methacillin-resistant *S. aureus*, needle biopsy may need to be considered to confirm the antibiotic sensitivity of the organism.

Differential Diagnosis

Although classic pyogenic infectious spondylitis has a relatively distinct clinical and radiographic pattern, other disorders to consider include Scheuermann kyphosis, tuberculosis, atypical bacterial or fungal infection, spinal epidural abscess, vertebra plana (Fig. 10), kyphosis (failure to segment anteriorly), osteoid osteoma, and rarely a malignant disease (primary vertebral body malignancy, metastatic disease, or leukemia with vertebral involvement).

Tuberculosis

Not all infectious spondylitis is bacterial. In the border regions of the Southwest United States, tuberculosis is still relatively common (Fig. 11). Before 1985, tuberculosis was considered to be under control in the United States, with most tuberculosis sanatoriums having been closed or reduced in size years earlier. However, a substantial increase in the incidence of new cases was reported in the late 1980s and early 1990s, with 26,283 new active cases reported in the United States in 1991, a 2.3% increase over 1990. In California, 3,500 active cases were reported in 1990, rising to 5,273 active cases in 1991 (38). Many social factors have caused the recent rapid increase in the incidence of tuberculosis, including immigration of infected foreign nationals, increased intravenous drug use, greater homelessness, the AIDS epidemic, and increased poverty (especially among children). These factors have led us to have a much higher suspicion of tuberculosis in children with back disorders. The most recent data suggest that increased awareness of these factors led to a stabilization of the incidence of tuberculosis in the late 1990s. The clinical history, a tuberculin skin test, and a chest radiograph help make the diagnosis. Other chronic granulomatous infections, such as brucellosis, must also be considered. In the era of empiric antibiotic treatment for spondylitis, physicians must remember that patients who fail to respond may require further diagnostic workup, including aspiration, open biopsy, or both, to establish the bacteriologic agent.

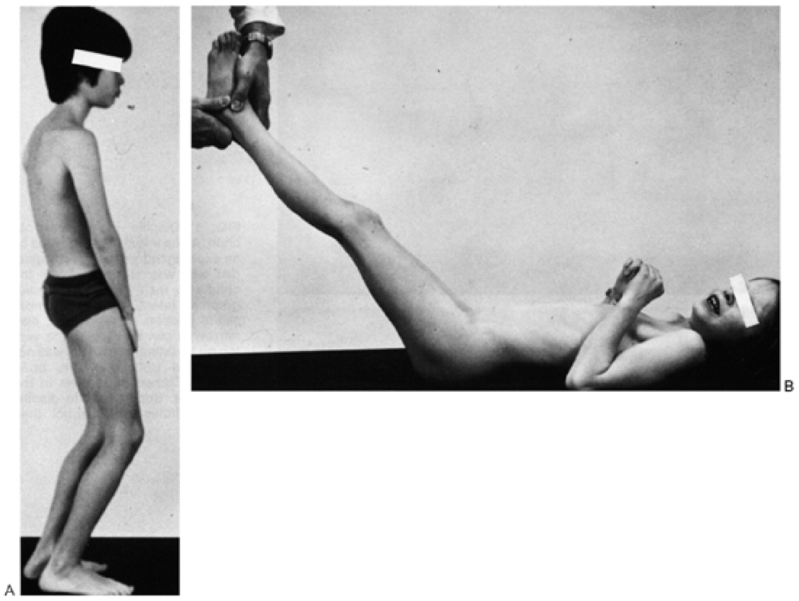

FIGURE 7. A: Child with pyogenic infectious spondylitis and abnormal posture due to tight hamstrings. **B:** Another child with pyogenic infectious spondylitis and a markedly positive straight-leg raising test.

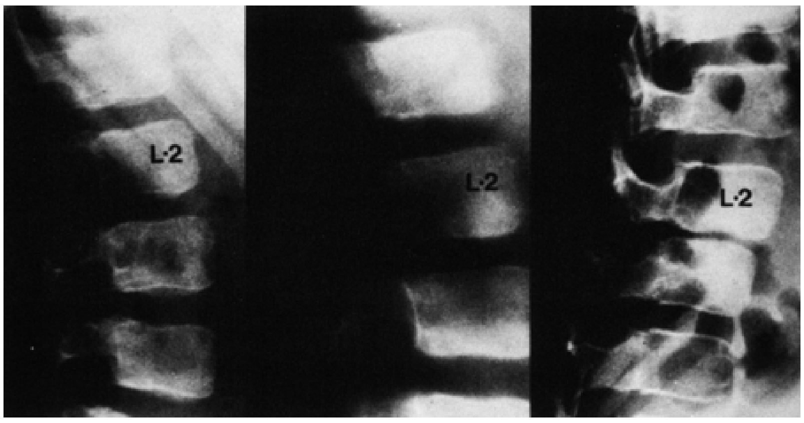

FIGURE 8. Radiographs in a 5-year-old with L2 to L3 pyogenic infectious spondylitis. The original films *(left)* and tomogram *(center)* were interpreted as normal. Two months later, marked disc narrowing was noted *(right)*.

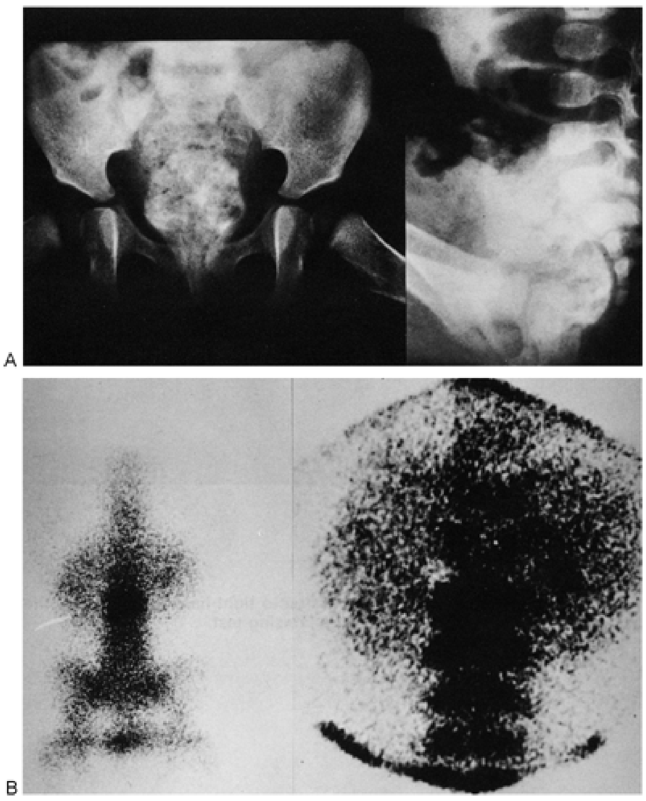

FIGURE 9. Pyogenic infectious spondylitis in a 2-year-old child. **A:** The initial films, ordered by an experienced pediatric orthopaedist who was worried about the child's hip, included a pelvis radiograph and lateral view of the lumbosacral junction. In retrospect, disc narrowing can be seen at the very top on the lateral view. This was not recognized until after the bone scan. **B:** Classic bone scan in the same case. Bone scans in pyogenic infectious spondylitis are sometimes less distinct than this.

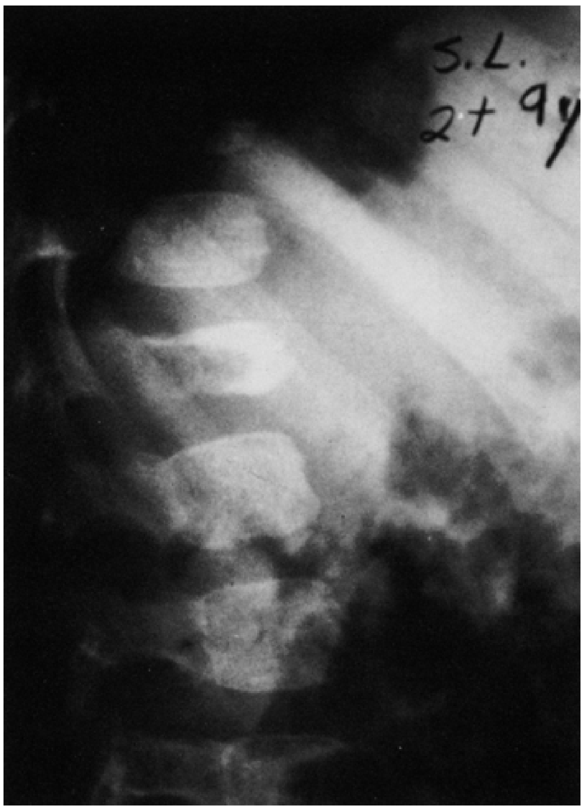

FIGURE 10. Three-year-old with vertebra plana. Because of an uncertain clinical picture (elevated sedimentation rate), the diagnosis of eosinophilic granuloma was confirmed by a computed tomography-guided needle biopsy.

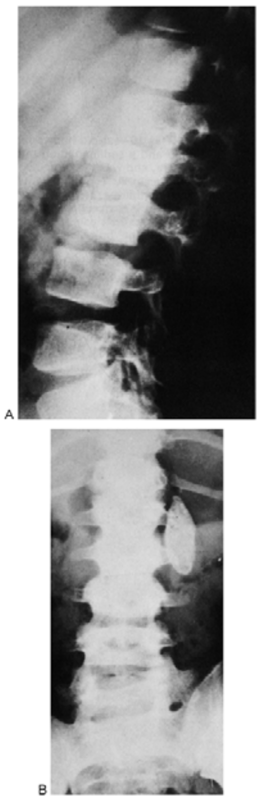

FIGURE 11. Ten-year-old with backache. **A:** The lateral radiograph shows loss of the disc space in the upper lumbar spine plus early vertebral wedging. **B:** The anteroposterior view shows a calcified psoas abscess, characteristic of established tuberculosis.

Other Disorders

Other disorders may present as back pain and require clarification by a bone scan. Disorders of the genitourinary tract are commonly identified, and the patient is referred to a urologist. Sacroiliac joint infections also cause obscure back pain and are best diagnosed by a bone scan. These patients have back, hip, and buttock pain; a positive Faber test; and pain with pelvic compression. The bone scan is often classic and diagnostic; sometimes, however, the scan is only minimally asymmetric, and a gallium scan or MRI may be required to confirm the diagnosis. We have seen several children whose early bone scans were normal but whose subsequent MRI studies demonstrated classic sacroiliac joint infection. Neoplasms may also present as nonspecific back pain. The history, physical examination, laboratory, and—in particular—imaging studies (notably MRI) are usually characteristic for these disorders and distinct from pyogenic infectious spondylitis. Any case that features substantial collapse, involvement of a single vertebra, or other uncharacteristic findings may merit a diagnostic biopsy.

Treatment

After the diagnosis of spondylitis has been established by a bone scan or MRI, blood cultures should be drawn and tuberculosis excluded by a skin test and chest radiograph if indicated. Because blood cultures are often negative and needle aspiration or biopsy is usually not indicated, an empiric course of intravenous antibiotics that covers *S. aureus* (usually a first-generation cephalosporin) is begun. Parenteral antibiotics are continued until the symptoms are largely relieved and the laboratory values approach normal. In most cases, after 3 or 4 days, a child who was unable to walk before treatment will be moving freely around the bed and, if allowed, walking around the room. Parental antibiotic therapy is followed by a 4- to 6-week course of oral antibiotics.

Large oral doses of cephalosporins have been recommended for the outpatient treatment of skeletal infections. It is unclear whether or not this is important in the treatment of pediatric pyogenic infectious spondylitis (6 ,7). The data from our series suggest that standard doses may suffice after appropriate treatment with parenteral antibiotics (45). Treatment with oral antibiotics alone may increase the risk for prolonged or recurrent symptoms or for development of an abscess requiring operative drainage. Compliance is always an issue with oral antibiotic regimens in children, particularly when large doses are prescribed.

A few cases will not respond to antibiotics and require acute surgical drainage. Figure 12 demonstrates a child with a classic bone scan for spondylitis who was placed on intravenous cephalosporin but continued to have a high fever and refused to walk. An MRI study showed a probable paraspinal abscess. Anterior exploration through a retroperitoneal approach revealed chronic edema and granulation tissue both near and within the disc, which was curetted and drained. The patient rapidly became afebrile and resumed walking. In a few cases, the disc narrowing is marked and the patient continues to have low-grade classic symptoms (Figs. 13 and 14). In two of 38 patients in our Toronto series, late anterior disc curettement and fusion were required to relieve symptoms. One case was in the cervical spine and the other in the midlumbar spine. In both cases, *S. aureus* was cultured from the anterior approach.

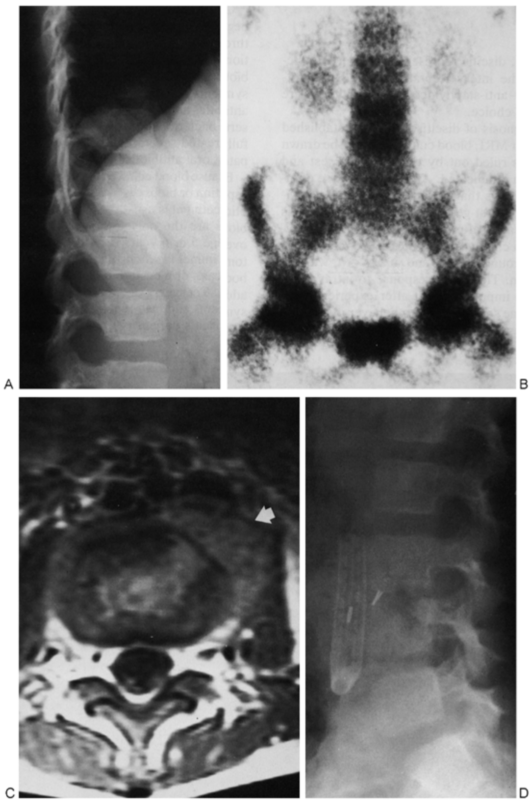

FIGURE 12. Several studies in a 4-year-old child with pyogenic infectious spondylitis who failed to respond to intravenous antibiotics. **A:** Plain lateral lumbar spine films were read as normal. **B:** The bone scan shows classic changes of L3 to L4 pyogenic infectious spondylitis, with a question of increased uptake in L2 as well. **C:** After the patient's failure to respond to antibiotic treatment, a magnetic resonance image was ordered, which demonstrates a paravertebral abscess *(arrow)*. **D:** Lateral radiograph after surgical drainage through an anterolateral retroperitoneal approach. The Jackson-Pratt drain is noted. The L3 to L4 disc is now narrowed. The culture grew *Staphylococcus aureus*.

Because deformity is uncommon and symptoms resolve rapidly with intravenous antibiotics, there appears to be little role for immobilization of the spine with a cast or brace (2 ,18 ,20 ,28 ,36 ,39). We prescribe temporary bracing for symptomatic relief on occasion. In juveniles and adolescents, back pain may be more prolonged and a corset or back brace may be required for several weeks. All patients should be followed for at least 1 year, with serial radiographs usually showing a continued but not complete narrowing of the disc (Fig. 15). In rare cases, the disc narrowing is marked; in others, there is partial reconstitution.

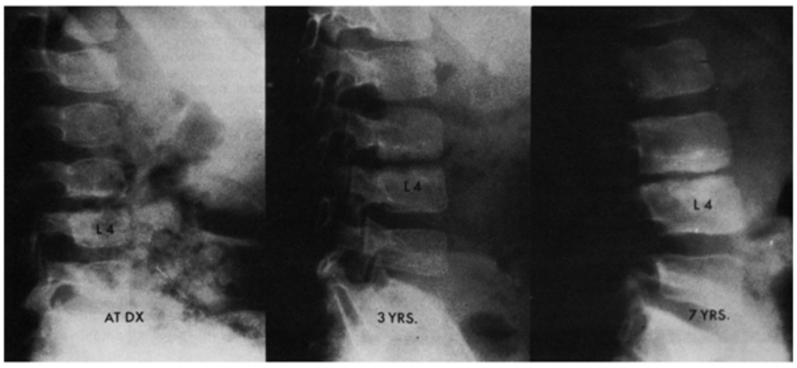

FIGURE 13. Early and late radiographs in a 6-year-old boy who continued to have back pain 9 months after onset. He eventually required anterior spinal fusion, and *Staphylococcus aureus* grew on the culture of the débrided L3 to L4 disc material.

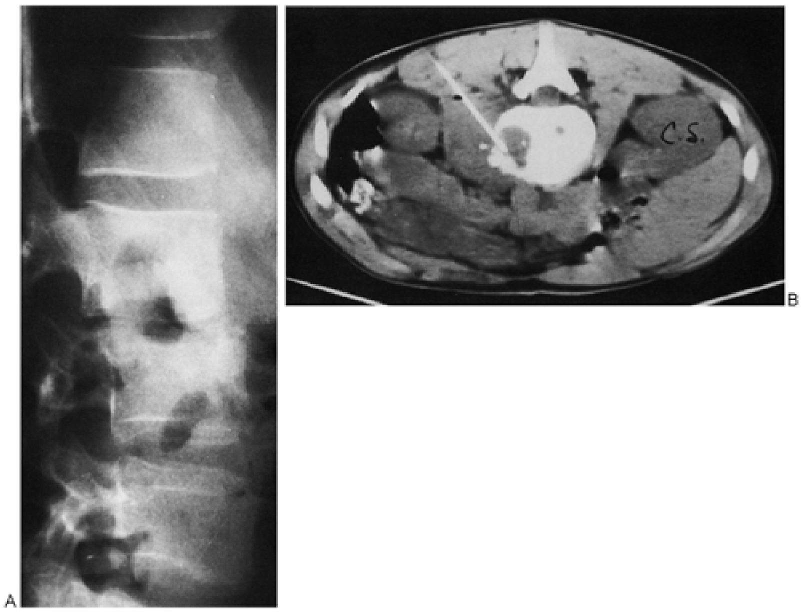

FIGURE 14. Fifteen-year-old boy with pyogenic infectious spondylitis. **A:** Plain radiographs show marked loss of disc space and suggested vertebral body involvement. **B:** Computed tomography–guided needle biopsy of lytic process in vertebral body near the end plate. *Staphylococcus aureus* grew on culture.

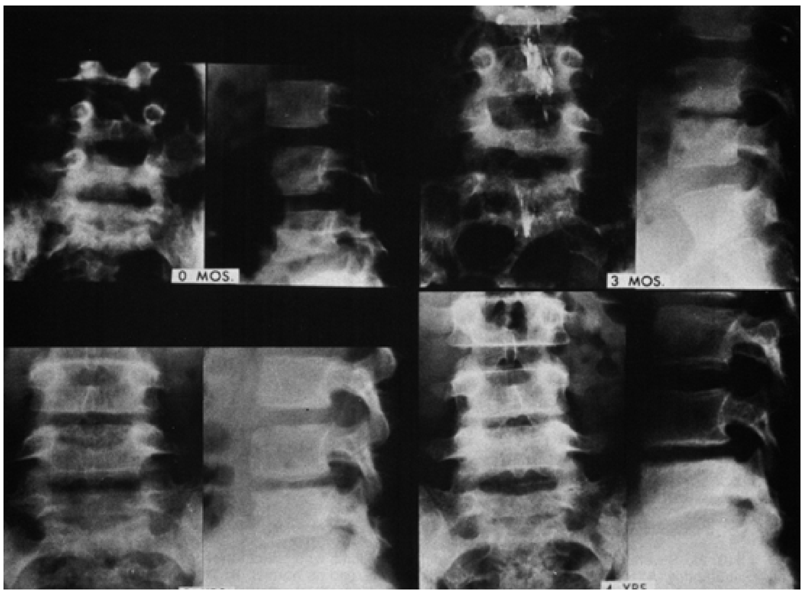

FIGURE 15. Radiographic chronology of L4 to L5 pyogenic infectious spondylitis in a child diagnosed at 4 years of age treated with antibiotics. The radiographic changes at baseline, 3 months, 2 years, and 4 years after onset are shown. The partial but not complete restoration of disc space height is typical of pyogenic infectious spondylitis in children.

Summary

The evaluation and treatment of pyogenic infectious spondylitis in children has greatly improved. The ability to make an early diagnosis has been aided by an increased awareness of the disorder and an understanding of its presenting patterns. The use of the radionuclide bone scan was a landmark event that has made early diagnosis more likely. The MRI has further advanced the ability to make an early correct diagnosis to understand the pathophysiology of the disorder with both vertebral body and disc involvement. The MRI is now the most specific noninvasive diagnostic tool for evaluating childhood spinal infection; however, the bone scan remains the best screening study when the presentation and symptoms are not specific.

The rapid response of severely symptomatic spondylitis patients to intravenous antibiotics that cover S. *aureus* provides convincing evidence that the condition is bacterial in most cases. Although a few centers continue to treat this condition with immobilization alone, we believe that such treatment is not specific and should not be the first choice.

Tuberculosis of the Spine

Keith D. K. Luk

John C. Y. Leong

Eric K. W. Ho

K.D.K. Luk, J.C.Y. Leong, and E.K.W. Ho: Department of Orthopaedic Surgery, University of Hong Kong, Queen Mary Hospital, Hong Kong.

The history of treatment of tuberculosis of the spine has gone through several stages. The classic scientific description of the disease by Percival Pott in 1779 (35) was an important step in its recognition as a distinct entity. Advances in treatment of tuberculosis of the spine were marked by two events. First was the description of the anterior surgical approach to the spine, a direct approach to the disease focus, first described by Ito and colleagues (20) in 1934. The second major event was the introduction of antituberculous chemotherapy in 1954.

Today, spinal tuberculosis poses the following problems:

- ixDiagnostic difficulty in industrialized countries because of its rarity, although the disease is appearing again in immunocompromised patients with chronic alcoholism and AIDS. In third-world countries, the disease is common, often involving complications and gross deformity. In children, when a significant number of vertebrae are involved, spinal deformity ultimately appears; with time, paraplegia of healed disease may also occur.
- Drug resistance in endemic areas
- Controversy over the best modality of treatment, that is surgical versus conservative management, especially in children in relation to spinal deformity progression

Epidemiology

The prevalence of this disease is inversely proportional to the socioeconomic background of the patient and the standard of public health in the area.

Despite advances in medical technology, the diagnosis of spinal tuberculosis is sometimes missed. Because the initial presentation is varied, its inclusion in the differential diagnosis of any spinal pathology is essential in industrialized countries. In third-world countries, the cases usually present late, with little diagnostic problem. In these late-presenting cases, however, the surgeon faces the problems of a patient with significant disease involvement, possible neurologic complications, and gross spinal deformity. These patients require expert management, which is usually available only in specialized centers with access to chemotherapy and experienced spinal surgeons.

Spinal tuberculosis is common in children, particularly in countries in which the disease is prevalent. The “childhood” type of disease is more malignant in extent and degree of abscess formation but has less associated paraplegia; the reverse is usually the case in the adult type (19). This may be related to differences in the immunologic response of children and adults.

Bacteriology and Pathology

Spinal tuberculosis is the result of infection by *Mycobacterium tuberculosis.* It is usually a secondary infection, with the primary extraspinal lesion usually occurring in the chest or genitourinary system. These primary sites may be quiescent (9). Spread of the organism through the lymphatics at the corresponding anatomic levels—for example, tuberculosis of the kidney spreading to the dorsolumbar junction—is possible. It may also spread by direct adjacent visceral extension.

In a vertebral segment, three patterns of involvement are recognized: paradiscal, anterior, and central lesions. The understanding of these patterns is important in appreciating the presentation of this disease. A *paradiscal* lesion is a lesion on either side of the intervertebral disc, usually with some narrowing of the intervertebral disc space. It is the most common pattern and is more common in adults than children. Bone infarction, necrosis, and impaction lead to decrease in vertebral size, which, if significant, may cause a kyphotic deformity. Paravertebral abscesses may develop (Fig. 4A). When the disease is healed, osseous interbody fusion occurs, especially in the presence of sinus discharge and superinfection by pyogenic bacteria.

An *anterior* lesion occurs with bony destruction under the anterior longitudinal ligament. With increasing accumulation in the abscess, tension rises and strips off the anterior longitudinal ligament and periosteum from the anterior surface of the vertebral body. Anterior scalloping occurs most commonly in the thoracic spine in children (Fig. 1B). There is minimal bone destruction, and kyphotic deformity is rare.

The *central* lesion, which is more common in children than in adults, generally involves the whole body. Vertebral collapse occurs (vertebra plana). This pattern of involvement is most likely to produce a kyphosis. The more vertebral bodies affected, the greater the severity of the kyphosis (37) (Fig. 6A).

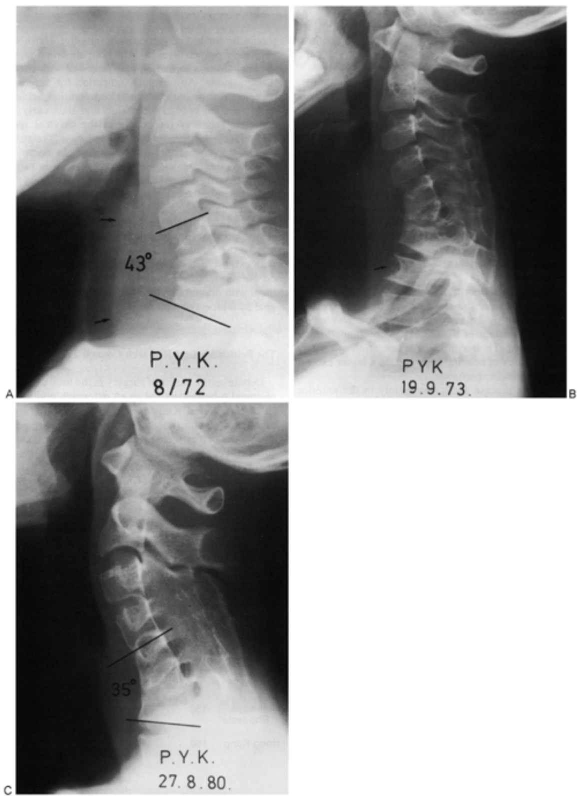

FIGURE 1. A: Preoperative radiograph of a 3-year-old boy with tuberculous involvement of C5 to C7. He presented with fever and refusal to eat. There is extensive prevertebral soft tissue swelling, indicating abscess formation *(arrow)*. There is significant corporeal destruction of C5, C6, and the upper part of C7, which resulted in a kyphosis. Speckles of calcification are present just in front of the C6–7 disc space. **B:** Radiograph taken 1 year after staged anterior and posterior spinal fusion from C4 to C7. There is spontaneous posterior fusion of C3 to C4 *(arrow)*. Some correction of kyphos has been obtained by insertion of oversized graft. Scalloping of T1 is present *(arrow)*. **C:** Postoperative radiograph at 7 years showing solid fusion circumferentially over C4 to C7 and posterior fusion over C3 to C4. The initial preoperative kyphos has been reduced. The aneurysmal effect of the abscess on T1 has resolved.

Tuberculous infection of the posterior elements of the spine is rare. The use of computed tomography (CT) scanning or magnetic resonance imaging (MRI) is helpful in making the diagnosis of posterior involvement (2).

The most frequent site of spinal tuberculosis is the thoracolumbar junction and the adjacent segments. Involvement of more than one segment is common (Fig. 4A). Sometimes, there is concomitant infection of the lumbar spine and the hip, especially in fulminating cases. Classically, a localized kyphosis at the thoracic or thoracolumbar junction appears. In the lumbar spine, there is loss of lumbar lordosis. Scoliosis may appear if bony destruction is asymmetric. A bayonet deformity and subluxation or dislocation may occur. With gross vertebral destruction, a reverse spondylolisthesis type of malalignment may also occur.

Unlike pyogenic infections, which destroy tissues by proteolytic enzymes, tuberculous infections causes destruction through a delayed hypersensitivity reaction of the body. This explains the typical low bacterial count within an active lesion. The actual sequence of infection in a spinal segment progresses from the “pre-pus” phase to paraspinal abscess formation. As the abscess expands, propagation of the abscess along the plane of least resistance (causing superficial abscess formation) or rupture into adjacent organs can occur. Healing produces fibrosis and bony reactions. If these consequences of healing take place in front of the vertebral body, bony bridging occurs. When the posterior part of the vertebral body is involved, paraplegia may result.

The pre-pus phase is the initial stage, characterized by granulation tissue proliferation. Histologically, epithelioid, round, and giant cells are evident. With proliferation of these cells and their disintegration, pus forms, leading to a paraspinal abscess.

The presence of a paraspinal abscess indicates an active disease. An abscess should be easy to diagnose. Hodgson (11) pointed out that about 10% of abscesses were missed clinically and were subsequently diagnosed at surgery. In the early stage, the pus is usually yellowish fluid; it eventually turns solid white and caseous. A large abscess, because of its mechanical effect, strips off the periosteum circumferentially. The blood supply of the peripheral portion of the vertebral body suffers, and a scalloping effect is produced in the form of an aneurysmal effect (aneurysmal syndrome) (Fig. 1B). The abscess may rupture into adjacent organs, which then produce symptoms of their own. A thoracic abscess may discharge into any organ in the mediastinum. The lung is most commonly involved (10%). Before actual rupture into adjacent organs, the space-occupying effect of the abscess may cause compression of adjacent structures (Fig. 1A); for example, a cervical spinal abscess may compress the trachea, causing inspiratory stridor in a child.

With advanced disease, intervertebral disc space narrowing occurs, partly because of the lack of nutrition from the subchondral bone. The detached disc may cause compression of the spinal cord or cauda equina. Multiple-level weakening of the vertebral body results in a “concertina” type of collapse. Profound destruction of multiple vertebral segments anteriorly results in a sharp kyphosis, which is especially marked at the thoracic or thoracolumbar junction (Fig. 6A). Under favorable conditions, the granulation tissue becomes fibrotic and subsequently calcifies and then ossifies. During this process of revascularization, bone reossifies and becomes dense. All these maturing fibrotic and bony elements may cause paraplegia of healed disease (see later). Spontaneous calcification of the intervertebral disc and paravertebral ligament may also occur. The corresponding posterior elements at the level of the disease may fuse spontaneously, especially in children.

Clinical Presentation in Children

Probably because of their low immunity, tuberculosis in young children is relatively malignant in its clinical course. However, in children there is a lower incidence of paraplegia. Aside from the usual systemic manifestations of chronic infection, there are interesting and important local manifestations unique to spinal tuberculosis in children. High thoracic spinal involvement with paraspinal abscess formation in children may cause significant bronchial compression and irritation. These symptoms may simulate asthmatic bronchitis (Millar asthma), especially when the patient lies down at night. With extensive destruction of the anterior elements of the spine, a significant angular kyphos appears. With differential growth of the intact posterior elements, progressive increase in the kyphos occurs, causing more deformity and restriction of visceral function. In severe cases, this may lead to restrictive lung disease or even secondary congestive heart failure.

The actual clinical presentation depends on the stage of the disease, the location of spinal involvement, the formation of a paraspinal abscess and its associated features, any associated obvious primary tuberculous manifestation (e.g., tuberculosis of the genitourinary tract), the immunologic status of the child, and prior antituberculous therapy. Neurologic involvement further complicates presentation by producing signs of meningitis, gait disturbance (psoas irritation), or frank paraparesis or tetraparesis and paraplegia or tetraplegia. Extreme spasticity in the limbs is associated with meningomyelitis caused by direct invasion of the meninges and neural tissue by the infected material. In patients with excessive systemic reactions, spinal involvement is part of disseminated tuberculosis.

Pott's paraplegia is a serious complication whose incidence averages about 10% (12). It is actually becoming rare in affluent countries, where presentation and diagnosis are made early and treatment is begun promptly. Classification into early and late types has been used by other authors (10 ,39), but we propose a more clinicopathologically oriented classification (15) (Table 1).

Healed disease often still harbors active infection. In a review of 22 cases of paraplegia of late onset (18), two thirds of patients still had active disease. This active disease group with late-onset paraplegia has a slightly better prognosis than the inactive healed disease group, in which neural compression is strictly mechanical in origin (because of fibrosis or anterior bony bridge).

TABLE 1. Clinical-Pathologic Classification of Pott's Paraplegia

Pathology	Cause of Paraplegia	Presentation	Prognosis
Active disease	Pus, sequestra, sequestrated disc, granulation tissue; increased contents, subluxation, dislocation, vertebral collapse	Paraparesis or paraplegia	Good with early treatment especially surgical decompression.
Active disease	Dural penetration, direct neural involvement; pachymeningitis, meningomyelitis	Signs of meningitis, extreme spasticity	Poor
Active disease	Compression from diseased posterior elements; data lacking	Same as for anterior element destruction	Rare
Healed disease	New bone healing replaces diseased bone, especially in spontaneous healing; anterior bony bridge is retropulsed and matures	Paraplegia (late onset)	Poor
Healed disease	Maturation of fibrous component of granulation tissue; slow mechanical strangulation of cord	Distal sensory and motor symptoms	Poor

Diagnosis

Diagnosis may be difficult in children, especially in the early stages of the disease. Systemic symptoms are similar to those of pyogenic infections, including malaise, easy fatigability, weight and appetite loss, and sometimes fever. Frank septicemia is uncommon. The most common local manifestation is pain over the involved spinal segment and a kyphosis. Advanced disease in a child may also produce a limping gait as a result of psoas irritation or weakness caused by Pott's paraplegia. A child presenting with additional respiratory embarrassment may have one of three complications: concomitant pulmonary tuberculosis, rupture of thoracic paraspinal abscess into the lung, or Millar asthma.

Radiologic manifestations can be bizarre and mimic many spinal lesions. The classic radiologic description depends on the site of infection. In central disease, which is common in children, a concertina type of collapse may appear, and clinically, there is paraplegia. Occasionally, a ballooning effect is seen instead. Because most parts of the vertebral body are affected, the products of inflammation expand the weakened vertebral wall, depicting an expansile lesion on the radiograph. Paradiscal disease is less common in children. Narrowing of intervertebral disc mimics discitis. Anterior disease signifies a spreading abscess. This phenomenon is common in children, especially in the thoracic spine, but it may be present anywhere in the spinal column. In healed disease, vertebral bodies sometimes have spontaneous fusion, simulating a hemivertebra (Fig. 2C, D). The vertebra-within-a-vertebra phenomenon (manifestation of arrested bone growth) may also be seen on radiographs. These radiologic features of tuberculosis of the spine have been well described by Hodgson and colleagues (16). Buchelt and associates (4), however, reported that many of these findings in plain radiographs are not pathognomonic of tuberculous infection and thus that differentiation from pyogenic spondylitis can sometimes be difficult.

There are other interesting changes in the segments of the spine adjacent to the acute kyphosis, especially in growing children. The vertebral bodies just above the kyphos lie more horizontally than usual. Because of a weight-relieving effect, the vertebral body increases in height. The anterior length of the vertebral body is also longer than its posterior length. This phenomenon is observed both radiologically and morphologically in postmortem studies. In addition to early narrowing of the intervertebral disc, calcification of the nucleus pulposus may occur but is rare. In children with gross thoracic kyphotic deformity, there may be lengthening of ribs and narrowing of their posterior portions.

In addition to plain radiographs, other useful investigations include myelographic studies, which are essential in patients with neurologic compression when compression at the internal kyphos needs to be demonstrated (Fig. 5A). Tomograms are useful to visualize the kyphos and ascertain the presence of a spontaneous posterior fusion. They are also useful at the upper dorsal and sacral areas to delineate the overlapping effect of the overlying bone. CT scans are helpful in demonstrating the extent of bony involvement, and sagittal reconstructions are useful in delineating the internal kyphos (Fig. 5B). Involvement of the posterior elements is also demonstrated by CT scan. An MRI investigation is useful to delineate the soft tissue involvement, concomitant abscess formation, and neural compression. A rim enhancement with contrast on a T2-weighted image helps in differentiating infections from a malignant condition (17) (Fig. 3A–D). A chest radiograph is necessary in cases of suspected pulmonary tuberculosis or rupture of abscess into the lungs.

Scintigraphic studies have low specificity and sensitivity, and the pattern of uptake can be similar to that seen in metastatic disease (43).

The erythrocyte sedimentation rate is a simple test that is useful for monitoring the progress of the disease. The Tine skin test is not specific in diagnosis, especially in endemic areas, where the chance of previous subclinical exposure to tuberculous infection is high.

The definitive diagnosis for inclusion into the MRC trial requires a positive culture and histology report on specimens obtained during surgery. With the advent of CT guidance and thoracoscopic or endoscopic assistance, biopsies can now be obtained easily in doubtful cases. Ziehl-Neelsen staining is helpful but was positive in only 47% of histologically proven specimens. Of these 47%, only 85% yielded a positive culture for the mycobacterium. Of the remaining 53% negative but histologically proven specimens, 87% yielded a positive culture for the mycobacterium.

A positive bacterial culture is thus indicative but not absolutely essential for a firm diagnosis of spinal tuberculosis. The confirmation of spinal tuberculosis is especially difficult for healing of chronic lesions. This is partly explained by the presence of fewer bacilli in osseous tuberculosis than in tuberculosis of organs such as the lung. In these cases with a low bacterial load, the polymerase chain reaction test (3 ,34 ,40), which involves amplification of the mycobacterium DNA in biopsy specimens, has been considered the most important breakthrough in the field of diagnostic mycobacteriology. The technique, however, still has limitations, especially in detecting extrapulmonary lesions (5).

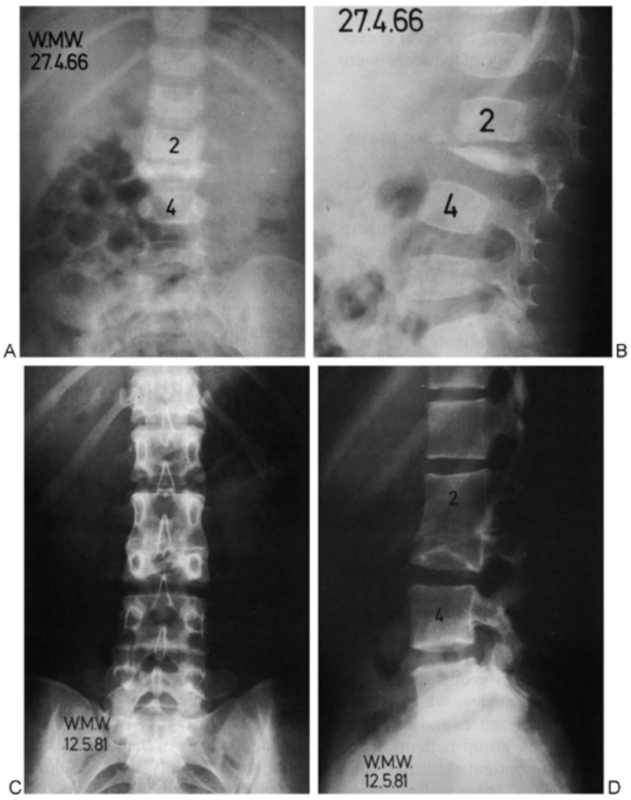

FIGURE 2. A, B: Preoperative radiographs of a 5½-year-old boy with spinal tuberculosis affecting mainly L3. Only the lower portion of L3 remains. The abscess detected at surgery was hardly visible on preoperative radiographs. **C, D:** Postoperative radiographs at 15 years follow-up after the Hong Kong operation at L2 to L3, showing total solid fusion simulating a congenital block vertebra. The inferior portion of L3 appears to have regenerated to some extent despite gross initial destruction. There is minimal kyphosis.

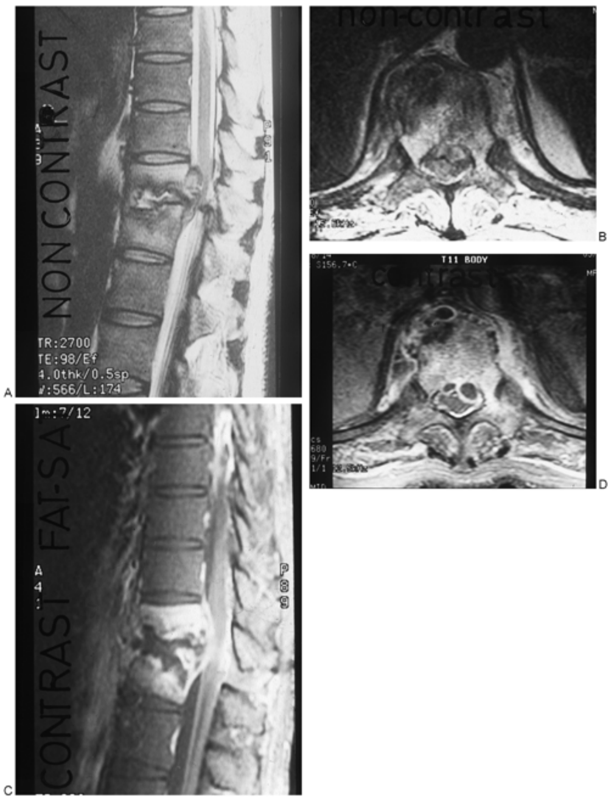

FIGURE 3. Magnetic resonance imaging study of a 25-year-old man with tuberculosis of the thoracic spine presenting with paraparesis of both lower limbs. Sagittal **(A)** and cross-section **(B)** T2-weighted images showing an abscess opposite T11 compressing the spinal cord. Note the hypointense signal of the abscess. Sagittal **(C)** and cross-section **(D)** images at the same levels after intravenous gadolinium infusion with fat-saturation sequence. The enhancement at the rim of the abscess is diagnostic of an infection.

Treatment

The basic treatment of all forms of active spinal tuberculosis is a complete course of chemotherapy. This consists of an initial first-line drug regimen: streptomycin, isoniazid, and rifampicin. The second-line regimen (ethambutol, pyrazinamide) may be necessary in cases of poor clinical-hematologic response, side effects, or demonstrable resistance of bacillus to the first-line drugs. (Readers are advised to consult pharmaceutical texts for dosage, side effects, and duration of the drugs mentioned.) The first-line drug regimen should be started 1 week before surgery, if feasible. Close collaboration between orthopedic surgeons and physicians improves the efficiency of drug delivery and patients' compliance with this prolonged chemotherapy. A short-course chemotherapy regimen has also been accepted (1). In a prospective controlled trial conducted in Korea by the Medical Research Council (MRC) on the duration of chemotherapy, 265 patients were randomly allocated to four chemotherapy regimens. The conclusion was that isoniazid plus rifampicin for 6 or 9 months was effective and as successful as the 18-month regimen of isoniazid plus paraaminosalicylic acid or ethambutol (31). This recommendation of a shorter regimen may improve the drug compliance of the patients.

Indications for chemotherapy alone (without surgery) are few. The medically unfit, high-risk patient should be treated conservatively initially. Those with early proven disease, little bony destruction, and minimal abscess formation may fare well with chemotherapy alone. Classically, chemotherapy and surgery to immobilize the spine were the standard treatment. A regimen of chemotherapy without immobilization was advocated by some authors in the early 1960s, partly because of lack of hospital beds and, to a lesser extent, lack of surgical expertise.

With advances in surgery and anesthetic technique, various surgical procedures to treat spinal tuberculosis have been developed over the years. Except in cases of demonstrated posterior element involvement (which is rare), almost all posterior surgery has been abandoned, and posterior decompression alone is mentioned to be condemned. Modified costotransversectomy still has a place when decompression of the internal kyphos is necessary in an extremely kyphotic spine. In these cases, the internal kyphos is deeply seated and therefore difficult to approach anteriorly. A costotransversectomy also avoids a formal thoracotomy in patients with already compromised lung function.

Because the disease focus lies mainly in the anterior bony column, it is rational to use an anterior approach. Hodgson and Stock (13) popularized such an approach in spinal tuberculosis in nearly all segments of the spine. The concept of having a direct approach to the disease focus satisfies the following aims: complete extirpation of the disease focus and the ability to place a strut graft into the débrided cavity.

Extirpation of the disease focus obtains diseased material for diagnosis. After evacuation of the abscess and thorough débridement, pain relief is almost immediate, and the general condition of the patient often improves markedly. Early complete débridement also prevents spread of the abscess to adjacent spinal segments. Débridement quickly decompresses any neural or visceral compression. During an anterior spinal approach, exposure and confirmation of organ penetration can be made and sometimes dealt with simultaneously.

The placement of a strut graft into the débrided cavity under compression allows for hypertrophy of the graft according to Wolff's law. Early fusion generally results (Fig. 4B, C). After solid anterior fusion has been achieved, late recurrence is rare; increasing spinal deformity and paraplegia of healed disease are avoided. Moreover, a slightly oversized graft produces some correction of kyphosis (Fig. 1A–C). Using this regimen, Hodgson and Stock (14) achieved complete recovery from spinal disease in almost all cases. The fusion rate was 93%.

An absolute indication for surgery is paraplegia of active disease. The operation achieves rapid relief of cord compression and thus early and complete recovery (especially in the cervical spine) (19). In fact, this surgery for active disease is relatively simple, and the results are rewarding. In paraplegia of healed disease, surgical decompression is usually difficult partly because of the gross deformity and partly because the compression is caused by hard bony ridges or diffuse fibrosis. In special cases of technical difficulty, stabilization procedures without decompression to prevent further deterioration of the paraparesis may be the solution of last resort. In children with extensive disease who are critically ill, radical excision may not be practical. In these cases, débridement with drainage of the abscess should be the initial goal as a life-saving measure.

The British Medical Research Council Trial

Debate on the merits of surgery in the total treatment of spinal tuberculosis led to an extensive multicenter study in 1965, initiated by the Medical Research Council of the United Kingdom (23 ,24 ,25 ,26 ,27 ,28 ,29 ,30 ,31 ,32). This study was based on well-controlled clinical trials comparing various modes of treatment (Table 2). The results of subsequent 10-year and 15-year follow-ups have clearly defined the role of surgery in spinal tuberculosis.

Groups of patients from Korea, Rhodesia, and Hong Kong were studied. All patients had at least 18 months of either a two-drug (INAH and PAS) or a three-drug (streptomycin, INAH, and PAS) regimen. These three groups were fairly homogeneous in their pretreatment factors, except that the Korean patients were all children; 82% of Rhodesian and 54% of Hong Kong patients were adults. The criterion for inclusion in the study was the presence of clinical and radiologic evidence of active spinal tuberculosis at any level except the cervical spine. Four categories of patients were excluded:

- Those with significant paralysis, such that the patient could not walk across a room
- Patients having 1 year or more of antituberculous chemotherapy
- Those in whom the presence of concomitant serious extraspinal disease was likely to affect the total management of a patient
- In Hong Kong, those with extensive destruction of three or more vertebral bodies because fusion by itself was justified in those patients

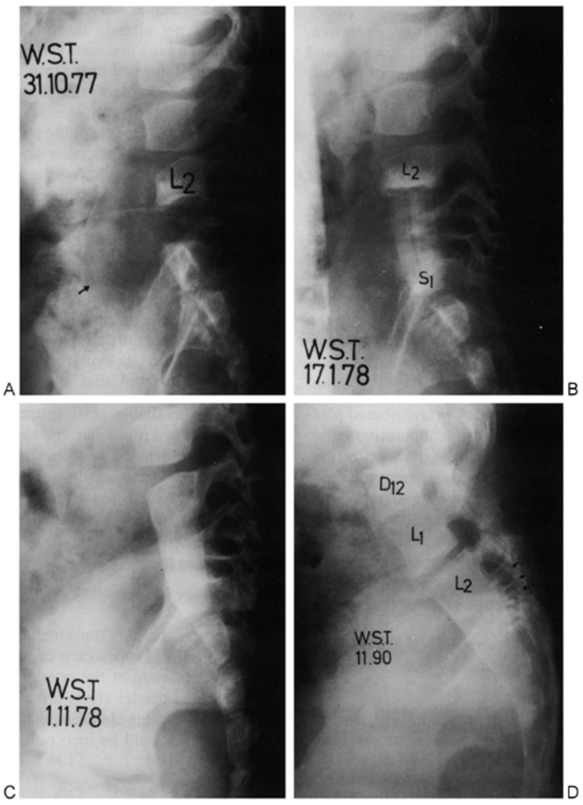

FIGURE 4. A: Preoperative radiograph of a 7-year-old boy with tuberculous involvement of the lower border of L2 to probably S2. The parents noticed a swelling over the child's back at 4 years of age, when a complete course of antituberculous chemotherapy was given. He developed a discharging groin sinus at about the time this radiograph was taken. This preoperative radiograph shows gross bony destruction of L3, L4, L5, and S1, with sparing of the posterior elements. A soft tissue swelling *(arrow)* is present. There is no significant kyphosis. **B:** Postoperative radiograph taken 4 months after anterior spinal débridement and circumferential fusion. The anterior grafts used were ribs obtained during thoracotomy. **C:** Radiograph taken 1 year postoperatively, showing no collapse of the graft. It also shows very good graft incorporation. There is no kyphosis. **D:** Radiograph at 13 years follow-up showing solid circumferential fusion from L2 to the sacrum. The remnant of the posterior element of the missing segments is still visible *(arrow)*. The patient is totally asymptomatic except for a shortened trunk.

TABLE 2. British Medical Research Council Protocol

Location	Number of Patients	Treatment Modality
Masan, South Korea	350 (total)	Inpatient bed rest for 6 months, then outpatient treatment; or, ambulatory outpatient treatment from the start
Pusan, South Korea	—	Outpatient treatment with a plaster jacket for 9 months, or ambulatory treatment without any support
Bulawayo, Rhodesia	130	Randomly, by débridement of spinal focus or by ambulatory treatment
Hong Kong	150	Randomly, by radical resection of lesion and insertion of autogenous bone grafts, or by débridement

The results presented at the 5-year report (28) already showed the advantage of the Hong Kong operation over other modalities of treatment, and this continued to hold true at the 10-year (29) and 15-year (32) follow-ups. Although at the final MRC report, all three groups of patients treated ([1] conservatively in Korea, [2] with débridement alone, and [3] with radical débridement plus fusion in Hong Kong) achieved the same 87% of favorable clinical results, 85% of the radical surgery group in Hong Kong had complete radiologic union at 18 months. This figure increased to 92% at 5 years, 97% at 10 years, and 94% at 15 years. The corresponding figures in Korea showed that, with conservative treatment, 54% of patients still had no signs of fusion at 5 years. The bony fusion rate remained at 73% and 72% at 10 and 15 years, respectively (Table 3).

TABLE 3. Bony Fusion Rate (%) at 5, 10, and 13 to 15 years

	0-18 mo	0-5 y	0-10 y	13-15 y
Korea				
Chemotherapy alone	15	46	73	72
Hong Kong				
Débridement alone	52	84	90	94
Débridement plus fusion	85	92	97	94

Modified from the Medical Research Council Working Party on Tuberculosis of the Spine (1998): A 15-year assessment of controlled trials of the management of tuberculosis of the spine in Korea and Hong Kong. *J Bone Joint Surg Br* 80:456–462, with permission.

Vertebral reconstitution was actually positive (0.2 of a vertebra) at 5 years in the Hong Kong group, contrasting with increased vertebral loss of 0.18 of a vertebra in the débridement group and 0.44 of a vertebra in the ambulatory chemotherapy group. These results were maintained at the 15-year follow-up.

The angle of kyphosis of the conservatively treated group showed an increase to 21 degrees at 5 years and further increased to 25 degrees at 15 years (32). About 5% of this group suffered an alarming increase in their final angles, which ranged from 51 to 70 degrees. The corresponding figures for the débridement group were 8 and 11 degrees, respectively. In contrast, the radical surgery group showed an improvement of 3 degrees at 5 years, and this was maintained at the final follow-up of 15 years. This preservation of the sagittal curvature is particularly important for the lumbar spine, where there is normally a lordosis.

Healing of sinuses and abscesses occurred in all the Hong Kong patients by 18 months. In Korea, 3% of the patients still had sinus tracts or abscesses after 5 years. There was no neurologic involvement during treatment in the Hong Kong group. In the ambulatory chemotherapy group, 5% of patients developed neurologic deficits during treatment.

The long-term follow-up report of the MRC trial confirms that the radical Hong Kong surgical approach can fulfill the aims of treatment in spinal tuberculosis. It produces rapid decompression and fusion, prevents late recurrence once healing has occurred, and, most important, prevents the development of progressive and severe deformity, which may be further complicated by paraplegia of healed disease (Fig. 2A–D).

Spinal Growth and Deformity After Fusion in Children

The MRC trial has a number of limitations. First, the results from children and adults were analyzed together; second, the long-term effect of fusion during early childhood on spinal growth was not studied; and third, diseases involving three or more bodies were excluded.

The only prospective longitudinal study on the long-term outcome of deformity in children who received radical or débridement surgery was by Upadhyay and colleagues in 1993 (41). They followed 80 children in the MRC trial in Hong Kong who underwent surgery before 10 years of age to maturity. Forty-seven had radical surgery and bone grafting at a mean age of 7.6 years, and the remaining 33 patients had débridement alone at a mean age of 5.1 years. Six months after surgery, 56% of the radical surgery group showed an improvement in the deformity angle of 5 degrees or more compared with the preoperative evaluation, whereas 69% showed deterioration after débridement surgery. At the final follow-up at a mean of 17 years after surgery, the status of the deformity was virtually unchanged. They also found that the problem of kyphosis was particularly important in patients who had lumbar tuberculosis in that 60% of patients in the débridement group had a 10-degree or more kyphus angle, whereas only one patient in the radical group had a kyphotic lumbar spine as a result of graft failure. The findings from this study further strengthen the merits of radical surgery in children.

The same group of researchers studied longitudinally the growth of the fused spinal segment in 33 patients who underwent radical surgery before 10 years of age. They found no difference in the growth pattern when compared with that in 71 patients who had surgery when 18 years or older. The authors concluded that there was no disproportionate posterior spinal growth after anterior spinal fusion and that routine posterior spinal fusion after anterior surgery in children was not necessary (42).

In contrast to the findings of Upadhyay and colleagues (42), Schulitz and associates in 1997 (38) reported in a series of 117 children that anterior fusion alone resulted in worsening of the kyphotic angle by an average of 12 degrees after 10 years, compared with an unchanged kyphotic angle in the posterior spinal fusion group. In the combined anteroposterior fusion and simple anterior débridement group, there were decreases in the kyphotic angle of -7 and -4 degrees, respectively. These investigators believed that destruction of the anterior growth potential and continued growth in the posterior neural arch reduced the remodeling power of the spine. This is especially true when the lesion is located in the thoracic spine and when several segments are involved. Although the difference in findings in these two series could be explained by the fact that the patients in Schulitz's series were on average 2.5 years younger than those in Upadhyay's series, one can see that there are still ongoing controversies regarding this issue.

Infections in Special Regions

Three regions of the spine deserve special consideration in treatment.

Tuberculosis of the upper cervical spine has special features of local pain and stiffness, paralysis, swelling of the retropharyngeal soft tissue, and atlantoaxial subluxation. This region is much less commonly affected than the subaxial region. Six patients with tuberculosis of the upper cervical spine were studied (8), with the above-mentioned features present in varying combinations. Cervical lymphadenopathy was present in all cases. Treatment necessitates transoral anterior débridement and often concomitant atlantoaxial fusion for stability. Halo immobilization is recommended at all stages of management and is also useful in some cases to achieve reduction. The transoral route also decompresses the large retropharyngeal abscess, thus avoiding acute dysphagia and asphyxia.

Tuberculosis of the subaxial cervical spine has been studied in detail in 40 patients (19). There is a distinct difference in the disease before and after 10 years of age. At a younger age, disease involvement is extensive and large abscesses form; the contrary occurs after 10 years of age. The incidence of paraplegia is much less in the childhood type (before 10 years of age) than in the adult type (after 10 years of age). Besides chemotherapy, anterior débridement and grafting are highly recommended; such a regimen gives rapid pain relief, decompresses abscesses that cause respiratory symptoms, and relieves paraplegia quickly. This operation also corrects kyphotic deformity significantly, ranging from 5.4 to 25.5 degrees (Fig. 1A–C).

Tuberculosis of the lumbosacral junction is a unique condition. Twenty-six cases have been studied, with an average follow-up of 20 years (36). Patients younger than 10 years of age presented with a discharging sinus or a pointing abscess and a visible kyphosis. Older patients presented with low back pain. Neurologic involvement was uncommon. Anterior débridement and strut fusion, although technically difficult, reduced the incidence and size of kyphosis (Fig. 4A–D). Conservative treatment resulted in a higher incidence of back pain, truncal shortening, and complications in pregnancy. Irrespective of their mode of treatment, all cases had radiologic fusion. The authors stressed the biomechanical importance of preserving the normal lumbosacral angle in management of this condition.

Surgical Management of Active Tuberculosis of the Spine

Management is divided into preoperative, operative, and postoperative management, including early and late surgical complications. Relevant details of the surgical approach to the spine are contained in a description by Leong (22).

Preoperative Management

Chemotherapy should be started a few days before surgery. Sometimes, in a dire emergency, when there is a neurologic or visceral complication, surgery can be performed before commencement of chemotherapy without added morbidity. Other preoperative assessments include checking vestibular nerve function because streptomycin may have an adverse effect on the eighth cranial nerve. Thrombocytopenia caused by rifampicin treatment should be watched for in patients receiving surgery. Preoperative halo immobilization may be necessary in infection of the cervical (especially the upper cervical) region. A prefabricated plaster shell is often required for an uncooperative child; it facilitates postoperative nursing and immobilization. The erythrocyte sedimentation rate should be evaluated before surgery. Radiologic investigation to delineate the site and extent of the lesion and to detect any complications (e.g., MRI scan for Pott's paraplegia, chest radiograph for rupture of thoracic abscess in lung) is necessary. CT is especially useful to study the anatomy of the kyphos before surgical decompression.

Operative Management

The operation is usually done using an anterior approach (22). Identification of the paraspinal abscess is easy unless the anatomy has been disturbed by a previous operation. The abscess is opened in a T-shaped fashion. Segmental vessels nearby have to be ligated if they are not already thrombosed. The abscess is evacuated and the diseased vertebra exposed. Radical excision is performed until fresh bleeding bone is obtained. The contralateral side abscess should be evacuated by suction and curettage as much as possible. This is done when the far side of the diseased vertebral bodies is reached. The excision sometimes leaves end plates exposed, in which case the normal disc and cartilage end plate of the adjoining healthy vertebra have to be removed to create a healthy bed for graft placement. The subchondral plate remnant is totally removed toward the back of the vertebral body until the posterior longitudinal ligament is visible. This ensures complete decompression and removal of remnants of subchondral plate in the posterior part of the vertebra. Slightly oversized graft is used and inserted after springing open the kyphos by gentle manual pressure over the kyphos apex posteriorly. The available graft sources commonly come from the excised rib or iliac crest blocks. Neck wounds are routinely drained, and chest tubes are used after thoracotomy. Occasionally, an extrapleural approach is used in thoracic disease, especially in patients with marked restriction of lung function. In this case, chest drainage is not necessary.

TABLE 4. Early Complications

Complication	Cause	Treatment
Worsening of neurologic deficit	Surgical neurapraxia of spinal cord	Observation; steroids for edema
Slippage of graft (especially long ones) impinging onto spinal cord	Graft replacement and better external immobilization	
Horner syndrome	Injury to cervical sympathetics	Observe; most will recover
Warm leg	Injury to lumbar sympathetic	Usually transient
Hemothorax, pneumothorax, atelectasis	Thoracotomy complication; poor drainage or intrinsic lung disease	General resuscitation, chest physiotherapy, and improved drainage of chest cavity; antibiotics if necessary
Paralytic ileus	Reflex reaction with surgery around dorsolumbar or lumbar spine	Usually transient; observation, fasting, and nasogastric suction
Residual abscess	Incomplete evacuation of contralateral abscess	Continue effective chemotherapy; exclude drug-resistant bacteria

Postoperative Management

Management at this stage includes fluid replacement and pain relief. Proper care of any drains to prevent fluid accumulation at the operative site is important. Prefabricated body jackets are useful for immobilization and for nursing children postoperatively. Halo immobilization should be incorporated into a body vest or plaster cast so that patients can be mobilized early. Staged supplementary posterior spinal fusion may be necessary when two or more vertebrae were diseased or removed anteriorly (21).

Postoperative complications may be early or late in onset. Complications are related to the spinal segment involved and may be neurologic or visceral in origin and related to the graft insertion or the residual disease (Tables 4 and 5).

TABLE 5. Late Complications

Complication	Cause	Treatment
Nonunion at graft site	Persistent infection—disease reactivation or resistant organism	Spinal restabilization if kyphosis increases; alter chemotherapy regime if necessary
Graft fracture (long graft at midportion) 12–18 mo after surgery	Stress fracture	Spinal immobilization
Graft reabsorption 6–12 wk after operation	Persistent infection (resistant organism)	Alter chemotherapy regimen if necessary reexplore if conservative treatment fails

Management of Paraplegia of Healed Disease

Paraplegia of healed disease is caused by impingement of the spinal canal by a sharp internal bony kyphos or from a constriction effect caused by fibrosis resulting from maturing granulation tissue around neural elements. Paraplegia can occur many years after the initial active infection, when the clinical deformity is apparently already nonprogressive. The documentation of compression requires early myelographic studies (Fig. 5A, B) or MRI.

Approach to the kyphos for surgical decompression requires detailed knowledge and surgical skill in anterior spinal surgery. An alternative is modified costotransversectomy with pediculectomy, which is particularly useful in a very severe angular kyphos. Anterior access to the apex of the internal kyphos is best obtained by tracing a nerve root proximally to the intervertebral foramen. The bony and fibrous material in front of the spinal cord must be removed carefully. The dura at the apex should be adequately exposed and protected. After thorough decompression, the dura should displace forward without tension and pulsate. Approaching the apex of the kyphos is fraught with dangers of injury to the spinal cord or dura. These complications occurred in 36% of patients with paraplegia of late onset treated surgically (18). Using better operating instruments, including high-speed burr, and intraoperative spinal cord monitoring, the operative morbidity has decreased significantly in our recent experience. Most of the cases of surgical complications occurred in paraplegia of late onset without concomitant active disease. Thus, the presence of active disease in this particular condition is of prognostic significance.

The overall prognosis of paraplegia of healed disease is poor, even with adequate decompression; recovery is usually prolonged and incomplete. The presence of active disease calls for additional chemotherapy. After adequate decompression, anterior strut graft fusion is performed using either the removed rib or an iliac crest graft.

Management of Severe Kyphotic Deformity

Significant angular kyphosis is a difficult problem that is common after spinal tuberculosis, especially in children with extensive anterior disease. The kyphosis is unsightly and, more important, may compromise visceral function. It may be associated with paraplegia of healed disease with or without residual active disease. Besides the deformity itself, the adjacent spinal segments develop compensatory hyperlordosis, which may pose additional problems in the future. There may also be secondary rib changes, sternal deformity, and spontaneous posterior fusion.

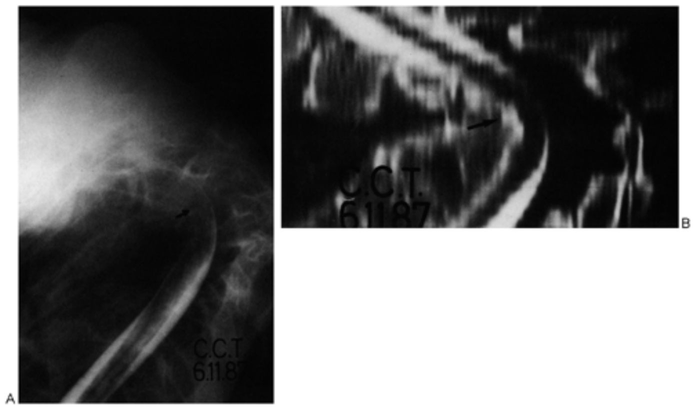

FIGURE 5. A: Myelogram of an 11-year-old girl with paraplegia of healed disease. Progressive paraplegia occurred 6 months before this investigation. There was multisegmental high thoracic disease that had been quiescent for many years. This myelogram showed a near right-angle kink of the contrast column, with significant anterior indentation *(arrow)*. The blockade is only partial, and the contrast column is visible above the kyphos. **B:** Computed tomography reconstruction demonstrated the internal kyphos remarkably well. This patient had an uneventful anterior decompression and fusion, with near total recovery of her neurologic function.

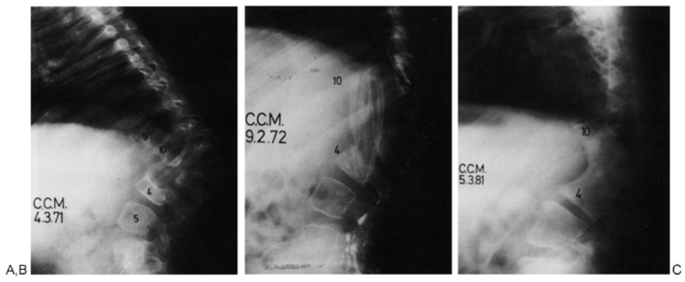

FIGURE 6. A: Preoperative radiograph of a 6-year-old boy with gross kyphotic deformity due to active spinal tuberculosis destroying the T11 to L4 vertebral bodies. He underwent anterior drainage and débridement followed by gradual halo-pelvic distraction. This was followed by a circumferential fusion after maximal gradual correction. **B:** Significant correction is noticed in the radiograph taken 9 months after fusion. The rib graft is still visible. **C:** At 10 years follow-up, the radiograph shows solid anterior fusion with some loss of correction. However, the final deformity is much less than the original.

Surgical correction is technically difficult because of the aforementioned problems in the anterior approach to the kyphos apex. The cephalad and caudad limbs of the kyphos may be in different planes, constituting a bayonet type of deformity. In multisegmental disease, the vertebral bodies intended to receive the graft may differ significantly in size after thorough débridement, making proper and adequate placement of strut grafts difficult.

The development of halo-pelvic distraction (33) enabled the circumferentially osteotomized spine to be distracted in a slow, controlled fashion. Strain gauges can be incorporated into the bars of the apparatus to register total tension in the spine, which should be at most one fourth to one third of the patient's body weight. During gradual distraction, frequent neurologic assessment is necessary. Avascular necrosis of the dens and spontaneous fusion of cervical segments are late consequences of prolonged traction in the cervical spine (6 ,7). The cervical spine should be radiographed before starting halo-pelvis distraction.

After achieving the required distraction, circumferential fusion is performed (Fig. 6A–C). This form of staged procedure needs a prolonged hospital stay and constant monitoring of the patient. There is significant mortality and morbidity associated with this treatment. Yau and colleagues (44) reported on a series of 30 patients who underwent such correction. There were three deaths, and complications in the cervical spine were common. The mortality and morbidity occurred mainly in the very early surgical experience. Cosmetic and pulmonary improvement were observed, however. This operation should be done only in specialized spine centers with the relevant expertise.

Fungal Infections of the Spine

Teddy S. Govender

T.S. Govender: Department of Orthopaedic Surgery, University of Natal, Durban, South Africa.

Definition

Fungi are plantlike organisms that are obligatory or facultative aerobes. Morphologically they appear either as single cells (yeasts), such as *Cryptococcus neoformans* and *Candida albicans*, or as multicellular filamentous colonies (molds), such as *Aspergillus* (6 ,10). The cells are larger and genomically more complex than bacteria, with a highly organized nucleus bounded by a nuclear membrane. Actinomycetes superficially resemble fungi but are a heterogeneous gram-positive filamentous bacteria.

Isolated fungal infection of the spine is uncommon in children, although spinal involvement may occur in systemic disease in the immunocompromised host (18 ,19 ,27 ,43 ,52). Spinal infections due to aspergillosis, candidiasis, cryptococcosis, blastomycosis, and coccoidioidomycosis have been reported in both immunocompetent and immunocompromised patients (1 ,3 ,5 ,7 ,8 ,11 ,14 ,16 ,22 ,23 ,26 ,28 ,36 ,45).

Epidemiologic Factors

Yeasts and mycelial fungi are ubiquitous organisms found in almost all types of organic substrates. They behave as pathogens by invading the tissues of patients whose normal immunologic defenses are impaired as a effect of the prolonged use of antibacterial or immunosuppressive drugs (6 ,8 ,10). Invasion may occur in patients with lowered resistance due to cancer, uncontrolled diabetes, organ transplantation, AIDS, chronic granulomatous disease (CGD), and long-term steroid therapy (8 ,21 ,25 ,36 ,38 ,51).

Candida albicans, the most common yeast pathogen, is a normal colonizer of the gastrointestinal and urogenital tracts (6). Candidiasis is undoubtedly one of the most widespread and prevalent mycotic diseases in humans, and this is especially true of the infections caused by the endogenous species (e.g., *C. albicans*) (1 ,28). The common predisposing factors in candidiasis are burns, infected central venous catheters, and intravenous drug abuse (1 ,28 ,39). Pigeon roosts are a common source of *Cryptococcus neoformans*, and the only known source of *C. neoformans* var. *gattii* is *Eucalyptus camaldulensis. C. neoformans* var. *gattii* has a propensity for causing disease in immunocompetent hosts (37 ,49). Aspergilli, which are opportunistic mycelial organisms, live as saprophytes by deriving nutrients from dead plants and animal matter (10). Because threshing areas and mills have high concentrations of aspergilli, which are readily disseminated into the air by wind currents, farm laborers are at increased risk of developing the infection (50).

Coccidioides and *Blastomyces* are true pathogenic infections, and inhalation of their spores results in a primary acute self-limiting respiratory infection (27 ,43). In the immunocompromised patients a fatal systemic mycosis may develop. *Coccidioides* is endemic to the arid southwestern United States, and in parts of South America. The infection is seen more frequently outside the traditional geographic areas due to the increasing number of immunocompromised patients (27). Blastomycosis is a systemic illness caused by the dimorphic fungus *Blastomyces dermatitides*, which is endemic in the midwestern, south central, and parts of the southeastern United States (2 ,3 ,4). Exposure to the infection begins insidiously and may be contracted during travel through an endemic area. The prevalence of osseous involvement due to blastomycosis ranged from 6% to 48% (32 ,43). Basset and Tindall (3) reported on 31 cases of blastomycosis of bone, and 26% (eight patients) included vertebral involvement.

Pathoanatomy

Cryptococcosis is a subacute or chronic infection usually involving the lungs, brain, meninges, and skeleton (8 ,11 ,25). The infectious organism enters the respiratory tract by inhalation, producing a primary pulmonary infection that is usually transitory, mild, and unrecognized (6 ,11). The tissue reaction of the host to *C. neoformans* is very broad and may vary from little or no inflammation to a purely granulomatous reaction with varying degrees of necrosis (22 ,29). In the immunocompetent patient the infection that is subclinical resolves rapidly, with minimal symptoms. In the immunocompromised patient the infection spreads to involve multiple organs, with a predilection for the central nervous system (CNS), which is affected in about 8% of AIDS patients in the United States (8). The lesion may have a glistening appearance and a slimy consistency on gross examination and can mimic both sarcoidosis and tuberculosis (11 ,34).

Aspergillus fumigatus is the most common isolated species associated with invasive and noninvasive aspergillosis. It may produce an allergic response, such as asthma, or bronchopulmonary aspergillosis (49). Invasive pulmonary aspergillosis is due to the *A. niger*. In chronic lesions, the center of the granuloma may become necrotic and/or liquefy, forming a cavity (50). Secondary, noninvasive pulmonary aspergillosis is characterized by the presence of a “fungal ball” or aspergilloma. This mycelial mass is usually located within a preformed pulmonary cavity (e.g., tuberculosis or bronchietatsis) (24).

Sixty percent of patients with coccidioidomycosis are asymptomatic and manifest only a positive skin test. However, 33% will develop a primary pneumonia and subsequently be at risk for extrapulmonary dissemination. Cutaneous, osseous, prostatic, and CNS involvement are the next most common in descending order (27).

Candidiasis is a relatively common mycosis of worldwide distribution and in the immunocompromised may manifest as endocarditis, meningitis, fungemia, or infections caused by other organisms (8). In recent years, the increasing incidence of infection due to *Candida* species in humans may be attributed to the use of broad-spectrum antibiotics, corticosteroids, immunosuppressive therapy, as well as the wider use of parenteral hyperalimentation and indwelling catheters (28 ,39).

Clinical Features

Fungal infections of the spine are uncommon in children and the clinical presentation is often subtle. The relatively nonspecific nature of the physical findings and the difficulty children have in communicating their symptoms frequently results in a delayed diagnosis. A detailed history from the child and the parents is essential in the evaluation of a child with back pain. The patient and the family should be questioned about alterations in neurologic functions, including changes in bladder and bowel habits and gait pattern. The young child may present with back pain, abdominal pain, and difficulty in walking or standing. Primary involvement of the psoas muscle may present as a swelling over the flank, with a pronounced limp (8 ,20 ,23 ,43). In children, a mass in the right flank may mimic an inflamed appendix, and an inadequate clinical evaluation may result in unnecessary surgery and a delay in the diagnosis (18). The psoas abscess can present as a presacral mass or extend inferiorly beneath the inguinal ligament into the thigh. In the older child, the presenting features include back rigidity, muscle spasm, excessive lordosis, or scoliosis. The back rigidity results in loss of the normal spinal rhythm. The spine may be tender to palpation, and progression of symptoms from local back pain to root pain, weakness, and paralysis is typical of an epidural abscess (8). The neurologic examination should be thorough, although the sensory examination may not be reliable in young children. In addition, these children may have spasm, tightness of the hamstrings, or a positive straight-leg raising test. These infections are more common in patients who are immunocompromised due to CGD, malignancy, immunosuppressive therapy, rheumatoid arthritis, organ transplantation, steroid therapy, and AIDS. The relatively low virulence of fungal organisms and the debilitated state of the compromised host can mask the physical findings of fungal infections (8 ,35). In patients for whom an antecedent *Candida* septicemia was documented, a striking delay was found between the septicemia and the onset of symptoms as well as the time of diagnosis. An average of 4.7 months elapsed between the septicemia and the time of definitive diagnosis by culture of the organism. Patients sought treatment for their back pain at an average of 5.3 months following the septicemia (1). *Aspergillus* osteomyelitis is a well-recognized, life-threatening infection in children who have CGD (21 ,23). In CGD of childhood, pulmonary aspergillosis involving the superior mediastinum may present with paraplegia due to contiguous involvement of the thoracic spine (45). Paraplegia may be due to mycotic spinal arachnoiditis or meningitis causing signs and symptoms of spinal cord neoplasm and is frequently associated with recent pregnancy, and the abuse of alcohol and narcotics (46). Mycotic thrombosis of the anterior spinal artery resulting in paraplegia due to *Aspergillus* has been reported in a formerly healthy patient (41).

Cryptococcosis presenting as a painful neck mass with weakness of the upper extremities due to contiguous involvement of the cervical spine may mimic tuberculosis (44). In areas where tuberculosis is endemic the fungal infection is normally due to secondary infection of a tuberculous cavitation and subsequent hematogenous spread to the spine (10 ,24). Depending on the extent of spinal involvement, these patients may have pain, deformity, and neurologic deficit and may present with concurrent tuberculosis and fungal infection (14). Very rarely isolated osseous involvement may occur in patients who are immunocompetent (11 ,15 ,20 ,52). CNS involvement often has an insidious onset characterized by headache and alteration in mental status (36). In addition, cough and hemoptysis following pulmonary invasion are common symptoms in patients with systemic involvement. Constitutional symptoms are nonspecific and include fever, weight loss, malaise, and fatigue (48).

Radiographic Features

Young children may require sedation or general anesthesia to obtain an optimum evaluation of computed tomography (CT) and magnetic resonance imaging (MRI) studies. Adequate communication between the clinician and the radiologist is essential in establishing a diagnosis (15 ,27 ,43). The thoracic and lumbar spine are the most common regions involved (Fig. 1A, B). Children commonly develop discitis, and in the early stages of the infection the anteroposterior and lateral spinal radiographs may be normal (20). Radioisotope bone scanning is sensitive in detecting lesions not seen on conventional radiographs and is important in the diagnosis of occult lesions or multiple sites of involvement (8 ,27 ,43). In established infections, disc space narrowing may be accompanied by erosive changes in the end plates (Fig. 2A, B). The radiologic features are nonspecific and include single-body involvement with a permeative lesion resulting in a platyspondyly (Fig. 3A). In established infection the radiographs may reveal lytic lesions often mimicking malignancies or bacterial osteomyelitis. Fungal infection can also mimic spinal tuberculosis, with two adjacent bodies (Fig. 4A, B) being involved with narrowing of the disc space and a paraspinal abscess. The paraspinal soft-tissue swelling may be present with cystic lesions

surrounded by sclerosis. The lumbar spine could be involved secondarily, with infection tracking along the psoas muscle, resulting in scalloping of the vertebral bodies. Dissection under the anterior longitudinal ligament may cause seeding to other vertebral bodies and skip lesions without involvement of the disc space (20). Spinal involvement in the immunocompromised patients may be extensive, involving multiple bodies and resulting in kyphosis (25 ,34). Cryptococcal infection involving the posterior elements of the lumbar spine and mimicking sciatica have been reported (30). The plain roentgenograms of the spine may be normal in patients with arachnoiditis or meningitis and in patients with an extradural abscess (46).

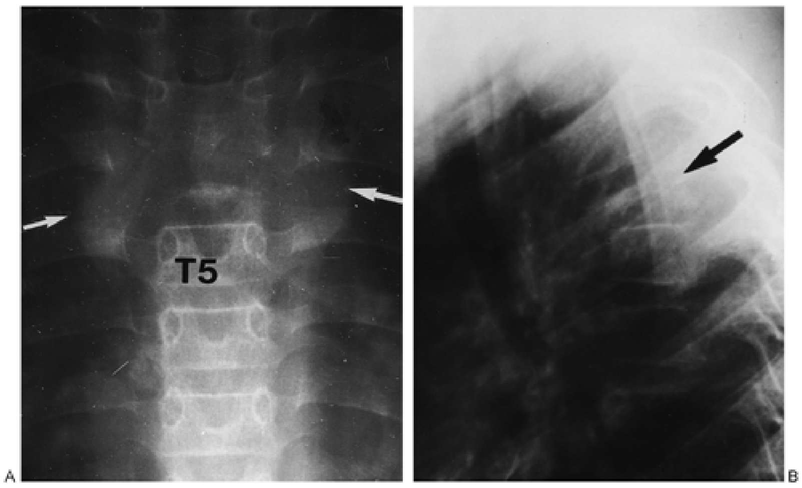

FIGURE 1. Anteroposterior **(A)** and lateral **(B)** radiographs showing a paraspinal mass *(white arrows)* and destruction of T4 *(black arrow)* in a 9-year-old child with paraplegia due to *Cryptococcus neoformans.*

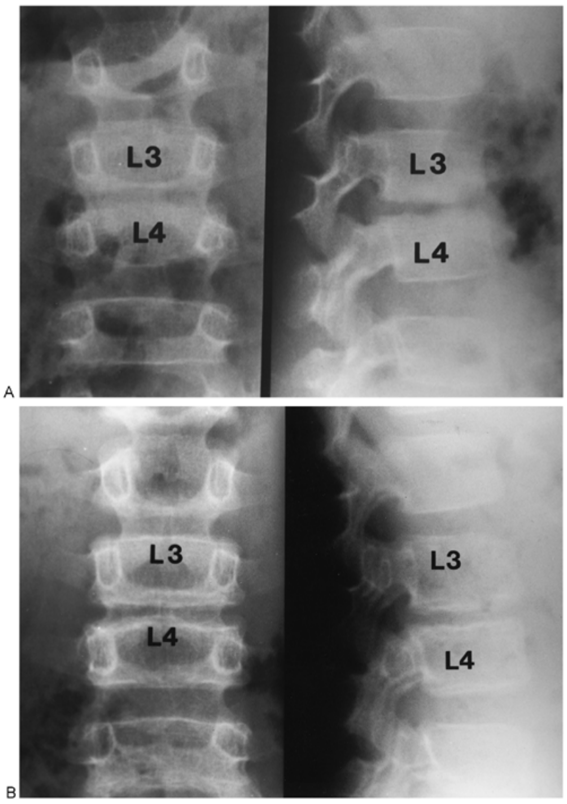

FIGURE 2. A: Disc space narrowing with irregular end plates (L3–4) in a 5-year-old child who presented with back pain. Three months prior to presentation the child sustained second-degree burns to the lower back. Closed-needle biopsy cultured *Candida albicans. B:* Radiographs at 15 months following antifungal treatment.

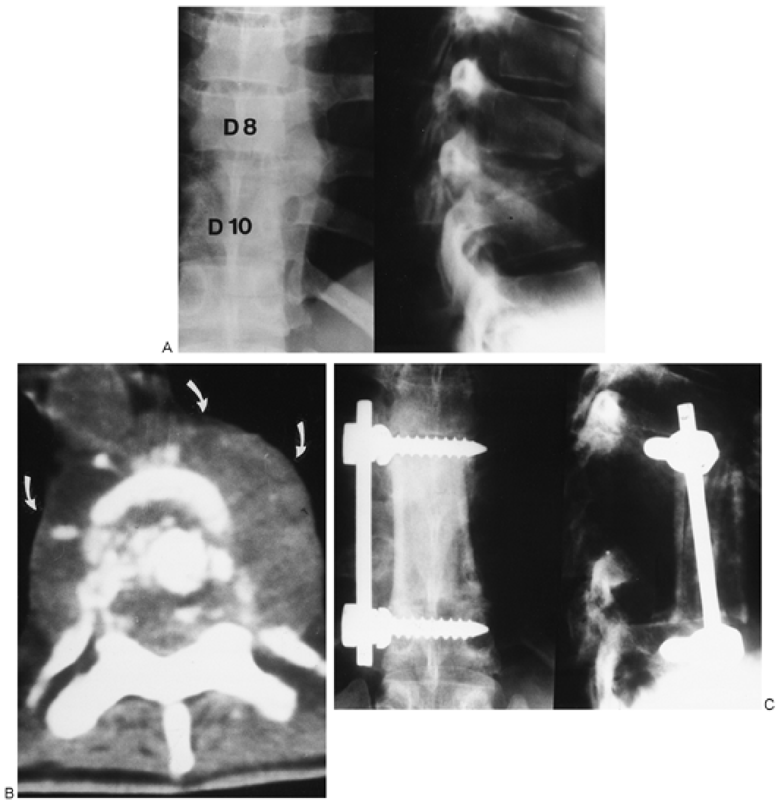

FIGURE 3. A: An 18-year-old girl developed paraplegia following collapse of D9 due to *Aspergillus fumigatus.* The patient had been treated for pulmonary tuberculosis 7 years previously. **B:** Computed tomography scan demonstrating paraspinal swelling *(white arrows)* with cord compression. **C:** Anterior spinal instrumentation with allograft at 27 months. There was complete neurologic recovery following surgical and antifungal treatment.

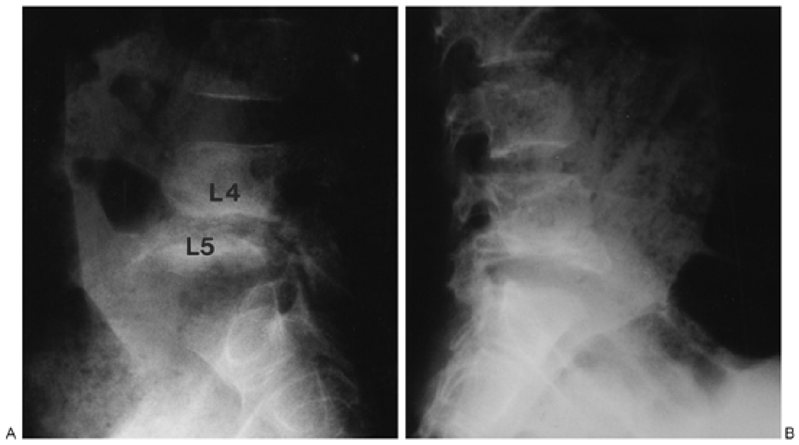

FIGURE 4. A: A 7-year-old child presented with low backache (L4–5), mass over left flank, and fixed-flexion deformity of the left hip. *Blastomyces dermatitides* was isolated following drainage of left psoas abscess and débridement of L4–5 disc space. **B:** Follow-up at 14 months following antifungal treatment.

Although the CT findings are nonspecific, they will define the extent of the lesions, provide information on the site of biopsy and aspiration, show evidence of extradural cord compression, and delineate the paraspinal soft-tissue mass (Fig. 3B). Gadolinium-enhanced MRI is useful in delineating the extent of the epidural abscess, facilitating the differentiation between solid inflammatory tissue and abscesses, and highlighting cases of paraplegia due to arachnoiditis and meningitis in which the conventional radiographs may be normal. In addition, gadolinium-enhanced MRI increases observer confidence in the diagnosis of disc space infection and osteomyelitis in patients with equivocal noncontrast MRI (40 ,42 ,43). The enhanced scans may differentiate active infections from those that responded adequately to medical treatment. The CT and MRI features of fungal infections are nonspecific and may mimic those of other granulomatous diseases, such as tuberculosis and brucellosis. Biopsy and culture are essential to establishing the diagnosis (42). The chest radiograph may show active pulmonary involvement or a healed focus of tuberculosis.

Diagnostic Tests

To avoid contamination all biopsy material should be placed in sterile containers for laboratory examination. The fungus should be demonstrated microscopically in clinical material, cultured repeatedly from clinical specimens, and if possible confirmed by serologic tests (6).

Cryptococcus is readily seen in India ink mounts of the material as round to oval, thin-walled, budding cells ranging from 5 to 20 μm in diameter (6 ,10). The organisms are usually surrounded by wide, refractile, polysaccharide, gelatinous capsules. The yeast can be cultured on Sabouraud glucose agar at room temperature, and in tissue sections the organism can be demonstrated with hematoxylin-eosin (H&E) stain. Serologic tests for cryptococcal antibodies include indirect fluorescent antibody (IFA) techniques, enzyme immunoassay (EIA), and tube agglutination (TA). Procedures for detecting cryptococcal antigens are the latex agglutination (LA) test and enzyme immunoassay (EIA) tests. The antibody tests are useful in the detection of either early or localized cryptococcosis and to determine prognosis (6). However, the LA test is very specific and of diagnostic and prognostic value, and is useful in detecting cryptococcal antigens in the sera and cerebrospinal fluid. A titer of 1:4 or lower is suggestive of cryptococcal infection, but titers of 8 or more are indicative of acute cryptococcosis (35). Cryptococcal antigens were not detected in the cerebrospinal fluid and sera in an immunocompetent child with cryptococcal osteomyelitis (19). A commercially developed DNA probe is useful for easy, rapid, and accurate identification of this encapsulated yeast from a primary culture (6).

Microscopically, aspergilli appear as fragments of dichotomously branched septate hyphae 4 to 6 μm in diameter. Colonies can be isolated readily on Sabouraud glucose agar at 30°C to 37°C (6 ,10). The immunodiffusion (ID) test is an effective and specific method for the diagnosis of aspergillosis in patients with an intact immune system. In patients suspected of having invasive aspergillosis with serum negative for antibody, counterimmunoelectrophoresis (CIE) and radioimmunoassay (RIA) should be performed (6).

Wet mounts of *Candida* in 10% KOH show small, oval, thin-walled, budding cells, and the pseudohyphae are 2 to 6 μm in diameter (6 ,10). Colonies of *C. albicans* on Sabouraud glucose agar are cream-colored, smooth, and glistening and have a yeasty odor. The addition of penicillin and streptomycin or chloramphenicol to the medium reduces contamination in the cultures (6). LA, ID, and CIE are useful in detecting antibodies to *Candida* species in the sera of immunocompromised patients. A titer of 1:8 or greater by LA is diagnostic of systemic candidiasis (6).

Coccidioides can be cultured in Sabouraud glucose agar or blood agar. It appears as round, refractile, thick-walled spherules 20 to 80 μm in diameter, and with many small endospores (10 ,49). The culture develops into moist, membranous, gray colonies that later produce abundant white mycelia (6). The coccidioidin skin test is of limited diagnostic value but is of considerable importance in epidemiologic studies (27). The immunodiffusion complement test detects IgG antibodies, and a titer of 1:16 is significantly associated with the presence of extrapulmonary lesions (6 ,27). The test could be used to follow the progress of the disease. The sensitivity and specificity for *Coccidioides immitis* is 99% and 100%, respectively with commercially available gene probes (6).

Blastomycosis can be identified as a dimorphic fungus by its typical “shoe print” morphology with the periodic acid–Schiff (PAS) stain (9). In uncertain culture results, more sensitive serologic techniques and DNA probes have significantly improved the sensitivity of laboratory diagnosis (2 ,3 ,6).

Sputum examination is essential in patients with a cough and in those with radiologic evidence of pulmonary involvement. Anemia and a decreased lymphocyte and neutrophil count are frequently observed in immunocompromised patients. The erythrocyte sedimentation rate (ESR), though nonspecific, is frequently raised. The liver function is usually deranged, and the albumin levels are often less than 30 g % in most immunocompromised patients. Blood cultures are essential in patients presenting with fever.

Natural History

Isolated osteomyelitis due to fungal infections may occur without evidence of systemic disease and in the absence of a detectable underlying disorder (5 ,7 ,9 ,11 ,18). The prognosis is good in patients who have localized infections without gross pulmonary involvement (19 ,27). Patients with clinical features of AIDS and other immunosuppressive disorders develop a fulminating fungal infection and die (8 ,21 ,35). Meningitis is the most common cause of death in patients with disseminated cryptococcal infection (35). Tack et al. (47) concluded that isolated fungal infections are due to silent dissemination from a pulmonary source that had not been established. They found that the difference in survival rates between compromised and immunologically competent patients was statistically significant ($p < 0.00025$, φ^2). The presence of an underlying immunosuppressed state correlates highly with the ultimate survival rate. In children with CGD, spinal involvement due to aspergillosis is usually a result of contiguous spread from an adjacent pulmonary focus, and the prognosis in these patients is poor (23 ,38 ,51).

Treatment Recommendations

Fungal infections should be included in the differential diagnosis of spondylitis, especially in immunocompromised patients, those with CGD of childhood, and those who spent time in places where tuberculosis is endemic (8 ,35). The rising prevalence of human immunodeficiency virus (HIV) and intravenous drug abuse has increased the awareness and concern for the diagnosis and treatment of spinal infections in the immunocompromised host. The delay in diagnosis and treatment, especially in children, is commonly due to the insidious presentation of physical signs and symptoms of the disease. This diagnostic delay may create a more complex problem and a difficult solution because the disease may be well advanced at the time of initial diagnosis (18 ,20). Malnutrition, which is frequently associated with immunodeficiencies, is due to a decrease in the number of circulating T cells with impaired lymphokine production (8). In patients with no obvious underlying predisposing factors an immunologic survey is essential to exclude immunodeficiency (26). Children with CGD should have supportive immunotherapy to control and prevent fungal infections (23). Patients undergoing major decompressive and reconstructive surgery of the spine require adequate nutritional support prior to surgery because postoperative morbidity is significantly increased in malnourished patients (8).

Surgical Treatment

In patients who are neurologically intact, tissue diagnosis can be obtained by a needle biopsy using the CT-guided technique or with fluoroscopy. Percutaneous CT-guided technique is recommended for drainage of a psoas abscess for both diagnostic and therapeutic reasons (27 ,40). Open biopsy is indicated in all patients who have neurologic deficit or painful deformity, those whose histologic examination following the needle biopsy is inconclusive, those who are not improving on antifungal medication, and those who relapse after initial improvement (47). Adequate tissue samples for diagnostic purposes in children with lesions involving the cervical and upper thoracic spine are best obtained from an open biopsy. Because the vertebral bodies are commonly involved, an anterior approach is advocated to allow for thorough debridement and provide adequate tissue samples for histologic diagnosis. In patients who are compromised neurologically it is essential to perform a meticulous decompression of the spinal cord that is compressed by exuberant granulation tissue, sequestra, and disc (15). Tissue diagnosis is essential because the granulomatous tissue may resemble that of tuberculosis, although granulation tissue in cryptococcosis and aspergillosis has a slimy consistency. Antituberculosis medication has been administered to patients on the basis of clinical evaluation alone and following an inadequate survey of biopsy samples (18). In children, rib grafts, iliac crest grafts, and allografts have been successfully used in attempts to reconstitute the anterior column (Fig. 3C) (15 ,17). In children with CGD, surgical débridement of *Aspergillus* vertebral osteomyelitis is difficult due to the contiguous pulmonary lesion. Multiple surgical procedures have been performed in these patients using bone grafts and instrumentation for stabilization of the spine (12 ,38 ,45). Peripheral and posterior abscesses of the lung should be treated aggressively both medically and with operative debridement to prevent extension to the spine. Surgical treatment (debridement, radical excision) without antifungal agents has been successful with isolated lesions in immunocompetent patients, avoiding the potential side effects associated with antifungal medication (11 ,16). In young children with multiple vertebral involvement due to blastomycosis, a satisfactory outcome followed aspiration and drug therapy (20). In skeletal coccidioidomycosis it is now well accepted that surgical débridement is mandatory, as the results following surgical débridement and medical therapy are significantly better than the results of medical therapy alone (27). A delay in the diagnosis of more than 1 month increased the recurrence, which required further surgical intervention. Posterior spinal decompression is recommended when draining an epidural abscess and in lesions involving the posterior elements (29). In the immunocompromised patient, additional spinal stabilization with instrumentation may be necessary to promote fusion and facilitate rehabilitation (45). Following transthoracic procedures in children, it is essential that adequate postoperative analgesia and chest physiotherapy be implemented to prevent potential pulmonary complications (15).

Medical Treatment

Once the diagnosis is confirmed by microscopy, culture, and serologic testing, the immunocompetent patient's status should be reassessed to confirm or exclude the presence of an underlying disorder (19 ,20). The infective process should be monitored clinically, radiologically, and by serial serology during treatment.

The antifungal agents amphotericin B and flucytosine, which work synergistically, have been recommended for treatment of aspergillosis candidiasis, cryptococcosis, blastomycosis, and coccidioidomycosis (35). The recommended daily dosage of amphotericin B, which is given intravenously, ranges from 0.25 mg/kg to 0.7 mg/kg and flucytosine (200 to 400 mg/kg) is administered orally. Amphotericin B combines with sterols in the plasma membrane, resulting in an increase in permeability and cell death. The intravenous route is recommended, as absorption is negligible following oral administration. Fungal cells are susceptible if they convert flucytosine to fluorouracil, which inhibits DNA synthesis (11 ,16 ,22 ,50). It is important to monitor the full blood count and liver and renal functions, as amphotericin B depresses bone marrow function and is toxic to the liver and kidneys. Other potential side effects include alopecia, vomiting, and diarrhea. The duration of medical treatment is unknown and must be individualized with respect to side effects and therapeutic response (47), and the drug is temporarily discontinued when side effects occur. Amphotericin B remains the initial drug of choice for patients who are severely ill, have life-threatening disease, or have CNS involvement (8).

Due to the poor oral absorption and toxic side effects of amphotericin B, antifungal imidazoles and triazoles have been introduced. The synthetic antifungal imidazoles and triazoles (ketoconazole, fluconazole, and itraconazole) inhibit fungal growth by blocking the biosynthesis of fungal lipids, especially ergosterol, in cell membranes (13 ,22 ,35 ,50). Fluconazole is well absorbed from the gastrointestinal tract and diffuses readily into body fluids, including cerebrospinal fluid and saliva. Concentrations in cerebrospinal fluid are 50% to 90% of simultaneous values in plasma following a daily oral dose of 100 to 400 mg. Apart from being administered orally, these drugs have been shown to have a good blood-brain barrier and are effective in AIDS patients with meningitis (8).

Amphotericin B has been shown to be the most effective agent in the treatment of musculoskeletal coccidioidomycosis and blastomycosis. Generally up to a cumulative dose of 1 g is given, and further therapy may be completed with an oral azole agent (27). Satisfactory results were obtained with intravenous intraconazole for 7 days (200 mg twice daily for 2 days and then once daily followed by oral administration for 6 months). Combination therapy of an antifungal agent and surgical debridement of involved bone and joint has been significantly more effective than medical treatment alone (7). The treatment is monitored by serial evaluation of complement fixation titers. The treatment is continued until the titers fall below a ratio of 1:8. The titers are more accurate than sedimentation rates and white cell counts in following the disease progress and treatment response (27). Vertebral osteomyelitis in children with CGD is usually due to aspergillosis. Unfortunately, despite aggressive medical and surgical therapy, reported cases have been associated with treatment failure, recurrence, severe neurologic complications, and death (21 ,38 ,51). Reports have suggested the beneficial effects of granulocyte transfusions in patients with aspergillosis that did not respond to antifungal therapy (23). However, Cohen et al. (12) were unable to demonstrate a significant reduction in the rate of infection in CGD patients treated with granulocyte infusions as an adjunct to antifungal chemotherapy for disseminated infection. In a controlled clinical trial recombinant interferon-γ was found to reduce the frequency of serious infections in patients with CGD. Recombinant interferon-γ can augment the ability of CGD neutrophils to destroy *Aspergillus* hyphae in vitro (23).

Ambisome, a liposomal formulation of amphotericin B, has been used to treat aspergillosis, candidiasis, and cryptococcal infections refractory to amphotericin B (35). Early initiation of high-dose Ambisone therapy should be considered in patients with CGD and *Aspergillus* osteomyelitis of the spine (23). Treatment should be administered for 6 months or longer. Because of the risk of recurrence, a long-term treatment regimen with an oral antifungal agent should be prescribed. In the neutropenic patient with fungal infection, the administration of cytokines such as granulocyte-monocyte colony-stimulating factor (GM-CSF) and granulocyte colony-stimulating factor (G-CSF) has reduced the degree and duration of neutropenia (23).

Prevention of fungal infections should be a high priority in the management of all at-risk patients in a hospital environment (33). In candidiasis it is important not to disturb the resident flora by limiting the use of broad-spectrum antibiotics (28). People visiting endemic areas where blastomycosis and coccidioidomycosis is common should be counseled for possible pulmonary infection.

Summary

The history must be thorough with respect to the endemic area of exposure and the state of immunocompromise. Immunocompromised patients with HIV, history of intravenous drug abuse, organ transplantation, long-term steroid treatment, diabetes, and CGDs are prone to develop fungal infections. Decreased host immune response and the paucity of signs and symptoms in younger children may lead to a delayed diagnosis of spinal infections. With a timely diagnosis and appropriate treatment, the outcome of extrapulmonary fungal infection in the immunocompetent host is usually excellent, though some fatalities do occur. The physical examination should emphasize identification of pulmonary and additional foci. The overriding symptoms of back pain, radiculopathy, myelopathy, and sensory loss may accompany local pain and tenderness. Radiologic evaluation, including radioisotope bone scanning, CT, and MRI, is invaluable in planning treatment. The mainstays of treatment are identification of the responsible pathogen and implementation of appropriate medical and surgical treatment.

Rheumatic Diseases

Mary D. Moore

M. D. Moore: Department of Pediatrics, University of Iowa, Iowa City, Iowa 52246.

The term *rheumatic diseases* refers to a diverse group of inflammatory conditions primarily involving the peripheral joints and axial skeleton. With the exception of cervical spine disease in juvenile rheumatoid arthritis (JRA), spinal involvement is much less common in the childhood rheumatic diseases than in the adult rheumatic diseases. Spinal disease may be present at onset but more commonly develops during the course of the illness, often years later. The two most common childhood rheumatic conditions with spinal involvement are JRA and the spondyloarthropathies. Both of these conditions will be described in greater detail in this chapter. JRA usually involves only the cervical spine, whereas the spinal involvement in the spondyloarthropathies usually starts in the lumbar sacral spine and sacroiliac joints, and involvement of the cervical and thoracic spine occurs decades after onset.

Primary involvement of the spine is not typical in the other rheumatic diseases of childhood. However, spinal involvement may occur as a complication of the disease process or its treatment. Many of the rheumatic diseases are characterized by decreased bone mineral content with the problem of osteoporosis and the secondary complication of vertebral stress fractures. Back pain can be a presenting symptom of nonrheumatic conditions (e.g., malignancy), chronic pain syndromes, as well as referred pain from abdominal or renal diseases. The child who presents with nonorganic back pain can be a diagnostic challenge. It is important to identify those children early to avoid putting the child through an extensive and unnecessary evaluation and to focus on symptom control and return to school and normal functioning.

In evaluating all children with rheumatic complaints, the importance of a detailed history and physical examination, including a comprehensive family history, cannot be overemphasized. The working impression from the history and examination will greatly assist in the development of a well-considered, logical, and appropriate diagnostic and treatment plan. General goals of management include determination of the patient's diagnosis, control of pain, prevention of disability, adequate rest, and appropriate exercise. The family and child need to be educated in terms of the disease process, its treatment, and a realistic assessment of disease outcome.

Juvenile Rheumatoid Arthritis

JRA encompasses a heterogeneous group of idiopathic disorders, the hallmark of which is chronic synovitis, predominantly of peripheral joints. JRA refers to children under 16 years old; this age distinction is somewhat arbitrary, as adult rheumatoid arthritis (RA) can present in children, particularly in older female adolescents. The American College of Rheumatology has established classification criteria for a diagnosis of JRA. JRA is further subdivided into three main subtypes: systemic onset, polyarticular (more than five affected joints), and pauciarticular (four or fewer joints). JRA subtypes are based on the clinical course 6 months after onset (9 ,25). The different subtypes and the major distinctions between the JRA subtypes and spondyloarthropathy are summarized in Table 1 . Some U.S. pediatric rheumatology centers further divide the subtypes based on the results of serologic studies and the presence or absence of the histocompatibility locus antigen B27 (HLA-B27). The American College of Rheumatology classification is used extensively in North and South America. European investigators use the criteria of the European League Against Rheumatism, which reserve the term “rheumatoid” for children with a positive serum rheumatoid factor (37).

Epidemiologic and Etiologic Factors

In the United States and Europe, JRA occurs in approximately 1 to 22 per 100,000 children, with an estimated prevalence of 86.1 per 100,000, of which half would represent inactive cases (14 ,27). Epidemiologic studies of JRA have been mainly descriptive and are further complicated by the differences in diagnostic criteria, the marked heterogeneity in disease expression, as well as the inability to identify specific etiologic agents (14). Despite major advances in understanding of the inflammatory response, the cause of most rheumatic diseases remains unknown. Stress, infection, and trauma can all play a role in triggering the onset of arthritis, as well as causing exacerbations of existing disease. However, the actual contribution of each factor is not known. Genetic factors also contribute to development of JRA, but the association is much less consistent than the strong association of HLA-B27 in the spondyloarthropathies (17).

JRA probably encompasses several diseases of differing causes. In addition, other types of inflammatory arthritis, such as reactive arthritis and Lyme arthritis, can be difficult to distinguish from pauciarticular JRA. Another difficulty is that inflammatory conditions evolve over time, and it might be decades later that another rheumatic disease becomes evident. The typical example of this process would be a young boy diagnosed as having pauciarticular JRA who develops typical spinal involvement, intestinal disease, or psoriasis in adult life and is then correctly diagnosed as having a spondyloarthropathy.

TABLE 1. Overview of Juvenile Rheumatoid Arthritis and Spondyloarthropathy

Factor	Systemic	Pauciarticular	Polyarticular	Spondyloarthropathy
Gender	M = F	F>>M	F>M	M>>F
Age of onset (yr)	1-6	1-4	1-8	8-18
Laboratory studies				
Rheumatoid factor	-	-	+	-
Antinuclear antibody	-	+++	++	-
HLA B27	-	-	-	+++
Sites of joint disease				
Peripheral arthritis	+++	++	+++	+
Cervical spine	+	-	+	-
Lumbosocral spine/sacroiliac disease	-	-	-	++
Extraarticular manifestations				
Chronic iritis	-	+++	+	-
Acute iritis	-	-	-	+
Fever, weight loss, leukocytosis	++	-	+	-
Rashes	+++	-	-	++

-, not found; +, occasional; ++, frequent; +++, often.

Clinical Features of Cervical Spine Disease

The typical child with JRA will be a preschool-age girl who presents with an asymmetrical pauciarthritis. Pain will be mild; most children are identified by persistent swelling, limp, and/or contracture of peripheral joints. Morning stiffness may be prominent, and joint symptoms typically improve later in the day. Arthritis is often in the large joints of the lower extremities. Occasionally, children present with abrupt onset of inflammatory arthritis and fever, but the initial presentation is usually more indolent. Physical examination shows inflammatory arthritis. Joints are not usually red; pain and tenderness are mild to moderate. Acute phase reactants, such as the erythrocyte sedimentation rate (ESR) and C-reactive protein, will be mildly elevated. The peripheral white blood cell count may be elevated, and the child may have a mild anemia. However, these blood tests often are completely normal. Synovial fluid will show inflammatory fluid, with cell counts ranging from 1,000 to 50,000 cells per mm^3. On serologic testing, many JRA patients, especially those with pauciarticular JRA, have a low titer of antinuclear antibody (ANA). However, in contrast to adult RA, rheumatoid factor is present in only 10% of JRA cases overall. Children with systemic JRA (also called Still disease) present with systemic signs and symptoms, such as rash, fever, lymphadenopathy, serositis, leukocytosis, and marked increases in acute-phase reactants, and may be quite ill at presentation (9 ,20 ,46 ,55).

Cervical spine disease is common in JRA and occurs in 50% to 60% of children with polyarticular and systemic disease. Cervical spine disease is virtually absent in children who have a pauciarticular course (9 ,22). Rarely, cervical spine disease can be the sole initial presentation of JRA; and the child will subsequently develop signs of peripheral arthritis. Usually, however, peripheral arthritis presents first and the cervical spine disease appears later in the clinical course (52). Although cervical spine involvement is more common in JRA than in RA, complaints of neck pain and serious complications are less common in JRA than in RA (47). Isolated cervical spine arthritis is extremely rare in JRA, and careful evaluation will reveal involvement of other joints. The child with cervical spine involvement may present initially with torticollis, although the usual presenting complaint is stiff neck (especially in the morning) and decreased neck motion on examination (52). Thoracic or lumbosacral spinal involvement is extremely uncommon in JRA and would represent another disease, a complication from therapy of concurrent osteoporosis, or an overuse syndrome triggered by arthritis at other sites. Cervical spine complications can include fractures, erosions, subaxial subluxation, and atlantoaxial subluxation (which can lead to basilar invagination), resulting in neurologic impingement (Fig. 1). Rare spinal complications of JRA include spinal lipomatosis, developing as a complication of increased weight gain from glucocorticoid use (2) and rotary subluxation of the cervical spine (44).

Severe complications are rare in JRA cervical spine disease but should be watched for, especially in systemic or polyarticular JRA patients with severe and/or advanced disease in peripheral joints. Any history of neck pain, neurologic symptoms, or trauma to the neck (even relatively trivial injury) should be taken seriously in these patients, as they are at higher risk of fracture or dislocation resulting from concurrent osteopenia or ligamentous damage resulting from chronic inflammation. Pain and neurologic symptoms may be subtle and overlooked, particularly if the child has significant underlying inflammatory arthritis and concomitant pain. In the evaluation of suspected neurologic compromise, the child and parent should be specifically questioned about trauma, subjective weakness, gait changes, or urinary retention or incontinence. The child should be examined carefully for signs of myelopathy. Red flags would include persistent torticollis, progressive or acute paresis, weakness, spasticity, sensory loss, bladder symptoms, change in deep-tendon reflexes, or incoordination, and would call for immediate assessment (39). Plain radiographs should be obtained, followed by computed tomography (CT) or magnetic resonance imaging (MRI) as indicated (21).

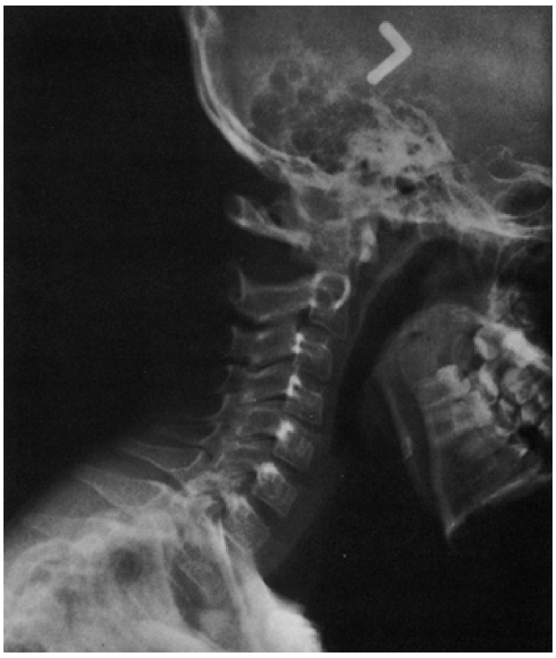

FIGURE 1. Anterior subluxation of C2 on C3 in an 11-year-old girl with seronegative polyarticular juvenile rheumatoid arthritis.

Radiographic Features

Standard radiographs are normal at onset of JRA joint disease. Typical destructive changes may take years to develop or not develop at all. Radiographs are obtained at onset for baseline studies for comparison and, more importantly, to rule out other causes of the articular symptoms. The first evident radiographic changes are soft-tissue swelling and juxtaarticular osteoporosis, followed by bone erosion and, later, loss of articular cartilage, decreased joint space, and bone destruction. A distinct feature in the developing child is regional overgrowth or undergrowth in joints with persistent disease. The most common example of this feature is a leg length discrepancy in a child with pauciarticular JRA of one knee. The chronic inflammatory process and increased blood flow in synovial tissue leads to advanced bone maturation, with the result that the involved leg is longer than the uninvolved extremity (9 ,25 ,30).

The most common radiographic findings of cervical spine disease in JRA are calcification of the anterior aspect of the first cervical vertebra, anterior erosion of the odontoid, and ankylosis of the apophyseal joint. Other radiographic features include growth disturbances of the vertebral bodies, spondylitis of the cervical spine, and micrognathia (22). To evaluate children for cervical spine disease or for preoperative assessment of the neck, the child should have routine anteroposterior, open-mouth, lateral, and extension-flexion radiographs of the cervical spine. Radiographic findings in advanced disease may include osteoporosis, abnormalities of the cervical curves, and erosion of vertebral end plates. This may be followed by spondylitis, vertebral subluxation, and destructive arthritis of the apophyseal joints with ankylosis (Fig. 2) (22 ,47 ,52). To evaluate for neurologic impingement or cervical spine fractures, radionuclide scanning or MRI can be particularly useful (21).

Natural History

The hallmark of the rheumatic diseases is inflammation of synovial tissue. There is a marked increase in macrophages and T lymphocytes, local production of inflammatory mediators, recruitment of neutrophils into the joint space leading to synovial hypertrophy, increased vascularity, and joint fluid secretion. Over time, the inflammatory process extends from the synovium, with local invasion of cartilage followed by erosion of bone. If inflammation does not remit or cannot be controlled by treatment, the final result may be end-stage joint damage and ankylosis (9 ,20 ,22 ,25 ,46 ,55).

The inflammatory process in the cervical spine is similar to that in the peripheral joints. The normal cervical spine has 32 synovial articulations. There is a synovial-lined bursa between the odontoid process and the transverse ligament. The three most common lesions that result in cervical instability are atlantoaxial subluxation, basilar invagination, and subaxial subluxation, or a combination. Expansion from synovitis may lead to distention and finally to rupture of the transverse ligament or to odontoid fracture, resulting in cervical instability; the atlas then slides anteriorly, and atlanto-axial subluxation is considered when the distance between the odontoid process and the anterior arch of the atlas in adults exceeds 4 mm. However, in children, the atlantoaxial distance is longer (up to 4 to 4.5 mm) (39 ,47 ,52). Although cervical spine involvement is more common in JRA than in adult RA, the children have less pain and a much lower incidence of neurologic involvement and complications (22). Overall, in adult RA, subaxial subluxation occurs in 20% to 25% of patients, with neurologic progression in up to one third of untreated patients (39).

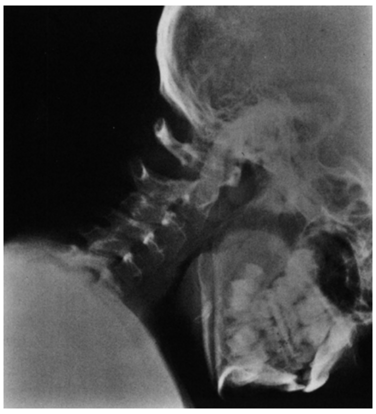

FIGURE 2. Fusion of C2–C3 in the cervical spine of an 8-year-old boy with systemic-onset juvenile rheumatoid arthritis.

The natural course of JRA is extremely variable. However, most children do well with early recognition and management. Remission rates vary from 26% to 65%, and severe disability occurs in 20% to 45%. This marked variation in outcome is due to differences in clinical criteria, length of follow-up, and types of treatment. Children with pauciarticular JRA do best, although this subtype is at high risk of inflammatory eye disease, with the additional risk of severe vision loss or even blindness if untreated. Those with the most severe outcome are systemic JRA patients with persistent polyarthritis and patients who have positive rheumatoid factor. Chronic inflammatory arthritis of more than 5 years duration is also predictive of more severe disability (9 ,13 ,20 ,46). An important consideration is that children initially diagnosed with JRA may be rediagnosed years later with a different rheumatic disease; this was seen in one series in 22% of JRA patients followed for decades, and most of those children were ultimately diagnosed with spondyloarthropathy (18).

Treatment Recommendations

All children with JRA need an individualized treatment plan and should be managed by a practitioner skilled in the treatment of these disorders. Pain should be controlled with appropriate nonnarcotic analgesics, with narcotics reserved for severe pain (26). Conservative therapies should not be overlooked and include moist heat, splinting or casting for comfort, use of crutches or canes, sufficient rest, and an appropriate exercise program (19). Younger children generally do not like topical medications and find the burning sensation or texture of many of these agents unacceptable. However, such agents can be useful in adolescents. Virtually all patients will be started on a nonsteroidal antiinflammatory drug (NSAID) for control of symptoms. NSAIDs reduce joint swelling, relieve pain, and have a modest effect on the overall inflammatory process. There are several NSAIDs from which to choose. In general, a NSAID that needs to be taken only once or twice daily is preferred, especially for the school-age child (5 ,9 ,25). Several selective inhibitors of cyclooxygenase-2 have been recently marketed in the United States and abroad, and can be useful in the child who cannot tolerate the usual NSAIDs. These agents (celecoxib, rofecoxib, among others) are similar to the other NSAIDs with a good safety profile, but they are more expensive and do not have the cardiovascular protective effect of the earlier NSAIDs (32). Salicylates, the first group of NSAIDs developed, are less commonly used in children due to increased risk of gastrointestinal toxicity, the small risk of Reyes syndrome, and the need for more frequent laboratory studies, including salicylate levels. Serum levels of the other NSAIDs are not useful clinically. In general, patients on chronic NSAIDs should have laboratory studies every 3 to 4 months, including a complete blood count, measurement of liver enzymes, and a urinalysis to monitor for drug toxicity (5). Short courses and/or low doses of glucocorticoid can be useful for rapid and sustained control of inflammation. However, glucocorticoids have the potential for significant long-term side effects; long-term use and high doses are reserved for children with severe systemic disease or incapacitating polyarthritis. Intraarticular injection of glucocorticoids is safe and a very useful tool for management of arthritis, especially in the child with involvement of only a few joints (36).

The past decade has seen major advances in the understanding and treatment of chronic inflammatory arthritis. There is increasing emphasis on early identification of patients at risk of severe disease and aggressive control of inflammation, often involving simultaneous use of several pharmacologic agents. Medications include methotrexate, leufludomide, hydroxychloroquine, sulfasalazine, and novel biologic agents that specifically inhibit inflammatory mediators, specifically interleukin-1 and tumor necrosis factor. Detailed discussion of these agents is beyond the scope of this chapter, and the reader is referred to the end-of-chapter references for more detailed information (24 ,35 ,43 ,49).

For children with cervical spine involvement, symptomatic treatment is similar to management of peripheral arthritis and would include analgesics, immobilization (in this case with a cervical collar or, rarely, by traction), and various physical therapy modalities. A short course of oral glucocorticoids may be useful for immediate relief of symptoms in the child with new onset of neck disease. Indications for surgery are neurologic abnormality, intractable pain, and impending neurologic deficit. Procedures include laminectomy, decompression of nerve roots or spinal canal, and spinal fusion. These procedures are described in other chapters in this textbook. The choice of procedure, anatomical location, and timing of the specific surgical procedure will be individualized and based on the child's clinical signs, symptoms, and radiologic evaluation. In general, outcome is favorable, and early identification of neurologic impingement and prompt surgical treatment provide the best outcome (9 ,22 ,39).

Spondyloarthropathies

The spondyloarthropathies encompass a group of diseases, with considerable overlap in clinical features. The majority of these conditions have in common the presence of HLA-B27 (overall about 75% to 90% of individuals with a spondyloarthropathy) and enthesitis (inflammation at sites of attachment to bone). The current American College of Rheumatology classification is spondyloarthropathy with the following diagnostic subcategories: ankylosing spondylitis, reactive arthritis (also called Reiter syndrome), psoriatic arthropathy, and enteropathic arthropathy (arthritis associated with inflammatory bowel disease) (7 ,9 ,25).

There is also a subset called “unclassified” or “undifferentiated” spondyloarthropathy for patients who do not yet meet diagnostic criteria for definite diagnosis (Table 2). Classic ankylosing spondylitis does not occur in young children. The child may present with an asymmetrical pauciarthritis and only later in adult life be correctly diagnosed; children presenting with isolated hip arthritis are particularly likely to develop a spondyloarthropathy (3). Some investigators define juvenile spondyloarthropathy as disease occurring in youngsters less than 16 years of age (6 ,13). Difficulties in the diagnosis include the considerable overlap in clinical features and the fact that decades may elapse before a specific spondyloarthropathy can be diagnosed.

TABLE 2. Spondyloarthropathies

Ankylosing spondylitis

Reactive arthritis/Reiters syndrome

Psoriatic arthropathy

Enteropathic arthropathy

Undifferentiated spondyloarthropathy

Epidemiologic and Etiologic Factors

The spondyloarthropathies are ancient disorders; ankylosing spondylitis in skeletal remains dating to the thirtieth century BC has been described. In contrast, adult RA appeared during the Renaissance (8 ,25). The incidence of ankylosing spondylitis is 2.1 in 1,000, with a male/female ratio of 3–9:1, depending on the series (8 ,27). Anklylosing spondylitis represents about half of all cases of spondyloarthropathy. In children, the spondyloarthropathies account for one third of cases of chronic arthritis, and most of these children fulfill JRA criteria as well (13 ,37).

The cause of the spondyloarthropathy is still unknown. There have been tremendous advances in the last two decades in the understanding of the immune response, in identification of microbial triggers of inflammation, and in delineation of the contributions of HLA antigens and enteric infections in these diseases. The actual role of HLA-B27 is still not entirely clear. Patients can have a spondyloarthropathy without the presence of this antigen. Theories of the role of HLA-B27 include molecular mimicry (where a bacterial antigen is similar in structure to B27) and posttranslational modification of the B27 molecule (resulting in an altered structure and subsequent autoimmune response); or the B27 molecule might be associated with a deficient or altered host response to various infectious agents, resulting in the triggering of a chronic immune response. A transgenic HLA-B27 rat model has also contributed to our understanding of these disorders.

Clinical Features

The hallmark of the spondyloarthropathies is enthesitis, which refers to inflammation at the sites of attachment of connective tissue (tendons, fascia, ligaments) to bone. Typical sites of involvement include the lower extremities (e.g., heel, plantar fascia) and the sacroiliac joints. Pathologically, sites of enthesitis show non-specific inflammatory changes, with lymphocytic inflammation and destructive changes in adjacent bone (34). In addition to enthesitis, these conditions may also be associated with synovitis, tendonitis, spinal disease (especially at the sacroiliac joint), as well as mucocutaneous features. The importance of a careful history and physical examination cannot be overstated. The patient should be specifically asked about symptoms of inflammatory pain, such as morning stiffness, nighttime and early-morning pain, and improvement of pain with exercise. The patient or parents should be specifically asked about a family history of any of the spondyloarthropathies, psoriasis, and inflammatory bowel diseases. For the busy practitioner, a checklist can be useful if completed before the physician examines the patient; this list can also be useful for clinical studies and has been tested in a variety of settings (46). Enthesitis, especially of the lower extremities, is often misdiagnosed as an overuse syndrome, and it may be decades before the youngster has a definable spondyloarthropathy (34). In one large series, the diagnosis of a spondyloarthropathy was made at a mean of 7.3 years (6).

For many young children, the initial presentation may be hip involvement. Indeed, isolated hip involvement is distinctly uncommon in JRA (3). In general, youngsters with spondyloarthropathy are older males. Other clinical features that are useful in distinguishing spondyloarthropathy from JRA are the presence of enthesitis and tarsal disease. In children later diagnosed with a spondyloarthropathy, the discriminative value of either enthesitis or tarsal disease approached that of the gold standard of diagnosis: axial disease (6). Back involvement in children with spondyloarthropathy usually originates from inflammation of the sacroiliac joints. Symptoms may be bilateral. Pain is inflammatory in nature: worse in the morning, associated with morning stiffness, and often relieved by exercise and improved by the end of the day. Pain is usually mild to moderate and persists for months. A careful and thorough physical examination should be done. The mouth should be inspected for lesions and the skin examined for psoriasis (especially the nape of the neck, elbows, knees, and umbilicus). Shoes should be removed and the feet examined carefully for nail pits, sausage toes (dactylitis), and signs of enthesitis. In addition to the standard examination of the back, a useful procedure is the Schober test (Fig. 3), which can indicate spinal limitation and suggest the presence of a spondyloarthropathy (25 ,50).

Determination of the presence or absence of HLA-B27 can be helpful, particularly when combined with the patient's medical history and examination, family history, and radiographic evaluation. However, this antigen can be negative and can only be used to support a clinical diagnosis. It is not a useful screening tool in asymptomatic individuals. In many patients, especially those with involvement of few joints, laboratory studies may be completely normal. Tests for rheumatoid factors and ANAs will almost always be negative. Patients with significant inflammation may have a low-grade anemia and elevation of acute-phase reactants, such as C-reactive protein and the ESR.

Ankylosing Spondylitis

Ankylosing spondylitis is uncommon in children younger than 16 years. Onset is usually in young adulthood, again primarily in males. Most patients will present with insidious, persistent, chronic low back pain. Other features include enthesitis, peripheral arthritis, and, less commonly, extraarticular manifestations. Typical radiographic spinal changes will not be present for years (53).

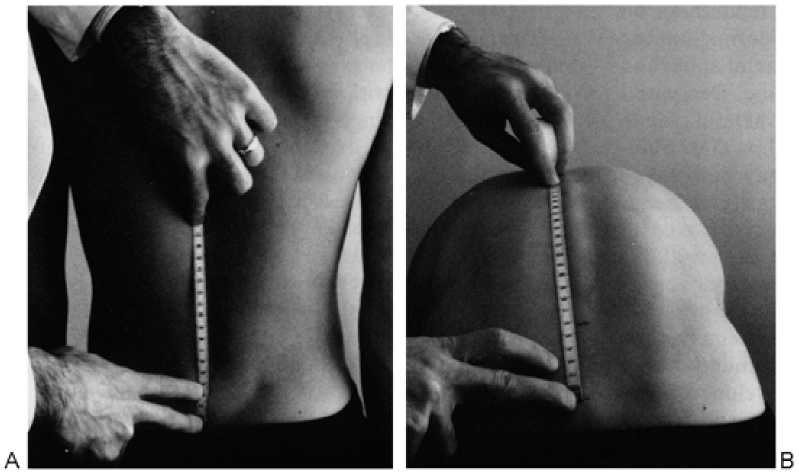

FIGURE 3. Measurement of spinal mobility in children using the Schober test. **A:** With the child upright, a line is drawn across the lumbosacral junction. A mark is placed 5 cm below and 10 cm above this point. **B:** With the child bending forward, the total excursion between the lower and upper points is measured. The normal measurement is 6 cm or greater.

Reactive Arthritis (Reiter Syndrome)

Reactive arthritis, also called Reiter syndrome, refers to an acute reactive arthritis occurring after an enteric infection or, less commonly, after a genitourinary infection, predominantly occurring in young white males. Onset will be quite abrupt, within a few days of the infection, and a large weight-bearing joint of the lower extremity is most often involved. The original description of Reiter syndrome is a triad of peripheral arthritis, conjunctivitis, and urethritis, but most patients present at first with peripheral arthritis alone. The arthritis will be self-limited, lasting for weeks to months, and patients can experience recurrences. Enthesitis is quite common. Similarly, most patients will develop conjunctivitis, low back pain, and mucocutaneous manifestations (mouth ulcers, rashes, nail changes). Back pain is most often attributable to sacroiliac involvement and is often unilateral; progression to clinically evident ankylosing spondylitis occurs in about 10% of cases (9 ,25).

Psoriatic Arthropathy

The arthropathy associated with psoriasis can be manifested in extremely varied ways, from peripheral asymmetrical arthritis, to a polyarthritis resembling RA, to spinal and sacroiliac disease, or even to a combination of these manifestations. Most patients will have typical psoriasis skin lesions before developing arthritis, but the psoriasis may appear at onset of the arthritis or, in a small percentage, years later. Psoriatic arthropathy is more common in adults, again with a male predominance, but does occur in children as well (14 ,16 ,25).

Enteropathic Arthropathy

Arthropathy occurs in about one third of patients with inflammatory disease and may be the initial manifestation. Acute arthritis in peripheral joints usually coincides with active bowel inflammation and will subside once the gastrointestinal disease is controlled. Ten percent of patients eventually develop spinal disease, usually sacroiliitis or, occasionally, ankylosing spondylitis. Other features include mouth ulcers, skin lesions (erythema nodosum, pyoderma gangrenosa), and uveitis. Interestingly, a substantial proportion of patients with other arthropathies have occult gastrointestinal inflammation (25 ,29 ,33).

Undifferentiated Arthropathy

Accurate classification of a spondyloarthropathy may not be possible for several years following onset of characteristic symptoms, as it will be years before the classic radiographic findings of sacroiliitis or spondylitis are present. This is particularly true in younger patients. This group of patients will again be predominantly male. Most will have HLA-B27 and will not have rheumatoid factor or other autoantibodies. An earlier term for the spondyloarthropathies was “seronegative arthritis.” However, RA and JRA patients can also be seronegative, and this designation is now used infrequently. A subgroup of undifferentiated spondyloarthropathy was previously called seronegative enthesopathy, or SEA syndrome, and these patients were primarily young males with chronic enthesitis. Most of these individuals followed over time will develop one of the spondyloarthropathies discussed above (7 ,25 ,53).

Radiographic Features

Routine radiographs will be normal early on, except for soft-tissue changes. The most common radiographic changes in the spondyloarthropathies are caused by enthesitis and by disease in the sacroiliac joints. At first enthesitis is characterized radiographically by bony erosion, then by sclerosis, and with longstanding disease by ankylosis of the adjacent bone. In sacroiliac disease, which can be unilateral, changes are similar and appear first on the iliac side of the joint (Fig. 4). Before significant radiographic changes can be seen on plain films, MRI will show profound alterations in the sacroiliac joint or, in the case of enthesitis, alterations in involved bone and attached connective tissues. Spondylitis occurs from a combination of arthritis and enthesitis; it begins in the lower spine and slowly progresses to involve the entire spine. Erosions develop at the vertebral corners, followed by formation of syndesmophytes and ultimately leading to the “bamboo spine” appearance. A late feature is ankylosis (12). For diagnosis of early disease, the more useful imaging procedure is MRI. Other useful procedures include ultrasonography and radionuclide scanning, particularly for evaluation of enthesitis. CT scanning is not useful for enthesitis but can be quite useful for evaluation of sacroiliac disease (34).

Natural History

Most youngsters presenting with a spondyloarthropathy do quite well, and permanent disability is not common. Long-term studies showing marked variation in progression to classic ankylosing spondylitis of 9% to 92%, mainly due to differences in classification criteria and length of follow-up. In a recent series of patients with childhood-onset spondyloarthropathy of at least 10 years duration, those with enteropathic or psoriatic arthropathy had remission rates of 50% to 70%, whereas no patient with ankylosing spondylitis was in remission (13); however this was a very small series. In a study of 100 adults with typical ankylosing spondylitis, more than 80% had daily pain, even after 20 years of disease, suggesting that ankylosing spondylitis does not “burn out,” as previously suggested (18). Similar findings were reported in a study of 328 patients with either ankylosing spondylitis or another spondyloarthropathy. In that series, factors associated with a more severe outcome included presence of oligoarthritis, sausage digits, hip or lumbar spine disease, young age of symptom onset (younger than 15 years), poor response to NSAIDs, and persistently elevated ESR. Severe outcome was much more likely with hip involvement and/or three of the above factors (1).

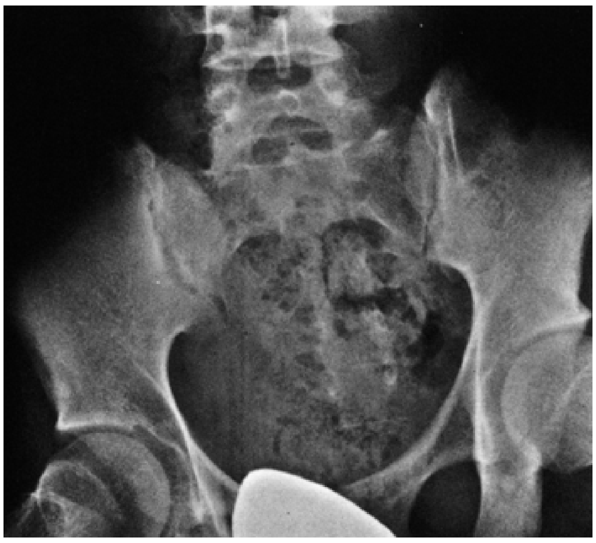

FIGURE 4. Bilateral sacroiliitis, as seen by hazy iliac margins in a 16-year-old boy with juvenile ankylosing spondylitis.

Treatment

Similar to treatment for the child with JRA, the initial focus is on pain control, appropriate balance of rest and exercise, use of analgesics, and a trial of NSAIDs. Exercises to preserve back flexibility, an appropriate exercise program, and inserts to protect heels or plantar fascia can all be useful. For reactive arthritis, this is usually sufficient to control disease. Many rheumatologists also treat an acute exacerbation of reactive arthritis with a course of doxycycline, as this has been shown to reduce the duration of the exacerbation (25). For more recalcitrant and persistent peripheral arthritis, other agents can be added, and the dose and types of agents are similar to those used to treat RA and JRA. Medications include sulfasalazine, methotrexate, doxycycline, chronic NSAIDs, low-dose prednisone, and potentially some of the newer biologic agents may control spondyloarthropathy as well (24 ,25 ,35). Injection of glucocorticoids into involved joints and bursae may provide considerable and longstanding relief of symptoms. Vertebral compression fractures (discussed below) are a common but often undiagnosed complication in adults with ankylosing spondylitis, as many such patients have significant osteoporosis of the spine as a complication of the disease process (38).

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is an inflammatory disorder of unknown cause, occurring predominantly in young women, with an increased incidence in certain ethnic groups (Asian, Hispanic, and African American women in particular). In the United States, the overall incidence is about 1 in 2,000 individuals (27). The hallmark of SLE is the production of multiple autoantibodies, vasculitis, and inflammation of multiple organ systems. Disease expression and long-term prognosis are quite unpredictable and variable. Diagnosis is based on exclusion of other rheumatic diseases and the presence of 4 of 11 specific classification criteria, including rashes, presence of certain serologic markers, arthritis, nephritis, serositis, and neurologic or hematologic abnormalities. As in many other rheumatic diseases (including JRA), most patients have positive ANA. Antibodies to double-stranded DNA and various cytoplasmic antigens are much more sensitive and specific for a diagnosis of lupus. A detailed discussion of autoantibodies is beyond the scope of this chapter.

A lupus patient presenting with back or neck pain should be carefully evaluated, as these patients are at high risk of unusual infections, fractures, and central nervous system (CNS) complications from active lupus. The differential diagnosis of neck or back pain is quite extensive in these patients. Cervical spine pain could result from lupus or from a concomitant infection. Meningeal inflammation with stiff neck and headache can occur in lupus vasculitis as the result of an opportunistic CNS infection (e.g., cryptococcal disease) or as an adverse effect of therapy (e.g., ibuprofen can cause aseptic meningitis in lupus patients). Back pain may be caused by an unusual infection, an inflammatory neuropathic process, or referred pain stemming from pleuritis, pericarditis, or an intraabdominal process. Patients with herpes zoster infections can present with burning radicular back pain several days before developing the typical vesicular eruption. Neurologic manifestations of lupus include transverse myelitis, polymyositis, aseptic meningitis, and peripheral neuropathies. A lupus patient may have back pain from osteoporotic stress fractures or mechanical back pain from muscle weakness or immobility. Consultation with a specialist who has expertise in lupus can be helpful in directing the evaluation of the patient's symptoms, as well as in determining therapy (9 ,25 ,27 ,41).

Noninflammatory Conditions

Fibromyalgia

Fibromyalgia is common, particularly in older female adolescents. These patients have diffuse, longstanding, chronic pain and often cannot identify a single site of pain. Review of systems reveals multiple diffuse somatic symptoms, including sleep disturbance, fatigue, mood disorders, generalized joint and muscle aches, backache, abdominal pain and chronic headaches. These children often have a lifelong history of vague chronic symptoms and positive family history of fibromyalgia or irritable bowel syndrome. Physical examination is completely normal, except for tender points across the back and anterior chest wall. The patient may occasionally have pain on joint motion but should have no clinical signs of inflammation. Laboratory studies should be completely normal, including serologic studies, acute-phase reactants, radiographs, and routine blood tests. There is significant overlap of this condition with chronic fatigue syndrome, as well as with the mood and somatization disorders (54). School problems and other stresses are often present. Treatment of these adolescents can be extremely challenging and, at times, frustrating. The diagnosis of fibromyalgia is based on the typical history of chronic, stable, diffuse pain; normal laboratory investigations; and the presence of tender points on physical examination. The focus is on pain control, use of nonnarcotic analgesics, physical therapy, stress reduction, and normalization of sleep schedules. Referral to support groups and treatment of any concomitant mood disturbance can be quite helpful. In the evaluation of these patients, an appropriate and limited workup is indicated, followed by a trial of conservative therapies and an agreement as to what types of symptoms would warrant further evaluation. Careful and consistent follow-up with a supportive health care provider can prevent a prolonged and unnecessary evaluation. In general, adolescents have a better prognosis than adults with fibromyalgia (9 ,25 ,45).

Osteoporotic Vertebral Compression Fractures

The past two decades has seen an explosion of research and new information on osteoporosis, in both the prevention and treatment of established bone loss. Approximately half of adult bone mass is acquired during adolescence, with bone mass increasing 8% each year during the adolescent growth spurt. Achievement of normal peak bone mass during childhood is important, as it may not be possible to correct this deficiency later in life (10). All children should be counseled about adequate calcium and vitamin D intake, as well as the importance of sufficient regular physical exercise. Children at high risk for decreased bone mass include amenorrheic female athletes, children with eating disorders (anorexia nervosa, in particular), metabolic diseases, and children with any disorder limiting physical mobility or requiring prolonged glucocorticoid administration. JRA patients have diminished bone mass, even in the absence of glucocorticoid use (4). Glucocorticoids are frequently used in the treatment of the rheumatic diseases. The risk and severity of glucocorticoid-induced osteoporosis is related to both the cumulative dose and the duration of treatment. A careful balance between disease control and use of the lowest dose of glucocorticoids is necessary. If the steroid dose cannot be reduced, other antiinflammatory agents should be added for disease control and to allow for a reduction in the daily steroid dose (steroid-sparing effect). Children identified with significant osteopenia from any cause should be referred for treatment, which may include estrogen (in estrogen-deficient girls), vitamin D, and treatment with one of the bisphosphonates, such as alendronate or etidronate. Although the bisphosphonates have been studied and are effective in postmenopausal osteoporosis and in steroid-induced osteoporosis in adults (42), there are few studies on the use of these agents in children or young adults. The treatment recommendations for osteoporosis are in considerable flux, and several large-scale trials are under way to determine optimal doses and duration of therapy, as well as to determine the indications in younger patients.

Children with glucocorticoid-induced compression fractures usually present with vague chronic back pain (Fig. 5). Occasionally, pain is more severe and abrupt. Physical examination is often normal, whereas the radiographs show dramatic changes. Progressive fractures can lead to significant kyphosis and poor posture. Management consists of administration of analgesics, bracing for comfort, physical therapy, as well as a focus on reducing the glucocorticoid dose if possible and referring the patient for treatment of the osteoporosis.

The Child with Nonorganic Back Pain

Back pain is discussed in more extensively in an earlier chapter, but will be briefly reviewed here. Back pain is an extremely common symptom and increases markedly with age. The incidence and prevalence in older adolescents is similar to adults. In adults, at any one time, 20% to 40% will have experienced back pain (defined as any back pain lasting longer than 24 hours) in the past month (51), and adults have a lifetime 70% to 90% probability of experiencing back pain (18). Over half of children have experienced episodes of back pain, and 8% to 30% have reported the presence of chronic back pain. Most of these children do not seek medical evaluation (28 ,48). Of those seeking evaluation, a specific cause will be found in only about half. A specific cause is more often found in younger children, particularly those younger than 10 years. In a large series of children presenting to a pediatric orthopedic clinic with back pain, no organic cause was found in 57%. Interestingly, the group of patients in this series with nonorganic pain had a higher incidence of psychosocial problems, disability claims, and pending litigation (11); similar findings have been seen in studies in adults with chronic back pain. The inability to find an organic cause is even higher in patients presenting to the general practitioner, and the cause is assumed to be myofascial in origin in most cases. In general, functional back pain is more common in patients with lower socioeconomic status, high stress, and in those patients with a higher incidence of self-reported physical or sexual abuse (11 ,51). Nonorganic back pain can be one of the more challenging conditions to evaluate, as patients can have severe pain, prolonged symptoms, and seek evaluation from multiple health care providers. Parents may become upset when no organic cause of their child's pain can be found.

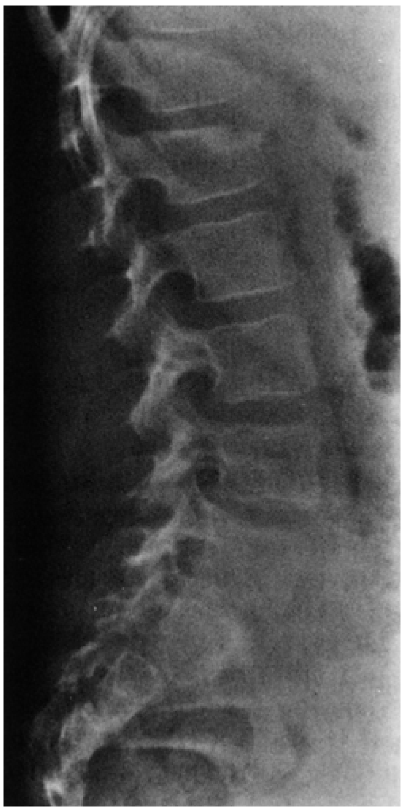

FIGURE 5. Multiple compression fractures in an 8-year-old boy with systemic-onset juvenile rheumatoid arthritis managed with oral glucocorticoids for 4 years.

All children with back pain should have a careful history and physical examination, including a family and social history. Red flags for an organic cause include young age (under 10 years), the presence of systemic symptoms (e.g., fever and weight loss), pain that interferes with sleep, inflammatory pain (worse in the morning with relief at the end of the day), neurologic signs or symptoms, and constant pain (23 ,48). Malingering and/or factitious causes are not common in children and can usually be ascertained by careful investigation. Nonorganic back pain is an important differential diagnosis to consider as it may spare the child an unnecessary and costly evaluation. Nonorganic pain should be considered in the older child presenting with extreme school absence; psychosocial stresses; bizarre, diffuse, and/or vague symptoms; and a normal physical examination. Often the child's reported disability and dysfunction is out of proportion to the physical examination. For these children, a limited diagnostic evaluation and careful observation and symptom control may be indicated as the first line of management. A trial of physical therapy, analgesics, and/or NSAIDs is recommended, and the child should be scheduled for a reexamination in 4 to 8 weeks. The child can keep a diary of symptoms and should be reassured in a sympathetic tone. The child should be strongly encouraged to return to school and to normal physical activity.

Preoperative Considerations in Rheumatic Diseases

The rheumatic diseases are complex, chronic conditions, and a careful preoperative evaluation is important for all children recommended for surgery (Table 3). Medications and other health problems should be reviewed, and consultations with anesthesiologists, nurses, surgeons, and other health care providers recommended as indicated. Steps should be take to reduce the child's fear and anxiety. Anesthesia can be particularly challenging for the child with severe JRA and polyarthritis. These children often have limited mouth opening, small mandibles, limited cervical spine extension, and osteoporotic bone, all of which lead to increased risks from anesthesia and endotracheal intubation. A careful preoperative examination of the neck should be performed on all children with JRA. Any child with neck pain or limited cervical spine movement should have cervical spine films (extension and flexion) obtained to expose possible subluxation or another abnormality. Consideration should be given to fiberoptic intubation and consultation with the anesthesiologist to determine the most appropriate choices of anesthesia (31 ,55).

TABLE 3. Preoperative Assessment of Children with Rheumatic Diseases

All Cases
History and physical examination
  Anesthetic history, prior anesthetic difficulties
  Careful attention to cervical spine and jaw examination
Medication history
Complete blood count
If indicated
Cervical spine x-rays—any child with neck symptoms or limitation of motion (especially patients with polyarthritis)
Corticosteroid stress coverage—children on corticosteroids for more than 1 mo the past 6 mo
Hold aspirin, consider holding other nonsteroidal antiinflammatory drugs for 5–7 d
Hold methotrexate and other immune suppressants for 1 wk

A child on chronic glucocorticoid therapy (more then 10 mg daily for more than 30 days) should receive intravenous stress coverage during the surgery and until he or she can resume the usual oral steroid dose. Antibiotic prophylaxis for endocarditis is not necessary unless the child also has a heart defect. Any NSAID medications may be stopped a few days before the surgery and then restarted a few days later due to the small risk of an effect on platelet function. Some rheumatologists recommend withholding methotrexate or other immune suppressants during the week of surgery because of the small potential for a delay in wound healing or an increased the risk of infection, though there are no firm data to confirm these risks. Omitting most rheumatic medications for a few days will have no long-term consequences on the underlying disease (31 ,47).

Inflammatory Diseases of the Spinal Cord, Leptomeninges, and Dura

Russell D. Snyder

R. D. Snyder: Department of Neurology and Pediatrics, University of New Mexico School of Medicine, Albuquerque, New Mexico 87131–5281.

This chapter considers inflammatory and infectious conditions of the spinal cord, the leptomeninges (the surrounding pia and arachnoid membranes), and the dura mater. Meningitis and epidural abscess are caused by bacteria. Arachnoiditis is an inflammatory response established by an agent, infectious or otherwise, that irritates the leptomeninges. Transverse myelitis has diverse etiologic factors, and frequently no specific cause can be determined. All of these conditions are rare but have major unfavorable consequences when left untreated—and sometimes even when they are appropriately treated. The chronic orthopaedic management of an individual who recovers from one of these conditions with significant deficit is not considered here. Also, other inflammatory and infectious conditions of structures surrounding the spinal cord, such as disc space infection and vertebral osteomyelitis, are considered elsewhere in this volume.

Bacterial Meningitis

Bacterial meningitis is a bacterial infection involving the pia, the arachnoid, and the subarachnoid space. The infection is usually acute.

Epidemiologic Factors

The peak attack rate was between 6 and 12 months of age until the introduction of *Haemophilus influenzae* immunization at an early age, when the median age shifted to 25 years (74). Bacterial meningitis is more common in winter except that *H. influenzae* type b peaks in spring and fall. Risk factors for *H. influenzae* type b include male sex, black race, Native American heritage, household crowding, and attendance at day-care centers (12 ,18).

Etiologic Factors

In the neonate, *Escherichia coli*, *Listeria monocytogenes*, and various gram-negative organisms are found. Between 1 and 3 months of age, similar organisms are cultured along with *H. influenzae*, *Streptococcus pneumoniae*, and *Neisseria meningitidis*. Between 3 months and 10 years of age, *H. influenzae, S. pneumoniae*, and *N. meningitidis* are the common organisms. In adolescence, *N. meningitidis* is an important organism. *Staphylococcus aureus* and *Staphylococcus epidermidis* are important etiologic agents in surgically acquired infections, as are *Klebsiella* and *Pseudomonas* species. With immunization against *H. influenzae* reducing the incidence of this organism, *S. pneumoniae* is gaining in importance. Infection with unusual organisms, such as *Mycobacterium tuberculosis*, must be considered in every case (97).

Clinical Features

Fever with neurologic signs or symptoms, especially if accompanied by a seizure, should raise a suspicion of meningitis (Table 1). The classic finding of fever and stiff neck is useful. Stiff neck is tested by flexion of the neck and not by rotation. In the very young and in the debilitated, neck stiffness may not be present. Other findings of meningeal irritation include Kernig sign (inability to fully straighten the leg that is flexed at the hip) and Brudzinski sign (flexion at the hips with passive flexion of the neck) (92). Headache is less common in children than in adults.

A history of a preceding upper respiratory or gastrointestinal infection is common. Instead of recovery from the initial illness, as is the usual occurrence in common childhood infections, the child becomes progressively more ill, developing septicemia and then meningitis. There is never a precise moment when a respiratory or gastrointestinal infection evolves into meningitis. The symptoms of bacterial meningitis usually run a rapid course, with progressive deterioration of neurologic function over several hours and seldom over more than a day or two

Seizures may be focal or generalized. Depressed consciousness is present, which may rapidly evolve into coma. A bulging fontanel and fever in a small child or infant is a strong indication of meningitis, especially if trauma is excluded. Focal neurologic signs, such as hemiparesis or cranial nerve deficits, occur later and are unusual as part of the presentation. The lack of specific neurologic symptoms or of meningeal signs in a febrile child who is lethargic or irritable does not exclude the possibility of meningitis.

Purpuric skin lesions may be found in *N. meningococcus* meningitis and, less often, in other forms of meningitis. Purpuric skin lesions may be a manifestation of meningitis complicated by disseminated intravascular coagulation.

TABLE 1. Signs and Symptoms of Bacterial Meningitis

Acute progression

Bulging fontanelle
Headache
Seizure
Focal neurologic signs

The infectious process surrounds the spinal cord, and the diagnosis of meningitis is made by recovery of organisms from the region of the cauda equina. However, clinical signs relating to the spinal cord are surprisingly rare. Paresis of one or more limbs and sphincter involvement secondary to spinal cord lesions can be found (34 ,86). A cauda equina syndrome with paraplegia, saddle anesthesia, and bladder and bowel dysfunction has been reported in *S. pneumoniae* meningitis (45). Children with meningitis may have such significant involvement of the brain that spinal findings may be hidden or overlooked.

Meningitis is an important consideration in any infant or child with a fever and neurologic symptoms or signs.

Differential Diagnosis

A common concern in differential diagnosis is the benign febrile seizure of childhood. Febrile seizures occur between 6 months and 4 years of age. They are usually single seizures, are generalized, and last for less than 5 minutes. Cerebrospinal fluid (CSF) and the electroencephalogram are normal.

Occasionally, head trauma is mistaken for bacterial meningitis. A child with head trauma may be depressed, have neurologic signs, have a full fontanel and fever. The presence of retinal hemorrhage is strongly suggestive of trauma and would be most unusual in meningitis. Associated evidence of trauma may be present in the skin or long bones.

Other concerns in differential diagnosis include sepsis, brain or epidural abscess, viral central nervous system (CNS) infection, intoxication, Reye syndrome, and tonsillar herniation.

Radiographic and Imaging Studies

Head imaging should be performed in any meningitis patient with an unfavorable clinical course to exclude extraaxial fluid collection, ventricular enlargement, vascular involvement (such as infarction or necrosis), empyema, and venous thrombosis (28). Vascular changes can be arterial or venous.

Magnetic resonance imaging (MRI) offers little advantage over computed tomography (CT) in the evaluation of acute bacterial meningitis, although experience is limited. The child with complicated meningitis may be acutely ill and on a ventilator, rendering MRI difficult.

Other Diagnostic Studies

Lumbar puncture with examination of CSF is the definitive test for meningitis. However, it should not be performed without consideration of possible adverse effects (59). In certain situations, the pressure changes produced by removal of CSF at lumbar puncture can result in shifts of intracranial contents and even brain herniation. Although the presence of increased intracranial pressure is a relative contraindication to lumbar puncture, the diffuse increased pressure of meningitis in infants or children seldom leads to difficulties. Papilledema or focal findings on examination suggest a mass lesion, a situation that may result in complications from lumbar puncture.

Brain imaging before lumbar puncture provides some assurance that lumbar puncture can be performed safely. In selected situations, sedation of the child prior to lumbar puncture may be indicated.

Initial antibiotic treatment can be started prior to lumbar puncture so that there is no delay in starting therapy directed against a suspected meningitis. A short regimen of antibiotics prior to CSF examination will not significantly interfere with the results.

Lumbar puncture should not be performed through an area of abscess or cellulitis. If the patient has a bleeding diathesis, correction of the diathesis should be undertaken before performance of the lumbar puncture. Inadvertent needle entry into the disc space can lead to subsequent pain and collapse of the disc space. The amount of CSF necessary for performance of testing will vary from one facility to another and according to the specific testing requested.

Headache 1 to 4 hours after the lumbar puncture is a troublesome but usually benign complication. This complication occurs in 10% to 25% of adults and appears less common in preadolescent children (59). The headache is frontal and is exaggerated by movement from a lying to a sitting or standing position. Post-lumbar puncture headache appears to be caused by continued leak of CSF from the site of lumbar puncture, with resulting low CSF pressure and pulling of the brain on pain-sensitive structures. The problem can be minimized by use of a small-bore needle and removal of a minimal amount of fluid. Pain in the lower back or legs occurs occasionally after lumbar puncture. This pain is of uncertain cause and usually resolves spontaneously in several days (80).

Opening pressure at lumbar puncture, a frequently overlooked procedure in infants and children, can easily be obtained if the patient is not struggling. It provides useful information as the opening pressure is usually elevated in bacterial meningitis.

The CSF may have a cloudy appearance. The cell count is increased, with the predominant cell being polymorphonuclear. On the initial lumbar puncture at the onset of illness, a predominance of polymorphonuclear cells may be found in bacterial or viral meningitis. In aseptic meningitis of viral origin, a predominance of polymorphonuclear cells on the second or third day is distinctly unusual (1). Protein is increased with depression of sugar content. Gram staining should be carried out. Cultures of CSF and blood should be obtained for bacteria and, in certain circumstances, for other organisms. Immunoassays for bacterial antigen can provide a rapid diagnosis. These antigen tests can be performed on CSF, blood, and urine. Both Gram staining and antigen testing are rapid, providing results in about 15 minutes, and become useful in guiding initial therapy. Culture of the CSF is the gold standard for etiology and can provide information concerning antibiotic sensitivities. When CSF is normal and a suspicion of meningitis persists, the lumbar puncture should be repeated. Blood culture can recover the organism of bacterial meningitis in about 70% of cases.

Pathoanatomy

The sequence of events in the pathogenesis of bacterial meningitis begins with bacterial colonization of the nasopharynx. From there the organism enters the bloodstream or, rarely, enters directly into the cranial vault. The bloodstream can carry the organism to the CNS. Direct spread is possible from a focus in the skin or sinuses, from a brain abscess, or from osteomyelitis of adjacent bone (57). Trauma from a surgical or diagnostic procedure involving the CNS may lead to entry of the organism. The purulent exudate in bacterial meningitis is within the subarachnoid space between the pia and arachnoid, which contains the CSF (Fig. 1). The basal cisterns, sylvian fissure, rolandic sulci, and perivascular spaces are prime locations for the infection (8). Vascular changes may be marked because of an associated vasculitis from the infection surrounding major vessels entering and leaving the brain (29 ,61).

Although bacterial meningitis is a disease of the brain and surrounding structures, the spinal cord and its surrounding structures are involved with the subarachnoid exudate. Historically, a bacterial infection of the subarachnoid space was called “spinal meningitis,” although this term has fallen into disuse. In severe cases, the spinal cord can be encased in purulent exudate (8). The recovery of organisms and inflammatory cells on lumbar puncture shows the widespread nature of the infection. The low incidence of clinical signs and symptoms referable to the spinal cord is surprising. Spinal cord findings appear related to cord infarction or necrosis (34 ,86).

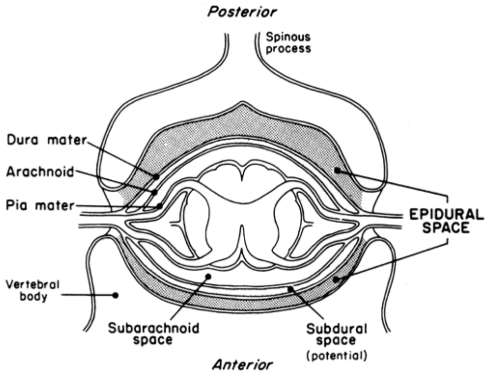

FIGURE 1. Transverse section of spinal cord showing relation of the spinal cord to the leptomeninges, the bone, and the various spaces mentioned in the text. (From Beland B, Prien T, Vanaken H (1997): Spinal and epidural anaesthesia in bacteremic patients. *Anaesthesist* 46:536–547, with permission.)

Replication of the organism within the CNS occurs easily. Pus accumulates, edema develops, and the CSF circulation becomes compromised. All blood vessels entering or leaving the brain must pass through the subarachnoid space. When this space is inflamed, vasculitis develops with ischemia and infarction.

Natural mechanisms and bactericidal antibiotics used in the treatment of meningitis result in the release of lipopolysaccharide endotoxin. Endotoxin in the CSF induces the production of cytokines that can initiate an inflammatory response even in the absence of bacteria. These cytokines are found in increased amounts in the CSF in experimental and human meningitis, especially after treatment with bactericidal antibiotics. They damage the CNS by direct cellular toxicity and by changes in the vascular milieu (72 ,84). Improvement in outcome depends on the development of techniques to counteract these mechanisms.

Complications

Complications occur in the management of bacterial meningitis, even when the diagnosis is prompt and appropriate therapy is rapidly instituted. Seizures are found in approximately 30% of children, usually early in the illness (68). Seizures may be caused by toxic products of bacteria or leukocytes, inflammation, vasculitis, fever, electrolyte imbalance, or an unrecognized process.

Focal signs, such as hemiparesis, may be found. Cranial nerve palsies occur. The eighth cranial nerve is involved in 5% to 20% of cases and may result in hearing loss, which usually has an early onset and is permanent (70).

Collections of extraaxial fluid, the so-called subdural effusions, are found over the brain convexities in some younger children. These collections seldom cause symptoms and can be followed on brain imaging until they regress or until intervention becomes necessary because of pressure or displacement of brain parenchyma. Hydrocephalus may occur. However, ventricular widening may also be the result of parenchymal loss. Surgical intervention should not be undertaken until the surgeon is assured that elevated intraventricular pressure is present. Temporary external drainage with serial brain imaging can determine if a shunt will be effective.

Disseminated intravascular coagulation is a complication in those who are severely ill with meningitis. Septic shock, cerebral edema, and the syndrome of inappropriate secretion of antidiuretic hormone also occur.

Natural History

Without treatment, bacterial meningitis is fatal in almost all cases. Following treatment most children recover without sequelae (87). In a series of children, 37% had neurologic abnormalities 1 month after meningitis. Within a year only 14% had persistent deficits (68). Subtle cognitive and learning problems may be found (88). Recovery from spinal cord involvement is poor (76).

Treatment

Nonsurgical

Antibiotics remain the mainstay of specific treatment. Recommendations change frequently, and expert advice may be needed. Initial empirical treatment is determined by the suspected organism. Once an organism is identified by immunologic means, Gram stain, or culture, the antibiotics can be adjusted to achieve ideal therapy.

In newborns the therapy is directed to organisms acquired during delivery. Empirical therapy includes ampicillin plus an aminoglycoside or a third-generation cephalosporin. Between 1 month and 3 months of age, ampicillin and cefotaxime or ceftriaxone are recommended. Between 3 months and 10 years of age, cefotaxime or ceftriaxone alone is used. In older children, ampicillin alone or penicillin G is appropriate. If *Staphylococcus* is a likely offender, methicillin can be utilized. Strains of *S. pneumoniae* are found that are resistant to penicillin and ceftriaxone (3). Research has suggested that steroids may reduce the suspected harmful effects of rapid bacterial lysis within the subarachnoid space and the associated release of biologically active products, at least in *H. influenzae* meningitis (43). Also, moderate and severe hearing loss may be decreased by dexamethasone after initial antibiotics (50). Dexamethasone decreases the duration of fever and CSF pleocytosis. Cytokines in the CSF are reduced when glucocorticoids are administered prior to the initial antibiotic (2). In a trial of dexamethasone administered 15 to 20 minutes prior to institution of antibiotic therapy, the CSF opening pressure was lower; 12 hours later, the evidence of inflammation in the spinal fluid had begun to disappear, the CSF contained lower concentrations of cytokines, and neurologic sequelae were less marked (66). Dexamethasone has not demonstrated similar effectiveness in *S. pneumoniae* meningitis (3) and probably should not be used routinely except in *H. influenzae* meningitis (67).

When seizures are severe or prolonged, lorazepam is effective. The intravenous (IV) dose is 0.05 to 0.1 mg/kg up to a maximum of 4 mg administered no more rapidly than 2 mg/min. Fosphenytoin may be effective in this situation in an initial dose of 10 to 20 mg/kg IV, administered no more rapidly than 100 mg/min; cardiac function must be monitored for signs of bradycardia or dysrhythmia. Phenobarbital can be administered in the dose of 10 to 20 mg/kg IV or intramuscularly. Once initial control is achieved, continuous anticonvulsant administration with phenobarbital or phenytoin can be undertaken for more prolonged coverage. The self-limited seizures that are found early in bacterial meningitis may not be an indication for prolonged anticonvulsant treatment.

Cerebral edema requires traditional management, with elevation of the head, osmotic agents, diuretics, and possibly hyperventilation. Supportive care is indicated, with attention to the skin and joints.

Recommendations change frequently. The physicians undertaking treatment of bacterial meningitis should check for current recommendations regarding antibiotics, fluid management, steroid use, brain imaging, and management of cerebral edema.

Surgical

Extraaxial collections must be drained if significant compression or shift of brain parenchyma is occurring, if the child remains symptomatic in spite of a good response to antibiotics, or if the extraaxial fluid becomes infected. Repeated tapping through the fontanel or continuous external drainage is appropriate if the collection is liquid. Shunting of the extraaxial space should be reserved for those cases refractory to more conservative measures (83). Rapid removal of large volumes of extraaxial fluid may have a deleterious effect secondary to shifts in intracranial contents. Continuous ventricular drainage or shunting is indicated in selected cases with persistent increased intraventricular pressure.

Neurosurgical intervention may also be necessary if the infection progresses to brain abscess or cerebral epidural abscess (17).

Spinal Arachnoiditis

Spinal arachnoiditis is a noninfectious or postinfectious chronic aseptic inflammatory process of the leptomeninges (94). The condition is not usually seen in isolation but occurs as part of another disease of the spinal cord, spinal subarachnoid space, or surrounding structures, or as sequelae of a procedure around the leptomeninges.

Epidemiologic Factors

Spinal arachnoiditis is unusual before adolescence. Males are affected more commonly than females.

Etiologic Factors

Many agents produce arachnoiditis. The common theme is violation of the arachnoid. Aseptic arachnoiditis is initiated by a variety of chemical and physical agents in the subarachnoid space and is seen as a sequela of a spinal or paraspinal infectious process including tuberculosis (47). Myelographic contrast material has been a particular offender, although newer contrast materials present less of a problem (22). Intrathecal steroids are implicated (40). Spinal arachnoiditis has been reported after epidural and spinal anesthesia (33 ,81), and after back surgery (25) and other forms of trauma.

Extrinsic or intrinsic spinal cord disease, including neoplasms and syringomyelia, can produce arachnoiditis. Arachnoiditis occurs following subarachnoid hemorrhage. Intervertebral disc disease can produce the condition. Aseptic and purulent infections of the meninges or adjacent areas of the spine can lead to spinal arachnoiditis; chronic infections, such as tuberculosis, cryptococcosis, and syphilis, have been offenders. Spinal arachnoiditis is found in adolescents with tuberculous meningitis (51).

A familial form of spinal arachnoiditis has been described (21). Arachnoiditis may appear in developmental disorders of the spine or spinal cord, such as meningomyelocele, neurofibromatosis type 1, and syringomyelia (15). Many cases remain idiopathic.

TABLE 2. Signs and Symptoms of Arachnoiditis

Chronic progression
Spotty and localized pain
Migratory paresthesias
Weakness
Spastic paraparesis
Sphincter disturbance
Symptoms out of proportion to signs

Clinical Features

The symptoms of spinal arachnoiditis are produced by cord compression, adhesions about nerve roots, constriction of blood vessels supplying cord and roots, and the formation of cysts (Table 2). The cord may become fixed from adhesions and then damaged by constant spine movement (15).

Onset may be rapid or gradual. Fever and other systemic manifestations are usually absent. Remissions occur. Symptoms may not appear for months or years after the initiating event. The first symptoms are pain and paresthesia (69). The pain is aching or burning and is poorly localized; it may follow a broad radicular pattern or be spotty. Movement and straining, as with coughing or sneezing, may increase the pain. Bed rest may also increase the pain. In some patients, the pain is worse upon rising. The paresthesias are described as tingling, numbness, the sensation of heat or cold, or a constricting sensation. The paresthesias may be in a neurologically inconsistent distribution and migratory. Sensory examination may be normal or may reveal areas of hyperesthesia or hypesthesia. Trophic changes are rare.

Weakness eventually appears, and the course then becomes one of slowly progressive spastic paraparesis. Painful muscle spasms and muscle atrophy develop with the passage of time. Sphincter problems evolve in one third of cases. Muscle stretch reflexes are increased or decreased depending on the location, duration, and nature of the lesions.

The straight-leg raising test is often positive. The back is tender and stiff, with limitation of motion. Symptoms are frequently out of proportion to signs. Arachnoiditis is responsible for the symptoms in some “failed back surgery” patients (79).

Differential Diagnosis

The differential diagnosis includes extramedullary cord tumor and syringomyelia.

Radiographic and Imaging Studies

The diagnosis of arachnoiditis should be made by clinical findings, with imaging providing supportive evidence. Arachnoiditis can be present on imaging without clinical symptomatology (40). Gadolinium-enhanced MRI is now the appropriate imaging examination in spinal arachnoiditis, as it is for all infectious and inflammatory diseases of the spinal cord (33 ,91). Partial or complete obstruction is present with irregularity of the thecal sac plus thickening and clumping of the nerve roots. The area of abnormality may have a considerable longitudinal extent. Arachnoid cysts can develop, compressing and distorting the cord (41).

Other Diagnostic Studies

Imaging should usually precede lumbar puncture, which is contraindicated if spinal block is present. The lumbar CSF is usually under normal pressure or, when a block is present, under reduced pressure. Fluid constituents are normal, or there may be a slight pleocytosis and slight elevation of protein. The pleocytosis can be either mononuclear or polymorphonuclear. The CSF protein will be markedly elevated below the level of a complete block (Froin syndrome).

Pathoanatomy

The arachnoid is a thin membrane throughout the CNS between the pia and dura. A potential space separates the arachnoid from the dura. CSF is located between the arachnoid and pia (Fig. 1). The pia is adherent to the CNS.

The arachnoid is relatively avascular and thus has difficulty participating in an inflammatory reaction. In response to chronic irritation, fibrosis with proliferation and thickening of the arachnoid is found, and adhesions develop between the arachnoid, pia, and dura, which may produce an associated compromise of circulation. The fibrotic bands may form cystic structures communicating with the subarachnoid space or containing loculated CSF. Constriction of the cord can develop as can compromise of nerve roots. The area of pathology is localized or diffuse. Arachnoiditis is one cause of arachnoid cyst (11). The mid-thoracic spine is most commonly involved, followed by the mid-cervical spine.

With time, a constrictive phase develops with obliteration of the subarachnoid space and a block of CSF pathways. Blood vessel walls become thickened. The constrictive and vascular effects result in intramedullary changes in the cord. The associated vasculitis can produce infarction of the cord. Compression of the spinal cord from arachnoid cysts also produces these changes. In tuberculous arachnoiditis, the spinal cord can be encased in a fibrous or gelatinous exudate (16).

Natural History

Progression of symptomatology commonly develops. Although cessation of progression may occur spontaneously, improvement is usually minimal (30).

Treatment

Neither medical nor surgical treatment is satisfactory (11).

Nonsurgical

Antiinflammatory agents, including steroids, are the mainstays of treatment. However, significant improvement is seldom realized. Of particular interest is the fact that intrathecal steroids may also incite the process of arachnoiditis (40). Antibiotics probably have no place in the management of this condition. Supportive care should be undertaken with physical therapy and other appropriate measures.

Surgical

The results of surgery have not been encouraging and remain controversial (23). A tangle of fibrous meninges and neural structures is found at surgery, and any attempt at dissection has the risk of producing further neurologic impairment and further compromise of vascular function. Surgery should only be considered when the process involves a small circumscribed area or when an arachnoid cyst is producing symptoms.

Spinal Epidural Abscess

An epidural abscess is a collection of pus between the dura and overlying bone. The terms *epidural* and *extradural* are interchangeable.

Epidemiologic Factors

The incidence of epidural abscess is 2 in 10,000 hospital admissions (36). Epidural abscess is more common in males except during childhood when females predominate 2:1 (71). All age groups are affected from infancy on (19). A review of 45 cases from the English language literature was reported in 1974 (6).

Etiologic Factors

Spinal epidural abscess is usually a complication of bacteremia. Urinary tract infections and furuncles are common sources of the infection, although decubitus ulcers, pulmonary infection, and dental infection are implicated. Altered immune status predisposes to epidural abscess (36). It has been reported secondary to intravenous substance abuse (82). Considering the frequency with which lumbar puncture is performed, epidural abscess is extremely rare after that procedure (7). Trauma to the back, back surgery, vertebral osteomyelitis, and spinal or epidural anesthesia (14 ,96) are sometimes associated findings. The abscess may develop by spread from a contiguous osteomyelitis (78). A focus cannot always be identified.

Staphylococcus aureus is the most common organism recovered, responsible for at least 50% of cases in both children and adults (71). Gram-negative organisms, such as *E. coli* and *Proteus*, are other etiologic factors. Tuberculosis is always a consideration.

Clinical Features

Spinal epidural abscess is a “painful, febrile, spinal syndrome” (31) (Table 3). A preexisting remote infection is usually present. Pain is the most consistent symptom, and discomfort evolves rapidly from localized back pain to radicular pain and is frequently severe. The radicular pain is appropriate for the dermatomes involved in the infection. There may be swelling and tenderness in the area of back pain. Headache and nuchal rigidity may be present.

TABLE 3. Signs and Symptoms of Spinal Epidural Abscess

Rapid progression
Fever
Tenderness and swelling about spine
Localized and radicular pain
Paresis
Sphincter involvement
Headache
Stiff neck

Progression can be extremely rapid. Clinical symptoms progress through four phases—(a) spinal ache, (b) root pain, (c) partial neurologic dysfunction, and (d) paralysis (35)—often within 24 hours of onset. The weakness is the result of spinal cord compression and ischemia. Bladder dysfunction, especially urinary retention, is an ominous sign. A sensory level is a late finding. When the cause is tuberculosis, symptoms evolve more slowly.

In children, back pain and fever may be the only symptoms preceding precipitous development of neurologic signs (71). In infants, the condition may present as fever and diminished limb movements. Prior antibiotic therapy masks symptoms. A high index of suspicion is necessary to make the diagnosis of spinal epidural abscess. Early diagnosis and treatment are of paramount importance (54).

To make the diagnosis the clinician must recognize that an acute spinal syndrome is present. Cardinal clinical features include fever, back pain, numbness, tingling, weakness, and bladder dysfunction. Imaging establishes that the condition is an epidural abscess.

Differential Diagnosis

Acute transverse myelitis can be confused with spinal epidural abscess. Fever and back pain are usually less prominent in acute transverse myelitis, and a sensory level is an early finding (27). Meningitis, spinal tumors, spondylitis, and herniated discs need to be considered. Spinal trauma, acute back strain, and Pott disease can all mimic spinal epidural abscess, but none of these conditions has a significant febrile response or other sign of infection. In the infant or young child, an acute discitis can present with diminished movements of the lower extremities and pain.

Radiographic and Imaging Studies

Immediate gadolinium-enhanced spinal MRI is indicated and should precede lumbar puncture (93). MRI shows a fluid collection between neural structures and bone. The entire spine should be imaged, even if symptoms are localized. MRI is noninvasive, readily available in the United States, and has the advantage of being able to detect other conditions, such as disc herniation, joint space infection, vertebral osteomyelitis, syrinx, intramedullary spinal tumor, spinal hematoma, and transverse myelitis (36). MRI is superior to CT-myelography in delimiting the extent of the lesion (Fig. 2).

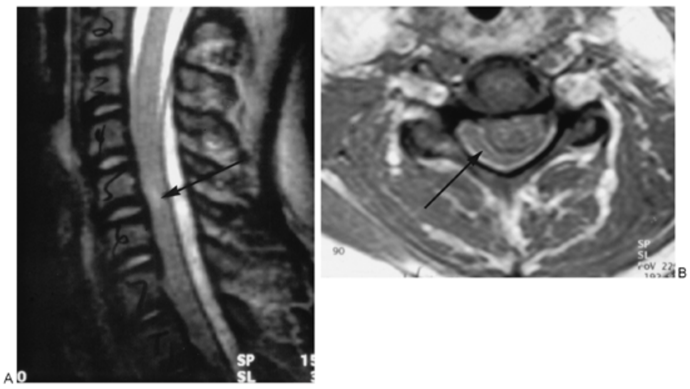

FIGURE 2. A 12-year-old girl with acute back pain, fever, incontinence, and numbness and weakness of arms and legs. **A:** Magnetic resonance image of cervical spinal cord in sagittal planes (TR: 4,000; TE: 90). There is increased signal in the central cord on longitudinal image that does not enhance with contrast and does not have mass effect, probably ischemia secondary to vasculitis *(arrow)*. Also, there is increased signal surrounding the cord secondary to *S. aureus* epidural abscess. **B:** On axial image, epidural mass *(arrow)* is compressing the spinal cord and displacing it anteriorly, secondary to *S. aureus* epidural abscess (TR: 700; TE: 17).

Other Diagnostic Studies

The sedimentation rate is consistently elevated. The peripheral white count may be slightly elevated with a left shift or the white count may be normal (96).

Lumbar puncture is contraindicated because of the possibility of increased symptomatology when either a partial or a complete spinal block is present (37). Also, lumbar puncture can inadvertently carry infectious material into the subarachnoid space, thus causing meningitis. If lumbar puncture is performed and purulent material is found before entry into the subarachnoid space, the needle should not be advanced further.

CSF may be turbid or xanthochromic, with elevation of protein, polymorphonuclear pleocytosis, and normal sugar (44). Normal CSF does not rule out the diagnosis of epidural abscess. As spinal epidural abscess is associated with bacteremia, the etiologic organism can sometimes be recovered by blood culture.

Pathoanatomy

Bacteremia underlies most cases of spinal epidural abscess, especially when the presentation is acute. Infection usually occurs by hematogenous spread and produces rapid neurologic dysfunction and purulence in the epidural space (Fig. 1). Batson's plexus is a low-pressure epidural network of veins. Bacteria from the pelvis may seed into the area of Batson's plexus during straining, such as in a Valsalva maneuver, and thus initiate the process of formation of an epidural abscess. Debilitation is a predisposing factor. The abscess produces neurologic symptomatology by nerve root and cord compression, by vascular changes induced by the inflammation with spinal cord infarction, and by obstruction of CSF flow (13). An infection of the epidural space may be produced by spread from contiguous structures such as bone or soft tissues. Purulent meningitis is surprisingly rare in spinal epidural abscess.

The epidural space consists mostly of fat and, similar to other fatty tissues, has a lowered resistance to infection (63). Epidural abscesses usually occur in the mid-thoracic and upper lumbar area, dorsal to the spinal cord where the epidural space is more capacious. Epidural abscess is less common in the cervical area, perhaps because the dura is more closely applied to the vertebral bodies in that area.

Natural History

Epidural abscess is a condition with a poor prognosis and a high mortality. Progression is frequently rapid, requiring early diagnosis with urgent appropriate intervention to achieve a favorable outcome (54). The outcome is related, at least in part, to the condition of the patient at the time of diagnosis. Appropriate management may prevent progression but does not always reverse the clinical deficits present at the time of surgery. Permanent neurologic sequelae result when treatment is delayed (60), and recovery may be incomplete (85). Preoperative paralysis is an especially ominous sign (36). Children and adolescents probably recover more completely than older individuals (75). If not promptly treated, an epidural abscess may spread beneath the dura and expand to produce spinal cord compression and CSF block.

Treatment

Spinal epidural abscess is a medical and surgical emergency (58).

Nonsurgical

Appropriate antibiotics should be started immediately after recognition of the condition, with initial empirical therapy directed against *S. aureus.* The physician is advised to consult appropriate sources for current antibiotic recommendations (53).

The role of glucocorticoids in the medical management of this condition is uncertain, although glucocorticoids are frequently used. Glucocorticoid treatment is associated with a poor outcome, although the most seriously ill patients are more likely to be placed on steroids (20). The use of very high-dose glucocorticoids in this condition has not been reported.

Claims have been made that spinal epidural abscess can be successfully treated by intravenous antibiotics without surgical intervention (55 ,62 ,82). Nonoperative treatment with antibiotics should only be considered when the pathogenic organism is known, antibiotic sensitivities are available, the neurologic condition is stable, and MRI is readily available for reevaluation (32). Nonsurgical treatment avoids the spinal deformities that develop in children after extensive laminectomies and is probably appropriate for patients who are poor surgical risks. No data are available concerning the epidural penetration of antibiotics.

Supportive care is appropriate with attention to skin, joints, and bladder.

Surgical

Epidural abscess with cord compression remains a surgical emergency. Aggressive surgical treatment is the mainstay of successful therapy (26 ,39). Immediate drainage and decompression are indicated, with culture of the purulent material. Antibiotic coverage is essential.

Acute Transverse Myelopathy

Acute transverse myelopathy is an acute monophasic intramedullary dysfunction of the spinal cord not related to trauma or extrinsic pressure in an individual without preexisting neurologic disease.

Epidemiologic Factors

Persons of any age between 18 months and 80 years may be affected. The peak incidence occurs between 10 and 19 years of age. In children, the condition is more common during spring, summer, and fall (24).

Etiologic Factors

Acute transverse myelopathy has multiple causes, such as postinfectious processes (64 ,90), response to immunization, vascular factors (4), direct infection by a virus (e.g., herpes, mumps [65], varicella-zoster, Epstein-Barr) or by bacteria, including Lyme borreliosis (52) and perhaps some instances of *Mycoplasma pneumoniae* infection. However, when transverse myelitis is found in association with *M. pneumoniae*, the neurologic lesions are frequently an immune response. Retrovirus infection is associated with a myelopathy that does not have an acute onset. Some cases of acute transverse myelopathy are clearly autoimmune (49), and acute transverse myelopathy is often a feature of acute disseminated encephalomyelitis. Acute transverse myelopathy has been found in a child with lupus erythematosus (5). Fibrocartilaginous emboli must be considered (95). Many cases remain idiopathic.

Multiple sclerosis is usually considered as a separate category and not as a cause of acute transverse myelopathy. Acute transverse myelopathy is rarely the first sign of multiple sclerosis (10 ,89). Acute transverse myelopathy with acute or subacute optic neuropathy, so-called Devic disease, may also not be a form of multiple sclerosis (56).

Clinical Features

Acute pain, usually interscapular, is the most common initial complaint (46) (Table 4). Paresthesias and leg weakness follow. The arms may be involved if the lesion is cervical. Urinary retention and overflow incontinence are almost universal findings. Progression is usually rapid, with maximum deficit present within 2 hours. However, progression has been reported for as long as 10 days (48).

To make the diagnosis of transverse myelopathy the clinician must recognize that an acute spinal syndrome is present. Cardinal clinical features include localized back pain, numbness, tingling, a sensory level, weakness, and bladder dysfunction. Imaging establishes that the condition is transverse myelitis.

Differential Diagnosis

Diagnostic difficulty occurs in differentiating acute transverse myelopathy and Guillain-Barré syndrome, disc disease, spinal epidural abscess, trauma, neoplasm, multiple sclerosis, poliomyelitis, and malingering. Urinary retention, common in transverse myelitis, is not a prominent feature of Guillain-Barré syndrome.

TABLE 4. Signs and Symptoms of Transverse Myelopathy

Rapid progression
Back pain, often interscapular
Paresthesias
Leg weakness
Sphincter disturbance
Sensory level

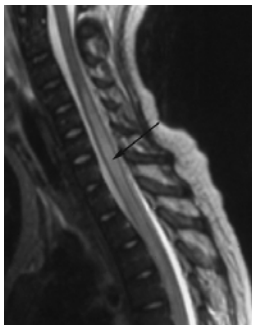

FIGURE 3. A 14-year-old girl with lupus and acute myelopathy. Postgadolinium-pentetic acid T2-weighted magnetic resonance image of cervical and upper thoracic spinal cord (TR: 4,000; TE: 102). There is a large longitudinal area of increased signal within the substance of the cord from C4 through T2, probably representing edema within the cord *(arrow)*. There is also transverse myelopathy caused by vasculitis or inflammatory changes.

Radiographic and Imaging Studies

Exclusion of an alternative diagnosis, such as a mass lesion, is an important aspect of management. An acute compressive cord lesion is a surgical emergency, whereas surgery is contraindicated in acute transverse myelopathy. MRI offers a noninvasive technique to determine the location and extent of the spinal cord lesion (38). MRI may show high signal in the area of the lesion on T2-weighted imaging and cord swelling, or may be normal. Gadolinium-enhanced MRI provides more precise clarification of the extent of the lesion (Fig. 3).

Other Diagnostic Studies

Examination of CSF should be postponed until imaging is obtained. The fluid will be normal or have an elevated protein with a pleocytosis, predominantly lymphocytic. Somatosensory evoked potentials are useful in diagnosis and follow-up. Visual evoked potentials and brain stem auditory evoked potentials should be normal. Electromyelography is claimed to be of value (42).

Pathoanatomy

The thoracic cord is the site of the lesion in 80% of the cases with the remainder of the lesions in the cervical or lumbar cord (24). The cord involvement is transverse (partial or complete) and may have considerable longitudinal extent. The pathology is necrotizing rather than demyelinating raising further doubt of its relation to multiple sclerosis (56). With the passage of time, cystic changes appear within the cord. Pathology is often not obtained until months after onset, adding additional confusion regarding characteristic pathology (4).

Natural History

Rapid onset of disability is associated with an unfavorable outcome. Recovery continues for many months. A significant return of function occurs in about half of cases (73). Prolonged bladder and sexual dysfunction may persist despite recovery of other neurologic function (9).

Treatment

Nonsurgical

Supportive care is indicated, with attention to skin, joints, and bladder. The place of steroids in the management of acute transverse myelopathy remains uncertain. High-dose methylprednisolone may lead to more rapid and more complete recovery (46 ,48 ,77). Appropriate antibiotics must be given when the cause is bacterial or an immune response to a bacteria, as in *M. pneumoniae* infection.

Surgical

No surgical treatment exists for this condition.

Back pain in a child should make the family doctor, pediatrician, or spine surgeon take note. A high index of suspicion is essential. It is easy to pass off back pain as nothing and to tell the patient and parents that it will get better. In the pediatric population, a history of persistent back pain always warrants further investigation and begins with a good history and physical examination (6). One should have a list of differential diagnoses (Table 1). Indeed, as compared with adults, in whom more than 80% of back pain is self-limited, fewer than 30% of children with back pain have a self-limited problem and in most cases there is a skeletal cause.

In children with persistent back pain, preliminary studies at least should be performed, including anteroposterior and lateral radiographs of the thoracolumbar spine and sacrum. Initial laboratory tests should include a complete blood count and determination of erythrocyte sedimentation rate (ESR).

Diagnosis

Early diagnosis of a tumor can be challenging, and misdiagnosis is an unfortunate reality in many cases. Most cases of back pain in children are believed to be due to recreational accidents, and the presence of a tumor is seldom expected as a cause of pain. In a series of 1,971 patients with musculoskeletal neoplasms in a 17-year period, only 29 patients, including eight children, had primary osseous tumors of the thoracic or lumbar spine (19). Spinal tumors are extremely rare and thus often unsuspected. However, common symptoms of spinal tumors do exist and should lead physicians to consider this in the differential diagnosis.

Symptoms

The most common symptom is pain (6). Although pain is a very nonspecific complaint, that associated with a tumor tends to be progressive and unrelenting, and is not closely related to activity. Night pain is a particular cause for worry. Pain occurs due to several causes. Tumor growth may cause expansion of the bony cortex of the vertebral body, which results in pathologic fracture and invasion of paravertebral soft tissues. Pain is also associated with acute or chronic compression of the spinal cord, resulting in focal and radicular symptoms of pain, paraparesis, or paraplegia. Spinal deformity may also be linked with pain and tumors.

Clinical Presentation

Clinical symptoms were nonspecific in 94 cases of bone tumors of the spine observed in pediatric patients at Rizzoli Institute during the period 1928–1994. Pain was the presenting symptom in all of the malignant lesions and in 69 of 74 benign tumors (93%); the average duration of pain was 29 weeks. Severe neurologic deficits (paraparesis) were reported in seven cases (7.5%), always in benign aggressive or malignant tumors. A palpable mass was observed in five cases (5.5%), arising from the posterior elements (e.g., osteoblastomas, aneurysmal bone cysts, or osteochondromas).

Weakness, usually in the lower extremities, may manifest sometime after pain is felt but is rarely the first symptom. Thus, maintaining a high index of suspicion when following patients is a necessity (86). Bowel and bladder dysfunction may also be a sign of a spinal tumor. The most important part of a correct diagnosis is the ability to evaluate the symptoms and to remain suspicious of a spinal neoplasm. In children, pain is not always expressed, but a change in personality, lethargy, instability, fever, limping, or bruising may be signs that must be taken seriously and investigated.

Imaging

Plain radiographs are the first step in the search for a spinal tumor. Anteroposterior and lateral radiographic views are often useful in determining the nature and behavior of the lesion and can help identify specific tumor types. Bone scans are used to locate the site of the tumor when a standard radiograph is negative; they distinguish between monostotic and polyostotic processes and are also helpful in identifying the most accessible biopsy site in polyostotic disease. In the spine, computed tomography (CT) and magnetic resonance imaging (MRI) are probably the most helpful procedures for early detection of a tumor. Likewise, in surgical preparation and perioperative planning, CT often remains the most beneficial imaging method (85). MRI has replaced myelography and is a useful tool in the diagnosis and treatment of spinal neoplasms. MRI is often used as the primary diagnostic imaging tool, whereas CT is often an adjunctive modality in planning. MRI has several advantages: there is no radiation, sagittal views of the entire spine are possible, and tumorous and nontumorous conditions can be more easily distinguished. MRI is probably best for describing the spinal cord in relation to its surrounding structures.

TABLE 1. Differential Diagnosis for Pediatric Back Pain

Scheuermann disease
Spondylolysis/spondylolisthesis
Herniated nucleus pulposus
Spondylolysis
Disc space infection/osteomyelitis
Spondyloarthropathies (i.e., ankylosing spondylitis, psoriatic arthritis, Reiter syndrome, spondyloepiphyseal dysplasia)
Trauma
Benign bone tumors
Malignant bone tumors
Spinal cord tumors, intra- and extramedullary
Metastatic tumors, neuroblastoma, and Wilms tumor

In evaluation of spinal tumors, MRI can help classify tumors by location as (a) intramedullary, (b) intradural extramedullary, (c) extradural, and (d) osseous. Tumors can be located in more than one of these sites and in more than one site in the spine, particularly in metastatic disease involving the vertebral bodies and extending into or throughout the extradural space. Intramedullary cord tumors are especially easy to identify by MRI. The microstructure of bone marrow consists of a bone framework surrounding fat cells, hematopoietic cells, reticulum cells, nerves, and vascular channels. The magnetic resonance image of the bone marrow depends on the chemical composition of the marrow. Red marrow is approximately 40% water, 40% fat, and 20% protein. Yellow marrow is 15% water, 80% fat, and 5% protein (28). T1-weighted images optimize the signal from fat and provide excellent anatomical detail of bone. Processes that replace fat in the bone marrow are best visualized on T1-weighted images. T2-weighted images help characterize abnormal tissue. Pathologic processes that increase the free water demonstrate increased activity on T2-weighted images as compared with normal fatty marrow. Disease processes that infiltrate or replace the red or yellow marrow can be delineated accurately on standard T1- and T2-weighted images. Such processes include benign and malignant tumors, leukemia, lymphoma, myeloma, infection, marrow abnormalities with degenerative disease, and avascular necrosis (7,82). MRI is also an excellent technique for delineating vertebral and paravertebral extension of tumor. This helps the surgeon in planning surgical intervention, surgical margins, and/or radiation therapy. Depending on the types of resections and instrumentation used, MRI may also be useful in detecting tumor recurrences and in distinguishing between benign and malignant processes associated with vertebral compression fractures.

Terminology and Staging

The lack of a logically organized paradigm contributes to the confusion associated with evaluating the results of treatment for primary spinal tumors. There is no common terminology (26), and there are difficulties in applying the current oncologic staging system (24) that is widely accepted for the study and treatment of bone tumors involving the limbs. The result is that the limb salvage procedures are performed for the treatment of different spinal tumors (51), notwithstanding the techniques of vertebral resection that are well known, at least for the thoracolumbar spine (68,76,78,80). What remains unclear in this evolution is the transfer of information to a common terminology. We purposefully use a common terminology throughout this chapter, and it is hoped that all in our profession will see this as the only way to efficiently and effectively measure outcomes in these difficult cases.

Terminology

Excision is piecemeal removal of a tumor (“curettage”). This is an intralesional procedure.

Resection refers to the attempt to remove the tumor en bloc. The pathologist must confirm that the resections around the tumor mass can be defined as intralesional, marginal-wide (10,13,24).

Radical resection refers to the en bloc removal of the tumor together with the complete compartment of origin. It is obvious that this is possible for a tumor arising in the scapula, or even in the femur, but is absolutely impossible for a vertebral tumor unless the spinal cord is sectioned above and below.

All of the surgical procedures that are directed to a functional response (e.g., cord decompression and fracture stabilization), with or without partial (piecemeal) removal of the tumor, are called “palliative.” In general, these procedures are only intended to facilitate a diagnosis, decrease pain, and possibly improve function.

The terms *vertebrectomy* and *corpectomy* (removal of all elements of the vertebra), and *somectomy* (removal of the vertebral body) have no significance from an oncologic viewpoint if they are not specified according to the aforementioned terminology.

Oncologic Staging

The oncologic staging system proposed by Enneking et al. (24) defines the biologic behavior of primary tumors and has proven effective in defining a relationship between tumor aggressiveness, surgery (intralesional, marginal-wide, or radical), and results for limb lesions. This system (24) divides benign tumors into three stages (S1, S2, S3) and localizes malignant tumors into four stages (IA, IB, IIA, IIB) (Fig. 1). Two additional stages include metastatic high-grade intra- and extracompartmental malignant tumors (IIIA and IIIB, respectively). This classification is based on clinical features, radiographic pattern, CT scan/MRI data, and histologic findings. It was formerly applied to bone tumors and applied to spinal tumors in some reports (8,10,14,34).

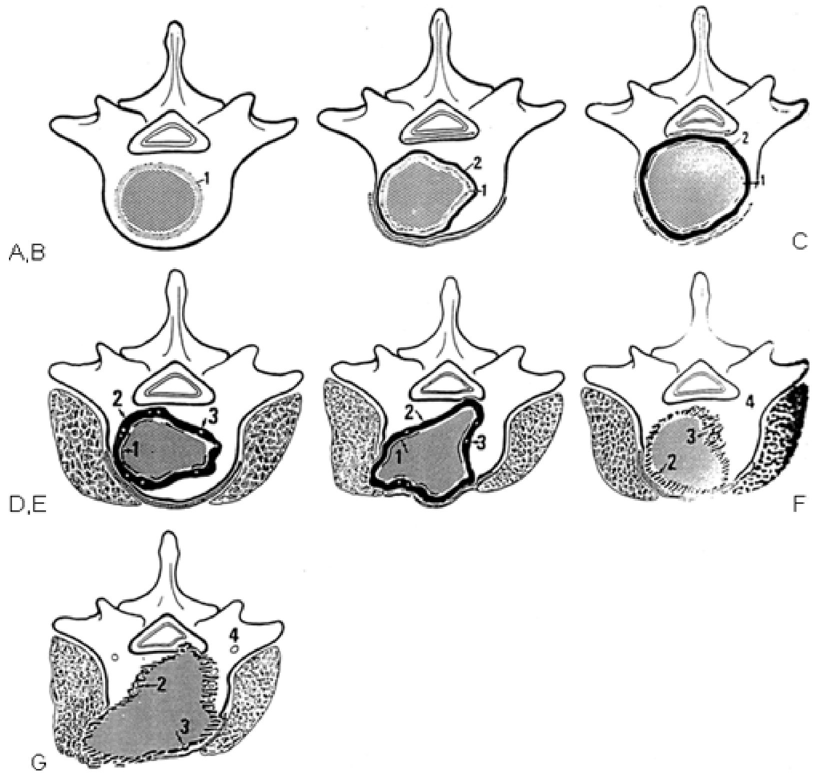

FIGURE 1. A: Benign tumors, stage 1: the tumor is inactive and is contained within its capsule (*1*). **B:** Benign tumors: the tumor is growing: the capsule (*1*) is thin and bordered by a pseudocapsule of reactive tissue (*2*). **C:** Benign tumors, stage 3: the aggressiveness of these tumors is witnessed by the wide reaction of healthy tissue (*2*), whereas the capsule (*1*) is very thin and discontinued. **D:** Malignant tumors, stage IA. The capsule—if any—is very thin (*1*); the pseudocapsule (*2*) is wide and containing island of tumor (*3*). **E:** Malignant tumors, stage IB. The capsule—if any—is very thin (*1*); the pseudocapsule (*2*) is wide and contains island of tumor (*3*). The tumoral mass is growing outside the compartment of occurrence. **F:** Malignant tumors, stage IIA. The pseudocapsule (*2*) is infiltrated by tumor (*3*). Island of tumor can be found far from the main tumoral mass (skip metastasis—*4*). **G:** Malignant tumors, stage IIB. The pseudocapsule (*2*) is infiltrated by tumor (*3*), which is growing outside the vertebra. Island of tumor can be found far from the main tumoral mass (skip metastasis—*4*).

Benign Tumors

The first stage of benign tumor (S1, latent, inactive) includes asymptomatic lesions bordered by a true capsule (Fig. 1A), which is usually seen as a sclerotic rim on plain radiographs. These tumors do not grow, or grow very slowly. No treatment is required unless palliative surgery is needed for decompression or stabilization.

Benign S2 (active) tumors grow slowly, causing mild symptoms. The tumor is bordered by a thin capsule and by a layer of reactive tissue (Fig. 1B), sometimes seen on plain radiographs as an enlargement of the tumor outline. Bone scan is positive. Intralesional excision can be performed with a low rate of recurrence (8). The incidence of recurrences can be lowered further by use of local adjuvants (e.g., cryotherapy, embolization, or radiation therapy).

The third stage of benign tumors (S3, aggressive) includes rapidly growing benign tumors; the capsule is very thin, discontinued, or absent (Fig. 1C). The tumor invades neighboring compartments, and a wide reactive hypervascularized tissue (pseudocapsule) is often found, sometimes permeated by neoplastic digitations. Bone scan is highly positive, plain films show fuzzy limits, CT scan shows compartmental extension, and magnetic resonance images clearly define a pseudocapsule and its relationship to the neurologic structures. Intralesional curettage, even if augmented by radiation, may be associated with a significant rate of recurrence (14,34). En bloc excision is the treatment of choice.

Malignant Tumors

Low-grade malignant tumors are included in stage I, subdivided into IA (the tumor remains inside the vertebra) and IB (tumor invades paravertebral compartments). No true capsule is associated with these lesions, but a thick pseudocapsule of reactive tissue permeated by small microscopic islands of tumor is seen (Fig. 1D, E). A resection performed along the pseudocapsule often leaves residual foci of active tumor; megavoltage radiation or proton-beam therapy can be added to reduce the risk of recurrence (77). The treatment of choice, if feasible, is wide resection. High-grade malignancies are defined as IIA or IIB. The neoplastic growth is so rapid that the host has no time to form a continuous reactive tissue (Fig. 1F, G). There is continuous seeding with neoplastic nodules (satellites). Moreover, these tumors can have neoplastic nodules at some distance from the main tumor mass (skip metastases). These malignancies are generally seen on plain radiographs as radiolucent and destructive; in many cases, they are associated with a pathologic fracture. Invasion of the epidural space is rapid in stage B, particularly in small-cell tumors characterized by semifluid tissue (e.g., Ewing sarcoma, lymphomas), and able to occupy the epidural space after infiltrating the cortical border of the vertebra.

The margin of the resection must be wide (it is not possible in the spine to achieve a "radical" margin), and courses of radiation and chemotherapy (according to the tumor type) must be considered for local control and for the avoidance of distant spread. Stages IIIA and IIIB describe the same lesions as IIA and IIB, with distant metastasis.

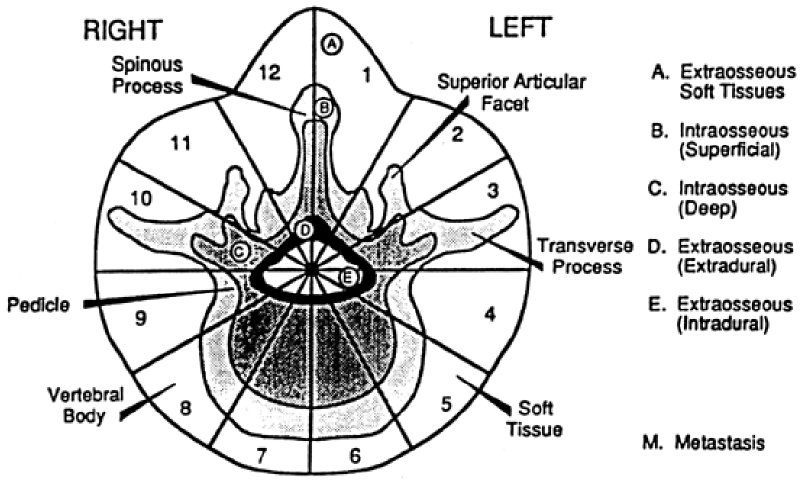

FIGURE 2. The transverse extension of the vertebral tumor is described with reference to 12 radiating zones (numbered 1 to 12 in a clockwise order) and to 5 concentric layers (A to E from the prevertebral to the dural involvement). The longitudinal extent of the tumor is also recorded.

Surgical Staging

For correct application of the above described grading, a complete preoperative workup must be performed. The first attempt to propose such a staging for surgical purposes of primary spinal tumors was introduced by Weinstein (85) and subsequently modified in collaboration with the Rizzoli Institute (10) to identify each lesion in a systematic computerized fashion. This staging system, called the WBB (Weinstein-Boriani-Biagini) system, has been subjected to clinical evaluation (34).

On the transverse plane, the vertebra is divided into 12 radiating zones (numbered 1 to 12 in a clockwise order) and into 5 layers (A to E from the prevertebral to the dural involvement). The longitudinal extent of the tumor is recorded. This system (Fig. 2) should allow for a more rational approach to the surgical planning, provided that all efforts are made to perform surgery along the required margins. The basic concept of a clock-face radiating zone system is that the crucial problem in performing en bloc resections in the spine is due to the presence of the cord in the longitudinal median axis of the vertebra. To save such a structure, the surgeon is compelled to resect circular sectors of the vertebra. For example, it is impossible to perform an en bloc resection of the vertebral body without first removing the posterior arch because the margins are the pedicles. Conversely, if the tumor occupies an eccentric area, the surgeon is compelled to remove the healthy contralateral parts of the vertebra, dislocate the dural sac, and perform radiating sections by chisel/osteotome.

Benign Tumors

Spinal tumors of any type are uncommon in children. In most cases, they are benign. Nearly 70% of primary bone tumors in children are benign. Osteoid osteoma, osteoblastoma, osteochondroma, and aneurysmal bone cyst account for more than 40% of all primary spinal lesions in younger patients (86). Out of 74 cases collected at the Rizzoli Institute, 53% affected females and the mean age at onset was 9.3 years (ranged 1 to 14 years). The thoracic spine was most frequently affected; nine patients had multiple locations (Fig. 3A–D).

Osteoid Osteoma

In 1953, Dr. H. Jaffee defined osteoid osteoma as a benign bone tumor characterized by a nidus of bone surrounded by fibrovascular tissue and a dense sclerotic bone margin (40). These lesions account for approximately 11% of all primary benign bone tumors, and 10% of them occur in the spine (18).

Osteoid osteoma is most prevalent between the ages of 6 and 17 years (3). In one review of 36 patients with osteoid osteoma, nine tumors were located in the spine, all in the posterior elements (42). Unrelenting pain, most noticeable at night (in about 60% of cases), is the common complaint of patients with osteoid osteoma. The lesions are usually 1.52 cm or smaller, with a small radiolucent nidus surrounded by osteosclerosis (2). The small size causes difficulty in identifying and locating the tumor. Bone scan is the most sensitive method of locating an osteoid osteoma (Fig. 4). Technetium bone scanning provides accurate localization of the lesion, decreasing the average duration of symptoms by providing an early diagnosis and allowing prompt treatment (61). In about 70% to 80% of patients, the diagnosis is made within 2 years of symptom onset. Prostaglandin activity or venous congestion is believed to be responsible for the night symptoms (35). Although aspirin is believed to provide symptomatic relief, it does not always do so. Osteoid osteomas can be associated with severe spinal deformities. Indeed, osteoid osteomas are probably the most common cause of painful scoliosis in adolescence (58). The lumbar spine is the most common location (more than 50%), followed by the cervical, thoracic, and sacral spine. Most osteoid osteomas are located in the posterior elements, lamina, or pedicles; rarely do osteoid osteomas occur in the vertebral body. Seventeen cases were observed at the Rizzoli Institute (11 males, averaging 8.2 years old). Nocturnal pain was the chief complaint in all cases, occurring in the lumbar spine in nine cases, in the cervical spine in five, in the thoracic spine in three. Only four cases arose anteriorly (sectors 4, 5, 8, and 9); all other cases arose in sectors 2, 3, 10, and 11.

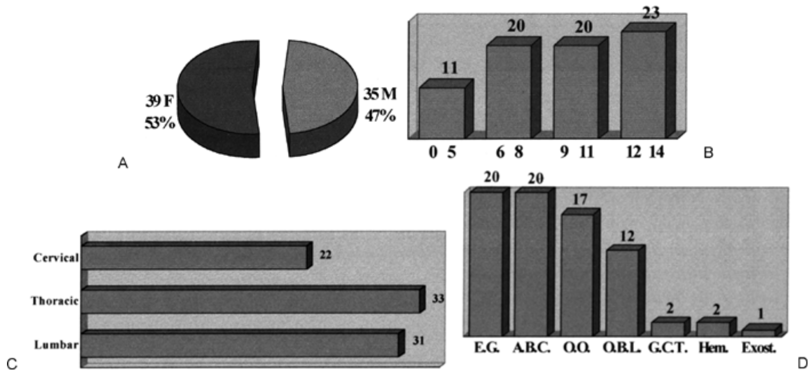

FIGURE 3. Benign bone tumors of the pediatric spine: 74 cases collected at the Rizzoli Institute. Demographics: **A**, sex; **B**, age; **C**, location; **D**, diagnosis.

Treatment

Long-term administration of nonsteroidal antiinflammatory drugs can often be as effective as excision for treatment of osteoid osteomas, without the morbidity associated with surgery, especially in patients in whom operative treatment would be complex or might lead to disability. Pain treated with antiinflammatory agents resolves in 30 to 40 months (38). Because there have been no reports of malignant transformation or metastases, nonoperative treatment remains a viable option. Radiation therapy is not necessary and may be harmful.

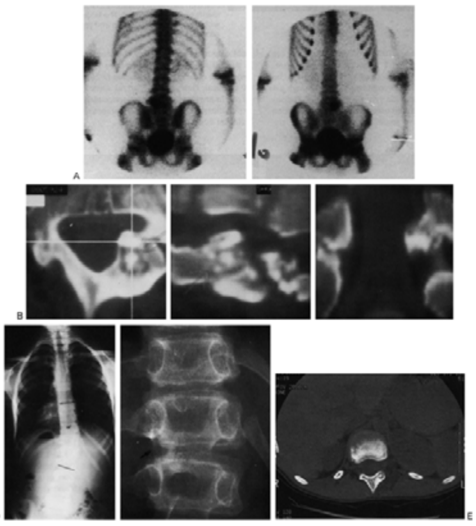

FIGURE 4. Osteoid osteoma. **A:** Posterior *(left)* and anterior *(right)* prone technetium bone scan of an 8-year-old boy who had night pain relieved by aspirin for approximately 6 months; however, the pain was interfering with activities of daily living. He constantly complained of pain during school, but more often at night. Increased uptake is evident at L5 *(left)*. **B:** A multiplanar computed tomography (CT) scan of the same patient identifying the nidus of the osteoid osteoma in the posterior elements in the axial *(left)*, sagittal *(center)*, and coronal *(right)* views. **C:** A 13-year-old boy with back pain caused by osteoid osteoma. Anteroposterior radiograph demonstrates thoracolumbar scoliosis. **D:** A 13-year-old boy with thoracolumbar scoliosis and pain. Coned-down radiograph demonstrates a probable nidus in the posterior elements of T12 on the left. **E:** CT scan of a 13-year-old boy with painful scoliosis demonstrates a nidus consistent with an osteoid osteoma in the posterior elements of T12 on the right. The lesion was excised with complete relief of pain and resolution of the scoliosis.

Surgical treatment can produce almost immediate pain relief in more than 95% of cases. On the other hand, incomplete excision is often followed by recurrence of pain. If the lesion does recur (one recurrence after incomplete excision in 17 pediatric patients treated at Rizzoli Institute), additional attempts at complete excision are recommended. Early diagnosis and complete excision frequently leads to relief of symptoms. Painful scoliosis that develops as a result of an osteoid osteoma is often relieved after excision of the benign lesion if it has not been existed for more than 15 months. Lesions that exist for more than 15 months are believed to have more fixed deformities that may not resolve after excision of the benign tumor (15,58). This is not confirmed by the experience collected at the Rizzoli Institute: 16 patients had osteoid osteoma-associated scoliosis (94% of cases); 12 deformities improved or disappeared, and four remained unchanged, irrespective of symptom duration.

Osteoblastoma

Enneking's stage 2 osteoblastomas are histologically indistinguishable from osteoid osteomas and differ mainly in size. Osteoblastomas are larger than osteoid osteomas. They are usually more than 2 cm in diameter. Stage 3 osteoblastomas are clinically and radiographically similar to other aggressive conditions, such as giant cell tumors (5). Osteoblastomas account for less than 1% of all bone tumors, and 5% of primary bone tumors are osteoblastomas. Osteoblastomas have a distinct predilection for the spine, especially the posterior elements. They occur most frequently in the lamina and pedicle and exhibit progressive growth (2). More than 40% of reported tumors have been located in the spine (49). Although osteoblastomas are less painful than osteoid osteomas, in a series of nine patients, all patients with osteoblastoma had back pain for 6 weeks to 36 months duration at the time of diagnosis (4). Osteoblastomas usually affect patients aged 10 to 15 years (4). Twelve cases were observed at the Rizzoli Institute in patients 4 to 14 years of age (average 11 years). In all cases, the presenting symptom was pain (average 54 weeks); in only two cases was there concomitant abrupt paraparesis, confirming that myelopathy is uncommon, whereas radiculopathy occurs in up to 50% of patients. Aspirin and nonsteroidal antiinflammatory agents do not relieve pain associated with osteoblastomas as effectively as they relieve the pain of osteoid osteoma. Scoliosis with a convex side away from the involved side of the vertebra, generally related to pain-producing lesions in the thoracic spine, is reported in up to two thirds of affected patients. The thoracic and lumbar spine are the most common sites involved, each accounting for about 30% to 40% of cases, followed by the cervical spine and sacrum. In the series collected at the Rizzoli Institute, two cases arose in both the cervical spine and in the lumbar spine, whereas 10 involved the thoracic spine. The posterior arch (sectors 10 to 3) was involved in all cases; the pedicles (sectors 4 and 9) in three; the vertebral body was never involved. The tumor invaded layer D in all five stage 3 tumors. This confirms that epidural expansion, as well as paraspinous soft-tissue involvement, is common. In about 5% of the cases reported in the literature, adjacent vertebrae are involved.

Radiographically, stage 3 osteoblastomas are destructive expansile lesions. Calcification is evident mostly in stage 3 lesions (approximately one third of all series) and, as in osteoid osteomas, radionuclide bone scanning is a reliable screening technique.
CT may be the best imaging procedure for defining the location and extent of osteoblastomas with regard to their osseous involvement. CT is also the best aid to surgical planning for extirpation and reconstruction. With radiculopathy or myelopathy, one may consider performing CT myelography or MRI (Fig. 5A–C).

Treatment

Osteoblastomas are slowly growing lesions that are locally expansive and destructive, yet it is said that complete surgical extirpation of the lesions appears to be curative (2,9,31,35,36,39,61,63,85,86). In the vertebrae, intralesional curettage is often used as the only possible technical solution (Figs. 5 and 6). However, the authors recommend selecting the treatment according to the oncologic stage (24). This makes it possible to significantly reduce the rate of recurrence (8), which in the literature is reported to be around 10%. Radiation therapy remains controversial and has been reported by some investigators to be ineffective (39,55). Malignant transformation, spinal cord necrosis, and aggravation of spinal cord compression has been reported (18,69). The author believes that radiation therapy should be used as an adjuvant to intralesional excision in stage 3 tumors not suitable for en bloc excision.

Aneurysmal Bone Cyst

Aneurysmal bone cyst is a pseudotumoral condition that typically arises in the spine during early life. The usual age of patients with aneurysmal bone cyst is 5 to 20 years, and females are affected more commonly than males. In 60% of cases, the cysts are localized to the posterior elements of the vertebra and occasionally expand directly into the vertebral bodies (45) (Fig. 7). Radiographs typically show an expansile osteolytic cavity, with strands of bone forming a bubbly appearance. The cortex is often eggshell thin and blown out (18). The lesion is often extremely vascular, but this feature is not often appreciated angiographically even though it is apparent pathologically.

Twenty patients were observed at the Rizzoli Institute, including those reported by Capanna et al. (8). This series includes 7 males and 13 females; their ages ranged from 5 to 14 years, with an average age of 10 years. The lesions occurred mostly in the lumbar spine (10 cases) and the cervical spine (7 cases). They involved only the posterior sectors (10 to 3) in 9 cases (a palpable mass was present in 3 cases), and both vertebral body and arch in the remaining cases. The epidural space (layer D) was invaded in 10 cases; in only 1 case was cord compression seen following the initial complaint.

Treatment

Excision and curettage are the best treatments for aneurysmal bone cyst. The procedures are frequently risky and sometimes

prevented by a significant interoperative hemorrhage, which can be controlled by rapid removal of the lining wall of the cyst at the time of surgery. Preoperative selective embolization with polyvinyl alcohol (Ivalon) or absorbable gelatin (Gelfoam) can significantly reduce the bleeding (75) and is itself a treatment option (20) (Fig. 7). Recurrence rates have been reported in the range 10% to 25% (8). Recurrence developed in 13% of cases in the review of Hay et al., but all cases were successfully treated by a second curettage or excision procedure (33).

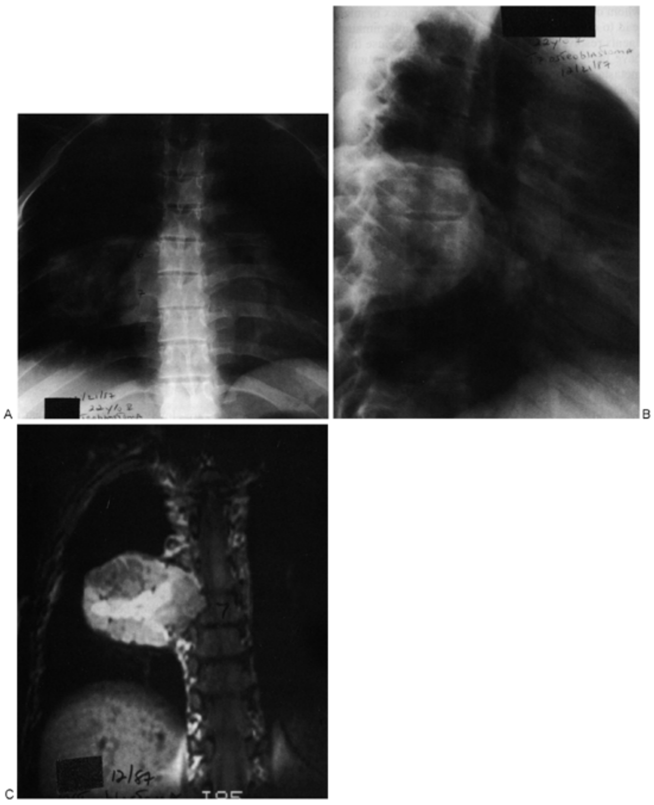

FIGURE 5. A T7 osteoblastoma. **A:** Anterior radiograph shows the expansile lesion from the body of T7 including and up to the body of T6; the ribs of T7 and 8 are clearly involved. Some calcification of the lesion is apparent. **B:** Lateral image shows a large expansile mass in the area of T6, T7, and T8, with some calcification. **C:** Coronal magnetic resonance image shows growth of a large osteoblastoma off the vertebral bodies of T6 and T7 with some central calcification.

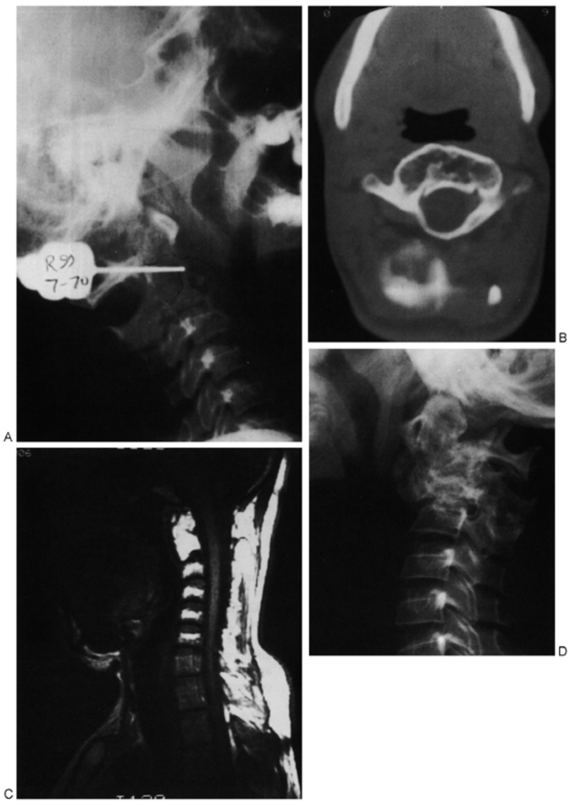

FIGURE 6. **A:** Lateral radiograph demonstrating a percutaneous biopsy of a C2 osteoblastoma. **B:** Axial computed tomography scan 15 years after curettage and bone grafting of C2. **C:** Magnetic resonance image of the patient 18 years after curettage and bone grafting. **D:** Radiograph 23 years after curettage and bone grafting of C2.

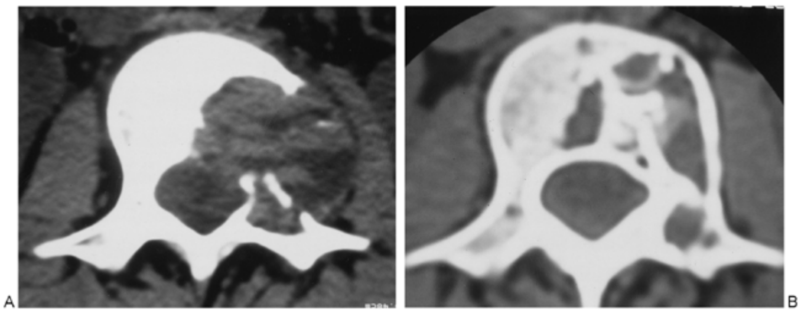

FIGURE 7. A: Aneurysmal bone cyst of L3 in a 12-year-old girl. It is interesting to note the double density levels within the radiolucent area occupying the vertebral body and eroding the cortex. The patient was submitted to selective arterial embolization. Biopsy was achieved by trocar computed tomography-guided biopsy. There was no surgery or radiation therapy. **B:** Five-year follow-up. No other treatment was given. The girl has no pain and has normal function.

Irradiation of these lesions has limited effectiveness and is associated with poor results (8) unless done as an adjuvant. One should remember that radiation also has an adverse effect on growth in children, with consequent late deformities and possible later effects on the spinal cord itself (e.g., myelopathy, myelitis, or sarcomas) (59,79).

The excision required is frequently so destructive and the effect of radiation so important that instrumented fusion must be considered in the operative planning.

At the Rizzoli Institute, two patients were treated by selective arterial embolization, one by radiation therapy, nine by intralesional excision, and eight by intralesional excision combined with radiation. Selective arterial embolization as a preoperative adjuvant was performed in eight cases. Only one recurrence was observed, after incomplete excision (performed without adjuvants), and healed following further intracapsular excision and radiation therapy. The patient affected by neurologic deficit (Frankel B) improved to Frankel D3. Five of 12 preoperative deformities (scoliosis and/or kyphosis) worsened, and two were worse after treatment that did not include stabilization. Surgery was performed in both cases.

Giant Cell Tumor

Giant cell tumors are extremely rare before the growth spurt. These tumors generally are histologically benign, but their clinical behavior is sometimes unpredictable, with a high recurrence rate if not correctly staged and treated. Prolonged disease-free survivals have been reported after curettage and radiotherapy, although some patients require two or more additional procedures owing to local recurrence (21); en bloc excision, when feasible, is curative (34). A high-grade sarcoma occurs in 5% to 15% of irradiated patients. On the other hand, benign giant cell tumors can produce pulmonary metastases without clear biologic relation to their radiographic appearance of aggressiveness. These metastases occasionally may regress spontaneously; they have been controlled by marginal excision. They can be lethal in 25% of cases.

In 70 years of survey, only two cases of giant cell tumor of the spine in the pediatric age group were observed at the Rizzoli Institute, both occurring in the thoracic spine. During the same period, 876 giant cell tumors were diagnosed and treated in the same institution, 34 of them occurring in the spine. Both of the pediatric patients had paraparesis as the presenting symptom. The first child died in 1928 after emergency decompression. The second child is disease-free with recovery of the neurologic functions 6 years after a second excision and one course of megavoltage radiation for multiple recurrences (en bloc surgery was not feasible).

Treatment

Based on CT and MRI (Fig. 8), followed by trocar biopsy under CT control, oncologic and surgical staging are helpful for the decision making process. Complete (extracapsular) excision seems to be effective for stage 2 giant cell tumor, whereas en bloc excision (or intralesional excision plus radiation therapy) are required for local control in stage 3 giant cell tumor (18,21,34).

Selective arterial embolization will reduce intraoperative bleeding and is therefore mandatory before intralesional excision can be performed. Radiation therapy must be considered only as an adjuvant after complete excision.

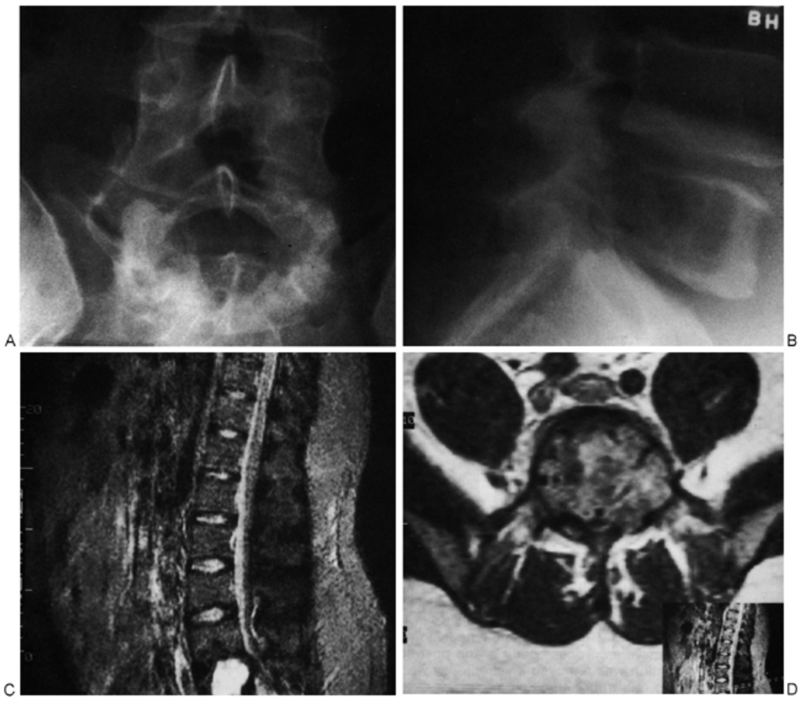

FIGURE 8. Giant cell tumor involving the L5 vertebral body. **A:** Anteroposterior radiograph. **B:** Lateral radiograph. **C, D:** Magnetic resonance image on T2 scale shows same giant cell tumor involving the vertebral body of L5 on both the sagittal and axial views with some encroachment of the vertebral canal evident on the axial images.

Eosinophilic Granuloma

Eosinophilic granuloma is a benign, self-limiting neoplasm that produces destruction of bone (38). This condition usually occurs in children younger than 10 years, and vertebral involvement occurs in 10% to 15% of cases. This disease has onset as one of a triad of syndromes: (a) isolated eosinophilic granulomas; (b) Hand-Schüller-Christian disease; or (c) Letterer-Siwe disease (27,57). Eosinophilic granuloma is the most benign form of histiocytosis and thus is not a true neoplasm. The lesion consists of an abnormal proliferation of lipid-containing histiocytes from the reticulo-endothelial system. Spinal eosinophilic granulomas can affect multiple spinal levels. They often present with localized pain but rarely with neurologic deficits. The vertebral body is often involved, particularly the lumbar or thoracic spine, and is usually partially or totally destroyed. The destruction of the bone often leads to significant pain, and neurologic symptoms may be associated. The degree of compression is dependent on the extent of vertebral body involvement. In younger children, there is often rapid vertebral body collapse because most of the body is involved, resulting in complete flattening or “vertebra plana." In older children or adolescents, lesser amounts of vertebral body involvement can cause a wedge-shaped deformity or punched-out lytic lesion of the vertebral body. Adjacent intervertebral disc spaces are often well maintained, and extraosseous paravertebral soft-tissue masses are rare.

Treatment

The "coin-on-end" appearance, or vertebra plana, is a classic description of eosinophilic granuloma of the spine, which actually represents the final evolution of the disease. It is sometimes observed incidentally on a radiograph, as eosinophilic granulomas often are self-limited and may heal spontaneously (57). The initial pattern is a lytic image that requires one to rule out infection, benign tumor, or malignancy such as Ewing sarcoma. Laboratory tests, well-marginated borders, and the presence or absence of a tumoral mass in the surrounding soft tissues are the most important elements to distinguish those conditions. Biopsy is mandatory before any treatment is instituted, unless it presents as a completely asymptomatic vertebra plana without any soft-tissue mass.

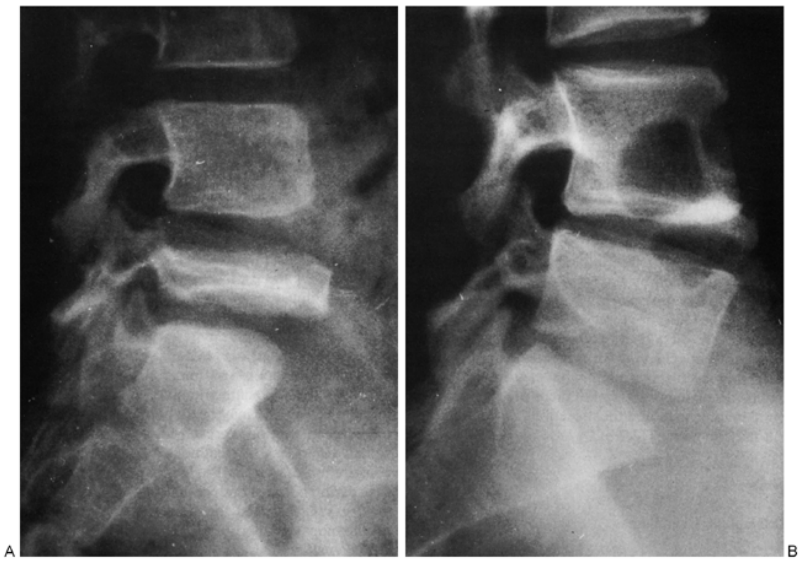

FIGURE 9. Eosinophilic granuloma. **A:** Lateral radiograph of a 5-year-old boy with an eosinophilic granuloma of L5. **B:** Follow-up radiograph of the same patient 7 years later, without treatment, shows reconstitution of the vertebral body.

Vertebral reconstitution is greater for younger patients and occurs regardless of treatment (71) (Fig. 9). Spontaneous reconstitution of vertebral height has been attributed to the sparing of areas of enchondral ossification (71).

The series collected by the Rizzoli Institute includes 20 patients (10 males, 10 females) with a total of 28 vertebral locations (6 multiple sites in the spine); 9 patients presented or developed extraaxial involvement. The lesion always occurred in the vertebral body, mostly in the thoracic spine (14 of 28). The vertebra plana was the initial pattern in 54% of cases. Five lesions were observed incidentally; all of the other patients complained of pain and 3 of them had neurologic symptoms (root compression). In 6 cases the lesion healed by othesic treatment in 12 to 45 months (average 28 months). In 6 other cases, chemotherapy was added due to systemic spread. Intralesional excision was performed in 8 cases, for diagnostic purpose. Radiation therapy (21 Gy) was added in 1 case, local corticosteroids in 4. Only one recurrence was observed, after incomplete excision followed by chemotherapy; 7 years later, no evidence of disease was found. The other 19 patients have been disease-free for an average of 70 months after treatment (range 24 to 183 months). Ten of

12 vertebra plana patients who were followed for a minimum of 37 months showed vertebral height restoration (10% to 90% of original height). One thoracic hyperkyphosis developed after conservative treatment.

The best treatment for this disease is not known. For acute pain, a short period of bed rest followed by use of an orthosis or body jacket often provides symptomatic relief. Local corticosteroid injection has been successfully performed. For patients with neurologic deficits, biopsy followed by low-dose irradiation and immobilization is indicated (30).

Multifocal occurrence is a sign of systemic disease; the patient should be referred to a pediatric oncologist for corticosteroids and chemotherapy.

Osteochondroma

Osteochondromas are very common lesions of bone. Solitary osteochondromas are noninherited malformations and are not true neoplasms. They are cartilage-capped bony growths on either a broad base or a stalk, first appearing in relation to the epiphyseal growth plate. Most are painless and are noted during the first two decades of life. Benign lesions are often elongated and point to the metaphysis of the involved bone. After closure of the growth plates, these lesions usually stop growing in 12 years. Vertebral involvement is very rare, around 7%, occurring mostly in the cervical or upper thoracic spine. A palpable mass is the most prominent symptom. Neurologic compromise is rare; only 16 osteochondromas have been reported to be associated with symptomatic cord compression.

Treatment

Biopsy is indicated when malignant transformation is suspected, and must include the cartilage component. Tumor excision should include the perichondral soft-tissue covering and all cartilage extending to normal cortical bone. It is indicated when the patient complains of pain and dysfunction resulting from pressure on adjacent soft tissues, such as nerves or blood vessels, or when malignant transformation has been confirmed. Adjuvant treatment is not indicated (Fig. 9A, B).

Premalignant Lesions in Children

Neurofibromatosis

The presence of multiple schwannomas is virtually diagnostic of neurofibromatosis. The involved nerves are often swollen, with margins indistinct from the tumor. Two distinct forms of neurofibromatosis have been identified. Both show autosomal dominance in transmission with high penetrance. If a person possesses this genetic defect, a characteristic condition is usually expressed. The classic picture is one of multiple cutaneous or subcutaneous neurofibromas that are pathopneumonic of the disease (18). Café-au-lait spots occur due to the abnormality of large melanosomes in the skin. This may be associated with kyphoscoliosis in about 2% of cases. Associated pheochromocytomas occur in 1% of cases.

Bilateral acoustic neuroma is the second form of neurofibromatosis. In this form, the gene is located on chromosome 22, whereas patients with type 1 neurofibromatosis, referred to also as von Recklinghausen disease, have a defect on chromosome 17. Both types are autosomal dominant and have high penetrance. Other abnormalities associated with neurofibromatosis are spinal and intracranial meningiomas along with astrocytomas. Whereas sporadic neurofibromas are almost always benign, it is estimated that 3% to 30% of lesions in von Recklinghausen disease undergo malignant transformation. Changes in spinal anatomy are related to neurofibromas of spinal nerves, spinal meningiomas, sympathetic chain neurofibromas, and sometimes neuroblastomas. Enlargement of the neural foramen, thinning of a rib, or deformation of the bone secondary to these soft-tissue tumors is common.

Treatment

Surgical treatment typically consists of fully exposing these tumors both interspinally, foraminally, and extraspinally through laminectomy and facetectomy. If the involved roots are not crucial, they are often sacrificed. However, if they are important, the schwannoma may be dissected free of the nerve fascicles using microsurgical techniques and intraoperative electrophysiologic recordings. Long-term results of dissectable lesions are generally good. More than 90% of patients can be cured of these nerve sheath tumors. If neurofibromas become malignant, they are generally locally destructive and resistant to radiation or adjuvant chemotherapy.

Multiple Hereditary Osteochondromatosis

Multiple hereditary osteochondromatosis (MHO) is inherited through an autosomal dominant gene and is characterized by multiple cartilaginous bony protrusions with cartilaginous caps (“exostoses”) that are radiographically and histologically indistinguishable from solitary osteochondromas. Malignant transformation to a chondrosarcoma occurs rarely, but is possible and more common than in solitary osteochondromas due to the greater number of lesions exposed to risk.

Treatment

As for solitary lesions, surgical excision is indicated for symptomatic or enlarging lesions.

Enchondroma

Solitary enchondromas are benign intramedullary tumors composed of hyaline cartilage arising from growth plate rests that rarely occur in the vertebral column (less than 1%). These benign tumors usually do not require treatment. Chondrosarcomatous degeneration is rare but is not uncommon in patients with Maffucci's syndrome (i.e., multiple enchondromas associated with hemangiomas). Those suspected of malignant degeneration should undergo biopsy, followed by appropriate treatment.

Malignant Tumors

Malignant spinal tumors in children are rare. Fewer than 30% of all primary bone tumors in children are malignant; an even smaller percentage is associated with the vertebral spine (86). Spinal malignancies in children generally have a very poor prognosis, and treatments to date have not been very effective. Of 20 cases collected at the Rizzoli Institute in the last 10 years, 60% involved males and the mean age at onset was 9 years (range 1.5 to 14 years). The thoracic and lumbar spines were equally affected, and five patients had two tumoral locations. The total number of tumor sites was 25 (Fig. 10).

Ewing Sarcoma

Ewing sarcoma is the most common malignant bone tumor in children and is most prevalent in patients aged 5 to 15 years (2). Approximately 3.5% of all Ewing tumors originate in the spinal column, mostly in the sacrum (87), and account for only about 0.5% of all primary malignant tumors of bone (65,67,88). The average time from onset of symptoms to diagnosis is about 8 months. The common symptom is pain; other symptoms are related to the proximity of the tumor to the spinal cord and/or nerve roots. Fever occurs in less than 25% of cases, and a mass may be palpated in 25%. Laboratory studies are generally nonspecific, but increased ESR occurs in slightly less than 50% of cases. The permeative appearance of Ewing tumors on radiographs can make diagnosis difficult, and a collapse of the vertebral body may produce a vertebra plana that is difficult to differentiate from eosinophilic granuloma (62,72) (Fig. 10) if not on the basis of the soft-tissue mass expanding quickly outside the site of occurrence. MRI is the preferable imaging study, as the tumors so quickly that frequently no destruction of the vertebra outline is appreciated even in presence of a large soft-tissue mass.

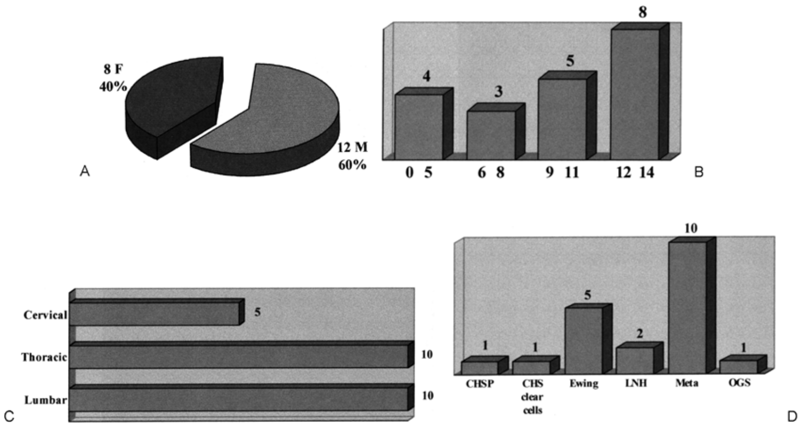

FIGURE 10. Malignant bone tumors of the pediatric spine: 20 cases collected at the Rizzoli Institute in the latest 10 years. Demographics: **A**, sex; **B**, age; **C**, location; **D**, diagnosis.

Treatment

Modern therapies have made local control and disease-free survival obtainable in terms of the spine, but the long-term outlook is still poor (43). There is no known best cure for this disease. Ewing tumors of the spine can be very large, with significant soft-tissue invasion (11). En bloc excision with appropriate margins is seldom feasible, and the risk of leaving an island of tumor behind is very high. Protocols of combined chemotherapy and radiation therapy must be considered as the first option to make en bloc excision feasible and oncologically appropriate (Fig. 11).

Metastases commonly involve the lungs and/or other locations in the spine, as well as ribs, lymph nodes, brain, and abdominal viscera.

Eight pediatric patients with Ewing sarcoma were observed at the Rizzoli Institute; most were referred before the 1980s and were treated only by palliative radiation therapy. More recently, two patients treated by combined radiation and chemotherapy who then submitted to en bloc excision are disease-free 4 and 5 years after the vertebrectomy (Fig. 11).

Osteogenic Sarcoma

Osteogenic sarcoma (“osteosarcoma”) is the most common primary malignant tumor of bone, with the exception of myeloma.

It accounts for approximately 20% to 25% of the bony neoplasms. It is more than twice as common as chondrosarcoma and three times more common than Ewing sarcoma. In the United States, there are approximately two cases per million, or approximately 1,000 to 1,500 new cases diagnosed annually (18,37,47). Approximately 50% of cases occur between the ages of 10 and 20 years, especially during the adolescent growth spurt. Although the cause of osteosarcoma remains unknown, it occurs not only in rapidly growing adolescents but as a secondary neoplasm in Paget disease, post irradiation, and in some benign bone tumors (22,23,36,56,81,83).

FIGURE 11. Retinoblastoma, a malignant tumor that occurs in the eyes of newborns and young children, is associated with an increased risk of developing osteosarcoma. This risk in children is approximately

2,000 times greater than that in the rest of the population and is independent of radiation administration (1). Osteosarcoma may be polyostotic and involve multiple skeletal sites at the same time or consecutively (60).

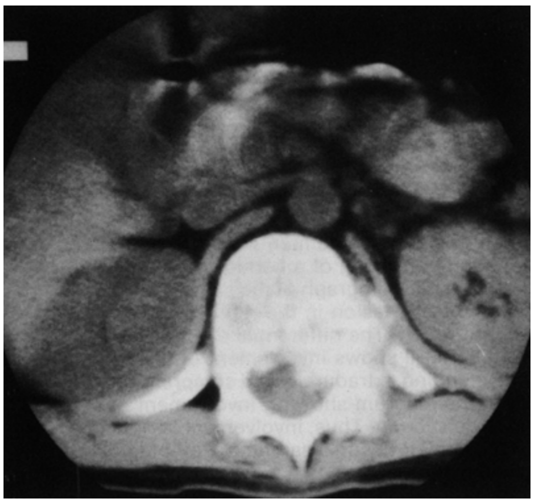

FIGURE 12. Osteosarcoma of T12 involving the vertebral body pedicle and entering the epidural space is evident on axial computed tomography scan of soft-tissue window.

Osteogenic sarcoma of the vertebral column is extremely rare and very deadly. Approximately 10% of osteosarcomas arise in the axial skeleton, including the vertebra as well as skull, ribs, and pelvis. Those specifically in the spine are believed to occur in 0.8% to 3% of cases (12,81). The lesions often originate in the lower portions of the vertebral column, causing pain as well as sensory and motor disturbances (Fig. 12). Two thirds of the patients reported in the literature had neurologic deficits at initial examination. Those with epidural extension of their tumor at time of diagnosis obviously are adversely affected because of some surgical limitations and the nature of the tumor. Radiographically, these tumors can be variable in their presentation. The most common finding in the spine is a mixed osteolytic and sclerotic lesion of the vertebral body. In 90% of cases, the tumor is located in the vertebral body, but the posterior elements also may be affected (Fig. 12). In children, one must distinguish osteosarcomas from osteoblastomas or aneurysmal bone cysts, more rarely from giant cell tumors and metastatic lesions. MRI is the preferred diagnostic imaging modality for the evaluation of soft-tissue masses, although CT/myelography is acceptable. Bone scans are of help in demonstrating skip or satellite lesions. Bone scans may also be used in follow-up treatment for residual or persistent or recurrent tumor.

Treatment

No prospective and/or standardized protocols exist for treatment of malignant lesions of the spine (e.g., osteosarcoma). After biopsy-proven diagnosis, usually by a CT-directed procedure, chest CT scans and bone scans should be obtained to rule out metastatic disease.

Rosen et al. (64) propose that surgery be delayed up to 16 weeks before resection of primary tumors while preoperative chemotherapy is given. The rationale for this treatment comprises several considerations. The first is that systemic micrometastases exist at the time of initial diagnosis; thus, chemotherapy is most effective when the burden of tumor is relatively small. Because the doubling time of osteosarcoma is estimated at 30 to 40 days, this is very important. Second, primary tumor regression and shrinkage potentially allows for more effective and less morbid surgical intervention. In spinal tumors, this may be extremely important because sometimes en bloc excision is possible. Finally, the effects of chemotherapy on tumors have been quantified histologically (66).

Local radiation therapy could be used when surgery is not oncologically appropriate and should be considered only after appropriate wound healing has taken place, generally in 3 to 4 weeks. Treatment also includes many postoperative courses of chemotherapy.

Outcome of Treatment

In the Mayo Clinic series of 27 cases, median survival was 10 months, and only seven patients survived for more than a year. One patient survived for more than 5 years (73). Similar results were reported by Barwick et al. (5). In their series, only one patient, a 3-year-old boy who had a thoracic tumor treated by external-beam radiation and chemotherapy and who survived for 6 years and 2 months, was considered a long-term survivor. Ogihara et al. reported a 15-year-old boy with a T4 osteosarcoma who, after laminectomy and three courses of adjunctive chemotherapy at 6-week intervals, was free of disease at follow-up 6 years later (58). In the Shives study from the Mayo Clinic, no patient had been treated intensively with the modern chemotherapy regimens currently available (73).

Metastatic disease exists at diagnosis in about 10% to 20% of patients. This does not necessarily preclude long-term survival. Current recommendations for treatment of metastatic disease suggest aggressive resection of pulmonary metastases, which may involve multiple thoracotomies. Forty-one percent of patients with pulmonary metastases can be rendered disease-free and achieve long-term survival (29). Recent data obtained with flow cytometry of the tumors has been of considerable help in predicting metastatic potential and the need for more intensive therapy (50). Patients with near-diploid stem lines have considerably better prognosis and decreased potential for metastatic disease than those with marked aneuploidy. With this knowledge and more advanced surgical techniques, better 5-year survivals may be achievable.

Leukemia

Leukemia is the most common cancer in children and can affect all organ systems. In 6% of children with leukemia, back pain and vertebral collapse are the initial findings at the time of presentation (9) (Fig. 13). Correct diagnosis is very difficult because patients often have several nonspecific symptoms. Lethargy, anemia, fever, and increased peripheral leukocyte count are all common symptoms (9). A very high index of suspicion is the key to correct diagnosis of this disease. Radiographs may not demonstrate any focal abnormality or may show focal lytic lesions, occasional sclerotic lesions, or isolated periosteal reactions (72). At some time during the disease process, approximately 10% to 15% of children will have at least one pathologic fracture of the spine. A seemingly insignificant injury or fall that has unexpected consequences should make the treating physician highly suspicious. If radiographs of the involved extremity are negative, a complete blood count and ESR should be obtained. The peripheral white blood cell count will be increased, as will the ESR; the platelet count often is decreased. This is enough to warrant further investigation. Radiography and/or other spinal investigations may not be diagnostic. Misdiagnosis of a septic joint or osteomyelitis is not at all uncommon. Bone scan generally is not useful. Again, a high index of suspicion is imperative.

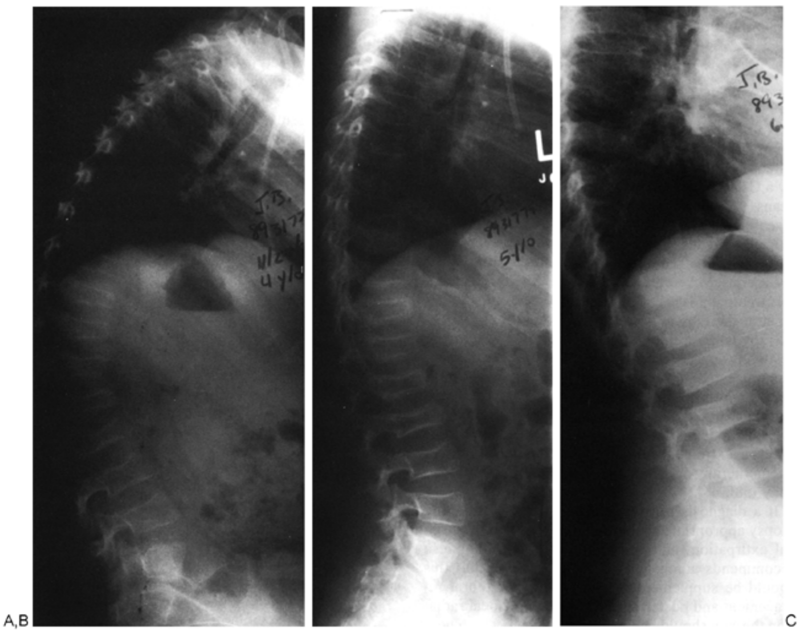

FIGURE 13. Leukemia. **A:** Lateral radiograph of a 4-year-old boy at time of diagnosis. Osteopenia and numerous compression fractures are apparent. **B:** Lateral radiographs during treatment. **C:** Lateral radiographs 2 years after diagnosis and treatment. Some vertebral height has been restored.

Treatment

Treatment of the specific types of leukemia with appropriate chemotherapy and/or radiation is the key. Spinal care is supportive in most cases.

Metastatic Spinal Tumors in Children

Although the metastatic diseases of adulthood do not generally occur in children, metastasis and/or contiguous invasion of certain tumors does occur in children, and one must be cognizant of such tumors. Neuroblastomas, embryonal carcinomas, and various sarcomas are all metastatic in children (Fig. 14). These lesions often have a poor prognosis, and most are treated nonoperatively with adjuvant therapy. Surgical experiences in such cases other than Ewing sarcoma has been limited. In the series of Fraser et al. (28), 30% of pediatric spinal tumors were metastatic neuroblastomas, and in the series of Leeson et al. (48), 41%

were neuroblastomas. Unfortunately, treatment in these cases is often delayed because of misdiagnosis (17). The pathogenesis of a metastasis is controlled by several factors, some of which are contact inhibition, cell adhesiveness, and cell membrane mediation. Tumor cell survival is dependent on antigen-stimulated macrophage response, nonspecific immunologic response to fibrin clot, and permeability of endothelial and basement membranes, lymph vessels, and capillaries (16,25) (Fig. 15).

Treatment

Appropriate treatment of children with spinal tumors only results from accurate diagnosis. A high index of suspicion, followed by appropriate diagnostic studies and biopsy at specialized institutions, is essential, as is the contribution of surgeons who can treat these children. Inappropriate biopsy and diagnostics can profoundly affect not only the short-term outlook but long-term survival as well. Today there are specialized centers for the diagnosis and treatment of childhood cancers. Experienced spine surgeons must work closely with their oncology colleagues to offer the best possible outcome for these children and their families. A mistake can be life threatening. To this end, an algorithmic approach may be helpful (Table 2). It is important to remark that spinal tumors in children are more frequently benign than those in adults. Therefore, the priority is to prevent permanent cord damage over the need to perform en bloc surgery in an uncontaminated lesion.

TABLE 2. Algorithm: Pediatric Spine Tumors

Spinal Fixation in Childhood Tumors

Most benign tumors can be resected and bone grafted with the patient's own iliac crest as graft material. On the other hand, some of the more aggressive tumors require extensive bone and soft-tissue resection, necessitating an adjunctive internal fixation device, or even a prosthesis for the reconstruction of the vertebral body. A sound reconstruction of the anterior column allows for immediate function recovery and long-term stability. To this purpose, the author's (SB) experience suggests the use of carbon fiber implants filled with autogenous bone cancellous chips (Fig. 11E). This system, connected with the posterior plates or rods, is rigid enough to allow for immediate weight bearing, whereas the piezoelectric features of carbon fiber implants enhance bone formation inside the prosthesis. However, more study is needed.

Spinal fixation devices today have evolved to a state wherein nearly any surgical extirpation can be reconstructed. Figure 16 shows the case of an 8-year-old boy who had mesenchymal chondrosarcoma of T12 and progressive paraplegia. Surgical intervention involved a laminectomy of T12 with en bloc excision of the lesion, including the right T12 pedicle. In this case, Luque instrumentation was used along with autogenous iliac bone graft from T9 to L3. The patient had 2 years of chemotherapy; now, 5 years after his resection, he has no signs of tumor recurrence.

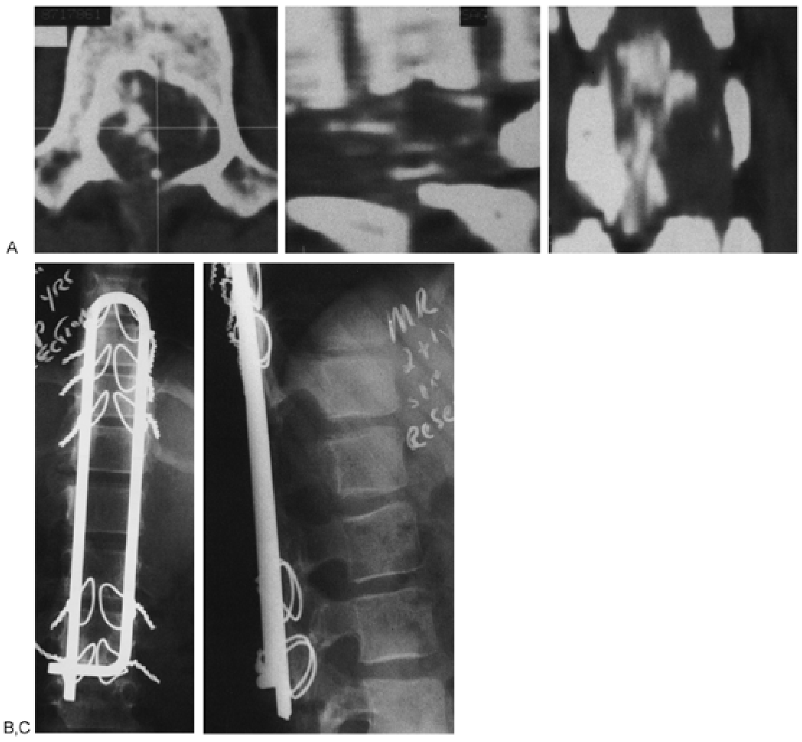

FIGURE 16. Mesenchymal chondrosarcoma of T12 in an 8-year-old boy who had progressive paraplegia. **A:** Computed tomography scan: axial, sagittal, and coronal cuts. **B, C:** Anteroposterior and lateral radiographs show Luque instrumentation from T9 to L3, 2 years after surgical extirpation.

Tumor resections, whether anterior, posterior, or both, often necessitate posterior instrumentation. On the other hand, anterior devices are not commonly used in the reconstruction of childhood tumors. Although Luque instrumentation has been used in almost all spinal regions, newer devices allowing distraction and compression and/or a combination using pedicular fixation, hooks, rods, plates, and various cross-linking devices offer experienced spinal tumor surgeons adequate alternatives for reconstructing childhood spinal tumors. Owing to the increased risk of infection and complications associated with cement and/or allograft, these materials are not generally indicated.

Complications

It is important to consider the complications in these most difficult cases, as sometimes management of complications is more difficult than management of the primary tumor. Second chances are often too late. The first chance not only is the most important but it may be the only chance. The ability to interface the best surgical and nonsurgical treatments can affect not only the immediate care of the patient but, more importantly, his or her long-term survival (86).

Several series have implicated acquired instability and deformity as the cause of lack of neurologic improvement and, occasionally, the progression of neurologic dysfunction. Hypermobility or acquired instability may be the result of inadequate reconstruction or stabilization at the time of initial surgery or of late failure of fixation owing to disease progression and/or implant failure. Obviously, attention to the mechanics of reconstruction is important. In Harrington's series of 77 patients treated with posterior stabilization and adjuvant methylmethacrylate, five patients had loss of fixation and required restabilization. In addition, six patients subsequently developed spinal hypermobility due to metastatic disease at adjacent levels of the spine (32). Of the 24 complications reported by McAfee et al. (53), only five occurred after anterior stabilization using methylmethacrylate. Of the 19 patients with posterior stabilization, 15 had loss of fixation and several developed significant kyphosis. Six patients developed deep infections; three had associated significant neurologic deterioration (53). In the series of Kostuik et al. (44), among 100 patients there were 3 cases of instrumentation failure; one occurred in a patient who had anterior reinforced methylmethacrylate with metastatic disease in the cervical spine. Failure occurred because it was not recognized that the disease extended into the proximal vertebral body. A second procedure was successful. Two other major failures occurred; both were in the thoracic spine, and both were associated with use of Harrington instrumentation without use of sublaminar wires. A proximal hook pulled out in one patient, and both lower hooks pulled out in another. Both patients underwent reconstruction without sequelae (44). In children for whom long-term survival may be possible, the author recommends using either autogenous bone graft and/or autogenous bone graft supplemented with various synthetic vertebral replacements, of which several are now available, rather than methylmethacrylate.

The complications of radiation have already been alluded to: sarcomatous degeneration and/or neurologic dysfunction, and stunted growth. Before surgery, radiation has a significant effect. Radiation can increase the risk of infection at the time of surgery by 36%.

In a review of technical considerations and complications in tumor surgery by McLain et al. (54), pedicle fixation was noted to confer significant technical advantages in spinal reconstruction, with complications comparable to those of other methods of posterior segmental fixation, although operative times were slightly longer. With this system, fewer levels had to be fused as compared with systems using sublaminar hooks or wires. Preoperatively irradiated patients experienced 42% of all complications and had 70% of the major complications. Wound infections occurred in 18%, vascular injuries occurred in 18%, and transient neurologic deficits occurred in 36%. Clinical pseudarthrosis developed in two patients, and tumor progression produced late instability in two patients with renal carcinoma. Thecal compression and late collapse led to therapeutic failure in four patients 12 to 18 months after surgery. Fixation failure occurred in four patients, resulting in loosening of the hardware devices. Failure to adequately address the anterior column disease was the primary cause of treatment failure in these patients; had it been addressed, the fixation devices may have remained intact throughout the illness. However, appropriate instrumentation provided rigid fixation and allowed more extensive tumor resection with sparing of vertebral motion segments. However, failure to address key technical and biomechanical principles can lead to serious complications. In the pediatric population, pedicle fixation may not be possible; but when it is, it appears to have the advantage of involving fewer motion segments.

Summary

In the United States, approximately 2,000 malignant tumors of bone are diagnosed each year (74). Of these, between 4% and 20% are primary spinal tumors (80 to 400). Therefore, it would be unusual if not impossible for any one institution to acquire the necessary understanding of the natural history of these tumors and their response to various forms of treatment. Therefore, the authors would prefer that an international registry be organized through which centers with special interest in these cases can work together. To this end, adopting the same terminology and possibly using the same oncologic and surgical staging system is mandatory (Fig. 2). Only through a collaborative effort will enough information be obtained to allow rational surgical and nonsurgical decision making on behalf of our patients.

Treatments for vertebral spinal tumors in children have evolved over the years. More aggressive treatment has helped tremendously, as have improved diagnostic techniques. Diagnosis is the most important factor in treatment of tumors. The earlier the diagnosis, the more beneficial treatment will be. Although no single technique has emerged as superior, combinations of techniques based on individual cases have given the best results. However, many problems in treating cancer, especially in children, remain. Many neoplasms still are not curable, and treatments for these tumors can in and of themselves lead to problems (e.g., excision of tumors in children may result in spinal deformity and instability of the spine). The younger the patient, the more susceptible to severe deformity he or she is. Complete excision is the best cure, although in the spine this can be very difficult. Radiation and/or chemotherapy may not only affect growth but can be responsible for sarcomatous degeneration and/or development of secondary neoplasms.

In the future, the origin of human cancer as explained by molecular and cellular mechanisms in the various stages of carcinogenesis may provide the most effective means for cancer prevention and treatment. The mechanisms by which normal cell growth fails and cells become malignant is believed to be related in part to the absence of tumor suppressor genes or an activated oncogene (70,84). The suppressor genes are involved in cell cycle control, signal transmission, angiogenesis, and development, indicating that they contribute to normal cell and tumor cell functions. These suppressor genes are believed to provide an untapped resource for anticancer treatment (70). It is hoped that this technology will bring us closer to understanding the cellular mechanism of cancer and that our currently crude methods will give way to a more basic and reasonable approach to patients with spinal neoplasms. Clearly, time will tell, but while we wait we must not intervene without cause or delay without reason. Surgical intervention can be a valuable adjunct and at times constitutes the primary treatment for spinal neoplasms. Although there are times when intervention may be worse for the patient than no intervention, at other times strong intervention is the best alternative.

Spinal Cord Tumors

J. Gordon McComb

Mark A. Liker

Michael L. Levy

J. G. McComb, M. A. Liker, and M. L. Levy: Division of Neurosurgery, Children's Hospital Los Angeles, Los Angeles, CA 90027.

The incidence of spinal cord tumors in comparison to brain tumors varies from series to series and is influenced by what is included under this heading (40). For instance, many series have included closed neural tube defects (NTDs) with lipomatous malformations under the category of lipomas, which in reality are hamartomatous rather than neoplastic lesions and are not included in this chapter. However, other closed NTDs, such as dermoids and neurenteric cysts, although not neoplastic, steadily expand in size and produce symptoms that are comparable to other benign neoplastic lesions in the spinal canal. Because the clinical presentation of dermoids, neurenteric cysts, vascular lesions and syringes are similar to that of other neoplastic lesions, they will be included in this chapter. Excluded are tumors of bony mesenchymal origin, which are discussed in another chapter. The incidence and types of spinal cord tumors are influenced significantly by referral patterns. For instance, a center that has an active neurofibromatosis program will have a disproportionate number of neurofibromas. If there is a very active oncology service, there will be a much higher incidence of epidural malignant tumors. Thus, although the incidence of spinal cord tumors is much lower compared with that of brain tumors, it varies considerably based on what is included and the nature of the referral patterns to a given center.

The classification of spinal cord tumors can also vary to a degree, although most reports divide tumors into extradural, intradural, extramedullary, and intramedullary categories (Fig. 1) based on location, as noted in Tables 1 and 2 . Some tumors can be in more than one location, such as neurofibromas, which are often intradural extramedullary, as well as extradural. On rare occasions, an intradural extramedullary tumor, such as a primitive neuroectodermal tumor (PNET), can spread to become extradural. It is even rarer yet, however, for extradural tumors to penetrate the dural barrier and become intradural. In Table 3 , the presenting signs and symptoms are listed in a rough order of decreasing frequency. Although some generalizations can be made, as seen in Table 4 , there is enough overlap so that the clinical presentation does not specify the position of the tumor with respect to the dura mater or spinal cord.

As noted in the generalizations in Table 4 , this group of lesions is fairly uniformly distributed throughout the pediatric age group and is fairly equally divided as to sex. Also, as another generalization, the location of tumors along the spinal axis is by and large in proportion to the length of the spinal segment.

Although there still is often a fair delay between the onset of symptoms and the time that the definitive diagnosis is made, the advent of magnetic resonance imaging (MRI) in addition to computerized tomographic (CT) scanning has made remarkable strides in being able to detect and assess the treatment of this group of lesions. Improved surgical techniques have also significantly improved the outcome in patients with these tumors. As noted in Table 4 , approximately two thirds of the neoplastic lesions are benign in the pediatric age group, whereas just the reverse is true for adults. This chapter provides an overview of this group of lesions, be they neoplastic or nonneoplastic masses that have the commonality of all being expanding lesions that will produce progressive neurologic deterioration if not addressed. In most, but not in all, instances, the best outcome will be obtained with a high degree of collaboration among a number of pediatric specialties residing at centers where these problems are frequently encountered.

Clinical Symptoms and Signs

Spinal cord tumors are notorious, in all but a small percentage of cases, for their indolent course because it is often months, if not years, before the correct diagnosis is made (39). With the advent of noninvasive MRI, however, the time between the onset of symptoms and diagnosis has been shortened considerably. In some cases, the progression of symptoms is relentless, whereas in many, the course is variable. The more malignant the tumor, the more likely that the progression is rapid and the time to diagnose shorter. A sudden change in spinal cord function can occasionally be seen in the face of hemorrhage, bony collapse, or extramedullary spinal cord compression that causes an ischemic stroke to the spinal cord.

Occasionally, the onset of symptoms is presumed to be the result of a minor traumatic injury, such as a fall. It may be that the preexisting myelopathy made the child clumsy and thus resulted in the fall. On the other hand, a minor injury could be enough to exacerbate the underlying pathophysiology, leading to spinal cord edema, microscopic hemorrhage in the spinal cord or surrounding tissues, and so on. It is frequent that the parents will pick up a very subtle abnormality long before any objective findings are noted. Many patients are often seen for orthopaedic evaluation because of gait abnormality or the development of kyphoscoliosis or back pain. Pain can be a significant factor, and many of the children have been prescribed various pain and antiinflammatory nonsteroidal medications for some time before the diagnosis being made.

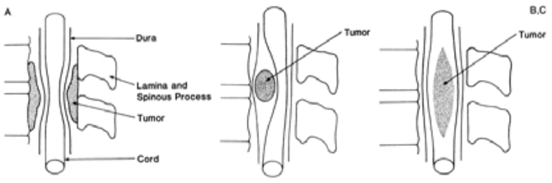

FIGURE 1. Different categories of spinal cord tumors. **A:** Extradural tumor lying outside of the thecal sac but within the bony confines of the spinal canal. **B:** Intradural extramedullary tumor lying within the thecal sac but outside of the spinal cord. **C:** Intramedullary tumor entirely in the substance of the spinal cord, causing cord widening.

TABLE 1. Intramedullary Tumors

- Astrocytoma—low grade
- Astrocytoma—high grade
- Ependymoma
- Ganglioglioma
- Mixed glioma
- Primitive neuroectodermal tumor (PNET) (same as medulloblastoma)
- Lipoma
- Neurenteric cyst
- Syrinx

TABLE 2. Extramedullary Tumors

- **Intradural**
  - Congenital
    - Dermoid
    - Teratoma
    - Neurenteric cyst
  - Other
    - Epidermoid
    - Lipoma
    - Ependymoma
  - Nerve Sheath
    - Neurofibroma
    - Schwannoma
    - Malignant nerve sheath tumor
  - Meningeal
    - Meningioma
    - Arachnoid cyst
  - Vascular
    - Arteriovenous malformation
    - Aneurysm
    - Hemangioblastoma
    - Hemangioendothelioma
  - Metastatic
    - Neural
      - PNET
      - Glioma
      - Melanomatosis
  - Extraneural
    - Lymphoma
    - Leukemia
    - Other
- **Extradural**
  - Neural Crest
    - Neuroblastoma
    - Ganglioneuroma
  - Mesenchymal—soft tissue
    - Ewing Sarcoma
    - Rhabdomyosarcoma
    - Unidentified sarcoma
    - Lymphoma
    - Leukemia
    - Germ cell
    - Wilms tumor
    - Other
  - Mesenchymal-bone (See other chapter)

TABLE 3. Symptoms and Signs

- Weakness
- Back pain
- Radicular pain
- Gait abnormality
- Kyphoscoliosis
- Torticollis
- Urinary incontinence/retention
- Loss of or delayed milestones
- Sensory changes
- Reflex changes
- Tenderness
- Atrophy
- Visible/palpable mass
- Muscle spasm
- Hydrocephalus
- Meningitis
- Subarachnoid hemorrhage

TABLE 4. Generalizations

Tumor versus location
  Overall distribution of tumors in the spine is proportional to spinal segment length
  Fairly well distributed as to location among the intramedullary, intra-dural extramedullary and extradural spaces
Tumor versus gender
  Overall equal distribution between sexes
Tumor versus age
  < 18 years – 2/3 benign
  > 18 years – 2/3 malignant
  Fairly evenly distributed throughout the first 18 years
  Gliomas are seen fairly consistently across all age groups
  Neuroblastomas, teratomas and PNETs seen more frequently in the very young
  Neurofibromas, schwannomas and hemangioblastomas seen more commonly in older children
Location versus presentation
  Extradural or intradural extramedullary tumors are more likely to present with pain
  Intramedullary tumors have a higher incidence of kyphoscoliosis
Age versus presentation
  Pain more likely to herald a tumor in older age group
  Weakness and bladder dysfunction more frequently noted in the younger age group

The signs and symptoms are roughly in frequency to the listing in Table 3 . In Table 4 , there are some generalizations, such as the extradural or intradural extramedullary tumors are more likely to present with pain, whereas intramedullary tumors have a higher degree of kyphoscoliosis as the initial symptoms. Also, pain is more likely to herald the presence of a tumor in the older age group, whereas weakness and bladder dysfunction are more frequently noted in those who are younger. In the infant, irritability or general fussiness may be all that is indicative of a spinal cord tumor. A tumor located in the cervical region can often present with a head tilt or torticollis. If there is upper extremity neurologic involvement from a cervical tumor, an infant or young child may switch hand dominance.

Pain is more commonly reported to be present at night. This presumes that the horizontal position may alter the pressure on the spinal cord or exiting nerve roots secondary to venous congestion or, perhaps, the absence of cerebrospinal fluid (CSF) hydrostatic pressure to distend the spinal subarachnoid space (SAS), or possibly, that fewer stimuli are present to act as distraction from pain that is present during the day but is less noted.

The striking feature is the subtlety, the variability, the often indolent nature of the process, and the lack of early objective findings that make it so difficult to diagnose spinal cord tumors and leads to the delay between the initial onset of symptoms and the establishment of a definitive diagnosis.

The ready availability of noninvasive high-quality MRI has, once again, markedly shortened the time from onset of symptoms to diagnosis, as well as providing examiners with the ability to exclude other entities that can be confused with spinal cord tumors.

Diagnostic Studies

Imaging Modalities

MRI has revolutionized our ability to detect the presence of various forms of spinal cord tumors and has largely replaced other modalities (1). The signal characteristics of a tumor and its response to contrast enhancement, as well as the superior anatomic detail, give precise information as to the size, location, and to a fair degree, the likelihood of the histology of the lesion. Postoperative studies will document the degree of tumor excision and provide a non-invasive way for subsequent monitoring.

Because MRI does not image bone well, CT scanning is particularly helpful with tumors that primarily involve the bone or significantly change the configuration of the surrounding normal bony structures. In some cases, three-dimensional reconstruction adds additional information that is beneficial in making clinical decisions. In some cases, it is helpful to obtain both MRI and CT images.

Myelography, with or without CT, is rarely needed for diagnostic purposes. The main indication at this point would be to determine if an area within the SAS is or is not in communication with the rest of the SAS, as with an arachnoid cyst, and cine-MRI is either not available or helpful.

Although abnormalities can be detected on plain spine x-rays (Fig. 2) their role is limited in detecting spinal cord tumors and they are used to assess the overall structural relationships and alignment of the vertebral column. Plain x-rays are of value to monitor the presence or progression of a kyphosis, scoliosis, or kyphoscoliosis of the spine.

Ultrasound does not readily penetrate through bone. This modality plays a minor role in making the diagnosis of an intraspinal lesion. In the first few months of life, the contents of the spinal canal can be imaged and, in some cases, used for screening purposes. If operative intervention is contemplated, MRI would also be indicated. The spinal canal can be imaged at the site of a laminectomy, although few clinical situations arise when this is clinically helpful and would not be better served with MRI. Intraoperatively, ultrasound is particularly useful for intramedullary tumors. The cystic and solid components can be readily detected once the spinal cord is exposed. In addition to helping with localization, intraoperative ultrasound may evaluate the presence of remaining solid tumor following excision in cases in which the echogenicity of the tumor is different from that of the normal spinal cord.

Bone scans, using various radiopharmaceuticals, can be helpful in detecting primary bone tumors before changes can be seen on plain x-ray studies, as well as detecting the presence of metastatic disease that involves the bone. A case in point is that of eosinophilic granuloma of the spine in a young child who is at risk of having multiple lesions. Bone scanning may also be helpful in monitoring the response of diffuse metastatic disease to chemotherapy and radiation therapy.

An angiogram is indicated when a vascular lesion, such as an arteriovenous malformation (AVM) or aneurysm, is suspected. Super selective catheter techniques and better equipment have greatly improved the ability to image vascular lesions.

Other *Modalities*

Much attention was previously given to the analysis of CSF and the response to manometric maneuvers before the advent of MRI and CT imaging. Modern imaging has rendered the examination of CSF unnecessary in all but a few select situations. In some cases, lumbar puncture may be contraindicated because it could lead to neurologic deterioration caused by the pressure differential created by removing CSF below a complete spinal canal block. Some cancer protocols still call for CSF cytologic determinations. Mounting evidence has shown this to be of limited value, because CSF cytology can be normal in spite of obvious lesions in the SAS on MRI (Fig. 3). However, CSF cytology can be helpful in ascertaining the presence or absence of central nervous system (CNS) involvement with leukemia and lymphoma. CSF protein levels may rise or fall in response to advancing or receding disease, but these levels are only a very gross indicator of change and often in a much delayed fashion. Once again, MRI is a much better measure. Alpha-fetoprotein and beta-human chorionic gonadotropin levels in CSF may help with the diagnosis as well as monitoring the response to treatment, in certain malignant teratomas and germ cell tumors, but these lesions are usually intracranial in location. Congenital dermal sinuses and associated dermoid tumors can produce both an infective as well as a sterile inflammatory response that would be reflected by a pleocytosis and positive bacterial cultures.

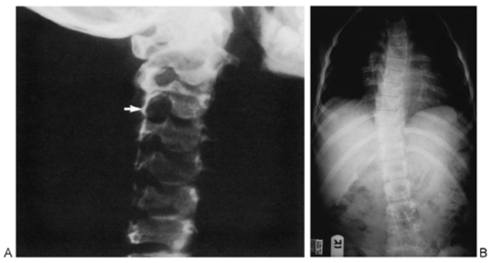

FIGURE 2. A: Plain radiograph of the cervical spine demonstrating widening of the C2–3 foramen by a neurofibroma *(arrow)*. **B:** Anteroposterior spine x-ray studies showing thinning of the pedicles in the thoracic region and scoliosis secondary to an intramedullary tumor and syrinx.

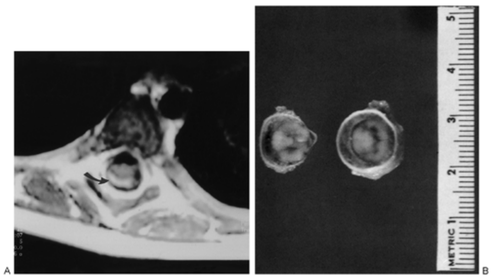

FIGURE 3. A: Contrast-enhanced magnetic resonance image of the spine showing the presence of a metastatic primitive neuroectodermal tumor (PNET) in the subarachnoid space *(arrow)*. **B:** Autopsy specimen demonstrating diffuse subarachnoid tumor. The subarachnoid space surrounding the spinal cord is completely filled with metastatic tumor, in this case a PNET.

Examination of the peripheral blood as well as bone marrow aspiration can be helpful in lymphomas, leukemias, and other metastatic disease entities. Measurement of the levels of the catecholamine breakdown products associated with neural crest tumors is often useful as a diagnostic tool, as well as a monitoring adjunct.

Differential Diagnosis

In addition to mesenchymal bony tumors, which are covered elsewhere, discitis (intravertebral disc infection) and osteomyelitis of the spine can present in similar fashion to that of spinal cord tumors.

Discitis is usually limited to the lumbar region in children younger than 5 years of age who present with progressive lower extremity weakness, refusal to walk, local tenderness, and either no fever or a low-grade fever. Vertebral osteomyelitis can present anywhere on the spine in an older group of children who primarily complain of back pain and are often febrile. In both entities, there is usually elevation of the peripheral white blood cell (WBC) count and erythrocyte sedimentation rate. Plain x-ray studies, CT scanning, and bone scans may all show changes depending on the stage of the disease. Once again, MRI will provide the most definitive information in distinguishing between discitis and osteomyelitis, as well as establishing that the process is not related to the spinal cord itself (11).

Demyelinating disease is uncommon in the pediatric age group and is only rarely a consideration in the differential diagnosis of spinal cord tumors. The onset of symptoms is usually much more rapid than with typical spinal cord tumors. Often, there are motor and sensory findings, with pain usually not being a significant factor. Also, the group most likely to be affected with a demyelination process is teenage girls. Once again, findings on MRI are the most helpful in making such a diagnosis, which is confirmed with CSF analysis.

Herniated discs are another entity that is uncommon in the pediatric age group and are most frequently encountered in the teenage group. The herniated discs are lumbar in location, present with back pain with or without radiculopathy, and occasionally, a neurogenic bladder. Once again, MRI is the diagnostic study of choice.

In the pediatric age group, brachial plexus, lumbar plexus, or peripheral nerve disease processes are rarely confused with spinal cord tumors and thus usually not a problem in the differential diagnosis, as is also true with myopathic entities. However, if there is any question, it is always better to image the spine with MRI.

Occasionally, a situation arises wherein an infant shows regression of milestones (i.e., stops walking or develops ataxia). The spinal cord is imaged, and nothing is found. Under these circumstances, it is necessary to image the head, because occasionally hydrocephalus by itself or associated with an intracranial tumor can present with symptom that could be confused with a spinal cord tumor.

Intramedullary Tumors

Astrocytoma—Low Grade

Low-grade astrocytomas are by far the most frequent intramedullary tumors seen in the pediatric age group (5 ,9). As the tumor slowly grows, it can reach considerable size before being diagnosed. As noted in Table 4 of generalizations, these tumors are fairly evenly distributed across all age groups and show no significant predilection for gender. They also tend to have a higher incidence of kyphoscoliosis and present less with pain (4 ,44). The tumor involvement can be localized to one or two spinal cord segments, or it may extend the entire length of the spinal cord from the medulla to the conus medullaris. A majority of these tumors are associated with syringes that are rostral to the tumor (Fig. 4), caudal to the tumor (Fig. 5), or often even both.

MRI shows diffuse widening of the spinal cord with areas of high and low signal intensity, depending on the presence or absence of cystic formation or hemorrhage in addition to the solid component. The enhancement is inhomogeneous and often is irregular. The MRI characteristics do not differentiate between high-grade and low-grade astrocytomas. These tumors have a low-grade histology, some of which will contain features that are pilocytic in nature.

Laminectomy or laminotomy begins at the midportion of the tumor and extends both rostrally and caudally as needed to gain access to the solid component. The cystic portion of the tumor either above or below the solid component need not be exposed, thereby limiting the amount of bony removal. Once the upper or lower limits of the solid component are reached, one will enter the cystic cavity and drain its contents, which usually consists of highly proteinaceous fluid that often congeals at room temperature. On opening the dura mater, one can see thickened arachnoid, with an increase in the vasculature on the dorsal surface of the spinal cord. The cord may be rotated by the tumor, so the midline may be off to one side. With careful inspection, the area that appears to be most in the midline is chosen for the site of myelotomy. Using the operating microscope, the myelotomy is made and extended over the solid portion of the tumor. The ultrasonic aspirator is used to debulk the tumor. The presence of the cyst at the end of the tumor makes it easy to know that the end of the tumor has been reached. In those cases without a cyst, the tumor tends to taper, making the extent of the myelotomy deeper. In such a case, it is helpful to angle the microscope considerably in order to remove the tumor from within the cord, without extending the myelotomy further. We have found it helpful to go over the length of the tumor many times, tilting the table and microscope in many directions so as to gain better exposure and feeling for where the interface between the tumor and spinal cord resides. Intraoperative ultrasound may be helpful in some situations. Localization of the cystic component in some cases can guide one's myelotomy, particularly if the tumor involves a very short segment of the spinal cord. When many segments are involved, it is just as easy to start where one knows solid tumor to be present and extend the dissection in either direction. If the signal characteristics of the tumor are similar to those of the spinal cord, the ultrasound will not help in determining the degree of tumor removal. Small residual amounts of tumor can also be eliminated with bipolar cauterization. If possible, the goal is to perform a gross total removal of the tumor. Following debulking of the tumor, the dura mater is usually easily closed with a running absorbable suture. The wound is then closed in a standard fashion.

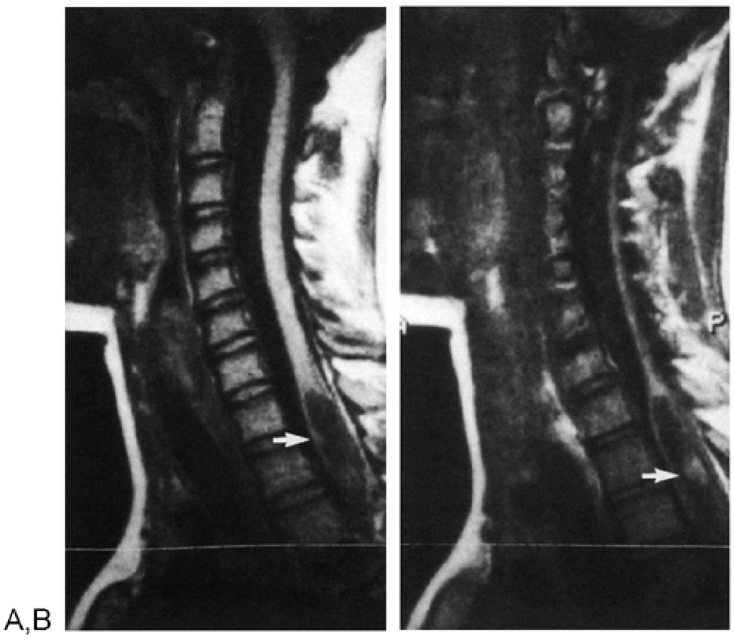

FIGURE 4. Intramedullary low-grade astrocytoma. **A** and **B:** Magnetic resonance image demonstrating the upper extent of tumor and associated cyst *(arrow)*. No postoperative adjuvant therapy was given after gross total removal of this tumor. This patient required an extensive spine stabilization procedure. Her neurologic condition remains stable, and there has been no evidence of tumor recurrence for almost 10 years.

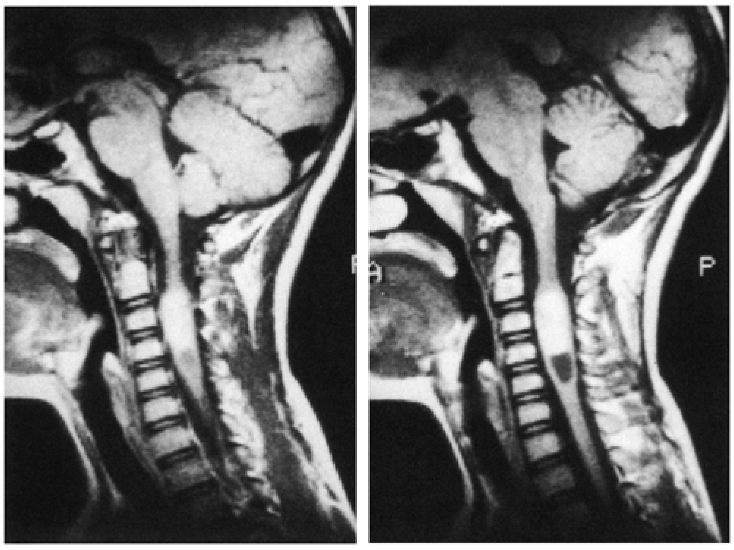

FIGURE 5. Intramedullary astrocytoma. Preoperative magnetic resonance image (MRI) with contrast enhancement. Note enhancing intramedullary mass with associated cyst.

Postoperative imaging studies are obtained to determine the degree of resection. If tumor is left behind, consideration should be given for an additional procedure to remove the remaining tumor (33). Postoperative radiation or chemotherapy are not indicated. Although there are undoubtedly viable tumor cells left behind, it would appear that, if their number is reduced to a certain threshold, the body's defense mechanisms appear to keep them in check from further growth. The long-term outcome can be quite favorable, with many patients being neurologically stable for years to decades following tumor excision (16 ,18 ,19 ,26 ,37 ,41). Surveillance imaging is indicated at progressively less frequent intervals if no change is noted on serial studies.

If the neurologic deficit is worse immediately postoperatively, often there will be a progressive improvement, such that the patient is the same as or better than before operative intervention was undertaken (6 ,8). There is no evidence that there can be any improvement in function for a patient who is paraplegic or quadriplegic before the operative procedure. In those situations in which recurrence does occur, consideration can be given to re-resection. Occasionally, although not common, these tumors can become progressively more malignant in histologic appearance. On occasion, low-grade astrocytomas can be present throughout the SAS, even before operative intervention. If enough of the SAS is filled with tumor, hydrocephalus develops, requiring CSF diversion. Although radiation therapy or chemotherapy is often initiated under these circumstances, the benefit of such is unknown and probably variable (13).

Astrocytoma—High Grade

Roughly 10% of intramedullary astrocytomas are classified as anaplastic astrocytoma or glioblastoma multiforme and thus are classified as high grade. The clinical progression is usually more rapid, although one cannot use this factor to distinguish between high-grade and low-grade astrocytomas. Imaging by MRI cannot discern the difference between high-grade and low-grade astrocytomas with any degree of reliability.

On opening the dura mater, one cannot always ascertain whether a tumor is high grade or low grade. Even while probing within the tumor, it may not be possible. Availability of reliable intraoperative neuropathologic assessment is key to knowing the nature of the tumor and how aggressive one needs to be with tumor resection. Less aggressive debulking of the tumor may be called for with high-grade astrocytomas, because it has not been shown to influence the prognosis positively, which in this group of patients is very poor. Also, the plane of demarcation between the tumor and spinal cord may be even more difficult to define compared with a low-grade astrocytoma (Fig. 6). In this situation, the dura mater is left open for decompression and oxidized cellulose is placed over the exposed spinal cord and dura mater before beginning closure. Radiation therapy, or chemotherapy, or both, are appropriate in these situations, with the outcome being similar to that of intracranial tumors with the same histology (32 ,38). Often, these tumors will disseminate widely through the SAS and result in increased resistance to CSF drainage, requiring CSF diversion.

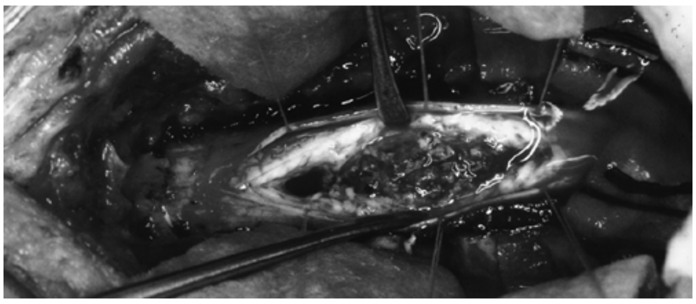

FIGURE 6. Intraoperative photograph of a high-grade astrocytoma. The tumor is diffusely infiltrating the spinal cord. There is no clear cut demarcation between tumor and spinal cord. The tumor was debulked, and the patient was given a course of chemotherapy and radiation. The patient subsequently died of disseminated disease.

Ependymomas

Ependymomas are the most common intramedullary tumors in adults (6 ,7 ,29) and the second most common in children. Nothing clinically distinguishes an ependymoma from an astrocytoma. The appearance of ependymomas on MRI is comparable to that of an astrocytoma in many respects, with the notable difference that the area of enhancement tends to be fairly uniform and better demarcated than most astrocytomas. Ependymomas grow in the spinal cord, mainly by displacing rather than invading neural structures, producing a well-demarcated plane around the tumor. This makes it easier to achieve a gross total removal with less possibility of causing neurologic damage. Following gross total removal of ependymoma, long-term survival without recurrence is the rule (18). If residual tumor is seen on the postoperative imaging study, consideration need be given to reexplore the spinal cord, with an attempt to remove the residual tumor unless deemed otherwise by the first operative procedure. In some cases, observation with serial imaging studies may be an alternative. There is little role for chemotherapy or radiation therapy in a grossly resected ependymoma. The benefits of these modalities in incompletely resected tumors remains uncertain (14).

Ganglioglioma

These are uncommon tumors that constitute but a small fraction of intramedullary tumors. It is a slow-growing tumor and has an indolent clinical course. On MRI, there is nothing specific that distinguishes this tumor from any other intramedullary tumor. The optimum treatment is gross total excision, which is easier in some cases than others, as the line of demarcation between tumor and surrounding spinal cord may be similar to that of a low-grade astrocytoma. As with an ependymoma, there is no need for adjuvant therapy in a completely resected tumor. For those tumors that are not completely resected, the same guidelines hold as for ependymomas.

Mixed Gliomas

A percentage of intramedullary tumors have mixed glial elements and thus are classified as low-grade astrocytoma and ependymoma, or low-grade astrocytoma and oligodendroglioma. As long as all of the components are low grade, the clinical course is similar to that of a low-grade astrocytoma. Ideal treatment consists of gross total resection without adjuvant therapy. With an incomplete resection, the same considerations hold for that discussed under low-grade astrocytomas.

Primitive Neuroectodermal Tumors

On rare occasions, PNETs can present as an isolated intramedullary tumor of the spinal cord. On some occasions, they can be a direct extension into the spinal cord from the posterior fossa or be a discreet tumor mass separated from that in the region of the fourth ventricle (Fig. 7). The surgical goal for these tumors is gross total resection, followed by either chemotherapy or radiation therapy, or both. These tumors can widely disseminate in the SAS, like those whose primary is in the posterior fossa.

Lipomas

These intramedullary tumors are usually found in the thoracic region, although they may extend to the cervical and lumbar regions to involve a large segment of the spinal cord (Fig. 8).

They are most likely congenital in nature and may or may not be truly neoplastic. They are not associated with any cutaneous markers for dysraphism. This type of tumor is different from that of the lipomatous malformation associated with a closed NTD that results in tethering of the spinal cord. The symptoms from this type of lipoma are that of spinal cord compression and may become manifest after weight gain or a growth spurt. The findings on MRI are typical of fat.

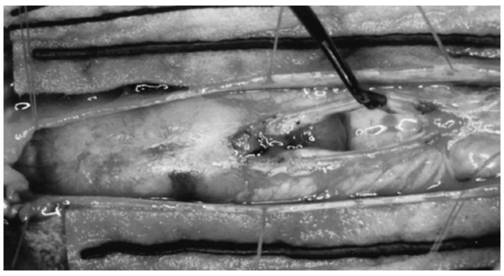

FIGURE 7. Intramedullary primitive neuroectodermal tumor (PNET). This patient had a posterior fossa PNET resected previously followed by chemotherapy and radiation therapy. On follow-up imaging studies, he was found to have an intramedullary mass in the cervical region, remote from the original posterior fossa tumor. This tumor had a clear-cut margin, and it was possible to grossly resect what was a histologically similar PNET. Note the syrinx rostral to the tumor. The patient died secondary to recurrence of the intracranial tumor component.

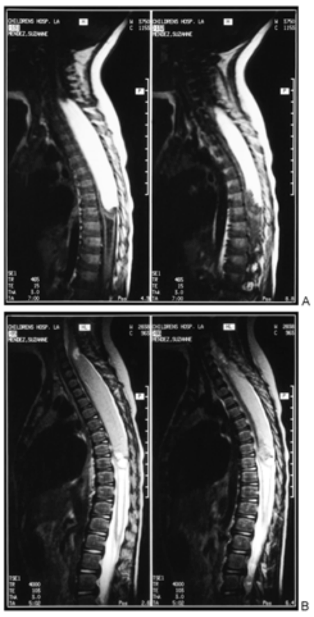

FIGURE 8. Fibrolipoma. **A:** This noncontrast T1-weighted magnetic resonance imaging study shows the presence of an intramedullary tumor, which is hyperintense to the spinal cord. It did not enhance with contrast. At the bottom of the tumor, one can appreciate the presence of a syrinx. **B:** The T2-weighted image shows the mass to have similar characteristics to adipose tissue. The syrinx is even better seen on this image. This 3-year-old child presented with developmental delay, scoliosis, weakness in her right lower extremity, and hyperactive reflexes. This patient underwent a thoracic laminectomy, with resection of over 50% of the mass. A postoperative scan showed a decrease in the syrinx. Her neurologic function remained stable. She did develop progressive kyphosis, which required stabilization.

The goal of surgery is to decompress the spinal cord through a subtotal removal of the lipomatous tissue using the ultrasonic aspirator. No attempt is made to perform a gross total excision, because these tumors appear to have limited growth potential and there is no clear-cut plane of separation between the fat and the adjacent neural tissue. The long-term prognosis is usually excellent.

Neurenteric Cysts

Neurenteric cysts may be intramedullary, extramedullary, or a combination of both. Because it is more common for them to be extramedullary, they are discussed in the section below.

Syrinx

Owing to the availability of noninvasive MRI of the spinal cord, syringes are being diagnosed with increasing frequency and earlier in the course of progression. The vast majority of these syringes result from a Chiari I malformation, a downward herniation of the cerebellar tonsils through the foramen magnum into the spinal canal that interferes with the normal movement of CSF between the cranial and spinal SAS. This alteration in CSF dynamics can result in CSF accumulating within the spinal cord to produce a syrinx. If the fluid accumulation is confined to the dilated central canal, it is referred to as hydromyelia, whereas if the fluid collection extends into the parenchyma of the spinal cord, it is termed syringomyelia. In practice, those syringes that are large enough to produce symptoms are a combination of both hydromyelia and syringomyelia for which the term hydrosyringomyelia is used and often referred to simply as a syrinx. Those syringes that are a few millimeters in diameter are of no clinical significance, whereas those in which the syrinx is larger than the diameter of the normal spinal cord definitely are significant (Fig. 9).

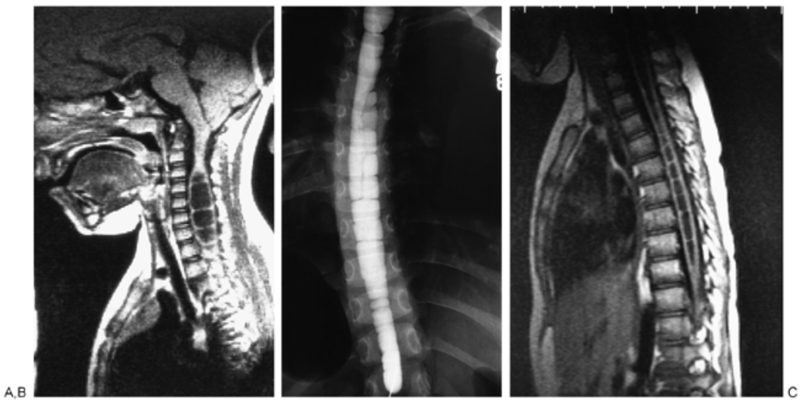

FIGURE 9. A: Sagittal T1 magnetic resonance image (MRI) showing the presence of a Chiari I malformation and marked dilatation of the spinal cord by a syrinx. **B:** A syringogram was performed during the period when MRI was first being used to evaluate syringes. This large holocord syrinx has multiple septated regions; however, there is complete communication from the rostral to caudal end of the syrinx. **C:** Definitive decrease in the size of the syrinx 2 weeks after a cervicomedullary decompression. Subsequent MRI scans showed nearly complete collapse of the syrinx. This 6-year-old boy presented only with scoliosis. The scoliosis did not progress and, in fact, with bracing, markedly diminished.

In our experience, the presenting symptom in the majority of these patients is a progressive scoliosis (24 ,27). Other symptoms in decreasing frequency were headache, upper extremity weakness, sensory abnormality, gait disturbance, and cranial nerve involvement. Hydrocephalus is rarely a factor. The diagnosis is easily made with MRI. Treatment consists of a cervicomedullary decompression to restore the normal CSF dynamics, whereupon in all but a few cases, the diameter of the syrinx slowly diminishes with time. Serial MRI is used to follow these patients, and reoperation is indicated should the syrinx recur.

These patients also need close orthopaedic follow-up of their scoliosis.

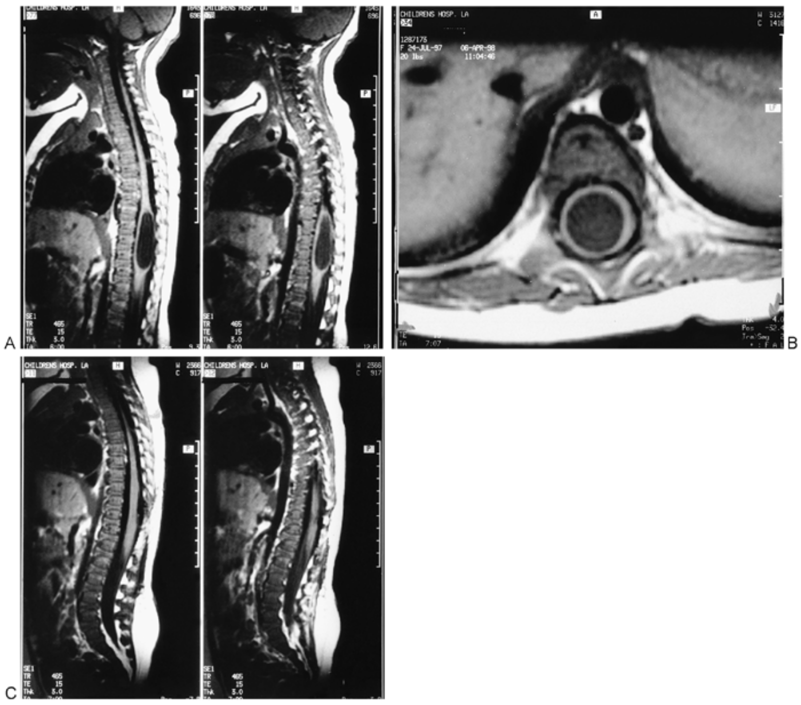

FIGURE 10. Isolated spinal cord syrinx. Sagittal **(A)** and transverse magnetic resonance images **(B)** showing an isolated syrinx in the spinal cord. There was no enhancement. **C:** Following a myelotomy, the syrinx collapsed and has not recurred. This 8-month-old infant presented with a 3-cm region of cutis aplasia and hypertrichosis in the lumbar region, which had remained unchanged since birth. Imaging of the rest of the central nervous system was normal. The patient had a normal neurologic examination preoperatively and postoperatively.

Occasionally, isolated syringes of the spinal cord not associated with a Chiari I malformation may also be encountered following MRI imaging for suspected spinal cord abnormality (Fig. 10) (35). These lesions are surgically treated by making a myelotomy in the spinal cord, allowing communication between the syrinx and the SAS.

Extramedullary Tumors—Intradural

Congenital

Dermoid

Dermoids, which contain both dermal and epidermal elements, can present anywhere along the spinal axis but overwhelmingly are found at the level of the conus medullaris or cauda equina and are associated with a congenital dermal sinus. These lesions are thought to arise from an abnormal adhesion or failure of normal separation between the ectoderm destined to form the neural tube and that which will form skin. Depending on the extent of the incomplete separation, the tract may end in the subcutaneous tissue or extend any distance inward to its ultimate embryologic terminus, which is the conus medullaris for lesions in the lumbosacral region and the central canal of the spinal cord for tracts at the thoracic or cervical levels (Fig. 11).

As noted in Figure 11A , those near the tip of the coccyx end in the fascia and do not extend to the SAS and, therefore, are usually of little consequence. The tract may be readily visible and be associated with other cutaneous markers, such as capillary telangiectasia, pigmentation changes of the surrounding skin, hair or debris exiting the orifice (Fig. 12), or with none of these markers, making it harder to detect. The capsule of dermoid usually adheres to the surrounding neural structures and becomes even more densely adherent in cases of inflammation from an infection or from the fatty acids of the degenerating material within the capsule should they enter the SAS. All tumors associated with a congenital dermal sinus should be dermoids embryologically; however, confusion exists because some reports, particularly in the older literature, do not correctly differentiate between dermoids and epidermoids and, in addition, the tissue sent for histopathologic examination may not reflect the lesion in its entirety or the dermal elements may have been destroyed by inflammation. Malignant change in these lesions is not a factor. The depth to which the congenital dermal sinus penetrates and whether it is associated with one or more dermoids will determine the clinical manifestations. A congenital dermal sinus may go unnoticed until the patient presents with infection, either meningitis or an extradural or intradural abscess. The usual hallmarks of a local infection may be present or, in some cases, completely absent when a deeper lying abscess or meningitis exists. Even without infection, the contents of the dermoid cyst can produce a chemical meningitis or dense arachnoiditis. Hydrocephalus can develop secondary to increased resistance of CSF absorption as a result of one or more bouts of bacterial or chemical meningitis. A progressively enlarging dermoid cyst along the tract will eventually result in compression of the conus medullaris or cauda equina, and the patient's symptoms will depend on the level of compression.

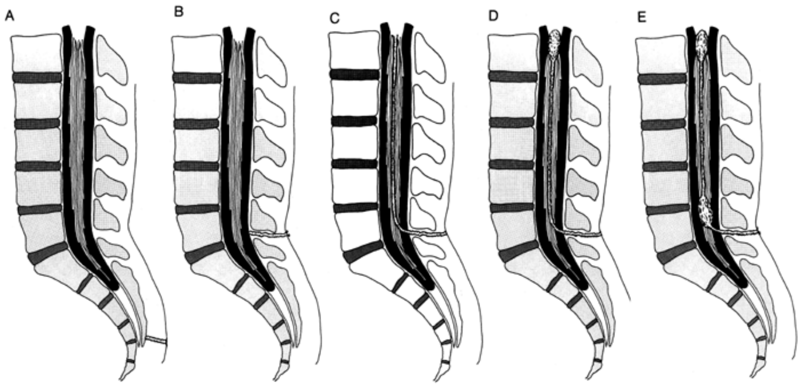

FIGURE 11. The varying anatomy of dermal sinuses and dermoid tumors. **A:** The tract ends at the coccyx and does not involve the neural elements. **B:** Dermal sinus. The sinus passes between spinous processes and ends at the dura mater. No dermoid tumor is present. **C:** Dermal sinus. The sinus enters the thecal sac and ends at the tip of the conus medullaris. No dermoid tumor is present. **D:** Dermal sinus and dermoid tumor. A dermoid tumor is present at the termination of the sinus at the conus medullaris. **E:** Dermal sinus and dermoid tumors. Two dermoid tumors are present along the course of the dermal sinus, one in the cauda equina and one at the conus medullaris.

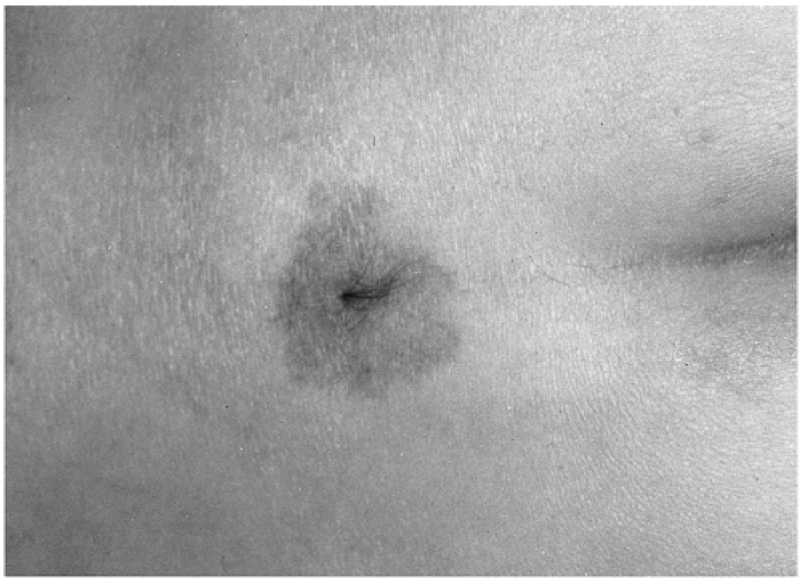

FIGURE 12. Congenital dermal sinus associated with two intradural dermoid tumors. Photograph showing congenital dermal sinus with hair coming from the orifice. There is an area of capillary telangiectasia surrounding the orifice.

A diagnosis of congenital dermal sinus and associated dermoid is clinical, and the imaging studies, particularly MR, is only augmentive (28). Negative findings on MRI do not exclude the need to explore the tract to its end and excise it along with any accompanied dermoid tumors (Fig. 13). The most important factor influencing the outcome in cases of congenital dermal sinuses and dermoids is total excision of the lesion before the development of infection or irreversible neural neurologic damage.

As shown in Figure 14 , dermoids can also be seen in association with an anterior sacral meningocele.

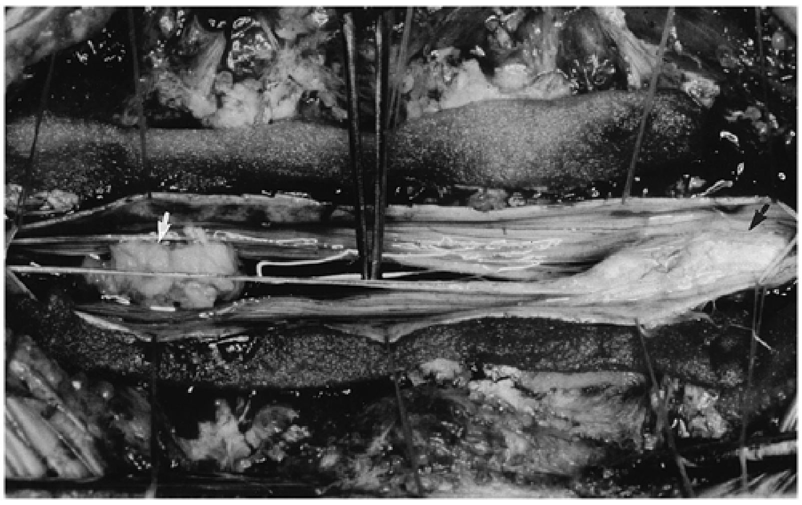

FIGURE 13. Intraoperative photograph showing the presence of two intradural dermoids, the first being in the lower lumbar region *(white arrow)* and the second being embedded in the conus medullaris *(black arrow)*. This patient presented with bacterial meningitis. Both of these tumors were subsequently removed, and the patient had a complete recovery.

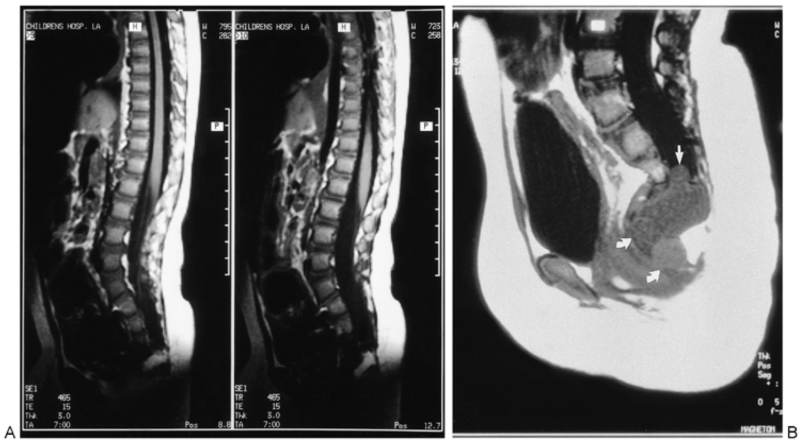

FIGURE 14. Anterior sacral meningocele with a dermoid. This infant was born with an anteriorly displaced rectum. Because of the known association of closed neural tube defects and rectal anomalies, a magnetic resonance image (MRI) study was obtained when she was 6 months of age. **A:** Sagittal T1-weighted MRI study showing the presence of a low-lying and tethered cord. The presence of the anterior meningocele was initially missed on this imaging study. **B:** Subsequent T1-weighted sagittal MRI study of the pelvis showed the presence of the anterior sacral meningocele and associated dermoid tumor. The *straight arrow* is at the interface between the dermoid and the subarachnoid space. The *curved arrows* demarcate the interface between the meningeal sac containing dermoid tumor with the surrounding pelvic structures. At the time of surgery, the dermoid was partially resected, the meningocele was closed, and the spinal cord untethered. Several months later, at the time of the definitive procedure to repair the rectum, the remainder of the dermoid, located anterior to the sacrum, was excised.

Teratoma

The vast majority of teratomas present as sacrococcygeal teratomas, are extradural in location, and are characteristic enough in that they are rarely confused with intraspinal tumors. Occasionally, teratomas can be present with anterior sacral meningoceles and other NTDs just like dermoid tumors (15).

The overwhelming number of teratomas present as masses of varying size extending outward from the sacrum and coccyx, often with involvement of one or both buttocks (Fig. 15). The overlying skin is perfectly normal unless the tumor has grown to such an extent that there is necrosis of tumor and the overlying skin. A small percentage can be totally intrapelvic without the presence of an anterior sacral meningocele and can be identified only on rectal examination. In most cases, it is easy to differentiate teratoma from an NTD.

Sacrococcygeal teratomas may consist of either cystic or solid components and may have completely mature tissue that is benign, a mixture of benign elements and tissue having malignant potential, or components that are frankly malignant. The prognosis depends on the histopathology of the tumor. The longer the tumor remains beyond early infancy, the higher the incidence of malignant transformation. Treatment consists of removal of tumor and the coccyx. Most of these lesions are excised by or in conjunction with a pediatric surgical specialist.

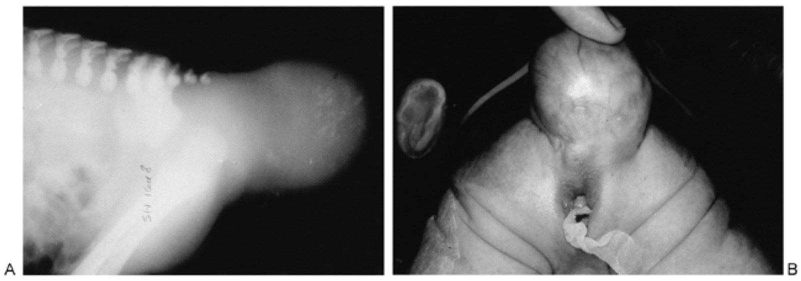

FIGURE 15. Sacral coccygeal teratoma. **A:** Sagittal plain x-ray study of a 16-day-old boy with a partially calcified mass distal to the tip of the coccyx. **B:** Operative photograph showing the relationship of this tumor to the anus. This was a benign teratoma that was completely resected. Postoperatively, the patient did well and had no neurologic deficit.

Neurenteric Cysts

The embryologic disorder responsible for neurenteric cysts appears to occur during gastrulation similar to that for a split cord malformation (diastematamyelia). These two types of NTDs can occur together.

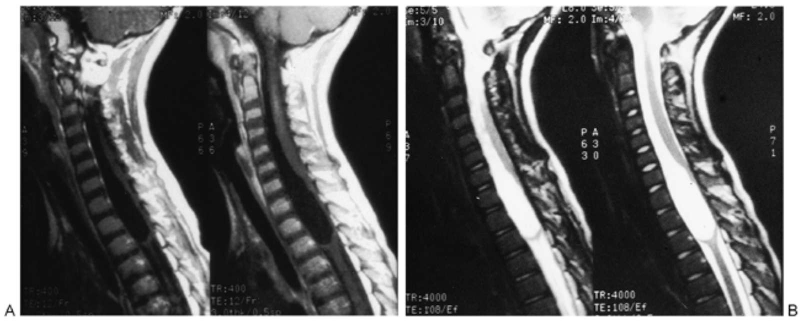

FIGURE 16. Neurenteric cyst. This 5-year-old girl presented with back pain and early symptoms of a neurogenic bladder. On examination, her back was normal without cutaneous markers for dysraphism. The neurologic examination was normal except for brisk reflexes in the lower extremities. **A:** Sagittal T1-weighted magnetic resonance image showing intraaxial and extraaxial characteristics of a cyst, which did not enhance with contrast. **B:** The T2-weighted image shows that the fluid content has similar density to cerebrospinal fluid. A midline myelotomy was made, and clear viscous fluid was encountered. The cyst wall was found to be neurenteric in origin and completely excised. In addition, there was an anteriorly located extramedullary arachnoid cyst that was fenestrated. Postoperatively, the patient had dyesthesia that subsequently cleared. At present, she is neurologically normal and free of pain.

Neurenteric cysts occur most frequently in the low cervical or upper thoracic region (Fig. 16) (34) and, occasionally, at the conus medullaris. The neurenteric cyst can be extradural or intradural, and if it is intra-dural, it can be anterior to, within, or posterior to the spinal cord or even between, as in the case of a split cord malformation (Fig. 17). The histopathologic features of the cyst can vary in complexity, but most cysts are lined by a single layer of stratified or pseudostratified or columnar

epithelium that stains positive for mucin. The vertebral column can be completely normal or may have significant segmentation abnormalities. Neurenteric cysts that are not associated with other NTDs will have no neurocutaneous markers for dysraphism. They are more common in males. Most neurenteric cysts have symptoms of a spinal cord compression, often with pain localized at the level of the cyst. Discharge of the cyst contents into the SAS can result an aseptic meningitis.

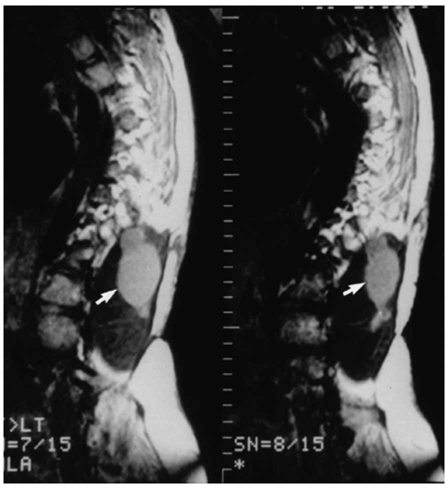

FIGURE 17. Neurenteric cyst. This is a sagittal T1-weighted magnetic resonance imaging (MRI) study, showing the presence of a mass *(arrow)*, which is hypointense to fat. This child had an open neural tube defect (myelomeningocele), closed at birth. He had a CSF diverting shunt placed. Despite the fact that his hydrocephalus was under good control, he had progressive loss of neurologic function. An MRI study was obtained and showed the presence of a neurenteric cyst and a split cord malformation. The bony spur was removed. His cord was untethered and the neurenteric cyst excised. Postoperatively, his neurologic deficit was worse and did not improve to his preoperative level.

As usual, MRI is the modality of choice. The contents of the cyst usually have a higher signal intensity on T1- and T2-weighted images than that of CSF. The capsule may enhance or be too thin to be seen. Spine and chest x-ray studies are indicated to assess for bony abnormalities and the possible presence of a paraspinal or intrathoracic mass.

Depending on the location of the cyst, the approach will vary. The goal is to completely remove the capsule if possible.

Other

Epidermoid

Unlike dermoids, these tumors have no dermal elements but only that of epidermal origin. The overwhelming majority of these tumors are located in the cauda equina and result from a lumbar puncture in the neonatal or early infancy period to rule out meningitis (Fig. 18). Often, a lumbar puncture is performed with a fine-gauge needle without a stylet, which allows the introduction of epidermal elements into the SAS. This technique is to be highly discouraged.

The presence of an epidermoid tumor is usually made known by compression of the adjacent nerve roots with pain at the level of the lesion. The goal of surgery is complete excision without leaving any remnants behind. The outcome, obviously, should be most favorable.

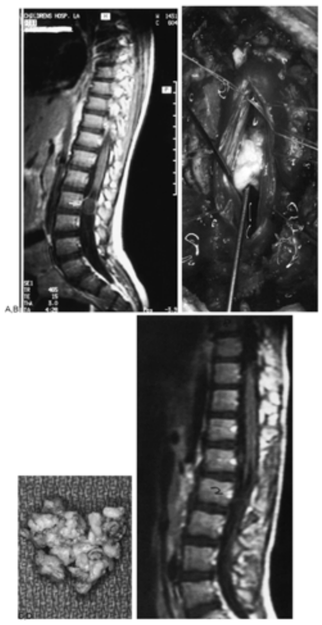

FIGURE 18. Epidermoid tumor. **A:** Magnetic resonance imaging (MRI), noncontrast T1-weighted, sagittal image shows a mass distal to the cauda equina that is hypointense to the spinal cord and did not enhance with contrast *(arrow)*. On a T2-weighted image (not shown) it was difficult to visualize the mass. **B:** Intraoperative photographs of a dermoid tumor among the roots of the cauda equina. **C:** Material from the epidermoid tumor. **D:** Postoperative MRI demonstrating no evidence of residual tumor. This 6-year-old child presented with progressive back pain. No neurologic deficit was present. As a neonate, this patient had a lumbar puncture for suspected meningitis.

Lipoma

Lipomas can be either intradural intramedullary or intradural extramedullary and, thus, are placed in both these categories. Intramedullary tumors are discussed earlier. The extramedullary lipoma is a true neoplasm with progressive increase in the number of adipose cells rather than being a hamartomatous malformation, as is the case with closed NTDs. These extradural tumors usually have a clear plane of demarcation from the spinal cord and dura mater, and usually are easily excised. They present

with spinal cord compression. On MRI, they have the typical features of adipose tissue. Following excision, the outcome should be excellent.

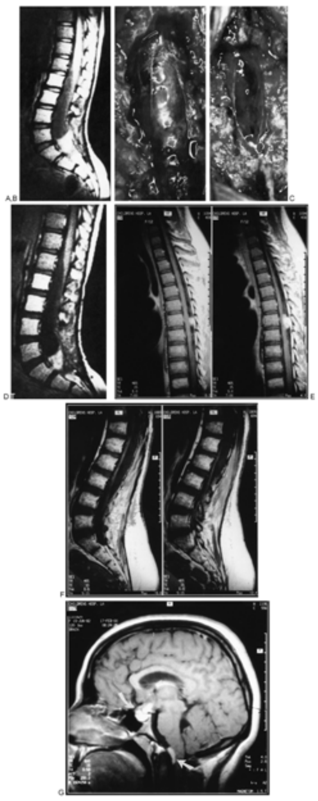

FIGURE 19. Myxopapillary ependymoma. **A:** Preoperative magnetic resonance image (MRI) with contrast demonstrating an enhancing mass filling the distal thecal sac. **B:** Intraoperative photograph demonstrating large intradural mass. **C:** Intraoperative photograph at the end of tumor resection. The unencapsulated ependymoma diffusely filled the subarachnoid space enveloping the entire cauda equina and thus negating the opportunity to excise this neoplasm completely. **D:** Postoperative MRI demonstrating degree of tumor resection. Residual tumor is present. This 10-year-old girl presented with back pain. There was local tenderness and limited mobility to spinal movement but no neurologic deficits. She received a postoperative course of localized radiation therapy. Two years later, she developed midthoracic back pain. **E:** An MRI showed the presence of a uniformly enhancing intradural extramedullary mass rostral to the field of radiation at T6–7, compressing the spinal cord. This mass, a myxopapillary ependymoma, was completely excised, and the thoracic spinal cord was radiated. The patient is now 19 years of age. **F:** A follow-up MRI study showed no residual tumor at the sacral, lumbar or thoracic levels. **G:** She has an enhancing mass anterior to the medulla and cervical spinal cord at the cervicomedullary junction *(straight arrow)* and a second lesion enveloping the hypothalamic-pituitary area *(curved arrow).* No attempt was made to resect these tumors, which are presumed to be myxopapillary ependymomas. The patient has just completed a course of radiation therapy to the head and cervical spine.

Ependymoma

These tumors can be intramedullary or extramedullary in location and are commonly found in the region of the conus medullaris and cauda equina in the pediatric age group. The histology of these tumors in this location is usually that of a myxopapillary variety and somewhat less aggressive than those ependymomas with a more malignant histologic appearance. These tumors present with evidence of either conus medullaris or cauda equina compression. The course is, as with most slowly growing tumors, indolent. The MRI characteristics are noted in Figure 19 .

In those cases in which the tumor is completely encapsulated, gross total removal can most often be accomplished. In such situations, postoperative radiation is not indicated. In some cases, the tumor is not encapsulated but completely fills the SAS and is intimately adherent to all of the nerve roots of the cauda equina (Fig. 19C). In such situations, it is not possible to remove the tumor completely but an extensive debulking should be undertaken, followed by a course of radiation. In this situation, long-term follow-up is indicated, as shown by the patient in Figure 19 , who had recurrence of tumor above the field of radiation.

This tumor was subsequently removed, but the patient then developed intracranial extension of tumor 9 years later (Fig. 19G). Thus, even though the histology of myxopapillary ependymomas is relatively benign, they can biologically behave in a more aggressive fashion. At present, chemotherapy has not be proven to be of any benefit in treating this type of ependymoma.

Nerve Sheath Tumors

The terminology for this group of tumors is confusing with the interchangeable terms, such as neurofibromas, schwannomas, neurinomas, neuromas, and neurilemomas being used. It is generally agreed that there are basically two types of tumors, namely neurofibromas and schwannomas. Neurofibromas appear to be derived from mesenchymal cells of fibroblastic origin, whereas schwannomas arise from Schwann cell precursors.

Histopathologically, they present different appearances that allow for separation into the two categories. Because the nerve fascicles are intimately intermingled with tumor tissue, it is almost always necessary to sacrifice the nerve root when removing a neurofibroma, whereas it may be possible to spare some or all of the fascicles when excising a schwannoma. In the pediatric age group, neurofibromas are much more frequent than schwannomas. The incidence of neurofibromas will vary directly with the presence of an active neurofibromatosis (NF) program. Although reports that roughly a quarter of neurofibromas are found in association with NF, in our experience, it has been the majority of patients with neurofibromas that have NF.

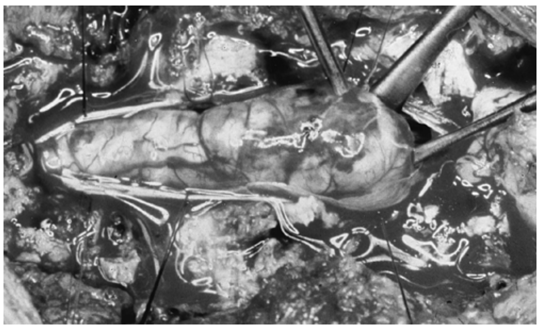

FIGURE 20. Neurofibroma. This 10-year-old child did not have neurofibromatosis but presented with back pain and limitation of forward flexion. There was no neurologic deficit. This operative photo shows the neurofibroma being completely removed from the region of the cauda equina. The patient made an uneventful recovery without any neurologic deficit.

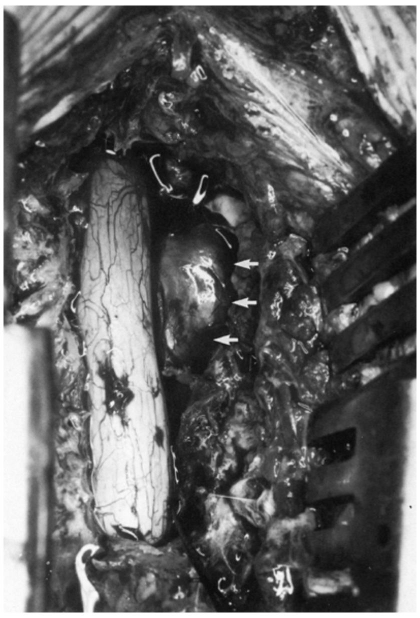

FIGURE 21. Neurofibroma at T12. Intraoperative photograph demonstrating a large extradural mass at T12 *(arrows)*.

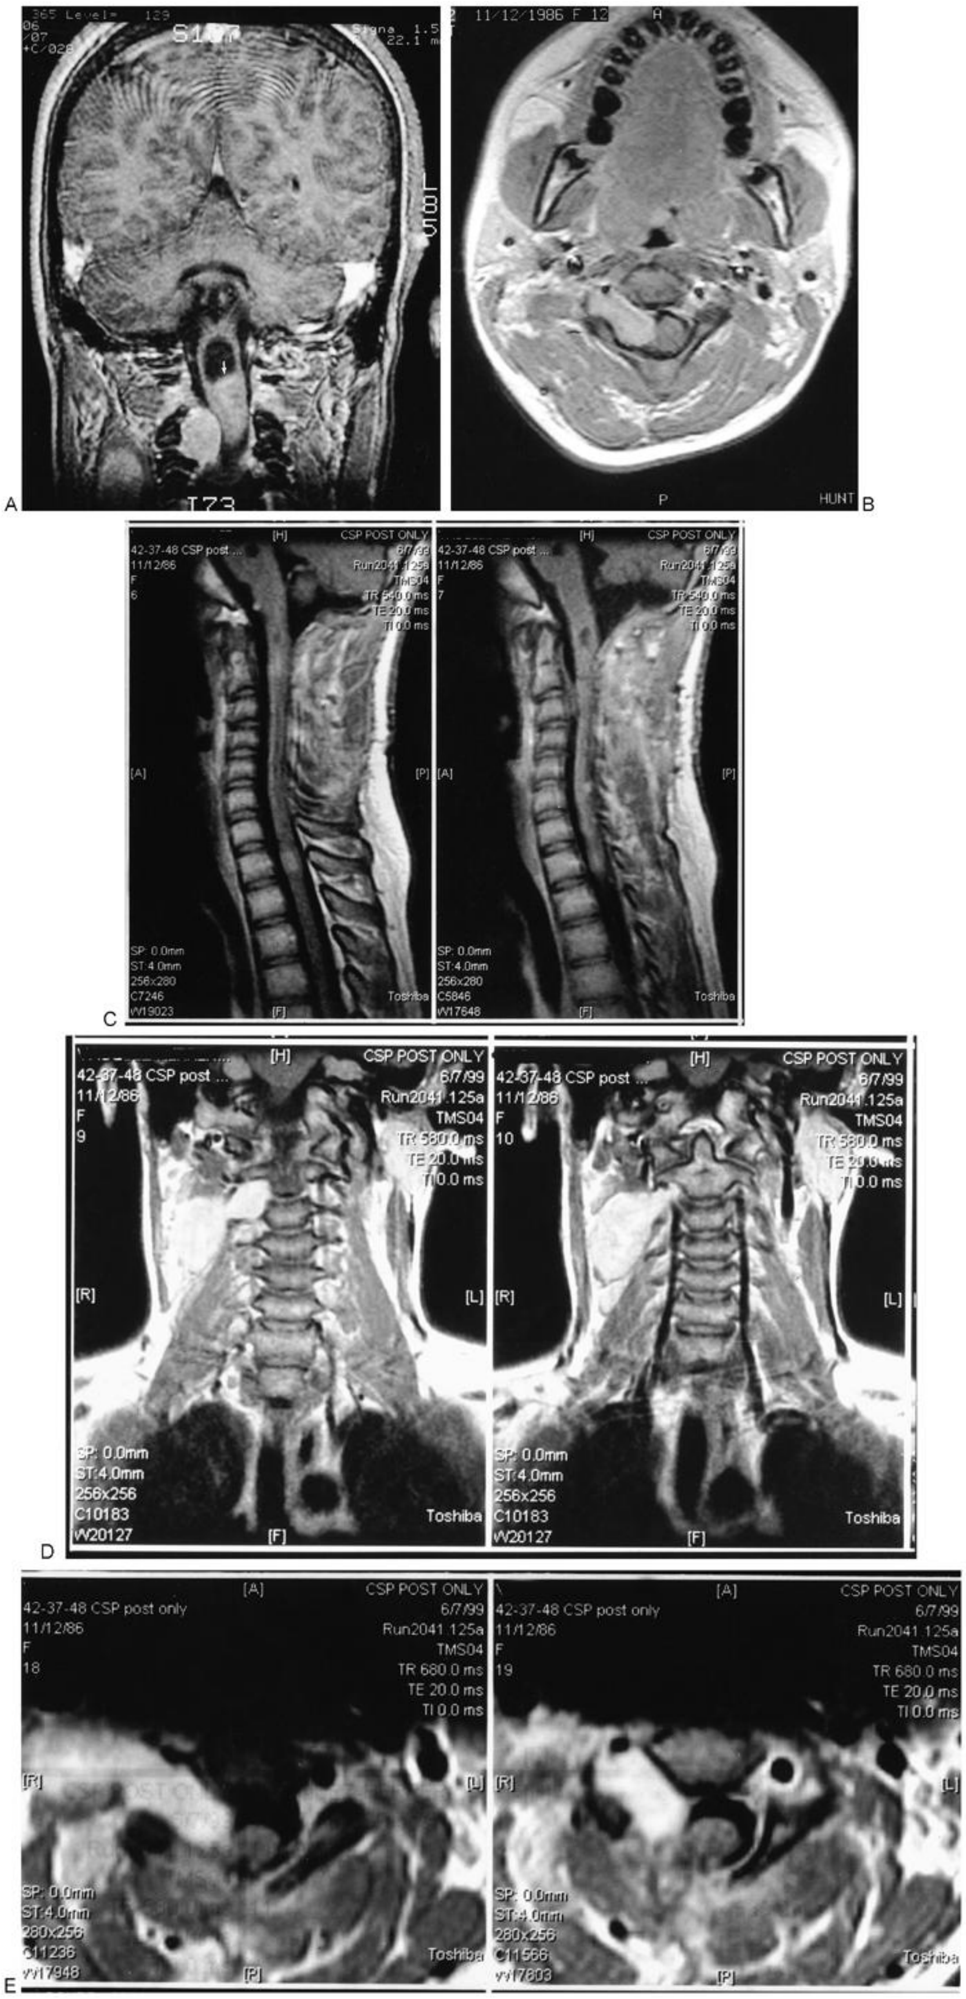
Nerve sheath tumors can be intradural (Fig. 20), extradural (Fig. 21) or, as often the case, a combination of both (Fig. 22). Symptoms are usually the result of a spinal cord compression or individual nerve root irritation. On MRI, they appear as discreet lesions that fairly uniformly enhance with contrast.

The vast majority of these tumors can be excised from a posterior approach with complete excision of the tumor. Some will extend into the foramen. It is possible to excise all of the tumor if it does not extend beyond the foramen. Occasionally, it will be necessary to remove the dumb-bell portion of the tumor extending beyond the foramen through another approach (Fig. 22).

The spectrum of NF varies widely. NF is often subdivided into NF I when there is primarily peripheral nerve involvement and an alteration in chromosome 17, whereas NF II tends to be more central and is particularly characterized by bilateral acoustic tumors and has an alteration of chromosome 22. There is, however, a considerable degree of variation and overlap, so as to make the difference in categories only relative. In NF, neurofibromas are frequently multiple, with occasionally

hundreds of tumors of varying size present throughout the spinal canal (Fig. 23). Only tumors that are symptomatic need to be excised. The other indication for excision is when there is rapid growth in a given tumor, because this could herald a malignant transformation that occurs in somewhat under 10% of patients with this disease entity. Every time a neurofibroma is excised, there is loss of a nerve root. At one level, there will usually be only a mild deficit; however, with multiple tumors removed at adjacent levels, the deficit can become profound.



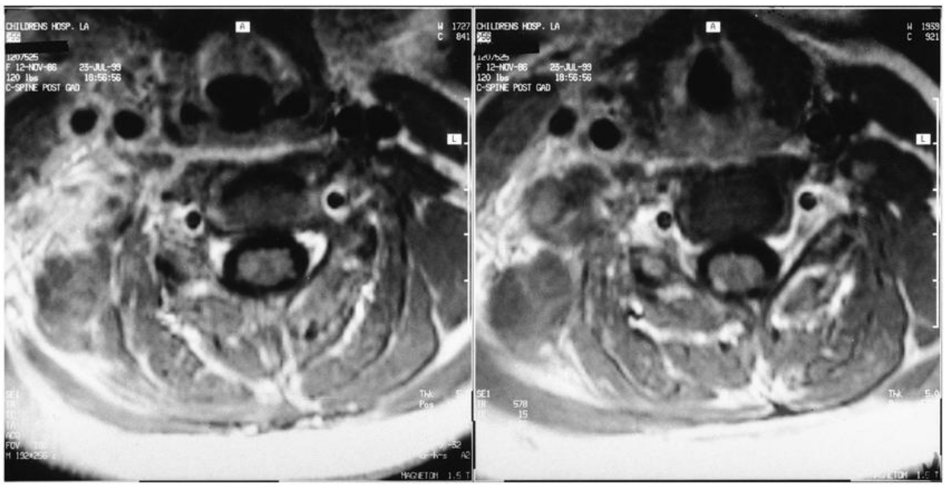


FIGURE 22. Multiple lesions in a patient with neurofibromatosis. Contrast-enhanced T1-weighted magnetic resonance image. Coronal **(A)** and sagittal **(B)** images showing an intramedullary contrast-enhancing tumor that has a rostrally located cyst *(arrow at tumor cyst interface)* and an extramedullary intradural and extradural neurofibroma at C2–3, which is compressing the spinal cord. As seen on the sagittal and axial images, the neurofibroma extended through an enlarged foramen to the cervical region. In addition to these spinal lesions, the patient also had multiple intracranial lesions associated with her neurofibromatosis. She presented with progressive weakness on the right side with long tract signs. At the time of surgery, both tumors were excised. The intramedullary tumor was a mixed astroependymoma. The neurofibroma was removed as far into the foramen as possible. **C:** Postoperative image showing complete removal of the intramedullary tumor, which has not recurred in spite of receiving no postoperative adjuvant therapy. The extension of the neurofibroma into the neck progressively enlarged. T1-weighted contrast-enhanced anteroposterior **(D)** and axial images **(E)** 5 months later showing regrowth of the tumor into the foramen, as well as the large neck mass. From a cervical approach, the remainder of the tumor was excised, as shown on the postoperative image **(F)**. The patient has received no adjuvant therapy. She is now developing brain stem compression from one of her bilateral acoustic tumors for which she will undergo surgery.

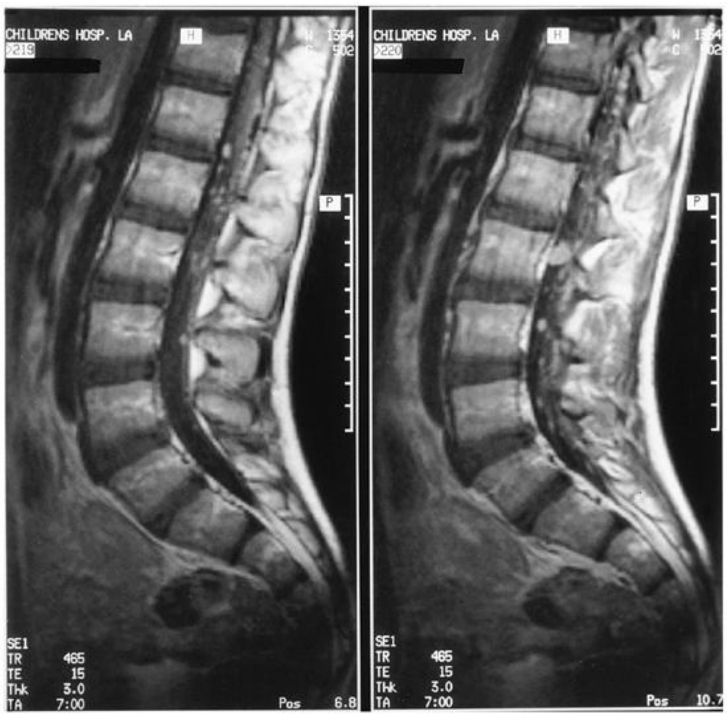

FIGURE 23. Neurofibromatosis. A sagittal T1-weighted contrast-enhanced magnetic resonance image (MRI) showing the presence of multiple neurofibromas in the regions of the cauda equina. This 8-year-old boy with neurofibromatosis previously had a neurofibroma removed from the thoracic region. Surveillance MRI studies have been used to monitor the other neurofibromas present. Only if the tumors show a significant increase in size would they be excised.

Another type of neurofibroma seen with NF is that of the plexiform neurofibroma (Fig. 24), which is usually seen in the cervical or thoracic region and can cause spinal cord compression either

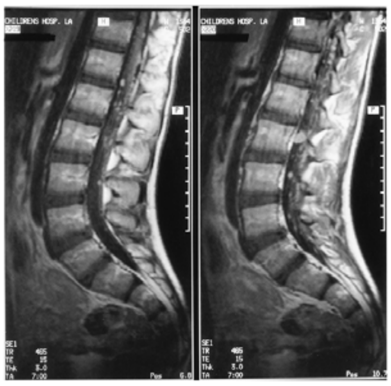

FIGURE 23. Neurofibromatosis. A sagittal T1-weighted contrast-enhanced magnetic resonance image (MRI) showing the presence of multiple neurofibromas in the regions of the cauda equina. This 8-year-old boy with neurofibromatosis previously had a neurofibroma removed from the thoracic region. Surveillance MRI studies have been used to monitor the other neurofibromas present. Only if the tumors show a significant increase in size would they be excised.

from tumor within the spinal canal or as a result of involvement of the vertebral columns, leading to a progressive deformity that narrows the spinal canal. The plexiform neurofibroma diffusely involves all of the surrounding structures, thus making it impossible to excise completely. Often, they will envelop structures in the neck and mediastinum and lead to progressive disability and ultimately death over a course of years to decades even without the malignant transformation seen in a small percentage of cases. Radiation and chemotherapy have been used to treat malignant nerve sheath tumors with only very limited success.

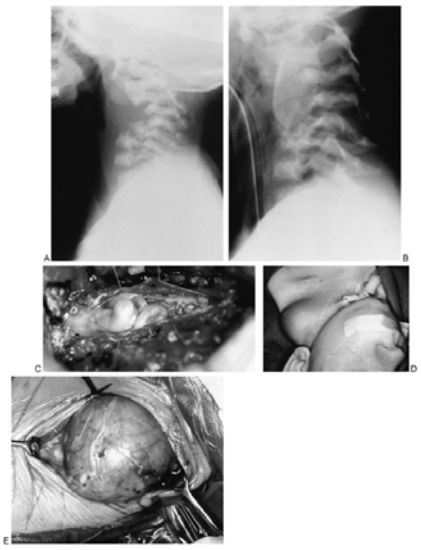

FIGURE 24. Plexiform neurofibroma degenerating into a sarcoma. This 3-year-old boy was rendered nearly quadriplegic by a fall from a swing. Multiple café au lait spots indicated that he had neurofibromatosis. **A:** Admitting lateral C-spine x-ray studies showing a marked gibbus deformity involving C2–3–4. **B:** Halo traction was applied, and the patient had an anterior approach with resection of the bodies of C2–3–4 and a strut graft inserted. This lateral spine x-ray study shows the postoperative result. **C:** The patient then underwent a posterior decompression and stabilization with the removal of the intradural portion of a plexiform neurofibroma. The patient's neurologic condition improved mildly postoperatively, and he was able to have functional use of one upper extremity. **D:** Ten years later, the patient developed rapid enlargement of a mass in the neck. His neurologic condition continued to be stable. **E:** Intraoperative photograph showing a portion of the tumor, which contained a malignant peripheral nerve sheath tumor arising from the plexiform neurofibroma. The sarcoma had diffusely infiltrated surrounding structures, so it was not possible to perform a gross total excision. The patient has received a course of focal radiation; however, he continues to deteriorate.

With NF, intramedullary spinal tumors have an increased frequency over that of the normal population, such as astrocytomas and ependymomas, as seen in Figure 22 .

It is recommended that patients with NF have routine surveillance MRI at regular intervals.

Meningeal Tumors

Meningioma

Meningiomas are exceedingly rare tumors in the pediatric age group. Their presentation, location, and MRI characteristics are similar to those of neurofibromas. They can occur in isolation or be multiple, and if they are multiple, they are much more likely to associated with NF. Treatment is total excision with an excellent outcome. Although meningiomas in the pediatric age group tend to be more aggressive when compared with those in adults, malignant transformation occurs but rarely.

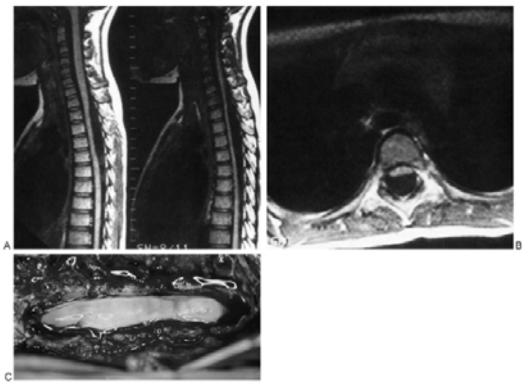

FIGURE 25. Intradural arachnoid cyst. Sagittal **(A)** and axial **(B)** T1-weighted magnetic resonance imaging demonstrating anterior displacement of the spinal cord by an intradural mass with the signal characteristics of cerebrospinal fluid. **C:** Intraoperative photograph of the intradural arachnoid cyst. This 8-year-old child presented with recurrent urinary tract infections and progressive constipation. The neurologic examination was normal. Her symptoms resolved postoperatively.

Arachnoid Cysts

Arachnoid cysts can be either intradural (Fig. 25) or extradural (Fig. 26) (10 ,36) in location but are not a combination of both. The intradural cyst results from an alteration of the arachnoid trabeculi that produces a loculation that traps CSF and results in slow enlargement over time to compress the adjacent neural structures. The extradural cyst arises from a hole in the dura mater that allows the arachnoid membrane to herniate through the dural defect, followed by slow enlargement that, with time, produces local symptoms. Many of these cysts appear to be congenital in nature but they may also be acquired as a result of arachnoid adhesions that develop following surgery. In our experience, there has been an association between intradural arachnoid cysts with previously operated open (myelomeningoceles) and closed NTDs (42).

The presentation varies widely and is dependent on location and the degree of compression of adjacent neural elements. The

MRI appearance is that of a cyst containing CSF without enhancement of the wall.

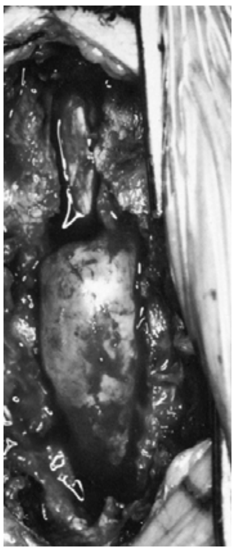

FIGURE 26. Intraoperative photograph demonstrating a large extradural arachnoid cyst. This 18-year-old female presented with S1 radiopathy that resolved postoperatively.

Treatment of intradural arachnoid cysts is fenestration. It is important to make certain that there is good communication into the surrounding SAS, both above and below the arachnoid cyst. If the cyst covers multiple levels, placement of an endoscope in the canal can aid in the fenestration while limiting the number of levels that require a laminectomy or laminotomy or both. With extradural cysts, it is necessary to find the defect in the dura mater through which the arachnoid has herniated and eliminate the area of communication. The outcome is generally excellent. Recurrence can be seen in some cases, especially of repaired NTD (21 ,22). If there is a question, either cine-MRI or CT myelography would be helpful in establishing that the area in question is isolated from the surrounding SAS (12).

Vascular Lesions

Arteriovenous Malformations (AVMs)

AVMs can been seen anywhere along the length of the spinal cord. They may be extramedullary, intramedullary, or a combination of both, as well as being associated with dural fistulae. They also can be seen in conjunction with some neurocutaneous syndromes, as shown in Figure 27 . Occasionally, they will present with an acute onset secondary to hemorrhage and resulting local compression or from blood within the SAS. More commonly, however, there is an insidious progression of a neurologic deficit.

MRI shows the presence of signal flow voids that are typical for such a lesion. The AVM also enhances. However, once such a lesion is suspected, angiography is the imaging modality of choice. Better equipment and super selective catheterization has allowed not only better visualization of these lesions but also the ability to embolize the feeders to the lesion. If embolization is a consideration, then arrangements should be made for such at the time of the initial angiogram, thereby saving the patient an additional procedure. Following embolization, the remainder of the AVM is surgically removed. The outcome is variable, depending on the extent of spinal cord involvement.

Aneurysms

Most spinal cord aneurysms are associated with AVMs, although isolated aneurysms of the spinal cord do occur. Although these previously have been classified as true aneurysms, a more recent examination suggests that many of these lesions are more correctly classified as intrathecal perimedullary AV fistulas with giant venous dilatation (Fig. 28) (23).

Hemorrhage is a rare occurrence, and these lesions usually make their presence known by a compression of adjacent neural structures.

As with AVMs, angiography is undertaken with the expectation of endovascular treatment of the lesion at the same procedure. These lesions may have a single large feeder, which may be occluded, thereby permanently blocking the inflow and thus eliminating the need for surgical intervention. The prognosis in these cases has generally been quite good.

Hemangioblastomas

These tumors are frequently classified as being intramedullary. They actually form on the pial surface and can extend both into and out of the spinal cord (Fig. 29). Frequently, they are associated with a cystic cavity, which is intramedullary in location. They are uncommon tumors in the pediatric age group and can be seen anywhere along the spinal cord, be single or multiple, and in our experience more likely to be associated with the Von Hippel–Lindau complex.

On imaging, the solid part is well circumscribed and shows a decreased signal intensity on T1, whereas the intensity will be increased on T2, and they will uniformly enhance with contrast. If a cystic cavity is present, the solid component will be as a mural nodule. Angiography is not indicated.

The lesions can be completely excised because there is a plane of demarcation between the lesion and the adjacent spinal cord. The outlook is excellent. Often, in the presence of Von Hippel–Lindau disease, multiple lesions are present. As with neurofibromatosis, some lesions remain small and do not increase in size with time and should not be surgically addressed. Only those

hemangioblastomas that show progressive increase in either the solid or cystic portion of the tumor with successive imaging studies should be excised. Hemangioblastomas are much more commonly found in the cerebellum. However, if the patient presents with initial spinal cord symptoms, imaging of the head is indicated. In select cases, it is also appropriate to perform an MRI study on close family members.

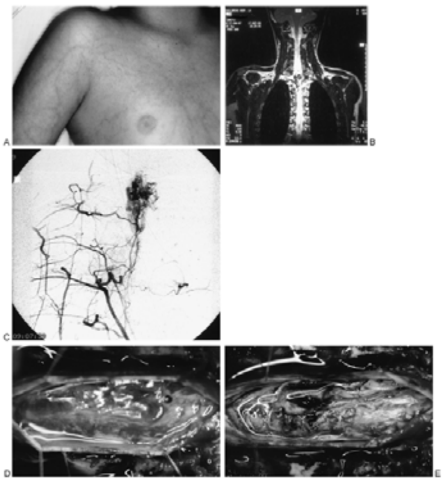

FIGURE 27. Spinal cord arteriovenous malformation (AVM). **A:** Photograph of a 13-year-old boy with Klippel-Trenaury-Webber syndrome. The right upper extremity was hypertrophic, and there was superficial dilatation of the blood vessels. The patient developed a progressive myelopathy. **B:** A T2-weighted magnetic resonance imaging study showed the presence of a large AVM at the cervicothoracic junction. Most of the lesion was intradural, but had some extramedullary components. **C:** An angiogram showed feeders from both vertebral arteries, the thyrocervical trunk, and the intercostal arteries. He underwent embolization with partial obliteration of the malformation. **D:** Intraoperative photograph showing a thickened arachnoid and dilated blood vessels. **E:** Operative photograph at the completion of removal of all of the malformation. Postoperative angiogram showed no evidence of a residual AVM. The patient's neurologic deficit was more pronounced following the operative procedure, but function has gradually returned and the patient has less neurologic deficit than preoperatively.

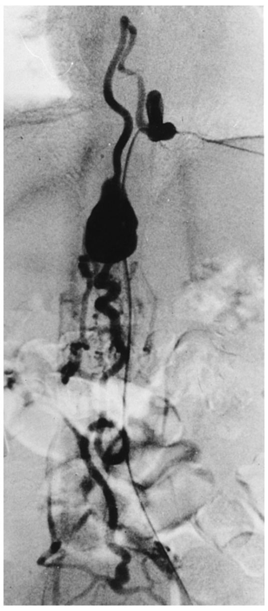

FIGURE 28. Aneurysm. Spinal angiogram showing the presence of an arterial feeder to a giant venus pseudo aneurysm. Using endovascular technique, the arterial feeder was occluded with a balloon, obliterating the flow to the aneurysm. This 3-year-old child presented with back pain and progressive myelopathy that nearly completely resolved over the course of many months.

Hemangioendotheliomas

Hemangioendotheliomas are rare vascular tumors that are histologically intermediate in appearance between a hemangioma and an angiosarcoma (2). These lesions can appear anywhere either inside or outside of the central nervous system (CNS), although CNS involvement is quite uncommon. The MRI signal characteristics are similar to that of a hemangioblastoma. Patients with these lesions may present with hydrocephalus because of elevated CSF protein content. Treatment is gross total excision, if possible. The use of interferon alpha may be of benefit in treating those lesions that are incompletely excised. The prognosis appears to be variable.

Metastatic

Neural

PNET is the most likely tumor to metastasize widely through the SAS. It is best detected with contrast enhancement MRI. This is more reliable than obtaining CSF for cytologic evaluation. The presence of diffuse spread of PNET into the SAS at initial presentation carries a poor prognosis, as does its presence at the time of intracranial tumor recurrence. Often, the patient will develop hydrocephalus and require CSF diversion.

Although high-grade gliomas are much more likely to metastasize than those that are low grade, occasionally one can see extensive spread of tumor in the SAS of low-grade astrocytomas. Thus, the biologic behavior does not always reflect the histologic characteristics of the tumor. These patients have a very poor prognosis and often develop hydrocephalus that requires CSF diversion.

Melanomatosis

The meningies have cells that contain melanin. On rare occasions, there will be a proliferation of these cells to produce a diffuse involvement of the SAS (Fig. 30). Initially, it can be difficult to make the diagnosis, and understandably, other etiologies are suspected before the correct diagnosis is obtained. On some occasions, the CSF can even be discolored by the presence of melanin. Usually, a biopsy is needed to make the diagnosis. Inspection of the meningies finds that they are thickened and dark or black in color. The histopathology shows the presence of considerable melanin, although the cells themselves may not have all of the characteristics of melanoma. There is an increased incidence of this particular problem that is associated with giant hairy nevus syndrome (Fig. 31).

Extraneural

Lymphoma and Leukemia

In addition to presenting as extradural lesions, lymphomas and leukemias can also be intradural. The CSF cytology is quite useful and very frequently diagnostic. It is rare that either lymphomas or leukemias in the SAS cause mass effect producing spinal cord compression. It is only occasionally that CSF resistance is elevated by the disease process to the extent that CSF diversion is required. Chemotherapy and radiation modalities are achieving ever-greater success in treating this constellation of disease.

Other

Infection with the human immunodeficiency virus (HIV) predisposes patients to many malignancies, particularly Kaposi's sarcoma and CNS lymphoma. In children, HIV infection has been associated with leiomyosarcomas and leiomyomas (3). With an ever-growing number of pediatric patients with HIV, these entities will likely to be encountered with increasing frequency. If such a tumor is encountered and the patient is not known to have HIV, such testing should be undertaken.

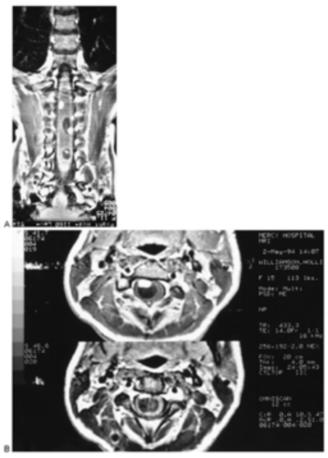

FIGURE 29. Hemangioblastoma. **A:** T1-weighted magnetic resonance imaging (MRI) study with an anteroposterior view of the cervical and upper thoracic spine, showing four uniformly contrast-enhancing intramedullary lesions, two of which are associated with cystic formation. **B:** Transverse MRI section showing one of the cystic lesions with a uniformly enhancing neural nodule located on the anterior aspect of the cervical spinal cord. This 15-year-old patient with Von Hippel–Landau disease presented with a progressive neurologic deficit involving the upper and lower extremities; however, she had no bladder or bowel involvement. All of the lesions were subsequently resected. The patient has generated no new lesions and is stable 6 years after the initial operative procedure.

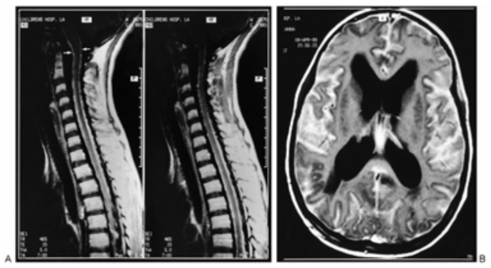

FIGURE 30. Melanomatosis. Contrast-enhanced T1-weighted sagittal spine **(A)** and axial head **(B)** magnetic resonance imaging studies showing diffuse enhancement of the leptomeningies *(arrows)*. The patient also developed hydrocephalus secondary to impairment of cerebrospinal fluid (CSF) absorption. This 10-year-old female had a 6-week history of progressive headaches, nausea, vomiting, and intermittent diplopia. Multiple CSF samples were abnormal but inconclusive. A single level laminectomy was performed for biopsy purposes. The leptomeninges, as anticipated, were quite thickened; however, they were also black and consistent with melanomatosis, which was subsequently confirmed histopathologically. Because of progressive hydrocephalus she required a CSF diverting shunt. Despite a course of intensive chemotherapy, the patient died 2 months later.

Extramedullary Tumors—Extradural

The vast majority of extradural tumors of childhood are of the metastatic variety. They can however, be divided into three groups: those derived from neural crest tissue, such as neuroblastomas and ganglioneuromas; those arising from mesenchymal soft tissue, such as sarcomas, germ cell tumors, lymphomas, leukemias, and Wilms tumor; or those derived from mesenchymal bony origins. Of this group, sarcoma and neuroblastoma (Fig. 32) are the most frequent owing to their overall higher incidence in the pediatric population.

Epidural spinal cord compression by malignant tumors occurs infrequently in children. Back pain is the most common symptom, and weakness and bladder dysfunction the most common signs. In our series of children with rapid progressive myelopathy, in which there was extensive encroachment of tumor into the spinal canal (50% or more), surgical decompression obtained better neurologic outcome than radiation or chemotherapy alone (43). Our patients had no morbidity or mortality from surgical decompression, and the pain of laminectomy was significantly less than that caused by the spinal cord compression. In adults, common epidural tumors causing spinal cord compression are lung, breast, and prostate carcinomas and result from tumor extension from a metastatic lesion in the vertebral bodies. The mass compressing the spinal cord is frequently anteriorly located and often associated with spinal instability. Most epidural compression in children with epidural malignant tumors occurs by direct extension of the tumor through the vertebral foramen without significant bony involvement. The tumor mass is primarily lateral in location and is readily accessibly via a posterior approach. Spine stability is usually not a factor. As a group, the children rarely had diffuse metastatic disease, and their overall health was much better than that of a typical group of adults with a similar profile. The consideration for operative intervention is based on the general condition of the child; the degree of spinal canal compromise; the location of the tumor relative to the spinal cord; the tumor type, if known; and the sensitivity of the tumor to radiation or chemotherapy.

Neural Crest

Neuroblastomas originate either from the adrenal medulla or the sympathetic chain; thus, the majority arise in the retroperitoneal region. Those from adrenal sources are most likely to be found in younger children. Approximately two thirds of these cases are identified in children younger than 4 years of age. Interestingly, there is evidence that in some young infants, the tumor may spontaneously regress. The incidence is equal in males and females. Histologic examination of a neuroblastoma specimen reveals sheets of blue cells similar to those of a PNET but with a greater component of fibroblastic stroma. High levels of homovanillic acid and vanillymandelic acid may be identified in the serum and 24-hour urine samples in more than 75% of patients (6). Cystathionine has been reported to be found in the urine in these patients in direct relation to the degree of malignancy. In the absence of marked spinal cord compression, these tumors are treated with chemotherapy or radiation therapy.

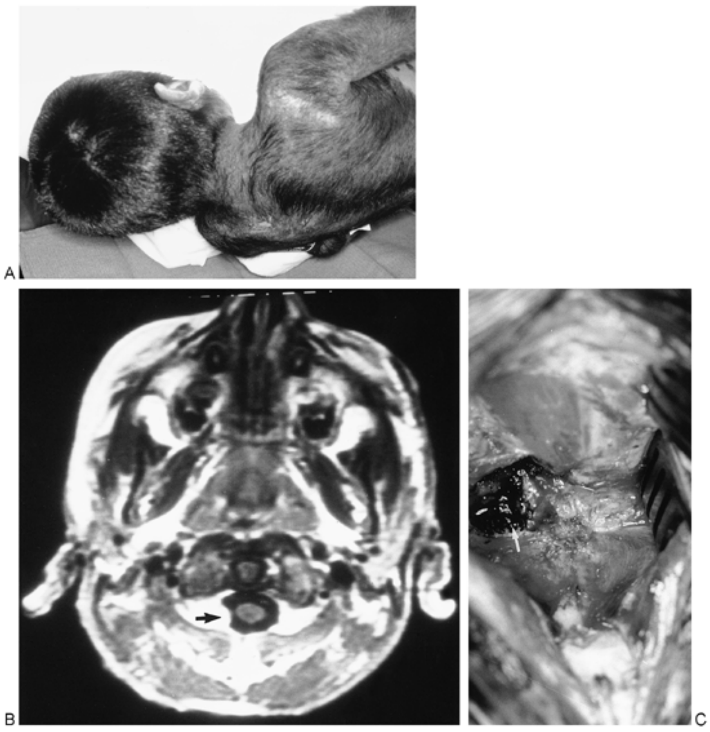

FIGURE 31. Melanomatosis. **A:** This 5-year-old had giant hairy nevus syndrome. The patient presented with an initial onset of seizures. There were no other neurologic symptoms and no focal neurologic deficit. **B:** In the workup, there was noted to be an enhancing mass in the high cervical region *(arrow)*. **C:** Intraoperative photograph showing melanoma tissue present *(arrow)*. The patient was treated with chemotherapy but subsequently died of his disease.

Ganglioneuromas are less common than neuroblastomas but are believed to represent the benign end of this spectrum of tumors that also includes ganglioneuroblastomas as an intermediary between the two. Gangliogliomas are also located in the retroperitoneum or retropleural spaces and are often asymptomatic until they become quite large. In contrast to neuroblastomas, older children and young adults in the second decade of life and females have a greater incidence. In addition, owing to the degree of differentiation, the survival rate is higher than that of patients with neuroblastomas (17). Involvement of the spinal canal is usually by direct extension. Treatment of gangliogliomas involves surgical resection only if there is spinal cord compression.

Mesenchymal—Soft Tissue

Approximately one quarter of pediatric extradural spinal tumors are metastatic either through distant or contiguous spread (1). Infrequently encountered metastatic tumors include genitourinary tumors such as malignant teratomas, embryonal carcinomas, renal cell carcinoma, and Wilms tumor. The thoracic spine is the most common site of spread for these because of its length.

Although bony changes can be noted on plain films or CT, MRI is the modality of choice for the evaluation of metastatic disease.

Leukemias and lymphomas are also common sources of metastatic disease to the pediatric spine. Of the leukemias, acute myelogenous leukemnia is the one most frequently associated with spinal metastatic disease and may be present in a third of newly diagnosed cases (30). The acute lymphocytic variety will metastasize to the spine often unless treated appropriately, after which the incidence of spinal involvement falls to under 10%. Spinal metastasis through vascular pathways occurs along dural or arachnoid planes. Lymphomas may histologically fall within the non-Hodgkin's or Hodgkin's varieties and either as a primary or secondary lesion. Non-Hodgkin's lymphomas are the more common of the two to metastasize to the spinal axis and more commonly seen as a primary lesion. Epidural involvement is the rule due to contiguous spread from bony or soft tissue sites.

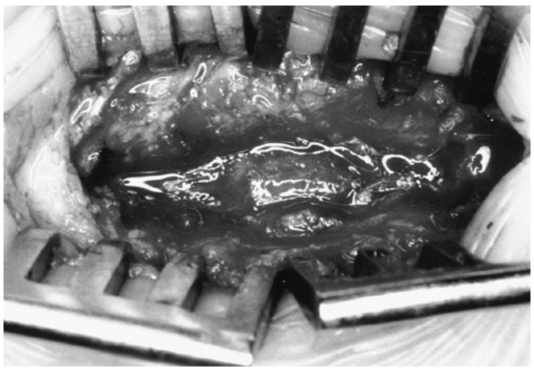

FIGURE 32. Operative photograph of an epidural neuroblastoma. This infant presented with irritability, and refused to stand. An MRI study showed the presence of a perivertebral mass with extension of tumor through the adjacent foramen to occupy more of 50% of the spinal canal. The patient underwent an emergency decompressive laminectomy with improved neurologic function.

Most leukemias and lymphomas do not require surgical intervention but respond well to adjuvant therapy, whereas sarcomas are much more likely to require a decompressive laminectomy. If operative intervention is undertaken, no attempt is made to remove as much tumor as possible but just to decompress the spinal cord (Fig. 32), as well as obtaining adequate tissue for the various diagnostic studies.

The other indication for surgery is if the histology of the tumor is unknown and the primary site is not discernible or is less accessible.

Mesenchymal—Bone

Primary bone tumors of the spinal column include osteomas, osteoblastomas, osteochondromas, osteosarcomas, giant cell tumors, eosinophilic granulomas, hemangiomas, and aneurysmal bone cysts. Surgical treatment requires complete *en bloc* resection, often followed by some form of fusion to address the problem of instability. They are discussed in another chapter.

Surgical Adjuncts and Considerations

Ultrasonic Aspiration

Ultrasonic aspiration has proved to be particularly useful for intramedullary tumors. At higher settings, it can rapidly debulk large tumors. When approaching the interface between the tumor and spinal cord, the power of the ultrasonic aspirator can be diminished in order to reduce the chance of injuring normal adjacent neural structures. Some units also have a pulse mode, which provides for very gentle aspiration at the interface between tumor and spinal cord. However, it is the neurosurgeon and not the ultrasonic aspirator that distinguishes normal from abnormal tissue and both types of tissue can be readily removed with this device.

The ultrasonic aspirator is a much less useful for non intramedullary tumors with the exception of a dumb-bell neurofibroma in which its use to resect tumor extending into the foramen can be quite helpful.

Laser

Soon after the introduction of laser technology to the operating room, there ensued a tremendous popularity in its use. This wave of enthusiasm has markedly subsided, and now lasers are only infrequently used for removal of spinal cord tumors. The laser's role is limited almost exclusively to that of intramedullary tumors.

Some neurosurgeons prefer making a myelotomy in the spinal cord with the laser because it will reduce or eliminate the bleeding at the myelotomy site, which can interfere with visualization of the underlying tumor. Only a small quantity of tumor tissue can be removed in a given interval of time. Thus, it is much more efficient to use the ultrasonic aspirator to debulk the vast majority of tumor tissue. Some neurosurgeons advocate use of the laser to remove the last residual tumor at its margin with the spinal cord. We have found that the use of bipolar coagulation is just as effective and see little advantage to use of the laser.

Evoked Potentials

In some centers, somatosensory evoked potentials (SSEPs) are customarily used to monitor spinal cord function during tumor removal. In those patients in whom the dorsal columns are preoperatively affected by the tumor, the SSEPs are often abnormal at the beginning of the procedure and thus of less value. Also, during an operative procedure, the SSEPs may change in response to a myelotomy, manipulation with tumor removal, or irrigation with lower than body temperature solutions. On some occasions, the decreased amplitude of the SSEPs during surgical manipulation does not reflect any permanent postoperative changes in the patient's neurologic function. On the other hand, the loss of signal or significant diminution of amplitude can indicate a permanent neurologic deficit. We believe that surgical judgement during intramedullary tumor resection is a better guideline than the responses seen on SSEPs. The use of SSEPs during intramedullary tumor resection is an option and is, by no means, a standard of care.

More recently, techniques have been developed to monitor motor evoked potentials (MEPs). We have no experience in their use. Reports state that they can be greatly influenced by the degree and type of anesthesia, surgical manipulation, and interpretation by the electrophysiologist. MEPs will require further evaluation to determine their usefulness.

Like with SSEPs, the use of MEPs can detect damage to the spinal cord; however, it is not able to distinguish that which is reversible or irreversible, and at this juncture, there is no way for any monitoring technique to alert the neurosurgeon in advance so as to avoid causing a permanent neurologic deficit.

Spinal Deformity

In a number of children, it is the presence of a progressive kyphoscoliosis that heralds the presence of tumor, particularly one that is intramedullary. The efficacy of a laminotomy over that of a laminectomy to prevent the progression of a kyphosis or kyphoscoliosis following tumor resection has been debated (25). As a general rule, the higher on the spinal axis, the more likely that there will be a progressive deformation (20). Laminectomies in the lumbosacral region are rarely associated with any deformity, whereas those in the cervical region are very frequently associated with a progressive kyphosis or swan neck appearance. As a general rule, bony removal is limited to as few segments as necessary, and the width of the bony removal is minimized only to the extent that is necessary to gain adequate exposure for tumor removal. The facets are kept intact. A laminectomy is less time consuming than a laminotomy, which can add additional operative time to what already can be a lengthy procedure. When performing a laminotomy, it is important not to generate too much heat while cutting the bone, because this can cause an injury to the adjacent nerve roots, resulting in a postoperative dysesthesia that can be profound. Also, care must be taken when replacing the posterior elements so as not to compromise the size of the spinal canal and thereby produce a postoperative stenosis. In addition to the loss of posterior elements, a deformity may result because of weakening or imbalance of the paraspinous muscles by the involvement of the nerves that innervate this musculature (31). Radiation to the spine can be a factor in causing a deformity as well. In spite of undergoing a laminaplasty, some children still develop a progressive deformity to the spine. However, the incidence may be less than when compared with a laminectomy. A longer term for follow-up of a larger number of patients is needed to clarify this issue further. As a generalization, however, there appears to be little need to do a laminotomy in the lower end of the vertebral column, whereas it is probably a worthy consideration when operating in the upper thoracic and cervical region.

General Considerations

For obvious reasons, most of the operative procedures are performed with the patient in a prone position. If the cervical or upper thoracic regions are the sites of operation, the patient's head is placed in a horseshoe. Care must be taken to pad the rest well and position it correctly so as not to cause any injuries to the face or globes. The authors do not advocate the use of the sitting position under any circumstance, because it offers little advantage and is associated with the risk of air embolism and hypotension. The lateral decubitus position is an option in certain situations; however, its main disadvantage is that the anatomic structures are not midline centered.

After initial paralyzation for intubation, the patients are kept in a nonparalyzed state until beginning the closure. This allows for intraoperative monitoring with a nerve stimulator, if needed.

Before coming to the operating room or at the beginning of the procedure, the patients are given a high dose of corticosteroids that are maintained in the initial post-operative period. Also, for whatever neuroprotective effect it may have, phenobarbital is used. With the exception of emergency situations such as from epidural spinal cord compression with rapid loss of neurologic function, dehydrating agents, such as mannitol, do not appear to play any significant role. Antibiotics are routinely administered for a day or two.

We do not advocate the use of any presently available synthetic dural substitutes. If it is necessary to leave the dura mater open, we cover it with a sheet of gelatin. Even under these circumstances, postoperative CSF leaks have rarely been a problem. In those cases in which CSF accumulation at the wound site is a factor, it may signal impaired absorption of CSF from the CNS and may indicate the need for a CSF diverting shunt. Closure techniques vary from center to center. We have rarely found it necessary to use drains or rotational flaps. If postoperative chemotherapy or radiation therapy needs to be given, it is preferable to wait approximately a week for sufficient wound healing before beginning adjuvant therapy if the patient's condition can tolerate this delay.

Idiopathic Juvenile Osteoporosis

Walter B. Greene

W. B. Greene: Department of Orthopedic Surgery, University of Missouri-Columbia, Columbia, Missouri 65212.

Definition

Idiopathic juvenile osteoporosis (IJO) is a rare and poorly understood pediatric disease that was first described by Schippers (54) in 1939. The 1965 report of six cases by Dent and Friedman (12) firmly established the validity of the disorder. Idiopathic juvenile osteoporosis, the term used by Dent and Friedman, is the preferred nomenclature, even though some authors have used terms such as idiopathic osteoporosis, juvenile osteoporosis, and even Dent-Friedman syndrome.

Generalized osteoporosis is the hallmark of IJO. However, the diagnosis can be made only after other causes of osteoporosis in children have been excluded (Table 1). Trabecular bone is more readily and dramatically affected by osteoporosis. Therefore, the spine and the metaphysis of long bones are prime targets in these patients.

Fewer than 100 cases of IJO have been reported in the English literature. For that and other reasons, IJO can be challenging to review. Some patients have been recycled through more than one report (5 ,25 ,29 ,38 ,45 ,52 ,55 ,56 ,60). Some cases were probably misdiagnosed. For example, one case report involved an 8-year-old girl who developed pain and osteoporosis limited to her feet after she was hit by a stone thrown by another girl (33). Her exam was characterized by painful passive and active movements of the foot. With encouragement to walk, this girl's problem completely resolved in 9 months. Reflex sympathetic dystrophy is a more plausible diagnosis for this case (13). Another probable misdiagnosis is found in the case of a 11-year-old boy, described by Jowsey and Johnson (29), who had a 9-year history of fractures and progressive osteoporosis. This patient also had a history of blindness and bilateral enucleation at age 6 weeks. Osteoporosis pseudoglioma syndrome is a more likely diagnosis for this patient (42 ,57).

Clinical symptoms in patients with IJO resolve over a period of several years. Therefore, even the landmark article by Dent and Friedman (12) and a recent review of 21 patients by Smith (56) include patients who were probably misdiagnosed. These atypical patients had multiple fractures and progressive osteoporosis that continued into adult life. They probably have a form of osteogenesis imperfecta.

Epidemiologic Factors

Table 2 summarizes the presentation and treatment of patients with IJO reported in the English literature (1 ,3 ,10 ,12 ,14 ,18 ,21 ,23 ,24 ,27 ,29 ,32 ,33 ,38 ,39 ,52 ,55 ,56 ,59 ,61). Excluded from Table 2 are patients whose diagnoses were questionable, series that did not provide adequate demographic information (31), and multiple reports about the same patient.

Age at presentation is typically prepubertal (1 ,3 ,43 ,56). The oldest patient included in Table 2 (Case 23) was noted to have delayed bone age, with onset of secondary sexual characteristics at age 17 years (28). Some authors (59) think that very young patients should not be diagnosed as having IJO; however, if other causes of generalized osteoporosis have been excluded and if the disorder resolves, then this author thinks that young children should be included. Patients younger than 5 years at diagnosis may have less pain and quicker remission of their symptoms; however, this is not always true.

Although IJO affects both sexes, the cases tabulated in Table 2 show a slight male predominance, with the male-to-female ratio being 1.5:1. The published cases of IJO mostly come from northern European centers, and no cases have been reported from institutions located in the southern part of the United States, South America, or Africa. Furthermore, no African American, native American, or African child has been noted with this disorder.

Pathoanatomy

Osteoporosis can result from increased bone resorption, decreased bone formation, or a combination of these factors.

Iliac crest biopsies from patients with IJO typically show thin, mature trabeculae with normal osteoid seams and normal marrow elements. Microradiographic evaluations of iliac crest biopsies were interpreted as showing an increase in osteoclastic resorption in two reports from the same institution (27 ,29); however, two other studies observed no evidence of excessive resorption on quantitative histomorphometry (17 ,56).

TABLE 1. Diseases Causing Osteoporosis in Children

- Blood disorders
  - Leukemia
  - Lymphoma
  - Thalassemia
- Chromosome disorders
  - Down syndrome
  - Turner syndrome
- Endocrine disorders
  - Cushing syndrome
  - Juvenile diabetes
  - Growth hormone deficiency
  - Hypogonadism
  - Hyperparathyroidism
- Genetic defects of bone formation/bone resorption
  - Hypophosphatasia
  - Osteogenesis imperfecta
  - Osteolytic disease
    - Acroosteolysis
    - Cranioskeletal dysplasia with acroosteolysis
    - Multicentric osteolysis
    - Winchester syndrome (skin lesions, corneal opacities, osteoporosis, and osteolysis)
  - Osteoporosis pseudoglioma syndrome
- Idiopathic disorders
  - Juvenile idiopathic osteoporosis
  - Regional transient osteoporosis
  - Reflex sympathetic dystrophy
- Immune disorders
  - Hyperimmunoglobulinemia E syndrome
  - Suppressor T-cell hyperactivity
- Immobilization
  - Cast therapy
  - Paralysis secondary to myelomeningocele, spinal cord injury, severe cerebral palsy, etc.
  - Painful skeletal disorders ranging from tarsal coalition to juvenile rheumatoid arthritis
- Metabolic disorders
  - Homocystinuria
  - Lysinuric protein intolerance
  - Renal osteodystrophy
  - Rickets
- Medications
  - Steroids
  - Retinoids
  - Antineoplastic agents
- Nutritional disorders
  - Anorexia nervosa
  - Malabsorption
  - Cystic fibrosis
  - Protein deficiency
  - Scurvy
- Radiation therapy
  - Cranial irradiation for leukemia, etc.

TABLE 2. Reports of Juvenile Osteoporosis in English Language Documents

Case	Ref.	Year	Location	Age at presentation	Sex	Chief complaint	Long-bone fracture	Vertebral collapse fracture	Therapy
1	3	1960	Sweden	12	M	Pain feet	NR	+	Calcium, vitamins, anabolic steroids

NR, not reported.

Etiologic Factors

By definition, the cause of IJO is unknown. Serum levels of calcium, phosphorus, alkaline phosphatase, thyroid hormone, and parathyroid hormone are consistently normal.

Calcitonin levels were low in one case report (27) but normal in others (52 ,61). Furthermore, treatment with calcitonin has not been helpful (5 ,27). Osteocalcin, a bone matrix protein that is typically elevated in diseases characterized by high bone turnover, has been reported to be normal in IJO (52). Collagen ratios from skin fibroblast cultures were normal in six patients with IJO (46). The serum level of certain collagen peptides was reduced (46 ,47), but the significance of these findings is unclear. Normal osteoblast function as determined by a 1,25-dihydroxyvitamin D_3 stimulation test was observed in six patients with IJO (2).

In an early study of patients who were extensively analyzed, Dent and Friedman (12) observed a negative calcium balance at presentation and a positive calcium balance on remission of the disease. Negative calcium balance at presentation has also been reported by other authors (3 ,31 ,59), but positive accretion of calcium by isotope studies has been described as well (32). Brenton and Dent (5) noted that a negative calcium balance was typically seen in those with moderate or severe involvement, and a positive calcium balance was seen in mildly affected patients and in those who were studied after menarche.

In three studies, decreased serum levels of 1,25-dihydroxyvitamin D were observed in seven patients (38 ,51 ,52). Furthermore, treatment with calcitriol apparently decreased the incidence of fractures in these patients. Other authors, however, have reported normal serum levels of both 1,25-dihydroxyvitamin D and 25-hydroxyvitamin D (24 ,27 ,36 ,39 ,56).

One can speculate that a mild deficiency of 1,25-dihyroxyvitamin D, either from a seasonal deficiency (15) or from a partial defect of either renal *α*-hydroxylase or insulin-like growth factor I (62), could play a pivotal role in the development of IJO. If the increased levels of 1,25-dihydroxyvitamin D needed during periods of rapid growth are unavailable, then calcium absorption would be mildly suboptimal, and bone formation would be affected. Bone resorption, an activity also stimulated by 1,25-dihydroxyvitamin D, could also be decreased. As a result, the bone-remodeling system would become uncoupled or slowed down, causing a further decrease in bone formation. A parallel situation may be observed in early postmenopausal osteoporosis, where reduced levels of 1,25-dihydroxyvitamin D are thought to retard bone resorption and uncouple the bone-remodeling system (11). The increased production of sex hormones during puberty—a significant factor in the increased bone density that occurs during adolescence (20)—would subsequently overcome the effect of this mild 1,25-dihydroxyvitamin D deficiency and allow remission of the osteoporosis. If IJO is truly absent in warmer climates, a possible explanation is that the greater sunlight exposure in these areas provides enhanced conversion of 7-dehydrocholesterol to vitamin D_3 and ergosterol to vitamin D_2.

Clinical Features

Symptoms typically begin during the prepubertal years with the insidious onset of back pain, lower extremity pain, or fractures. Knee and ankle pain are more common than hip discomfort. The child may walk with a limp or stiff-legged gait. Extreme difficulty with walking occurs in severe forms.

Back pain may be limited to the lumbar region, or the spine may be diffusely involved. Vertebral collapse or wedging is typical, but some patients only develop biconcave vertebra. Multiple thoracic and lumbar vertebrae are frequently involved. Kyphosis is common, but the degree of kyphosis has not been documented in the literature. Scoliosis has also been noted, but a severe spinal curvature has been reported in only one patient whose spinal deformity apparently preceded the onset of IJO (1). Spondylolisthesis was noted in two of the 14 patients reviewed by Houang et al. (25), but the degree of vertebral slippage did not require treatment.

Fractures of the long bones may be multiple or may not occur at all. The incidence of fractures is higher in the lower extremities, but the upper extremities may also be affected. Many of the injuries are of the low-impact type, most frequently causing nondisplaced or unicortical metaphyseal fractures; however, displaced fractures of the diaphysis and of the femoral neck may also occur (25). Some fractures, particularly those in the feet or those characterized by metaphyseal buckling, have only been recognized after skeletal radiographic surveys have been obtained.

Brenton and Dent (5) classified their series of 17 patients into mild, moderate, and severe categories. Those in the mild category typically had pain limited to the back and had a limited number of collapsed vertebra. Their activity was only temporarily restricted, and their ultimate loss of height averaged 4 cm.[1] Patients in the moderate category presented with back and extremity pain and had numerous vertebral and metaphyseal fractures. Activity restriction was prolonged, and many of these patients required temporary use of a wheelchair. The ultimate height loss ranged from 4 to 12 cm, but these patients eventually recovered full activity levels. Those in the severe category had numerous vertebral and metaphyseal fractures and frequently demonstrated diaphyseal fractures. Their ultimate loss in height ranged from 12 to 35 cm. Although cessation of spontaneous fractures ultimately occurred, these patients demonstrated only partial recovery to normal activity levels. As previously noted, some of these patients may have actually had a type of osteogenesis imperfecta.

Radiographic Features

Generalized osteoporosis is the hallmark radiographic feature of IJO. Loss of trabecular bone in the vertebrae and metaphyses is particularly striking. On plain radiographs, the skull appears to be spared.

Cortical thinning is noted in the long bones of the appendicular skeleton. Unlike osteogenesis imperfecta, the long tubular bones in IJO do not become thin and gracile. Two of the 14 patients in the radiographic review by Houang et al. (25) demonstrated protrusio acetabuli. Two patients in this review also had coxa vara associated with a fracture of the femoral neck.

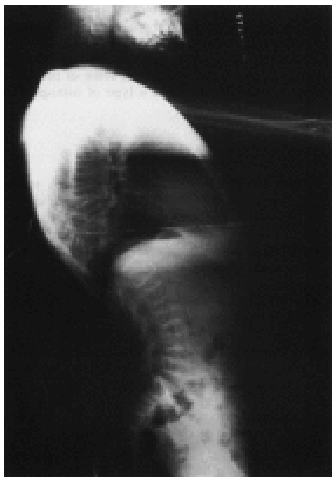

FIGURE 1. Standing lateral radiograph of a 10-year-old girl with idiopathic juvenile osteoporosis. Note diffuse osteopenia, multiple “codfish” vertebrae in the thoracic and lumbar spine, and “coin” vertebrae in the upper thoracic spine secondary to extreme collapse. (Courtesy of Stuart L. Weinstein, M.D., Department of Orthopedic Surgery, University of Iowa.)

Radiographic features in the vertebrae range from wedging to collapse, with the vertebral body having a “codfish” deformity with biconcave superior and inferior borders. With extreme collapse, the vertebral body has a “coin” appearance (Fig. 1) (25).

Other Imaging Studies

Routine radiographs permit limited assessment of osteoporosis. In the spine approximately 50 percent of the bone mass must be lost before osteoporosis can be consistently diagnosed on plain radiographs (48).

Bone densitometry studies have revolutionized our ability to quantify osteoporosis and should be obtained in all patients with IJO. Dual-energy x-ray absorptiometry (DXA) is preferred. In comparison with quantitative CT measurement of bone density, DXA has superior precision, lower cost, and minimal absorbed doses of radiation (16). Furthermore, age-adjusted DXA standards are available to determine bone mineral density *Z* scores (standard deviation above or below the age-matched normal mean). This is important because gender and race do not affect bone mineral density (g/cm^2) in children, but age is a significant factor that must be taken into account. Of note, the difference in bone mineral content between males and females at the end of growth is mostly related to differences in bone width (19).

For patients with IJO, bone mineral density should be measured in both the lumbar spine and proximal femur. The DXA lumbar study assesses axial skeletal trabecular bone density, whereas the proximal femur reflects appendicular trabecular bone strength. Although measurements in these two areas correlate highly, for the individual patient the difference is often significant, particularly when the bone mineral density is abnormal (22).

Although DXA studies are preferred, limited data are available on these measurements in IJO. Villaverde et al (61) observed a -4.21 DXA lumbar *Z* score in a 8.5-year-old girl 2 years after onset of symptoms and a -5.30 DXA lumbar *Z* score in 10-year-old boy at presentation. Similar strikingly low values have been noted in two patients in the series reported by Smith (56).

Single-photon absorptiometry measurements performed in the standard fashion at the midradius have been reported in at least seven patients with IJO (27 ,38 ,52). Midradius absorptiometry primarily measures cortical bone density, but these studies provide some insight into the variability and natural history of IJO. In the patient reported by Jackson et al. (31), the bone density was 6 standard deviations (SD) below the mean for age. This patient's recurrent fractures ceased at the onset of puberty, but the bone density measurements had increased to only 4 SD below the mean by that time. In a patient treated with calcitriol, the bone density was markedly depressed at presentation, steadily improved while the patient was receiving the medication, but showed a precipitous increase at menarche (38). Serial measurements were helpful in monitoring medical treatment in the series reported by Saggese et al. (52). Two of their patients were taking calcitriol and achieved normal bone density of the midradius. The third patient was not on medication, never achieved normal bone density, and had continued problems with fractures at the 30-month follow-up visit.

Other Diagnostic Studies

The diagnosis of IJO is one of exclusion. Therefore, in the workup of a patient with IJO, it is necessary to perform diagnostic studies for disorders that cause osteoporosis in children. Screening studies should include a complete blood count, as well as measurement of serum calcium, phosphate, alkaline phosphatase, parathyroid hormone, calcitonin, 25-hydroxyvitamin D, and 1,25-dihydroxyvitamin D levels.

It is most important to exclude *leukemia* in a child who presents with generalized osteoporosis (53) (Fig. 2). Patients with leukemia have decreased bone mineral density at diagnosis (34), but fortunately, only a small percentage present with generalized osteoporosis and vertebral compression fractures. This scenario occurred in only one of 250 children in the study by Leheup et al. (35). However, it is this type of patient who is particularly prone to be misdiagnosed as having IJO, a situation that has occurred in at least two patients (12 ,35). Children with leukemia who present with generalized osteoporosis and vertebral compression fractures typically have no organomegaly and a low-normal white blood cell count (4 ,12 ,53). Such parameters obviously do not permit differentiation of IJO from leukemia. A bone marrow biopsy should be part of the evaluation of any child with generalized osteoporosis unless a pediatric hematology consultant believes that leukemia can be ruled out by other means.

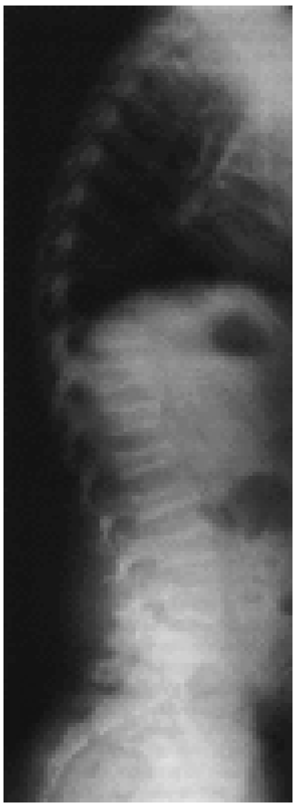

FIGURE 2. This 6-year-old girl presented with severe back pain and inability to walk. Note diffuse osteopenia and multiple compression fractures. Diagnostic evaluation revealed acute leukemia. (Courtesy of Stuart L. Weinstein, M.D., Department of Orthopedic Surgery, University of Iowa.)

Cushing syndrome, or hyperadrenocorticism, may also cause generalized osteoporosis in children. Twenty-four-hour measurement of total free urinary cortisol and an 8 a.m. determination of serum plasma cortisol level are usually adequate screening for Cushing syndrome. If these two laboratory measurements are abnormal, then a more complete workup to localize the source of the hyperadrenocorticism is indicated.

Lysinuric protein intolerance should be considered in a young child who presents with osteopenia and fractures (8 ,58). This autosomal recessive disease results from defective transport of cationic amino acids. Measurement of urinary amino acids in these children demonstrates hyperlysinuria. Osteoporosis in this disorder is thought to result from defective matrix protein synthesis caused by protein deprivation and deficiency of cationic amino acids. Although these patients are often recognized by their aversion to protein and frequent vomiting, these symptoms may not be present or obvious; therefore, urinary amino acid levels should be obtained in children with unexplained generalized osteoporosis. Diagnosing lysinuric protein intolerance is important because citrulline supplementation therapy not only increases protein intake but improves bone density as well (8).

Type I homocystinuria, a disorder that is phenotypically similar to Marfan syndrome, also causes osteoporosis in children. The screening study for this disease is measurement of urinary levels of homocystine. The diagnosis of type I homocystinuria can then be confirmed by demonstrating increased serum levels of methionine (63).

Hyperimmunoglobulinemia E syndrome can also cause osteoporosis and recurrent fractures in young children (30). Monocytes from patients with hyperimmunoglobulinemia E syndrome probably increase bone resorption by abnormal production of prostaglandins (37). This syndrome is associated with recurrent pyogenic infections, chronic eczematoid dermatitis, and mucocutaneous candidiasis. The diagnosis is confirmed by marked elevation of serum immunoglobulin E levels.

Osteogenesis imperfecta is another disorder that must be differentiated from IJO. The typical patient with osteogenesis imperfecta has the onset of fractures during infancy or early childhood; but some of these children do not have fractures until they are older than 5 years (44). Because the features of IJO and osteogenesis imperfecta overlap, it is reasonable to obtain skin fibroblast cultures for collagen type evaluation in any child who presents with generalized osteoporosis and fractures of unknown cause.

Natural History

The natural history of IJO is eventual remission, typically at the onset of puberty (12). The associated kyphosis typically improves, but measurements of thoracic kyphosis on standing films have not been performed. Recurrent fractures also cease, and apparent reconstitution of bone occurs. However, long-term studies have not documented whether the bone density returns to normal. This is critical because it is now apparent that development of an adequate bone mass at the completion of growth is critical (7 ,9 ,40 ,41 ,49). The variance of peak vertebral bone density in young adults is high—in the range of 25% (26). By comparison, the subsequent rate of bone loss, ranging from less than 1% to 2% per year, is relatively small (7 ,50). Therefore, if patients with IJO have low bone mineral density at completion of growth, they are at significant risk for developing recurrent osteoporosis during their later adult years.

The variable severity and the rarity of IJO make evaluation of medical therapies difficult. Recent reports have advocated the use of calcitriol or bisphosphonates (23 ,38 ,52), but whether any medication influences the natural history of IJO remains to be proved.

Treatment

Nonsurgical

Treatment includes modification of activities, dietary counseling, consideration of calcium and vitamin D supplements, and supportive therapy for spinal deformities and fractures. The orthopaedic surgeon must work with the child and the family to outline activities that will strike a reasonable balance between those that cause repeated fractures and those that restrict physical activities to such an extent that the osteoporosis is exacerbated. This program obviously has to be individualized, depending on the severity of the disease and whether remission of the osteoporosis has commenced.

A nutritional assessment should be done to confirm that the patient is getting adequate dietary calcium (12 ,29). Because phosphates may affect intestinal absorption of calcium, it is appropriate to ensure that the patient does not have excessive phosphate intake. Judicious restriction of soft drinks not only decreases phosphate intake but also helps control obesity, a problem that may develop in children with IJO (12 ,59).

A trial with calcitriol may be indicated if 1,25-dihydroxyvitamin D levels are depressed. Marder et al. (38) noted better results when calcitriol was given in two divided doses, as opposed to 1.0 µg given as a single daily dose. Saggese et al. (52) recommended 0.50 µg/d in two divided doses for two older children and 0.25 µg/d in a 2-year-old patient. Of note, single-photon absorptiometry measurement of midradius cortical bone mineral density normalized in two IJO patients in this study (52). Optimal therapy requires ongoing assessment of 1,25-dihydroxyvitamin D levels to maintain normal limits for the child's age. Hypercalcemia is a possible side effect of calcitriol therapy, and that possibility should be monitored.

Bisphosphonates (oral pamidronate) has been used to treat six children with IJO (6 ,23). Symptomatic improvement as well as normalization of calcium balance and significant improvement in DXA lumbar spine bone mineral density *z* scores were observed. Radiologic changes during treatment included a striking sclerosis at the metaphysis of the long bones and vertebrae. No change in skeletal maturation was observed, and the bisphosphonates were well tolerated. These studies have impressive early results but can be criticized because all patients underwent treatment during puberty. The authors speculated that IJO resulted from excessive bone resorption and that the bisphosphonates suppressed the hyperactive osteoclasts.

The most common spinal problems are back pain and kyphosis. A hyperextension brace worn only during the daytime was noted by Cloutier et al. (10) to control lower back pain in one patient. A lumbosacral corset was thought to partially alleviate back pain in one report (32), but in another case it did not seem to help (3). Jones and Hensinger (28) noted gratifying results after using a Milwaukee brace in two children with IJO and kyphosis.

A lumbosacral corset should be tried if the patient's main complaint is low back pain. If increased thoracic kyphosis is present, a Milwaukee brace should minimize progression of the kyphotic deformity. A rigid total-contact spinal orthosis is contraindicated, as this type of brace might accentuate or cause bony deformity. Rapid weaning from the brace is recommended (28); this minimizes the effect of stress shielding on the osteoporotic bone.

As most fractures in IJO are of the unicortical or nondisplaced pattern, short-term immobilization with coaptation splints usually constitutes satisfactory treatment. Displaced fractures require longer immobilization, but prolonged casting should be avoided to minimize the osteoporotic effect of immobilization. For a child who has recurrent fractures or painful ambulation, the use of a light-weight orthosis will protect the extremity while maintaining weight-bearing function. In this situation, bracing will provide a better environment for improving bone strength.

Surgical

Operative treatment of spinal deformity has been reported in only one patient with IJO (1). A posterior spinal fusion was performed at age 13 years for progressive scoliosis, apparently before the osteoporosis was recognized. The operation was fraught with difficulty. The laminae were so soft that Harrington instrumentation could not be utilized. Despite obtaining a solid fusion, this patient's curvature continued to increase from apparent bending of the osteoporotic bone. After bone densitometry studies demonstrated recovery, this patient underwent a two-stage operation at age 17 that included osteotomies of the fusion mass during the first operation followed by halo traction, followed by repeat posterior spinal fusion with multiple Harrington rods.

Operative therapy was apparently successful in stabilizing a metaphyseal fracture of the femoral neck in one patient with IJO (25). Villaverde et al. (61) reported that surgical realignment of genu varum was helpful in one case but provided no other details. The extreme osteoporosis associated with the active phase of the disease narrowly restricts the indications for surgical treatment. Bony deformity that results from either vertebral collapse or recurrent fractures should be operated on after remission of the disease, if possible. By then, the bone strength would be improved, and internal fixation would be more reliable.

The Spine in Osteogenesis Imperfecta

John P. Lubicky

J.P. Lubicky: Department of Orthopaedic Surgery, Rush Medical College, Shriners Hospitals for Children, Chicago, Illinois 60707.

Osteogenesis imperfecta is a heritable disease of connective tissue in which the chief abnormality is in the collagen matrix of bone. It is a genetically heterogeneous condition. For this reason, both the type of inheritance and the severity of involvement can vary from patient to patient. The chief feature of this condition is the brittleness of the bones throughout the body; there are abnormalities in other tissue as well. Patients with osteogenesis imperfecta characteristically are of short stature and have peculiar triangle-shaped faces. They often have blue sclerae, abnormal teeth, deafness, and frequent fractures. They also have ligamentous laxity (11 ,19 ,35 ,36 ,38 ,45) (Fig. 1). Because the bones are weak, bowing of the long bones takes place and may be accelerated by fractures in the area of bowing. Deformities of other bones occur, including molding deformities of the skull and distortion of the pelvis. Ligamentous laxity and weak bone both contribute to the development of spinal deformities (Fig. 2).

The currently accepted classification system for osteogenesis imperfecta is that proposed by Sillence (35 ,36) (Table 1). It incorporates the clinical features with the mode of inheritance. Although this classification is not perfect, it is a good working scheme for this condition. Additional features of the condition may sort out the type in the Sillence classification. Versfeld et al. (41) found that all of 16 patients with type III osteogenesis imperfecta had markedly elongated vertebral pedicles. They did not find this true of other types. They also found posterior rib angulation in type III.

A complete discussion of the genetics and pathophysiologic mechanisms of osteogenesis imperfecta is beyond the scope of this chapter. Osteogenesis imperfecta can be transmitted by both autosomal dominant and autosomal recessive modes (35 ,36). In the biochemistry of the disease, calcium, phosphorus, magnesium, vitamin D, and parathormone levels all are normal. The abnormality is in the composition and architecture of the collagen matrix. There seem to be abnormally high amounts of types III and V collagen in bone. There is also an abnormality of the cross-linking of the collagen chains (45). With this background of the general features of osteogenesis imperfecta, this chapter examines the various spinal problems associated with it.

Incidence and Pathogenesis of Spinal Deformity

Although repeated fractures and bowing of the long bones are the chief orthopaedic problems associated with osteogenesis imperfecta, spinal deformities have been discussed frequently in the literature. A review of various series reveals that the incidence of spinal deformities is 20% to 80% among patients with osteogenesis imperfecta (2 ,3 ,4 ,7 ,9 ,11 ,17 ,25 ,32). A number of factors influence the development and progression of spinal deformities, including severity of the disease, age, history of long bone fractures, and ambulatory status.

Two reports on spinal deformities in osteogenesis imperfecta were the result of a review of more than 100 patients from the Shriners Hospitals for Children, Chicago (3 ,4). The authors found that patients with severe disease who could not walk, had numerous long-bone fractures, and had chest deformities were at risk of development of scoliosis. They also found that the incidence varied with age. Among patients younger than 5 years, the incidence of scoliosis was 26%, but among those older than 12 years, the incidence was about 80%. Cristofaro et al. (7) also found that the severity of osteogenesis imperfecta seemed related to the incidence of scoliosis. Among their patients with osteogenesis imperfecta congenita and osteogenesis imperfecta tarda type I, 80% had scoliosis with an average curve of 47 degrees. The patients with osteogenesis imperfecta tarda type II had a 50% chance of having scoliosis with an average curvature of 26 degrees. Engelbert et al. (10) found in a group of 47 children that severe spinal problems are more likely in types III and IV rather than in type I. Children in this study who had dentinogenesis imperfecta also seemed more prone to scoliosis than those who did not (10). Similar findings were reported by others (2 ,11 ,27).

Hanscom and Bloom (17) devised a classification system (grades A through E) that correlated the patient's degree of osteogenesis imperfecta and the risk of scoliosis. Again, this system indicated that severity of the disease correlates with risk of development and severity of scoliosis. As with other forms of scoliosis, continued progression is possible after skeletal maturity (2). One of the possible mechanisms of the pathogenesis is additional compression fractures due to superimposition of osteoporosis on already weak bone in an already deformed spine.

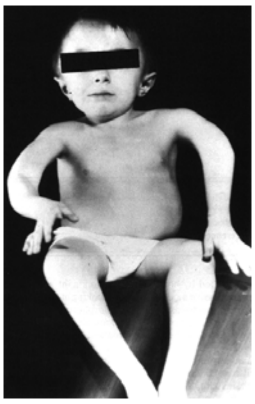

FIGURE 1. Child with osteogenesis imperfecta with typical features of triangular face, distorted trunk, and bowed extremities.

A number of curve patterns occur with or without kyphosis. Cristofaro et al. (7) found that 43% patients had double curves, 28% had thoracic curves, 26% had thoracolumbar curves, and 3% had cervicothoracic curves. Renshaw et al. (32) found that 14 patients with osteogenesis and scoliosis had thoracic curves, nine of 28 had lumbar curves, and 4 of 28 had thoracolumbar curves. Almost one half had kyphosis greater than 45 degrees. Engelbert et al. (10) also found a rather high incidence of a kyphotic component to the scoliosis, 18 of 22 patients. Benson et al. (3) found little rotation in the scoliotic spines of their patients.

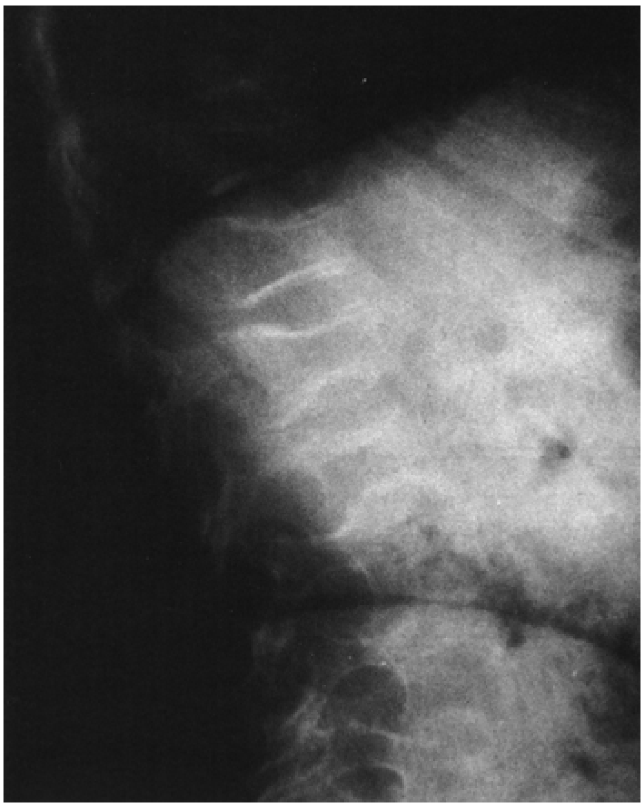

FIGURE 2. Lateral spinal radiograph shows multiple compression fractures with preservation of the discs, giving the typical appearance of codfish vertebrae.

TABLE 1. Classification of Osteogenesis Imperfecta

Type	Blue Sclerae	Bone Fragility	Hearing Loss	Dentinogesis Imperfecta
IA	Present	Mild	20–30 y of age	Absent
IB	Present	Mild	20–30 y of age	Present
II	Unknown	Severe	Absent	Unknown
III	Less blue with age	Severe	Absent	Absent
IVA	Absent	Moderate to severe	Absent	Absent
IVB	Absent	Moderate to severe	Absent	Present

Modified from Sillence D (1981): Osteogenesis imperfecta: an expanding panorama of variants. *Clin Orthop* 159:11–25, with permission.

The pathogenesis of spinal deformities in osteogenesis imperfecta seems to be a combination of weak bone and ligamentous laxity. This weak bone is prone to microfractures, which may involve the vertebral growth plates, which then do not grow normally. This abnormal growth may produce abnormally shaped vertebrae. Additional macroscopic compression fractures may further alter vertebral shape, perpetuating the deformity. This explanation is compatible with the finding that in general, the incidence and severity of the spinal deformity correlate with the severity of involvement of osteogenesis imperfecta. Results of a number of studies have indicated that the incidence increases with age. This may have something to do with upright posture and the effect of axial loading on the weak spinal column (2 ,3 ,17 ,27). It has been found (2 ,3 ,4 ,32) that the intervertebral discs are stronger than the bone of the vertebral bodies and that compression fractures give the vertebrae a codfish appearance. Progression eventually stops and may be related to settling of the deformed rib cage onto the pelvis.

Information obtained with various imaging techniques can help identify and quantify abnormal bone in vertebrae affected by osteogenesis imperfecta. Moore et al. (24) found that decreased bone mineral density as identified with dual-energy x-ray absorptiometry (DEXA) may be associated with osteogenesis imperfecta. Patients with osteogenesis imperfecta had a low bone mineral density and bone mineral content for weight and age as determined (8). Fredricks et al. (14) used quantitative computed tomography to assess trabecular bone mineral concentration. All three patients with osteogenesis imperfecta in the multidiagnosis study had abnormally low values. Frater et al. (13) used bone and DEXA to examine a woman with type I osteogenesis imperfecta and back pain. The findings were intense uptake in several vertebral bodies that had no deformity and osteopenia. Glorieux et al. (16) used DEXA to evaluate the effectiveness of medical therapy for osteogenesis imperfecta. They found evidence to suggest that a lower *z* score was associated with greater likelihood of having more severe scoliosis. The results of all these studies give credence to the fact that the weak bone of the vertebra contributes to the development of spinal deformity.

Management of Spinal Deformities

As with other types of spinal deformities, both nonoperative and operative methods have been used. In general, criteria used for other types of scoliosis, such as curve magnitude, age, patient maturity status, have been applied to curves associated with osteogenesis imperfecta.

Observation is one form of nonoperative treatment. All children with osteogenesis imperfecta, especially those with extensive disease involvement, should undergo regular clinical and radiographic spinal evaluations. Although it is not 100%, the incidence of scoliosis does increase with age.

Because the weak bone of osteogenesis imperfecta has a large part to play in the development of spinal deformities, strengthening the bone to help prevent deformity or to facilitate brace or surgical treatment may be helpful. Nagant de Deuxchaisnes et al. (26) in 1990 described the use of enteric-coated sodium fluoride and calcium in the treatment of a group of 101 patients who had low bone mineral density as determined by dual-photon absorptiometry of the lumbar spine; three of the patients had osteogenesis imperfecta. The investigators found that bone mineral density increased in a linear manner with time, regardless of the diagnosis.

In a more recent report, Glorieux et al. (16) described an uncontrolled observational study with 30 children and adolescents who had severe osteogenesis imperfecta. The patients were treated with cyclic administration of pamidronate. The drug was administered intravenously at 4 to 6 month intervals. The investigators found decreases in serum alkaline phosphate levels and in urinary excretion of calcium and type I collagen *N*-telopeptide. There was a mean annualized increase in bone mineral density of almost 42%, and the *z* score improved from -5.3 to -3.4. The investigators also found increases in cortical width in the metacarpals and in the size of the vertebral bodies, both suggesting that new bone had been formed. There was a statistically proved decrease in radiographically documented fractures. The children expressed a sense of improved well-being from relief of pain and fatigue. The results of this study suggest that medical treatment may correct some of the metabolic abnormalities of the bone that contribute to the development of spinal deformities. Another implication may be that medical treatment of those who have substantial spinal deformity before surgical intervention may aid in achieving better correction and security of the implants.

Brace treatment has been reviewed in a number of series (2 ,4 ,17 ,32 ,44). Bathgate and Moseley (2) stated that there may be a place for bracing—perhaps in management of smaller curves—but that exact indications are unclear. In their study, bracing was generally unsuccessful because it either was started too late or had to be stopped because of brace-related complications, especially rib deformities. Benson and Newman (4) found that bracing did not control curve progression and caused chest and rib deformities. Recommendations for bracing and for electrical stimulation—a treatment now not generally used, were put forth by Hanscom and Bloom (17), but no results were given. Renshaw et al. (32) found that some patients had chest deformities with bracing. Except for two patients treated in suspension orthoses, the patients were treated with conventional braces and had progression of the curve. Yong-Hing and MacEwen (44) reviewed the records of 73 patients treated with a variety of braces. Fifty-eight patients had curve progression, and 15 patients had a decrease in or stabilization of the curve. Early bracing for smaller curves did not give better curve control. A number of complications occurred, and most patients were still in braces at the time the report was written.

In summary, it appears that bracing does not change the course of scoliosis in osteogenesis imperfecta and frequently causes complications. Use of this modality must be questioned in light of these findings.

Surgical treatment, usually consisting of at least posterior spinal fusion, has become popular as a means of controlling scoliosis in osteogenesis imperfecta (2 ,4 ,5 ,6 ,15 ,17 ,40 ,44). Bathgate and Moseley (2) pointed out that marked correction cannot be expected with surgery, and loss of correction is greater without instrumentation. The best results combined Harrington instrumentation and segmental wires. Benson and Newman (4) recommended spinal fusion with instrumentation and local bone grafting for progressive curves. They found that loss of correction was twice that among those who underwent fusion without instrumentation (Fig. 3).

Eight patients underwent surgery in the series by Cristofaro et al. (7). All underwent posterior spinal fusion, five with instrumentation. One also had an anterior spinal fusion. Gitelis et al. (15) combined the use of halo gravity traction, anterior spinal fusion with Dwyer instrumentation, and posterior spinal fusion with Harrington instrumentation to treat a patient with severe scoliosis (Fig. 4).

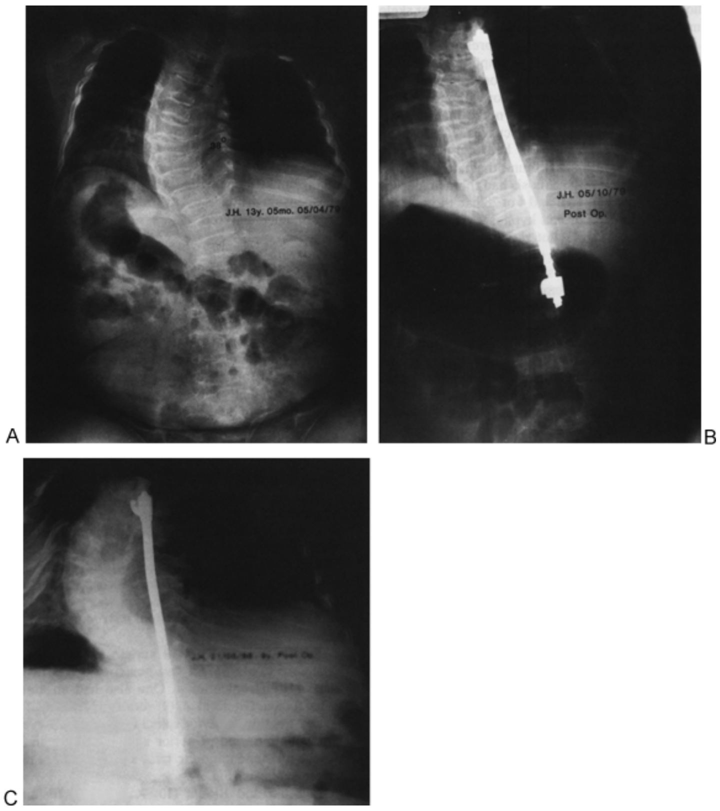

FIGURE 3. A: Sitting posteroanterior radiograph of the spine shows a 38-degree thoracic curve. **B:** Postoperative radiograph shows Harrington instrumentation supplemented with methyl methacrylate. Improvement in the curvature is evident. **C:** Posteroanterior radiograph obtained 9 years postoperatively shows the instrumentation in place and progression of the thoracic curve. Even in the presence of instrumentation—in this case, nonsegmental instrumentation—increasing curvature can occur postoperatively.

Hanscom and Bloom (17) recommend fusion for curves greater than 45 degrees in patients with mild osteogenesis imperfecta and for curves greater than 35 degrees in patients with more severe disease. They also advise the use of segmental instrumentation. Trotter (40) found segmental instrumentation superior to fusions in situ and fusion with nonsegmental instrumentation in maintaining spinal alignment and preventing progression (Fig. 5).

Yong-Hing and MacEwen (44) described 60 patients undergoing surgical treatment. Fifty-five patients underwent posterior spinal fusion, 39 with instrumentation. Three of four patients undergoing anterior spinal fusion had Dwyer instrumentation as well. A modest increase in the amount of correction was found among patients who underwent instrumentation. A

number of complications occurred, the most frequent of which were excessive blood loss and instrumentation problems. The authors found that in addition to stabilization of the curve, many patients achieved better sitting balance.

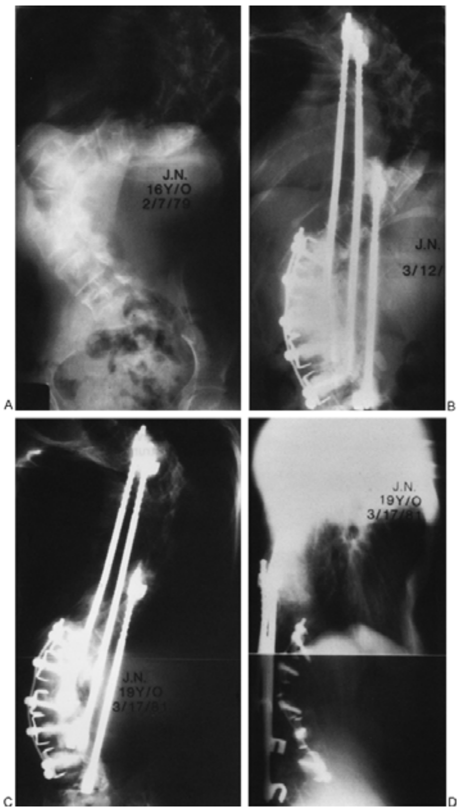

FIGURE 4. A: Posteroanterior upright thoracolumbar spinal radiograph shows severe double curve. **B:** Postoperative posteroanterior radiograph shows several posterior Harrington rods supplemented with methyl methacrylate and the anterior Dwyer instrumentation. Marked correction, particularly of the lower curve, has been achieved, although there is still substantial deformity of the trunk. Posteroanterior **(C)** and lateral **(D)** upright radiographs obtained 2 years after the operation show that there has been some loss of alignment on the frontal image. However, instrumentation has not completely failed. The kyphosing effect of the Dwyer instrumentation is evident in the anterior aspect.

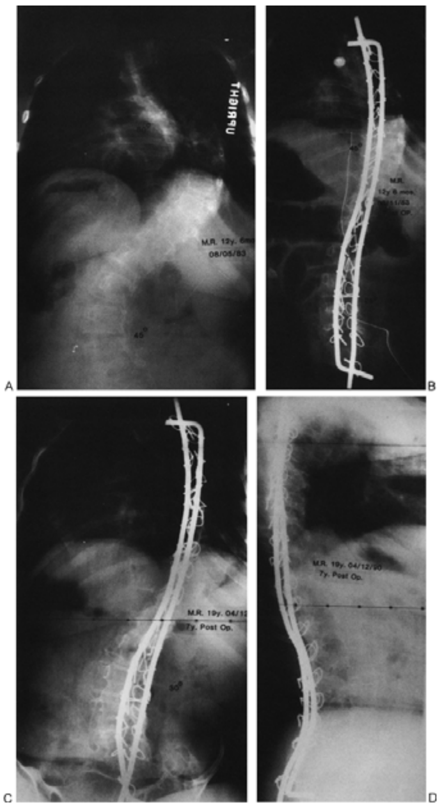

FIGURE 5. A: Posteroanterior upright radiograph shows severe scoliosis before surgical intervention. **B:** Postoperative anteroposterior radiograph shows Luque instrumentation in place and considerable correction of both curves. Posteroanterior **(C)** and lateral **(D)** upright radiographs obtained 7 years postoperatively show some loss of correction of both curves and some disruption of the instrumentation.

Poor bone stock provides poor purchase for instrumentation. Herron and Dawson (19) found that methylmethacrylate used around Harrington hook sites reinforces the construct. Methylmethacrylate has become an accepted adjunct to the use of hook-rod instrumentation in osteogenesis imperfecta (2 ,4 ,5 ,15 ,17 ,40) (Figs. 6 , 7). However, the use of totally segmental instrumentation may obviate use of methylmethacrylate.

Although the main deformity described in all these series is scoliosis, many patients have associated kyphotic deformities—either true kyphosis or rotational kyphosis. Collapse into this kyphotic position is an additional deformity to be considered. It may play a role in the development of instrumentation problems, such as instrumentation cutout caused by continued kyphotic forces over the posterior instrumented segment (Figs. 8 , 9).

It can be seen from this review that bracing is ineffective in controlling scoliosis in osteogenesis imperfecta and has some rather serious side effects. Surgical stabilization is the management of choice of progressive curves. The operation should entail posterior spinal fusion with segmental instrumentation and local and bank bone graft. A great deal of correction cannot be expected, however. Although instrumentation should be planned for all patients, the bone sometimes is so soft that instrumentation cannot be used. In such cases, in situ fusion is the only recourse. Therefore, when a curve has evidence of progression and has reached 35 to 40 degrees, it should be fused regardless of the age of the patient. Progression usually starts at approximately 8 years of age. Waiting for continued spinal growth in the face of unrelenting curve progression does not lengthen the trunk, even after surgical treatment, because significant correction of the curvature and elongation of the trunk cannot be expected. Attention also should be given to the sagittal plane. For patients with marked kyphosis, consideration should be given to anterior spinal fusion to ensure healing of the fusion and curve control.

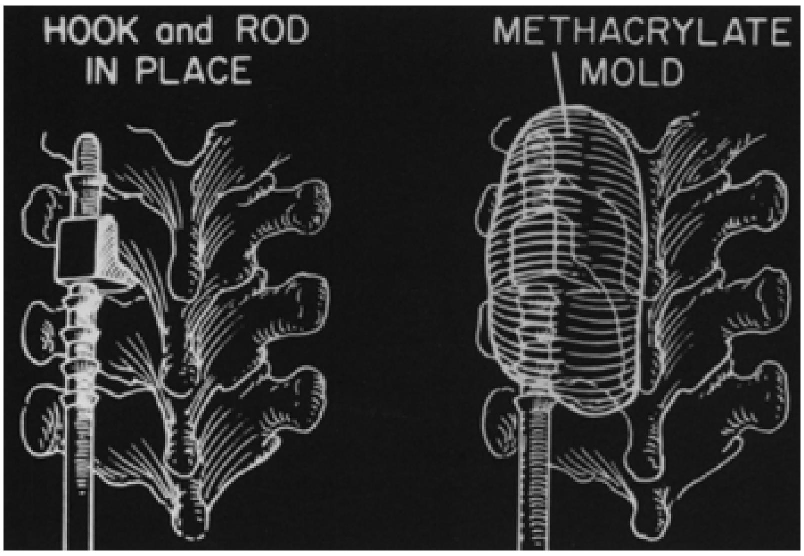

FIGURE 6. Illustration shows Harrington hook in place in the facet joint, which later was supplemented with the use of methylmethacrylate around the hook and onto the lamina.

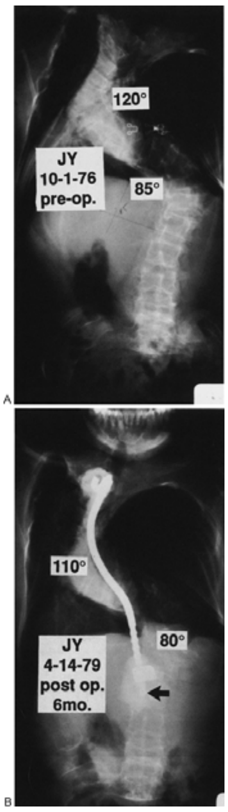

FIGURE 7. A: Preoperative posteroanterior upright radiograph shows severe scoliosis. **B:** Postoperative radiograph shows a contoured Harrington rod in place and hook sites supplemented with methylmethacrylate (*arrows*).

Complications, especially instrumentation problems, should be anticipated (37). (Medical pretreatment to improve bone stock may decrease some of these bone-instrument interface problems.) Because most of the patients are small and have low physical demands, postoperative immobilization may not be necessary, especially with the use of segmental instrumentation. However, a removable plastic brace may provide some support during healing of the fusion.

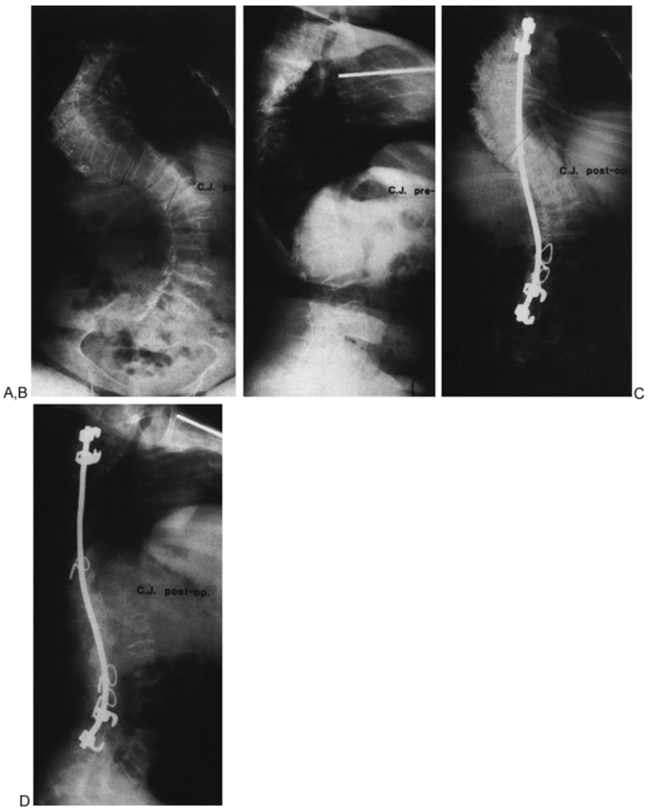

FIGURE 8. Preoperative posteroanterior **(A)** and lateral **(B)** upright radiographs of a 13-year-old girl with severe osteogenesis imperfecta. Sitting caused back pain. Postoperative posteroanterior **(C)** and lateral **(D)** upright radiographs show moderate correction and balance with the use of limited Cotrel-Dubousset instrumentation. Bone quality was quite poor. Lateral radiograph shows preservation of normal sagittal contour.

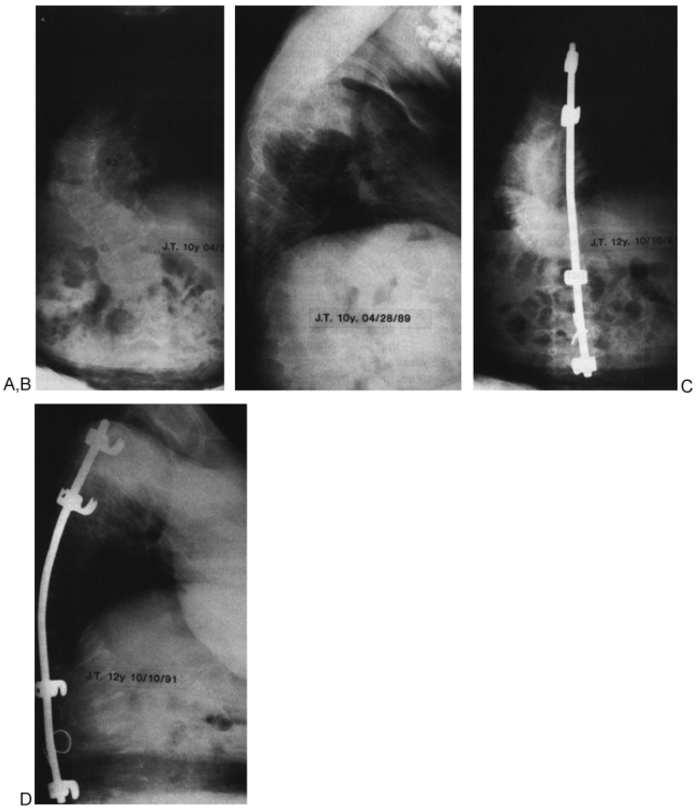

FIGURE 9. Posteroanterior **(A)** and lateral **(B)** sitting radiographs of the spine show severe curvature. Posteroanterior **(C)** and lateral **(D)** sitting radiographs obtained 2½ years postoperatively show limited Cotrel-Dubousset instrumentation supplemented with a sublaminar wire in the lumbar spine. Only minimal correction was achieved because of the quality of the bone. Lateral radiograph shows contouring of the rod. Adequate contouring prevents hook cutout from excessive kyphotic forces against a straight rod.

Anesthetic Considerations

Anesthetic management for patients with osteogenesis imperfecta can be challenging, especially for those undergoing major spinal surgery. Libman (22), drawing on extensive experience with patients with osteogenesis imperfecta at Shriners Hospitals for Children, Chicago, defined several areas of particular concern.

First, because of their fragility, these patients can sustain fractures during transfer from the stretcher to the operating table or while being positioned on the surgical frame. Intraoral manipulation can easily fracture abnormal teeth. Even the use of tourniquets for insertion of intravenous catheters and the use of blood pressure cuffs can cause fractures. Second, airway problems can be caused by the relatively large heads and tongues and short necks of these patients. Third, chest deformities interfere with normal respiratory mechanics and often impair pulmonary function. Because of deformities of the spine and extremities, normal measurements for the prediction of lung volumes may be inaccurate, making pulmonary function test results suspect. Last, there is a tendency toward hyperthermia and diaphoresis. This is not true malignant hyperthermia, but it can be nearly as severe and can be managed as such if it becomes serious. Hyperthermia is thought to be caused by hyperthyroidism among some patients. The hyperthermia can be induced by certain anesthetic agents and may be triggered by atropine. These children tend to be high-strung, and their natural nervousness and tendency to sweat seem to be exacerbated by atropine. In addition to avoidance of triggering agents, the usual methods for temperature control should be used. Dantrolene also can be used to prevent hyperthermia, but it is not recommended for routine use.

Standard anesthetic regimens can be used for patients with osteogenesis imperfecta, including controlled hypotension. When used as a paralyzing agent, however, succinylcholine can cause muscle fasciculation, which may cause fractures among patients with severe osteogenesis imperfecta. Therefore, succinylcholine should not be used at all or should be used only with pretreatment with a nondepolarizing agent. Although regional blocks can be used in operations on older patients, the deformities and bone fragility may make such use difficult. Close monitoring and careful handling are essential to avoid iatrogenic problems.

Craniocervical and Cervical Abnormalities

Although there is a fair amount of information regarding deformity of the thoracolumbar spine (2 ,3 ,4 ,5 ,6 ,11 ,15 ,27 ,32 ,40 ,44), fewer reports address problems of the craniocervical area and the cervical spine in osteogenesis imperfecta (6 ,11 ,12 ,18 ,21 ,29 ,30 ,34 ,39 ,42 ,46). Most of the large series already cited either do not mention this area at all or state that no particular problems were seen. It is thus difficult to know the true incidence of such problems.

One of the most serious abnormalities that can occur is basilar impression, although many patients may have no symptoms. Pozo et al. (29) looked at three patients with basilar impression and reviewed their clinical histories. The weak bone of the craniocervical junction and the relatively large head often of patients with osteogenesis imperfecta both probably contribute to the development of basilar impression. When basilar impression occurs, the foramen magnum invaginates into the posterior fossa. This and medial migration of the occipital condyles cause stenosis and interfere with cerebrospinal fluid dynamics; the interference with flow of cerebrospinal fluid causes internal hydrocephalus. Direct compression of the cerebellum, brain stem, and upper cervical cord, various cranial nerve abnormalities, long-tract signs, and respiratory depression also can occur. Pozo et al. (29) found that their patients with basilar impression were not severely affected by osteogenesis imperfecta.

Harkey et al. (18) described the surgical management of basilar impression. They found that although the classic treatment is posterior decompression, this technique does not decompress the area sufficiently and often causes instability. These authors described the technique of anterior transoral decompression of the anterior arch of C1, the odontoid process, and part of the clivus. They suggested that the procedure be accompanied by a posterior occiput to cervical fusion with instrumentation. Unfortunately, they reported on only four patients. As an alternative to the transoral approach to anterior decompression, they also described the possibility of using LeFort midface osteotomy combined with the midline hard and soft palate split. They also suggested using internal fixation as an adjunct to posterior fusion. Recovery of function seems to be related to both the severity and duration of the symptoms.

Ziv et al. (46) reported on a patient who with paraplegia that developed at the thoracic level after a fall. The patient had been an independent ambulator. Because of neck pain and a history of low back pain, he underwent chiropractic manipulation but soon had progressive paralysis with sacral sparing. Evaluation showed C7–T1 spondyloptosis. The authors performed anterior decompression, but after walking in a halo vest, the patient again became paralyzed. Posterior decompression and fusion resulted in progressive improvement.

Ransford et al. (30) described posterior internal fixation from the skull to the cervical spine for patients with severe instability after decompression of basilar impression. They used a specially contoured Luque rod secured to the skull with wires through burr holes and sublaminar wires in the cervical spine. Because of subsequent spinal collapse, rendering the craniocervical junction unstable through decompression may cause recurrence of the neurologic deficit that was initially improved with the original decompression. This “second insult” should be avoided with stabilization of the spine at the index operation.

Frank et al. (12) and Wang et al. (42) described patients with respiratory depression due to basilar impression. Decompression of the brain stem and shunting of the hydrocephalus resulted in improvement (12). The association of basilar impression, hydrocephalus, and hydrosyringomyelia has been reported by a number of authors (6 ,12 ,34 ,39)

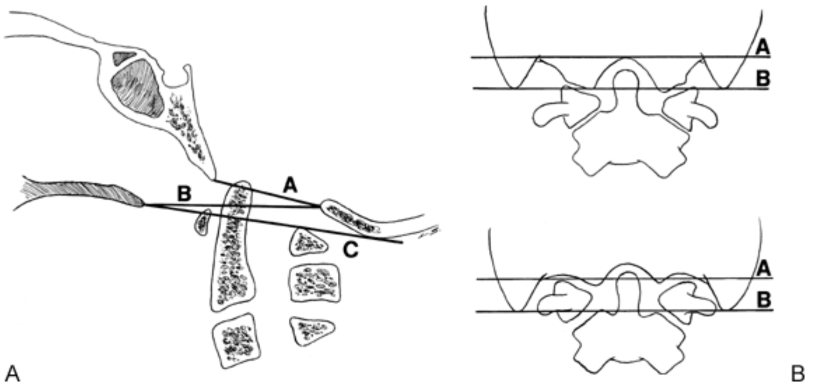

FIGURE 10. A: Drawing of lateral view of the craniocervical junction in basilar impression. Image shows position of the tip of the odontoid process with respect to the McRae line (*A*), Chamberlain line (*B*), and McGregor line (*C*). **B:** Drawing of open-mouth anteroposterior view of the craniocervical junction shows a line connecting the digastric grooves (*A*) and the Fishgold line (*B*), which joins the tips of the mastoid processes. The normal situation is depicted in the *top* drawing, and basilar impression in the *bottom.*

The diagnosis of basilar impression is a radiographic one. A number of radiographic features are common to basilar impression from osteogenesis imperfecta and other causes. Upward migration of the cervical spine into the base of the skull (or descent of the skull onto the cervical spine) may be obvious, particularly on lateral cervical spinal radiographs. When the deformity is more subtle, however, various measurements on the radiographs help make the diagnosis. The Chamberlain, McRae, and McGregor lines can be drawn on lateral cervical spinal radiographs (Fig. 10A). Protrusion of the odontoid process above these lines indicates basilar impression. On an anterior open-mouth radiograph or tomogram of the base of the skull, the Fishgold line can be drawn and should pass through the occiput-C1 junction (18) (Fig. 10B).

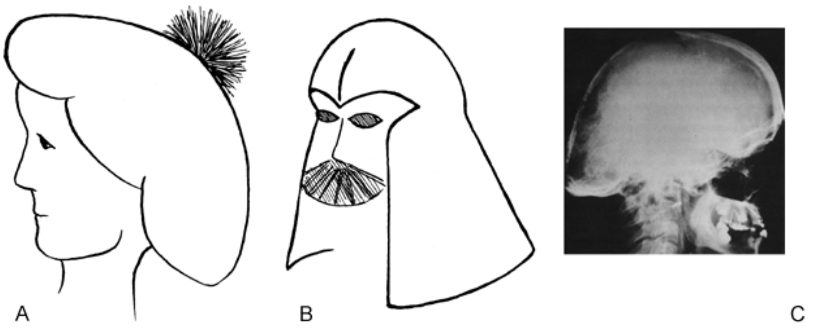

FIGURE 11. Drawing shows “tam-o'-shanter” **(A)** and a “Darth Vader” helmet **(B)**. **C:** Lateral radiograph of the skull and cervical spine of a child with severe osteogenesis imperfecta. Distortion of the craniocervical junction and overhang of the occipital bones of the skull (tam-o'-shanter) are evident.

Somewhat more characteristic of basilar impression with osteogenesis imperfecta is the shape of the skull. Basically, two patterns are seen—the “tam-o'-shanter” and the “Darth Vader” (10 ,18) (Fig. 11A, B). The tam-o'-shanter skull is reminiscent of the floppy cap worn in Scotland. The anatomic reason for this appearance is overhang of the temporal and occipital bones (Fig. 11C). When the overhang is more acute and angular, flattening of the interparietal area gives the appearance of the helmet worn by Darth Vader of *Star Wars* fame (17).

In summary, even though patients with osteogenesis imperfecta may have severe thoracolumbar spine deformities, evaluation of the craniocervical junction and the cervical spine is especially important if such patients have neurologic signs and symptoms. Patients with mild forms of osteogenesis imperfecta may be the very ones to have such problems. The role of prophylactic decompression in the care of patients with radiographic evidence of basilar impression without appreciable symptoms is unclear. However, for patients with documented basilar impression with neurologic deficits, appropriate imaging studies followed by decompression of the neural elements and spinal stabilization are recommended.

Spondylolysis and Spondylolisthesis

Because the bone of patients with osteogenesis imperfecta is weak enough to cause multiple compression fractures of the vertebrae, an increased incidence of spondylolysis and spondylolisthesis (with pars defect or elongation of pars or pedicles) is expected (Fig. 12). It makes sense that an isthmic type—Wiltse type ID (28)—fracture could easily occur with the usual stresses found at the lumbosacral junction. A number of authors have described a few cases of spondylolysis and spondylolisthesis (2 ,17 ,20 ,29 ,41 ,43). Many series dealing with spinal deformity in osteogenesis imperfecta do not mention problems of spondylolysis or spondylolisthesis at all. Rask (31) described a single case of a 4-year-old with mild osteogenesis imperfecta, but disorder was probably traumatic. Wiltse (43) stated that “defects in the pars in children with teogenesis imperfecta] seem to occur too frequently,” but he did not have any statistics to support that statement. Barrack et al. (1) described spondylolysis in a patient who had undergone posterior spinal fusion with instrumentation, but the spondylolysis probably was iatrogenic. It is evident from this review that either the incidence of spondylolysis and spondylolisthesis is truly low or these conditions are just not recognized or do not cause symptoms.

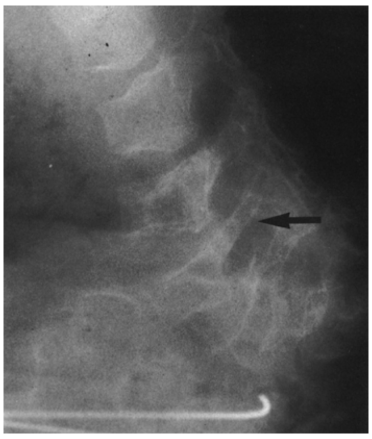

FIGURE 12. Sitting lateral radiograph of the lumbar spine shows severe elongation of the pedicle of the lower lumbar spine (*arrow*).

The literature contains no reports of specific therapy for these problems in osteogenesis imperfecta. However, Barrack et al. (1) mentioned that among their patients the preexisting fusion was extended to the sacrum. Isolated spondylolysis or spondylolisthesis that is progressive or symptomatic (unresponsive to nonoperative measures) should be managed by means of appropriate posterior lateral spinal fusion after appropriate imaging studies (5). The use of instrumentation is dictated by the size of the vertebrae and the quality of bone. Posterior spinal fusion for scoliosis that extends low into the lumbosacral spine probably should extend across the lumbosacral junction in an effort to eliminate the stress of a long fusion over only one or two mobile segments. The loss of these motion segments, particularly by a patient who does not walk who has severe involvement, would do little to decrease function. However, this approach may decrease the likelihood of development of either spondylolysis or spondylolisthesis or compression injury below the fusion. The incidence of pseudarthrosis across the lumbosacral junction in these situations cannot be determined with the available literature.

Spinal Fractures

The abnormal bone of osteogenesis imperfecta is said to be weak, and that fact is offered as one of the causes of spinal deformity. The typical ligamentous laxity and repeated microfractures without substantial trauma cause progressive collapse of the vertebral bodies. This gives them a typical codfish appearance, which can progress to a wedge shape with further deformity (2 ,3 ,4 ,23). It is also observed, at least among younger patients, that the intervertebral discs are stronger than the vertebral bodies, and their shape is preserved even in the presence of surrounding vertebral body compression.

None of the references cited at the end of this chapter mention anything about truly traumatic fractures of the thoracolumbar spine. Two reports, however, described fractures of the cervical spine (23 ,33). The progressive collapse of the spine caused by compression fractures often is mentioned. It is common knowledge that postmenopausal osteoporosis can cause recurrent compression fractures, even among women without other systemic diseases. This process can be extensive. In the presence of preexisting scoliosis or kyphosis, it can cause severe deformity. Paterson et al. (28) reviewed the records of 65 adult patients with osteogenesis imperfecta and found that the incidence of fractures of all types increased after menopause. The fracture rate among postmenopausal women was seven times that of the general population. The incidence of backache, loss of height, and scoliosis was higher among women than among men. The authors concluded that spinal fractures are a major cause of disability among older women with osteogenesis imperfecta. Even those who had apparently mild disease as children can have severe problems after menopause. Girls with osteogenesis imperfecta should therefore be counseled and should seek the help of an endocrinologist to begin early treatment to avoid age- and hormone-related bone loss.

There is no reason to believe that patients with osteogenesis imperfecta cannot sustain traumatic spinal fractures. No series of such patients is mentioned in the literature. Among the many patients treated at the Shriners Hospitals for Children, Chicago, including those with compression fractures, only one had an unstable fracture that necessitated surgical treatment (Fig. 13).

Patients with acute compression fractures that are not believed to be unstable after appropriate imaging should be treated with the usual measures. These measures include an initial period of bed rest with gradual mobilization with external support. When there are preexisting compression and osteoporosis, it is sometimes difficult to determine when healing has occurred. In these situations, an arbitrary period of support can be prescribed and correlated with symptoms of back pain. Patients with unstable fractures or who have neurologic deficits should be treated as any other patient with a spinal fracture. The technical points mentioned with regard to scoliosis should be applied to those with fractures. Adequate anterior column support must be provided to patients with traumatic kyphosis and vertebral body crush. Segmental posterior instrumentation offers the most secure fixation. Even in situations in which segmental spinal instrumentation of one kind or another is used, postoperative external support may be indicated.

Summary

Spinal problems in osteogenesis imperfecta run the gamut of spinal deformity, craniocervical abnormalities, spondylolysis or spondylolisthesis, and spine fractures. It appears that bracing is not effective in controlling progressive spinal deformity. In such situations, spinal fusion with instrumentation, preferably segmental instrumentation, should be used to control the deformity. This should be done when curves demonstrate that they are progressive and before severe deformity occurs, because significant correction cannot be anticipated (Figs. 14 , 15). Craniocervical problems are uncommon but may cause catastrophic neurologic problems. Early recognition of basilar impression and prompt decompression and stabilization of the craniocervical junction improve symptoms and prevent the instability of the upper cervical spine that occurs with decompression only. Commonsense management of spondylolysis or spondylolisthesis and spinal fractures is indicated in the care of patients with osteogenesis imperfecta. Patients with osteogenesis imperfecta have peculiar physiologic characteristics that necessitate special attention during anesthesia. Careful handling of these fragile patients is essential. A whole new era of medical management of osteogenesis imperfecta appears to be dawning. Improvement in the quality of bone may preclude the development of deformity, lessen its severity, or at least make the bone stronger so that spinal instrumentation can be more secure if surgery is needed. Only time will tell how effective this kind of therapy will be.

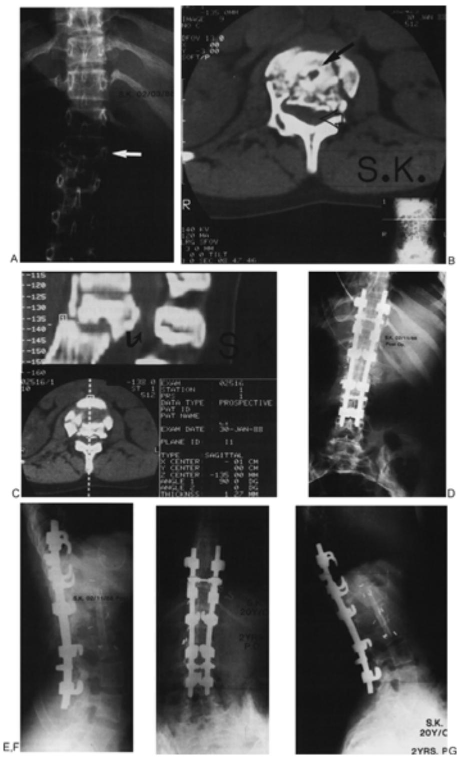

FIGURE 13. A: Supine anteroposterior radiograph of the thoracolumbar spine of an 18-year-old patient with mild to moderate osteogenesis imperfecta. Widening of the pedicles of L1 (*arrow*) and loss of height of L1 are evident. **B:** Axial computed tomographic (CT) image at L1 shows the burst component of the vertebral body (*solid arrow*) and canal compromise (*open arrow*). **C:** Lateral CT reconstruction shows the canal compromise (*arrow*) and the overall kyphotic alignment at that level. Anteroposterior **(D)** and lateral **(E)** radiographs after posterior instrumentation and realignment of the spine and anterior decompression with strut grafting. Anatomic alignment is evident on the anteroposterior image and preservation of the sagittal contour on the lateral image. Posteroanterior **(F)** and lateral **(G)** standing radiographs 2 years after the operation. In the area of previous instrumentation, the spine remains in the correct anatomic position. Pelvic obliquity due to leg length discrepancy is present on the posteroanterior image (the patient sustained a tibial fracture with shortening about 1 year after the spinal fracture). The lateral image shows preservation of the sagittal contour and incorporation of the fibular graft.

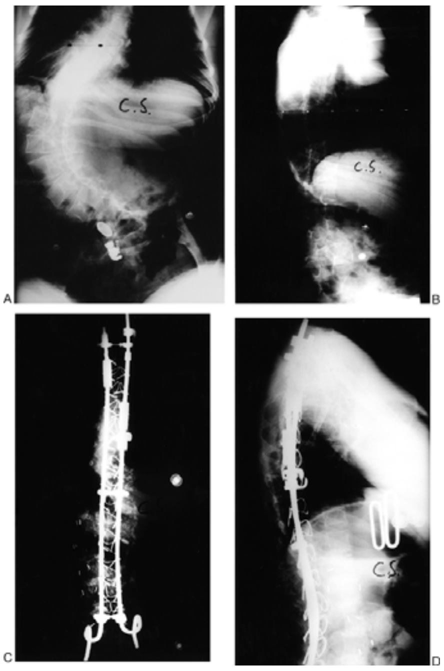

FIGURE 14. Images of a 16 year-old girl with osteogenesis imperfecta who had progressive thoracolumbar scoliosis. Although she had many long-bone fractures and had undergone surgical therapy for them, the patient could walk. Posteroanterior **(A)** and lateral **(B)** radiographs show severe left thoracolumbar scoliosis with pelvic obliquity and an abnormal sagittal contour, respectively. The sacrum is deformed and horizontally oriented, the L5 pedicles are elongated, and the L5–S1 disc is oriented vertically. Posteroanterior **(C)** and lateral **(D)** radiographs after staged anterior release and fusion followed by posterior fusion and Cotrel-Dubousset instrumentation supplemented with sublaminar wires. Coronal correction is excellent, and the sagittal contour has normalized. Dunn-McCarthy pelvic fixation was used in this construct.

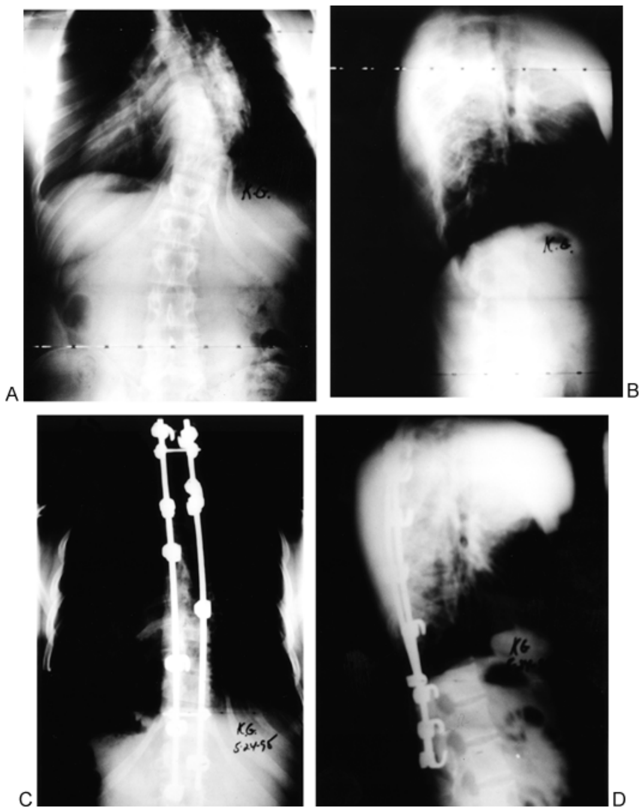

FIGURE 15. Images of a normally active 18-year-old man with osteogenesis imperfecta show normal stature despite multiple long-bone fractures as a child. The scoliotic deformity gradually increased and was associated with a large right rib hump. Posteroanterior **(A)** and lateral **(B)** radiographs show right thoracic curve with a structural left upper thoracic component. The normal thoracic kyphosis is flattened. Posteroanterior **(C)** and lateral **(D)** radiographs show the correction and balance achieved after posterior fusion, right thoracoplasty, and use of Moss-Miami instrumentation. Coronal correction and balance are quite good, and the sagittal contour has been improved.

Mucopolysaccharidosis

Mucopolysaccharidosis (MPS), Hurler syndrome in particular, presents unmistakable signs and symptoms. These include blindness, hoarseness, pasty complexion, large ears, bushy eyebrows, hypertelorism, a snub nose, open mouth, prognathism, hirsutism, clawed fingers, a pot belly, knock knees, flat feet, knobby jointed, dwarfism, and mental retardation. Abnormality of a macromolecular storage substance causes the nonosseous features of this fatal recessive disease (30 ,38 ,53 ,118 ,121 ,125).

MPS is a family of recessively inherited diseases that have as a common feature a defect in lysosomal storage (83 ,84 ,96 ,126). Mucopolysaccharides accumulate as a result of deficiencies of specific degradative enzymes. There is a wide spectrum of clinical severity not only from one type to another but also within the various types (16 ,57) (Fig. 1).

Mucopolysaccharides are linked to specific noncollagenous proteins and in combination with collagen form the matrix of connective tissue. The mucopolysaccharide unit or glycosaminoglycan consists of a core protein to which side chains of polysaccharides are attached. The polysaccharide chains consist of repeating disaccharide units. The polymers of disaccharides are specific to each type of glycosaminoglycan.

The three mucopolysaccharides that accumulate in the MPS syndromes are dermatan sulfate, heparan sulfate, and keratan sulfate (108). The sites of specific enzyme defects on a portion of the polysaccharide chain of dermatan sulfate and heparan sulfate are shown in Table 1 . Morquio syndrome (type IV MPS) is a defect of catabolism of keratan sulfate (50 ,55 ,101), which is present only in cartilage, nucleus pulposus, and cornea (57). The characteristics of all types of MPS are summarized in Table 2 .

Hurler Syndrome and Scheie Syndrome

Hurler syndrome (type IH MPS) is synonymous with gargoylism, dysostosis multiplex, or lipochondrodystrophy. Scheie syndrome (type IS MPS, formerly type V) is a relatively milder variant of Hurler syndrome. There is also an intermediate form—Hurler-Scheie compound (type I H/S MPS). Recessive mutations are responsible for these disorders, and they rarely occur. The incidence of type IH MPS is estimated to be 1:100,000, type I H/S MPS to be 1:112,000 to 1:500,000, and type IS MPS to be 1:500,000 (35 ,40 ,77 ,133).

Etiology

Hurler and Scheie syndromes are caused by an enzyme deficiency in the same enzyme, *α*-L-iduronidase, required to degrade both heparin sulfate and dermatan sulfate (9 ,10 ,110 ,129 ,144). The degree of enzyme deficiency varies, resulting in the three forms of the disorder.

Clinical Features and Pathologic Anatomy

Hurler syndrome is characterized by short stature, severe and progressive mental deterioration, and grotesque facies with protruding eyes, thick jaws, and a large tongue. The joints are stiff and cannot be fully extended. A thoracolumbar kyphotic deformity is common because the vertebral bodies are small (76). Mild scoliosis also can occur (129). Children often have recurrent upper respiratory infections. Corneal clouding is present, as are hepatomegaly and splenomegaly. Cardiomegaly also may be present. There is a normal appearance at birth (32). The bone changes of dysostosis multiplex (multiple radiographic skeletal abnormalities) begin by 6 months of age among infants with Hurler syndrome, 1 to 2 years among children with Hurler-Scheie syndrome, and 7 to 10 years among children with Scheie syndrome.

The skeletal changes of Hurler syndrome include severe dysostosis multiplex with gibbus deformity. In Hurler-Scheie syndrome, mild to moderate dysostosis multiplex occurs with no gibbus deformity. In Scheie syndrome, there are mild dysostosis multiplex and no gibbus deformity. Hurler syndrome appears to be associated with an increased incidence of hypoplasia of the odontoid process and the presence of abnormal, excess soft tissue adjacent to the odontoid process (132 ,136).

TABLE 1. Sites of Specific Enzymatic Defects in Glycosaminoglycan Catabolism in Mucopolysaccharidosis Involving Heparan Sulfate and Dermatan Sulfate

There is a high incidence of airway problems in association with Hurler syndrome. Factors that contribute to airway problems include thickening of the soft tissues of the oropharynx, narrow nasal airway, narrow trachea, short neck and trunk, kyphoscoliosis, and hepatomegaly. Careful preoperative assessment by an experienced anesthesiologist helps to minimize the potential for airway complications (7 ,102 ,106 ,112 ,143).

The ultimate height in types IH and IH/S MPS is short, but height is normal in type IS MPS. Intelligence is normal in type IS MPS and normal to mildly retarded in MPS IH/S. Fibroblast studies demonstrate deficiency of α-iduronidase activity in all forms of type I MPS (37 ,129).

Radiographic Features and Findings of Other Imaging Studies

The chief radiographic features relating to the spine are hook-shaped vertebrae on the anterior surface; small vertebral bodies, especially at the thoracolumbar region; and thoracolumbar gibbus (23) (Figs. 2 , 3). The beaking defect is seen at T12-L2, and the greatest defect is superior and anterior. When C1–2 subluxation occurs, failure of development or hypoplasia of the dens is best seen on lateral radiographs of the cervical spine (25 ,145).

Calcification of the stylohyoid ligament is frequent among children with Hurler syndrome (150). The ligament is normally calcified to some extent in approximately 25% of all children. When calcification occurs among healthy children, the ossification pattern is a relatively thin configuration. Calcification is a helpful sign in the radiographic examination of children believed to have MPS, but it does not have an appreciable clinical effect (92).

TABLE 2. Characteristics of Mucopolysaccharidosis

Mucopoly-saccharidosis	Eponym Mucopoly-sacchariduria Abnormality	Enzyme Defect	Inheritance	Chromosomal	Location	Life Expectancy (y)	Intelligence	Spinal

Treatment

Primary therapy for Hurler syndrome is bone marrow transplantation. The greatest benefit is gained when transplantation is performed early (34 ,93 ,147).

Course of Disease

The course of type IH MPS is rapid progression to death before 10 years of age. In type IH/S MPS, there is intermediate progression of disease. Slow progression occurs in type IS MPS (129).

Hunter Syndrome

Type II MPS, or Hunter syndrome, is another form of dysostosis multiplex in which the characteristic skeletal changes develop more slowly than they do in type IH MPS, but they can become severe in adolescence (39 ,122). Hunter syndrome appears to have a wide spectrum of clinical manifestations (82 ,138). Three forms of Hunter syndrome are generally recognized: type IIAXR MPS, the severe form; type IIBXR MPS, the mild form; and type IIAR MPS, the autosomal recessive form.

Epidemiology and Etiology

Hunter syndrome is rare. One estimate is an incidence of 0.66 cases per 100,000 births (82). This is the only sex-linked recessive lysosomal storage disease. All reported patients have been boys (39 ,51 ,91 ,142). Hunter syndrome is caused by a deficiency of L-iduronate sulfatase. Persons with this syndrome store large amounts of sulfated acidic glycosaminoglycans (dermatan sulfate and heparan sulfate) in the tissues and excrete them in urine. Inheritance of all the other known MPS syndromes is autosomal recessive.

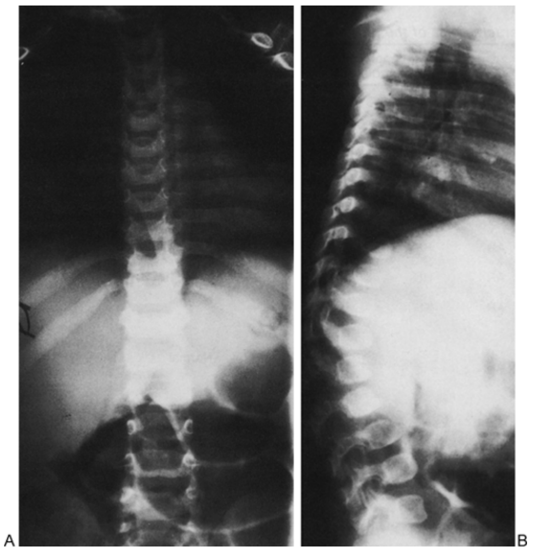

FIGURE 2. A: Hurler-Scheie syndrome. **B:** Hurler-Scheie syndrome with mild thoracolumbar kyphosis and minimal dysplastic changes.

Clinical Features and Pathologic Anatomy

The clinical phenotype in type II MPS is less severe than in Hurler syndrome (39). Life span is longer, and mental deficiency is not as severe. The mild and severe phenotypes have been reported to occur within the same set of siblings (148). Extensive multisystem involvement occurs, including papilledema, upper airway obstruction, and degenerative changes at the hip (39). Cervical stenosis caused by dural thickening and cervical kyphosis have been reported. A case has been reported of isolated neurogenic bladder as the only initial symptom of cervical stenosis (65 ,103 ,141).

Radiographic Features and Findings of Other Imaging Studies

The skeletal changes of dysostosis multiplex are similar to those of Hurler syndrome, but the findings are less severe and develop more slowly (Fig. 4). The skeletal changes may become severe among adolescents. Thoracolumbar kyphosis occurs with development and is associated with a hooklike deformity of the upper lumbar vertebrae on the anterior surface. This may occur among patients as young as 2 years (133). Ventriculomegaly, atrophy of the brain, cystic lesions within the brain stem, periodontoid soft-tissue thickening, and disc dehydration in association with platyspondylisis all have been found at magnetic resonance imaging (MRI) of the brain and spinal cord (Fig. 5) (98 ,103).

Course of Disease

The life span of patients with Hunter syndrome is longer than that of patients with Hurler syndrome (39). One long-term report discussed the findings for a 31-year-old man. Although he had no signs or symptoms of spine-related problems, life-threatening complications, including laryngeal edema and tracheal narrowing, did occur. The patient also had recurrent episodes of chest infection and painful degenerative arthritis in both hips (149). Treatment options are limited, but there have been reports of successful bone marrow transplantation that eased some of the clinical manifestations of Hunter syndrome (17).

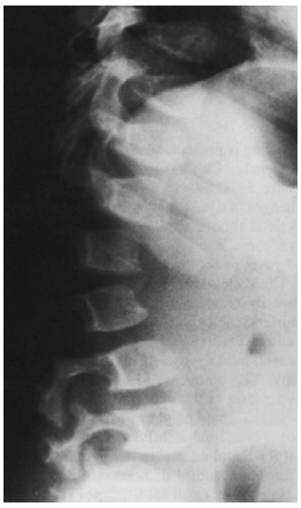

FIGURE 3. Hurler-Scheie syndrome with mild thoracolumbar kyphosis. The hook shape of the anterior surface of the vertebrae is evident.

Sanfilippo Syndrome

Sanfilippo syndrome (type III MPS with subtypes A, B, C, and D) is a lysosomal storage disease characterized by mental retardation and relatively mild somatic involvement.

Epidemiology and Etiology

It is generally agreed that Sanfilippo syndrome is the most common form of MPS, which is rare in all its forms (3 ,120 ,139). A series in the Netherlands had 75 patients, for an incidence of 1:24,000 (139). The enzyme deficiencies of Sanfilippo syndrome are divided into four biochemical types, designated as types A, B, C, and D. The inactive enzymes are 2-deoxyglucoside-2-sulfamate sulfatase in type A; *a*-*N*-acetylglucosaminidase in type B; acetyl-coenzyme:*a*-glucosaminide *N*-acetyl-transferase in type C; and *N*-acetylglucosamine-6-sulfate sulfatase in type D (31 ,56). All diseases are transmitted in an autosomal recessive mode. The enzyme deficiencies impair heparan sulfate metabolism, and this glycosaminoglycan accumulates in many different tissues and organs. Large amounts of heparan sulfate are detected in the urine of patients with Sanfilippo syndrome (31).

Clinical Features and Pathologic Anatomy

Mental retardation with relatively mild somatic involvement characterizes Sanfilippo syndrome. In general, early development is normal but is followed by progressive, severe deterioration. These children are not strikingly dwarfed, the corneas are not clouded, and joint stiffness is mild (46). Changes of dysostosis multiplex are minimal, and the skeleton may be normal. The enzyme activity in fibroblasts may not be a true reflection of the in vivo activity in the liver, brain, skin, and other tissues. Variability in enzyme activity from organ to organ may explain the differences in progression (56).

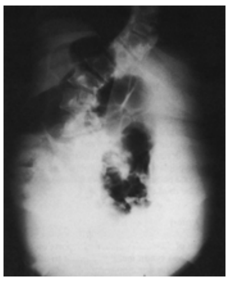

FIGURE 4. Hunter syndrome with less severe findings of dysostosis multiplex. Scoliosis is severe.

Orthopedic problems, including severe kyphoscoliosis, have been reported in a follow-up study of adult patients with MPS III B (107).

Radiographic Features and Findings of Other Imaging Studies

Radiographs show minimal changes of dysostosis multiplex. Results of the skeletal radiographic evaluation may be nearly normal. Thickening of the calvaria occurs. Irregular configuration of the lumbar vertebral bodies and occasionally T11 or T12, including an ovoid shape on the lateral projection in the thoracic and lumbar areas, is reported (31 ,68). This mild radiographic abnormality has not been associated with gibbus deformity (36). One of the involved vertebrae may be hypoplastic or retroplaced (68). The transverse process may be hypoplastic. One patient in a long-term follow-up study was found to have severe kyphoscoliosis (140). The ribs may be thickened.

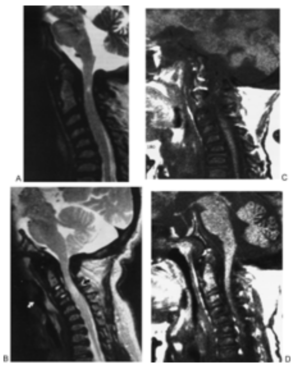

FIGURE 5. **A:** Midline sagittal image of retroodontoid soft tissue leading to cord compression shows high signal changes in the cord and a giant cisterna magna. **B:** Sagittal image shows high signal changes in the cord (*black arrow*), upper airway narrowing (*white arrow*), and platyspondylysis. **C:** Parasagittal image shows the low signal cystic areas in the thalamus. **D:** Sagittal image shows abnormal ossification of the odontoid peg with thickening of the parapharyngeal soft tissues. (From Parsons VJ, Hughes DG, Wraith JE (1996): Magnetic resonance imaging of the brain, neck, and cervical spine in mild Hunter syndrome (mucopolysaccharidosis type II). *Clin Radiol* 51:719–723, with permission.)

Course of Disease

Because of the small number of reports of children with Sanfilippo syndrome, it is difficult to make a specific prognosis for duration and quality of life (59). The onset of detectable abnormalities occurs in early childhood. Mental deterioration begins by school age and becomes severe in the teens. Survival past the age of 40 years has been reported among persons with mild Sanfilippo B disease. All patients in that report had severe mentally retardation, as is usually the case. One had severe uncontrolled kyphoscoliosis (59 ,140).

Morquio Syndrome

Morquio syndrome, or type IV MPS, is synonymous with Morquio-Brailsford disease, Morquio-Ullrich disease, chondroosteodystrophy, osteochondrodystrophy deformans, and eccentro chondroplasia (48 ,54 ,95). It is an autosomal recessive lysosomal storage disorder characterized by short-trunk dwarfism and dysostosis multiplex with universal platyspondyly, normal intelligence, and excessive urinary excretion of keratan sulfate (14 ,48 ,66 ,78 ,109 ,150). Clinical heterogeneity of the condition is known (90).

Epidemiology and Etiology

Morquio syndrome is rare. Of the 80 cases reported in a literature review in 1964, approximately 41 represented Morquio disease and 39 another condition. An incidence of 1:100,000 births was estimated by Eggli and Dorst (40). This specific mucopolysaccharide storage disease is caused by a deficiency of the enzyme *N*-acetylgalactosamine-6-sulfate sulfatase (8 ,79 ,113). This deficiency has been designated type IVA MPS, and a ß-galactosidase deficiency is designated type IVB MPS (113). The metabolic lesion responsible for this disease is not uniformly expressed in all cell types; thus it appears to be a cell-type-limited mucopolysaccharide storage disease, with excessive mucopolysaccharide accumulation in specific tissues. Whether tissue specificity is caused by unique tissue distribution of the deficient enzymes, unique tissue distribution of mucopolysaccharide substrates, or other factors is unknown (48).

Clinical Features and Pathologic Anatomy

Morquio syndrome is characterized by short-trunk dwarfism, corneal opacities, dental abnormalities, cardiopulmonary complications, normal intelligence, and dysostosis multiplex with universal platyspondylisis, increased thoracic kyphosis, knock knees, lumbar lordosis, and pectus carinatum (43 ,90 ,111). Cord compression caused by odontoid dysplasia and thickened retrodental soft tissue is well established in this syndrome (33 ,79). Excessive urinary excretion of keratan sulfate occurs in type IVA MPS, but type IVB MPS is a non–keratan sulfate–excreting form (48 ,89).

Abnormalities are not suspected until after the child begins to walk. Acute traumatic quadriparesis, chronic myelopathy of variable rate, and sudden death due to respiratory arrest have been associated with dysplasia caused by abnormal ossification or complete absence of the odontoid process and the inevitable development of atlantoaxial instability (21 ,33 ,79). Ligamentous laxity also plays an important role in the development of C1–2 instability (33). The incidence of cord compression in Morquio syndrome is such that investigators have recommended prophylactic elective posterior cervical fusion in all patients (21 ,41 ,69 ,79).

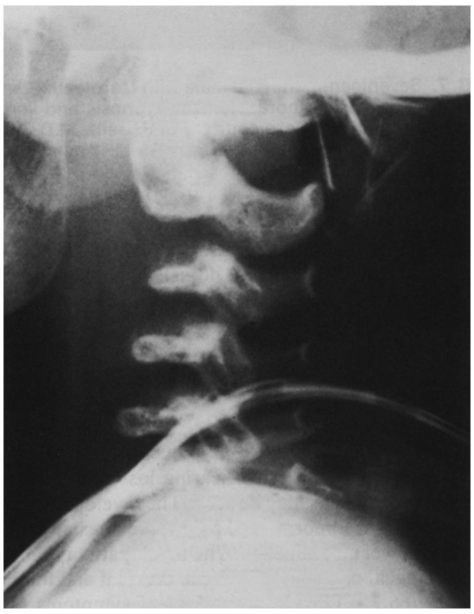

FIGURE 6. Morquio syndrome with C1–2 subluxation after posterior C1–2 fusion with autologous (only) iliac bone graft and halo application.

In a review of 11 selected patients, 6 had neurologic signs and symptoms, and 5 had quadriparesis. The age at onset of the neurologic symptoms ranged from 19 months to 35 years (79). Acute onset of quadriplegia has been reported to occur after atlantoaxial subluxation during general anesthesia (15 ,62). In addition to subluxation of C1 on C2 in 10 patients, there were abnormally small canals at these vertebral levels (range, 10 to 15 mm) (79).

Radiographic Features and Results of Other Imaging Studies

The dysostosis multiplex is generalized and severe. Universal platyspondylisis is evident. Smallness or disappearance of the odontoid process causes atlantoaxial subluxation and narrowing of the spinal canal at this level (15 ,21 ,79 ,133) (Fig. 6). The margins of the vertebral bodies are irregular. The thoracic vertebrae are oval in infancy; older children have an anterior tongue from the center of the vertebral body (Fig. 7). The vertebrae are flat and rectangular in adults. Hyperlordosis and kyphoscoliosis have been found in long-term follow-up studies. In Morquio syndrome B, the radiographic skeletal abnormalities are similar to those of Morquio syndrome A but are of a milder nature (133).

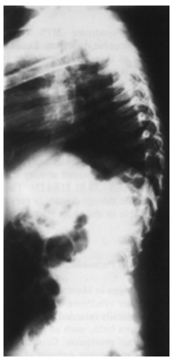

FIGURE 7. Morquio syndrome with severe dysostosis. Anterior tongue from the center of the vertebrae is evident.

Radiographs of the cervical spine should be obtained by the age of 2 years. Patients with symptoms need posterior fusion. For patients who do not have symptoms, the space available for the cord (more than 13 mm observed, less than 13 mm at MRI) can be assessed in flexion and extension to determine whether spinal cord changes are present. When cord changes are evident, posterior spinal fusion should be undertaken (86 ,107).

Course of Disease

Survival to 67 years of age has been reported. The patient had short-trunk dwarfism, clear corneas at gross examination, scoliosis, and genu valgum. The vertebrae were markedly flattened and osteoporotic. The patient died of unexplained episodic apnea. Postmortem examination showed abnormalities of cartilaginous structures, such as the laryngeal cartilage, sternum, and thoracic vertebrae.

Maroteaux-Lamy Syndrome

Maroteaux-Lamy syndrome (type VI MPS) is synonymous with polydystrophic dwarfism. Skeletal changes may be as severe as those of Hurler syndrome. Mental deficiency does not occur.

Epidemiology and Etiology

Type VI MPS is a cytosomal storage disorder transmitted through autosomal recessive inheritance. It is associated with decreased lysosomal enzymatic activity of arylsulfatase B and increased urinary excretion of dermatan sulfate (19 ,82 ,124 ,130). This form of mucopolysaccharide storage disease is very rare. Few reports are available to define the frequency of occurrence (133). Three forms based on the severity of symptoms have been recognized: infantile, most severe; juvenile, intermediate; and adult, mildest (52).

Clinical Features and Pathologic Anatomy

The skeletal changes of Maroteaux-Lamy syndrome rival those of Hurler syndrome in severity. Children with Maroteaux-Lamy syndrome, however, do not have mentally retardation, and certain physical signs are present from birth, such as prominence of the forehead and sternal protrusion. Growth may be normal to 4 years of age but may cease entirely at 8 years. Hurler-like changes include dysostosis, corneal opacities, and hepatosplenomegaly (130). The bony abnormalities are variable (Fig. 8). The two conditions (type VI MPS and type IH MPS) can be differentiated at radiographic examination. Mucopolysacchariduria occurs with a preponderance of dermatan sulfate (chondroitin sulfate B), and there are abnormal granulations in leukocytes. Cervical and lumbar radiculopathy and cervical myelopathy have been reported (104). Hypoplasia of the odontoid process is associated with cervical myelopathy and narrowing of the spinal canal. Lumbosacral radiculopathy has been associated with spinal stenosis due to dural thickening (104 ,117).

Radiographic Features and Findings of Other Imaging Studies

The radiographic skeletal changes can be variable in severity and extent. The vertebral bodies are oval or bullet shaped. Kyphosis be present at the lower thoracic or upper lumbar region. A wedge-shaped vertebra may be present at the center of the kyphosis, and there may be posterior displacement. The ribs may be paddle shaped. Narrowing of the cervical spinal canal has been reported to be caused by concentric impingement on the subarachnoid space. Cord compression can be caused by dural thickening in the cervical region, narrowing of the subarachnoid space in the occipitocervical junction, dysplastic arch of C1 protruding dorsally into the foramen magnum, and displacement of the cervical cord (117 ,133).

Course of Disease

Neurologic deterioration may occur in the form of optic atrophy, progressive hearing loss, or myelopathy. Hydrocephalus may be present. The myelopathy may manifest as gait abnormality, pain, paresthesia, or urinary or bowel incontinence. The myelopathy is caused by meningeal changes in both the cervical and lumbar regions (117 ,133). Symptoms may improvement after bone marrow transplantation (67 ,133). Patients may survive into late childhood or even into adulthood. Persons with milder forms of the disease have survived to their forties (10 ,124).

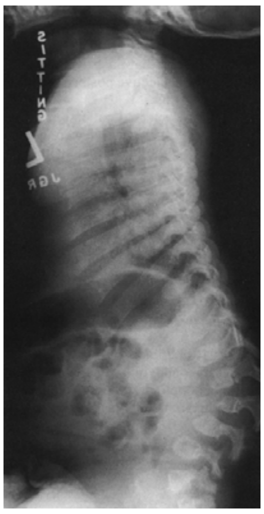

FIGURE 8. Seventeen-month-old boy with Maroteaux-Lamy syndrome. Thoracolumbar kyphosis and vertebral body changes are evident. (Courtesy of F. Deitz, MD.)

Sly Syndrome

Sly syndrome (type VII MPS) is a severe form of dysostosis multiplex.

Epidemiology and Etiology

Sly syndrome is rare. By 1985, only 17 cases had been reported in the literature (71). It is caused by accumulation of chondroitin-4-sulfate and chondroitin-6-sulfate from a deficiency of lysosomal β-glucuronidase activity (114 ,115). Both the clinical and biochemical manifestations can vary, a deficiency of β-glucuronidase being the only consistent finding. The mode of inheritance is autosomal recessive.

Clinical Features and Pathologic Anatomy

The clinical features of Sly syndrome include short stature, hepatosplenomegaly, progressive skeletal deformities of the thorax and spine, granular leukocytic inclusions, frequent pulmonary infections, and developmental delay (115). Thoracolumbar kyphosis or kyphoscoliosis is common. This disorder occurs among patients whose only clinical finding is kyphosis or scoliosis (71). Laboratory findings include mucopolysacchariduria and the absence of β-glucuronidase in leukocytes and cultured skin fibroblasts.

Atlantoaxial instability has been reported, but in this case report, it may have been a posttraumatic finding (105). The patient died 3 months after cervical fusion, at home in his sleep with no foreshadowing signs or symptoms. For patients with Sly syndrome, detailed preoperative evaluation is recommended, including assessment for cervical instability, chronic hypoventilation, and upper respiratory infections.

Radiographic Features and Findings of Other Imaging Studies

Various degrees of dysostosis multiplex with considerable phenotypic variation occur with Sly syndrome. Platyspondyly is present and is associated with vertebral beaking. Thoracolumbar kyphosis and kyphoscoliosis have been reported (29 ,40 ,49 ,133). The odontoid process is dysplastic (115), and atlantoaxial instability may occur.

Course of Disease

The onset of symptoms is in early infancy and childhood. Severe thoracolumbar kyphosis or kyphoscoliosis may develop. Death in early childhood occurs in the severe form (133).

Diferrante Syndrome

DiFerrante syndrome (type VIII MPS) is the last of the identifiable and classified disorders of mucopolysaccharide metabolism. The deficient enzyme is glucosamine-6-sulfate sulfatase. Because of the rarity of this syndrome, it is not discussed herein.

Mucolipidosis

In 1975, Spranger (120) and others found that other conditions had combined features of MPS and sphingolipidosis and had be classified separately. To delineate these intermediate conditions, the term *mucolipidosis* was coined. The term is a misnomer in the biochemical sense, however. First, a mucolipid is not a known chemical compound; second, in many forms of mucolipidosis, there is no true storage of either mucopolysaccharides or lipids. Children with so-called mucolipidosis excrete excessive amounts of oligosaccharides in the urine (73). The term *oligosaccharidosis* may therefore be more appropriate, but the term *mucolipidosis* remains. Clinically and radiographically, the mucolipidosis resembles the MPS syndromes, but urinary mucopolysaccharide levels are normal. The spectrum of severity in the various forms of mucolipidosis is even wider than in MPS. The severity of dysostosis multiplex is surprisingly variable.

Epidemiology and Etiology

These Hurler variant syndromes are rare. From 1 to approximately 20 cases had been described for each specific enzyme defect, according to the report by Spranger and Wiedemann in 1970 (127). Mucolipidosis is an inherited metabolic disease characterized by accumulation of excessive amounts of mucopolysaccharides and sphingolipids in visceral and mesenchymal cells. The differentiating features of the forms of mucolipidosis, including the enzyme defect and the major storage substance, are as follows.

Mucolipidosis I is a neurodegenerative disorder in which neuraminidase deficiency is the only defect that has been demonstrated (128). Spranger (120) described mucolipidosis I as a nosologic entity that combines clinical and radiographic features of MPS with signs of a neurodegenerative process that affects gray and white matter. To establish the diagnosis, in addition to thin-layer chromatography, urine and fibroblast sialic acid measurements are needed (128).

Mucolipidosis II is an autosomal recessive Hurler-like disorder caused by deficiency of the lysosomal hydrolase glycoprotein *N*-acetylglucosaminylphosphotransferase. This deficiency occurs in cultured skin fibroblasts (97).

Mucolipidosis III is an autosomal recessive inherited disorder, closely related to mucolipidosis II. The specific enzyme deficiency has not been clearly established.

Mucolipidosis IV is a recessively inherited lysosomal disease found in relatively high frequency among Ashkenazi Jews (2 ,6). The definitive diagnosis is made by means of electron microscopic examination, which reveals storage organelles typical of mucolipidosis (2).

Clinical Features and Pathologic Anatomy

Biochemically mucolipidosis is a lysosomal storage disease with multiple primary defects of lipid, mucopolysaccharide, and glycoprotein metabolism in various combinations (127 ,137). Noteworthy is the thoracolumbar scoliosis or kyphosis of mucolipidosis I. Thoracolumbar kyphosis occurs in I-cell disease (mucolipidosis II), along with calcification of the intervertebral discs (5 ,87). Clinically, mucolipidosis resembles the MPS syndromes. Urine mucopolysaccharide levels are normal, however. The spectrum of severity of mucolipidosis is even wider than that of the MPS syndromes.

In mucolipidosis I, the major manifestations are coarse facies, cloudy cornea, hepatosplenomegaly, joint limitation, developmental delay, and dysostosis multiplex (18). Kyphosis is a common finding (42). Mucolipidosis I should be included in the differential diagnosis of disorders that display a Hurler syndrome–like phenotype in infancy (58).

In I-cell disease (mucolipidosis II), the skeletal findings are so severe that they resemble those of Hurler syndrome (20 ,72 ,99 ,100 ,131). Atlantoaxial subluxation and cervical myelopathy following minor injuries have been reported. A cartilaginous, noncalcified composition of the odontoid process may contribute to the instability (44). Calcification of the intervertebral disc occurs in I-cell disease and presumably is related to the excessive cartilage degeneration that takes place in this disorder (87). There have been no reports of morbidity associated with this finding. A developmental thoracolumbar gibbus similar to that of Hurler syndrome is common.

Mucolipidosis III, or pseudo-Hurler polydystrophy, is closely related to mucolipidosis II, but onset of signs occurs somewhat later. It is characterized by growth retardation, severe dysostosis multiplex, joint stiffness, tight indurated skin, swollen eyelids, late-onset hepatosplenomegaly, corneal opacities, and only slight impairment of mental and neurologic development (47). Thoracolumbar kyphosis is a common finding.

The clinical manifestations of mucolipidosis IV include profound psychomotor retardation and visual impairment in the first year of life. In type I or generalized gangliosidosis, the dysostosis may be identical to that of Hurler syndrome. The dysostosis multiplex is milder in most of the other types of mucolipidosis, such as type II gangliosidosis, fucosidosis, mannosidosis, juvenile sulfatidosis (Austin type), Farber disease, and mucolipidosis I.

Radiographic Features and Findings of Other Imaging Studies

Mucolipidosis I is a neurodegenerative disorder similar in clinical presentation to Hurler syndrome in infancy. Thoracolumbar gibbus may manifest in late infancy, and mild to moderate thoracolumbar kyphoscoliosis may be seen in early childhood (42 ,58 ,123 ,128). In mucolipidosis II (I-cell disease), radiographic features include ovoid vertebral bodies, narrowing of the interpediculate distance in the lower thoracic vertebrae, and intervertebral disc calcification (87) (Fig. 9). In early childhood, the thoracolumbar vertebrae have a short anteroposterior diameter, there is inferior beaking of the vertebral bodies at T12 through L3, and the occurrence of thoracolumbar kyphosis and scoliosis is variable (13 ,64 ,74 ,97 ,133 ,134 ,146).

In mucolipidosis III (pseudo-Hurler polydystrophy), radiographic changes are similar to the dysostosis changes of the Hurler and Hunter syndromes. In the spine, these include beaking of upper lumbar vertebrae with mild thoracolumbar kyphosis, varying degrees of platyspondylisis, and absence of hypoplasia of the dens (4 ,47 ,60 ,61 ,85 ,94 ,145). Mucolipidosis IV is characterized by psychomotor retardation and ophthalmologic abnormalities but not by skeletal deformities (2).

Course of Disease

Patients with mucolipidosis I have a variable course of progressive neurologic deterioration. Cardiomegaly and hepatomegaly may predominate and contribute to early death. Although kyphosis is known to occur, serious morbidity related to the deformity of developmental thoracolumbar kyphosis or kyphoscoliosis has not been reported (58).

Children with I-cell disease (mucolipidosis II) have extreme psychomotor delay and failure to thrive. Death has been reported to occur as early as 2 weeks of age and as late as 8 years (74 ,146). Significant morbidity relating to C1–2 instability has been reported

(44), but serious morbidity associated with the thoracolumbar gibbus has not. The latter has not been studied with advanced imaging studies such as MRI. The use of MRI as a noninvasive diagnostic tool may lead to more specific treatment recommendations.

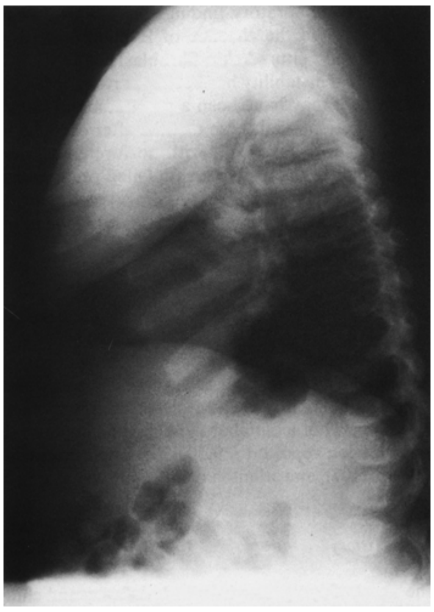

FIGURE 9. I-cell disease with mild thoracolumbar kyphosis. The vertebrae are ovoid.

The course of mucolipidosis III has been described in one of a pair of dizygotic twin girls. The odontoid process was short in the affected child, but no neurologic deficits occurred. Growth deficiency and moderate mental deficiency did occur. When the girl was 10 years of age, the chronic course of the disease continued (75).

The course of mucolipidosis IV among 20 patients between the ages of 2 and 17 years has been described (2). The highest developmental level was 12 to 15 months in language and motor function. The disease may be slow and protracted, however, with little deterioration despite the infantile onset (2). Substantial musculoskeletal involvement has not been reported.

Homocystinuria

Homocystinuria is an autosomal recessive disease caused by an inborn error of methionine metabolism. In its most common form, homocystinuria is caused by a deficiency of cystathionine ß-synthase activity (22 ,26). In classic homocystinuria, methionine and homocysteine accumulate in tissues and blood and are excreted in large amounts in the urine; cysteine levels are low. The clinical signs and symptoms are heterogeneous (12 ,22).

Epidemiology and Etiology

The incidence of homocystinuria has been estimated to be about 1:24,000 to 1:200,000 (22 ,135). The cause of homocystinuria in its most common form is clearly defined as an inborn error of methionine metabolism due to a deficiency of cystathionine ß-synthase activity. This enzyme sulfurates homocysteine—the metabolite of the essential amino acid methionine—to cystathionine, which is converted to cysteine. Homocystinuria as an end pathway is a feature in two other extremely rare inherited metabolic defects—Imerslund-Grasbeck syndrome and a deficiency of 5-methyltetrahydrofolate-homocysteine methyltransferase (22 ,88). In defects of amino acid metabolism, it appears to rank second in frequency to phenylketonuria. The causative gene is located on chromosome 5p15.2–15.3.17 (70).

Clinical Features and Pathologic Anatomy

The most frequent clinical signs of homocystinuria are dislocated lens (ectopia lentis), premature arteriosclerosis and serious thromboembolic complications, osteoporosis, scoliosis and kyphoscoliosis, arachnodactyly, pectus excavatum or carinatum, mental retardation, and neurologic and psychiatric disorders.

The clinical resemblance of homocystinuria to Marfan syndrome often leads to misdiagnosis. Although the two diseases are similar, differences have emerged. Florid arachnodactyly and scoliosis are more common in Marfan syndrome. Patients with homocystinuria have osteoporosis at a young age and a high incidence of vertebral involvement, including biconcavity and flattening. The osteoporosis associated with homocystinuria is caused by a dearth cross-links in type I collagen (80). Patients with Marfan syndrome do not have osteoporosis and may have excessively tall vertebrae. Mental retardation and thrombosis are common in homocystinuria but not in Marfan syndrome (22 ,24). The therapeutic relevance of misdiagnosis is that the patient with homocystinuria is deprived of treatment with pyridoxine, folic acid, and methionine restriction, which has a favorable clinical effect in most instances (22).

Children with homocystinuria are considered to be healthy at birth. Motor and speech development may be slow by 1 year of age. Gait may be clumsy or awkward, and a regression in motor and speech skills may occur. With growth, the extremities appear long but not well muscled. The characteristic facial feature is malar flush. The hair is thin and often slightly curled and blond or light brown (12 ,28).

The most life-threatening components of the disease are venous and arterial thrombosis. Early death of myocardial infarction, pulmonary embolism, mesenteric thrombosis, and cerebral vascular accident has been reported. Venous thrombosis has occurred frequently enough after surgery or illness that a surgeon may be reluctant to perform an elective surgical procedure (12 ,27 ,63).

The skeletal manifestations of homocystinuria include long thin extremities, scoliosis, chest deformity, genu valgum, cubitus valgus, and cavus or flat feet. Pectus carinatum or excavatum may be present in the absence of scoliosis. The most common pattern of scoliosis are right thoracic and left lumbar, the left lumbar curve being greater. Osteoporosis also usually occurs (12).

Radiographic Features and Findings of Other Imaging Studies

Marked generalized osteoporosis is the radiographic feature that differentiates homocystinuria from Marfan syndrome. There are no characteristic radiographic abnormalities at birth (116). Other radiographic features described include coxa valga, slender and possibly bowed bones, biconcave (codfish) vertebrae, scoliosis and kyphoscoliosis, retarded bone age, hyperaeration of the sinuses, and enlarged carpal bones (12 ,81 ,82) (Fig. 10).

Course of Disease

More than one third of patients with homocystinuria have skeletal deformities. Of 26 patients in one series, 14 died of arterial or venous thrombosis (135). Survival rate appears to be highly variable and related to the absence of major complications such as thrombosis.

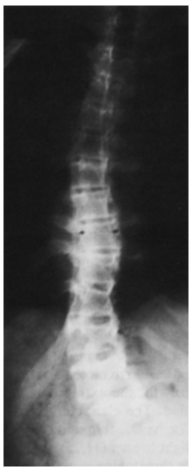

FIGURE 10. Spinal radiographs of an 18-year-old man with homocystinuria, moderate scoliosis, and osteoporosis.

Treatment Recommendations for Patients with Mucopolysaccharidosis and Mucolipidosis

Nonsurgical

Enzyme replacement therapy is not yet available as a primary therapy for the enzyme deficiencies in these lysosomal storage diseases. Therefore, all treatments are secondary and consist of management of the phenotypic expressions of the diseases. The effect of multiple transfusions on a patient with Hunter syndrome was studied. For this patient, who also had Cooley anemia, the usual clinical manifestations of Hunter syndrome were fully developed and did not appear to be ameliorated by the transfusions (11).

Bone marrow transplantation has been used to manage Maroteaux-Lamy syndrome (67). Full engraftment occurred, and arylsulfatase B activity, which was previously deficient, increased to normal levels in peripheral lymphocytes and granulocytes. Hepatosplenomegaly was substantially decreased, and cardiopulmonary function was normal. Bone marrow transplantation provided a source of enzymatically normal cells, which altered the metabolic and clinical course of the disease (67).

Subluxation of C1 on C2 occurs in Hurler syndrome (136) and in Morquio syndrome. This may or may not be associated with quadriparesis. Immobilization in traction is recommended until definitive posterior cervical fusion is performed with postoperative immobilization in a halo vest.

Atlantoaxial instability and myelopathy following minor injuries occur among children with I-cell disease (mucolipidosis II). It is reported that the atlantoaxial joint is unstable because the transverse ligament is incompetent and there is infiltration by storage cells. A cartilaginous rather than calcified composition of the odontoid process may contribute to the instability (44). Posterior cervical fusion with halo-vest immobilization is recommended for demonstrated or suspected instabilities. Temporary immobilization of the cervical spine is used until the operation is performed.

Dysplasia of the odontoid process and subsequent atlantoaxial instability with or without quadriparesis occur at such an alarming rate in Morquio syndrome that cervical fusion has been recommended for all patients with Morquio syndrome (79 ,119). Cervical cord signs become evident during the first two decades of life. Spinal cord compression has been documented in two patients with Morquio syndrome at the level of thoracolumbar kyphosis. In one, the patient had labored walking and corticospinal tract signs at 36 years of age. Myelographic findings confirmed cord compression at the level of the gibbus. The other patient also had onset of symptoms during the fourth decade of life (21). Preventive measures against the development of thoracolumbar kyphosis, such as the use of a thoracolumbosacral orthosis (TLSO) or cervical-TLSO, have been reported and are being used. The experience with prophylactic bracing is not extensive enough to allow conclusions regarding effectiveness.

Management of the thoracolumbar kyphosis associated with many of these disorders is not well studied or well documented. Whether the course of kyphosis can be modified or reversed is not known. It remains debatable whether bracing should be considered. On the one hand, there is little or no documentation of any neurologic deterioration, such as paraparesis or cauda equina syndrome, that may be associated with this deformity (except in Morquio syndrome). On the other hand, as the prospect improves for primary enzyme replacement therapy, prevention of progressive spinal deformity and neurologic deficit may become imperative. As long as immobilization in a custom TLSO does not impair pulmonary status and does not contribute to the development of atelectasis, pneumonia, or upper airway obstruction, it is reasonable to recommend bracing for management of thoracolumbar kyphosis associated with these diseases when the child begins an upright posture.

Surgical

Posterior cervical fusion is recommended for demonstrated atlantoaxial instabilities. Fusion of C1–2 is recommended for all patients with Morquio syndrome (21 ,41 ,69 ,79). The suggested technique is a posterior muscle-splitting midline procedure performed after application of a halo and the anterior portion of the vest. The halo-vest application allows for initial stabilization of the cervical spine after induction of anesthesia and appropriate airway management. Preoperative planning must include assessment for cord compression due to either displacement and relative fixation of C1 in relation to C2 or stenosis associated with dural abnormalities (107 ,117). If cord compression is found, stabilization and fusion alone may not resolve signs of cord compression. Adjunctive posterior decompression of C1 or C2 and possible durotomy and grafting of dural defects may be needed. When cervical fusion is performed for Morquio syndrome, bone for the graft is best obtained from the proximal tibial metaphysis, because the iliac crest is a poor source of graft bone in this disease (1).

Posterior spinal fusion, with or without anterior fusion and possible anterior decompression, is recommended for progressive thoracolumbar kyphosis. Few or no reports are available in the literature on the results of surgical management of this spinal deformity in these rare lysosomal storage disorders. It is recommended that in the event of cord or cauda equina compression, anterior decompression of the ventrally compressed cord be performed. Adequate decompression can be achieved by means of removal of the middle column portion of the involved vertebrae and discs with preservation of the anterior column.

Anterior discectomy and fusion of the kyphotic region and posterior fusion in situ of the kyphotic region with postoperative casting would appear appropriate for preadolescent, juvenile, and infant patients. The addition of instrumentation in the treatment of adolescents and adults is recommended, because there is no narrowing of anteroposterior diameter of the intraspinal canal. In the absence of substantial deformity, reduction should be judiciously evaluated.

Treatment Recommendations for Homocystinuria

Nonsurgical

Management of homocystinuria with pyridoxine, folic acid, and methionine restriction has a favorable biochemical response and clinical effect (22). Few reports are available on the nonoperative management of scoliosis and kyphoscoliosis in this rare disorder. Clinical indications used in the management of idiopathic scoliosis can be applied to the care of children with homocystinuria, scoliosis, and kyphoscoliosis.

Surgical

Life-threatening thromboembolic complications, including myocardial infarction, are associated with illness of and surgical procedures on patients with homocystinuria. Appropriate and in-depth consultation with a hematologist experienced in treating patients with this rare disorder is recommended before an operation is scheduled. Surgical plans and techniques used to manage idiopathic scoliosis can be applied to the care of patients with homocystinuria. The principles include posterior fusion with instrumentation, anterior fusion with instrumentation for thoracolumbar curves, and staged anterior spinal release or fusion and posterior fusion with instrumentation.

Section XI Neuromuscular Disease

44

Neuromuscular Spinal Deformities

John E. Lonstein

J.E. Lonstein: Department of Orthopedics, University of Minnesota, Twin Cities Spine Center, Minneapolis, Minnesota 55317.

This chapter reviews the general principles of neuromuscular spinal deformities as a basis for discussion of each etiologic subgroup.

Etiology

Neuromuscular spinal deformities form a diverse group of diseases and conditions that have involvement of the neuromuscular system in common (4 ,11 ,12 ,13) and share principles in course of disease, evaluation, and management. These deformities have been classified by the Scoliosis Research Society into neuropathic and myopathic conditions. The neuropathic conditions have been subdivided into upper and lower motor neuron lesions. The upper motor neuron group includes diseases such as cerebral palsy, syringomyelia, and spinal cord trauma; the lower motor neuron group includes poliomyelitis and spinal muscular atrophy. Certain conditions such as myelodysplasia and spinal trauma have both upper and lower motor neuron involvement. The myopathic conditions include arthrogryposis, Duchenne muscular dystrophy, and other forms of myopathy. The prevalence of spinal deformity in these conditions is much higher than that in idiopathic scoliosis, varying from 25% to 100% (Table 1). In general, the greater the neuromuscular involvement, the greater are the likelihood and severity of scoliosis.

Although the foregoing conditions vary greatly in causation, they share many features. Many are genetic in origin, and they all involve more than one systems, necessitating evaluation by a multidisciplinary team. Whereas idiopathic scoliosis is only a spinal deformity, patients with neuromuscular disorders have many possible attendant problems, such as contractures, dislocated hips, seizures, mental retardation, insensate skin, and pressure sores. Thus the evaluation of these patients cannot be confined to the spine alone; it must encompass all these areas.

At first glance, it may be easy to assume that scoliosis in these conditions is caused by muscle weakness. But this conclusion is difficult to support, because some conditions are accompanied by spasticity and others by flaccidity. No consistent pattern of scoliosis is associated with a particular pattern of weakness or side of weakness. Real understanding comes with an appreciation of spinal muscle control and control of spinal balance by the central pathways.

Curve Patterns

Because spinal surgeons typically see more cases of idiopathic scoliosis, and therefore base their principles of evaluation and treatment on that condition, the neuromuscular deformities need to be contrasted to idiopathic scoliosis. The curve patterns in idiopathic scoliosis are well recognized and constant, the thoracic deformity being lordoscoliosis. The curve patterns in neuromuscular conditions are varied; some resemble idiopathic scoliosis patterns, and others are long *C* curves that collapse into scoliosis or kyphosis. A common curve pattern is a thoracolumbar curve that extends to the pelvis, the sacrum being a part of the curve.

Kyphosis is important in neuromuscular deformities, and it has two possible causes. The kyphosis can be caused by true posterior angulation of the vertebrae, as in collapsing kyphosis or in myelodysplasia developmental kyphosis. The second cause of what appears clinically to be kyphosis is vertebral rotation—what Stagnara (15) called *kyphosing scoliosis.* Because of vertebral rotation at the apex of the curve, the deformity appears as posterior spinal angulation (kyphosis) rather than as lateral deformity (scoliosis). The apical vertebra, when rotated 90 degrees, continues to deviate laterally in relation to itself, but because of the rotation, this appears as kyphosis related to the torso as a whole.

Course of Disease

When considering the course of neuromuscular disease, there are two aspects to consider. The first is the course of the underlying disease: Is it progressive, as in Duchenne muscular dystrophy, or nonprogressive, as in cerebral palsy? The answer may affect decision making and definitely affects discussions with the family. Certain conditions are not progressive but cause progressive weakness with growth, such as spinal muscular atrophy. As the body or extremities grow, the weak muscles cannot control the increased length or weight of the body or extremity; thus the weakness “progresses” while the underlying disease is unchanged. The second aspect of the course of disease is progression of the spinal deformity. In neuromuscular spinal deformities, progression occurs much more frequently than in idiopathic scoliosis. In addition, progression often continues into adulthood.

TABLE 1. Prevalence of Spinal Deformities in Different Neuromuscular Diseases

Disease	Percentage
Cerebral palsy	25
Myelodysplasia	60
Spinal muscle atrophy	67
Friedreich ataxia	80
Duchenne muscular dystrophy	90
Traumatic paralysis (before 10 y of age)	100

The long-term effects of the spinal deformity in these neuromuscular conditions are more disabling to the patient than are those of idiopathic scoliosis. There is a loss of sitting ability with an accompanying loss of functional ability, especially loss of hand use. In addition, there is a marked effect on pulmonary function. In idiopathic scoliosis, the effect of a 70- or 80-degree curve on pulmonary function is minimal. In neuromuscular scoliosis, the effect of this curve added to the pulmonary compromise caused by weak intercostal muscles can be devastating.

Patient Evaluation

The evaluation of a patient with neuromuscular scoliosis involves more than assessment of the spinal deformity. Accurate diagnosis of the underlying disease entity is essential and often entails muscle biopsy. The patient and family should be counseled in every case. Counseling should include information about the inheritance and course of the disease and the spinal deformity.

A full family history should be obtained. The physical examination should cover the underlying disease, all aspects of involvement in all the systems, and the spinal deformity. Of special importance is assessment of nutrition and feeding and of pulmonary function. Regarding idiopathic scoliosis, all such information is obtained from the patient and family. Regarding neuromuscular problems, however, additional information is sought from the child's caregivers, attendants, teachers, and physical therapists. In no area is this information of more use than in an appreciation of the patient's functional level. How does the patient move around? Is assistance necessary? Does the patient use a wheelchair? What is the sitting ability? What is the hand use? Has this functional level changed? For example, has there been a loss of sitting ability, loss of hand use, increased weakness, or a change in respiratory function with increased frequency of pneumonia? In assessing a change in functional level, one must ascertain whether it is caused by increasing spinal deformity or progression of the underlying neuromuscular disease. Questions are asked to evaluate the growth pattern and, in the second decade, to determine whether the child is in the growth spurt.

The physical examination is divided into three areas: general patient evaluation, orthopaedic evaluation, and evaluation of the spinal deformity. The patient's overall size, height, weight, and nutritional status are documented. Signs of puberty, such as development of breasts and pubic hair are documented and graded according to the Tanner system (17). Members of the multidisciplinary team evaluate intelligence, hearing, and vision. The orthopedic examination includes assessment of all extremities and joints for contractures and an evaluation of hand function. If the patient can cooperate, the muscle strength of each muscle group is tested. The spinal deformity, decompensation, and shoulder balance are documented.

Ambulatory status is evaluated, and patients are classified as walkers, sitters, or nonsitters. Further subdivision is based on whether the activity (walking or sitting) depends on assistance. For sitters, the amount of help necessary to achieve a balanced upright posture is assessed. The flexibility of the scoliosis is evaluated clinically with a supine assessment and by means of passive side bending of the patient to judge the rigidity of each curve. Is there any pelvic obliquity? If there is obliquity, which side is high? Can the pelvis be leveled in the supine and sitting positions (10)?

The entire musculoskeletal system is evaluated for contractures and the range of motion of each joint (3). The status of the hips is important among these patients. There may be contractures or dislocation, or the hips may be windswept, which is adduction contracture of one side combined with an abduction contracture of the opposite side, the hip on the adducted side usually being dislocated or subluxed. Areas of pressure breakdown on the sacrum or greater trochanter must also be sought. Whenever possible, full muscle testing and an evaluation of sensation in the upper and lower extremities is performed.

A general medical evaluation is performed with emphasis on nutrition (7). This includes the nutritional history, feeding history, and a battery of blood tests when necessary to evaluate current nutritional status. These include hemoglobin, total lymphocyte count, red blood cell mean corpuscular volume, total protein, albumin, electrolytes, serum blood urea nitrogen, creatinine, and transferrin (18). Other areas of involvement are evaluated depending on the specific neuromuscular disease. These include, when necessary, hearing, vision, intelligence, communication, and hand function, as well as assessment of any seizures and their control.

Radiologic Evaluation

An accurate, consistent radiologic examination is essential. For very young patients and those who do not sit, a supine anteroposterior spinal radiograph is obtained. For all other patients, upright radiographs are obtained—standing for patients who can stand, sitting for the others. The posteroanterior position is used for those able to stand, and the anteroposterior position for sitters. All these upright radiographs are obtained with minimal support. Standing patients do not support themselves with crutches, and the sitters use no hand support. This gives an accurate appreciation of the true magnitude of the spinal deformity under the effect of gravity and of pelvic obliquity and spinal balance. Clinically spinal balance is the relation of the head and torso to the pelvis; radiographically, it is the relation of the torso to the pelvis and of the spinous process of C7 to the midsacral line—a vertical drawn from the middle of the sacrum (the spinous process of S1).

All curves are identified and measured. To evaluate the flexibility of the curves (either scoliosis or kyphosis), a traction radiograph is obtained. This can be done in the radiology department with manual distraction with a head halter and leg traction. This is not very effective if the patient has spasticity or hip flexion contracture, as in cerebral palsy. For these patients a better method is to obtain a traction radiograph on a Risser-Cotrel frame.

Treatment

The treatment options are the same as those for any spinal deformity—observation, nonoperative, and operative. The choice depends on the initial problem, such as curvature, loss of sitting or function, or pressure sores, and the child's age and maturity.

Observation

Observation plays an important role in the management of spinal deformities in neuromuscular diseases. Because of the high prevalence of spinal deformities, routine clinical or radiologic evaluation should be performed regularly. This means yearly examination in the multidisciplinary or neurology clinic with a spinal examination or radiography. When a curve is present, it is followed by the clinic, or the patient is referred for appropriate spinal care—continued observation or nonoperative or operative treatment.

Nonoperative Treatment

Nonoperative treatment of patients with neuromuscular spinal deformities is directed at two areas: seating and curve treatment. The curves of these patients are either postural—the spine collapses in the upright sitting or standing position because of a lack of muscle control—or structural in nature. Seating systems are used for patients who are unable to sit without support. For curve control, orthoses are used—either a Milwaukee brace or a thoracolumbosacral orthosis (TLSO).

Seating Support

If the patient is unable to walk, seating support is necessary. There are many choices, and the appropriate type of seating support depends on the patient's sitting balance. Sitting balance is evaluated by means of seating the patient on the side of the examining table to see whether he or she can sit unaided. When the patient cannot sit unaided, support is given in a progressive way until the patient can sit upright. First the pelvis is supported, then the lateral and anterior thorax, then the head. The seating support needed for each child is determined in this evaluation.

Firm Seat and Back

When minimal or no support is needed, a firm seat and firm back are adequate to supply a stable pelvis. This can be accomplished with the addition of a padded wooden or plastic seat and back to the wheelchair, or the sling seat and back can be pulled taut to supply the required support.

Upholstered Sitting Support

When pelvic support and some lateral thoracic support are needed, an upholstered sitting system is best (Fig. 1). This can be made of wood or molded thermoplastic. Gillette Children's Hospital developed a molded thermoplastic seating system that comes in a number of sizes. Upholstered pads can be added to hold the pelvis, and lateral thoracic supports can be used where necessary. A thoracic vest can be added if anterior support is needed. The advantage of this system is that it can be tailored to the individual support needs of the patient, and it can be adjusted for growth by varying the thickness of the lateral pelvic pads.

Molded Sitting Support

When more support is necessary because of the lack of sitting balance or the size of the patient, the Gillette sitting support orthosis has proved ideal (Fig. 2). This is a molded polypropylene shell made from a positive mold of the patient. It is a total-contact orthosis. Support is provided from the distal posterior thighs to the shoulders or occiput. This orthosis gives excellent pelvic and thoracic control, and because of the total-contact concept, skin problems are few. A thoracic vest is added to give anterior thoracic support; a head support is added when necessary.

When it is necessary to control the tendency of the head to flex, head control can be aided by means of reclining the entire seating system.

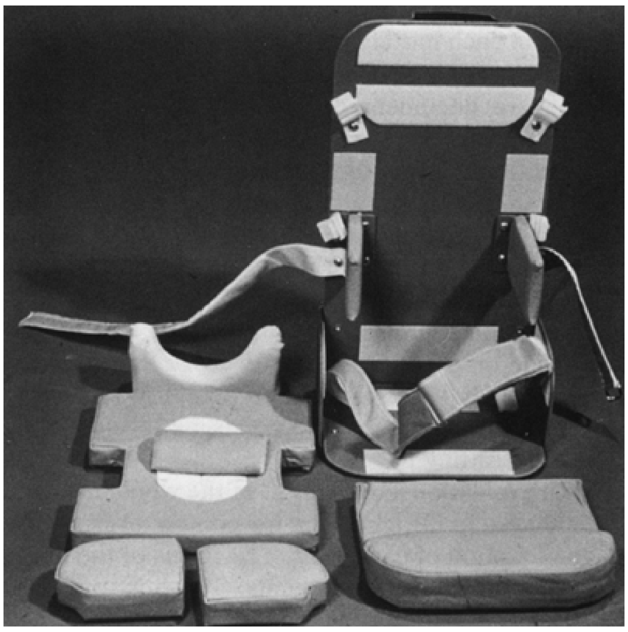

FIGURE 1. Upholstered sitting support orthosis consists of a molded plastic frame that has back, seat, and side support. There are covered foam inserts for the seat, back, and sides of the pelvis. The latter inserts can be made in varying thicknesses to accommodate the child's growth.

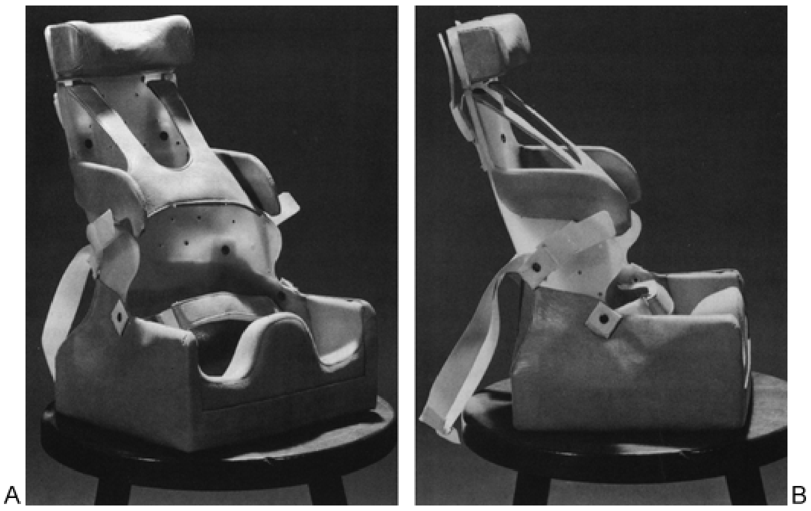

FIGURE 2. Gillette molded sitting support orthosis. The orthosis is made from a positive mold of the child. There is total contact from the back of the thighs to the head, with lateral pelvic and thoracic support. A lap belt and thoracic vest are added to keep the child positioned in the orthosis. The orthosis is shown in oblique front **(A)** and side **(B)** views. The orthosis is tilted back to aid in head control.

All these sitting systems have to support the pelvis and posterior thighs, the latter being essential to distribute the pressures in sitting. The feet have to be placed on footrests to prevent too much popliteal pressure. In all sitting supports, a lap belt is mandatory to hold the pelvis in the support and to prevent the pelvis from sliding forward. When these supports are placed in a wheelchair, they must be held there with a seat belt.

Commercial Sitting Supports

There are a variety of commercially available supports to aid these patients with sitting. For a very young or small child, a car seat can provide support. For these children, a system of plastic molded supports—Tumbleform seats—also is available. These seats come in a number of sizes and can support very flexible curves, but they place the child in a reclined position, which is not conducive to interaction on the child's level. A large number of commercial chairs (e.g., Mullholland, Orthokinetic) usually have some type of pelvic and thoracic support. These are effective for very flexible spines, but they do not work well for larger children or in cases of severe spasticity. It is essential to assess the effect of the support on the spine with radiographs. With the straps and supports in place, it is impossible to assess curve control clinically.

These sitting supports also help control the collapsing postural curve—scoliosis or kyphosis—by holding the patient in an upright, balanced posture. If a structural curve is present, the sitting support helps sitting balance without controlling the curve. When the child is small, it is easy to support the spine and control postural curves. With growth the spine becomes longer, the child becomes heavier, and the postural curves become more difficult—and at times impossible—to control.

Curve Control

In idiopathic scoliosis, the aim of bracing is to control the curve and prevent the need for surgical intervention. In neuromuscular deformities, the aim of bracing is to control the curve during the period of growth and delay the need for surgical stabilization. For most of these patients, this control is possible in the juvenile years. With the onset of the pubertal growth spurt, however, control is lost, and surgical stabilization is necessary. It is foolhardy to delay fusion until the end of growth. At the onset of puberty, approximately 85% to 90% of spinal growth has already occurred. In addition, during puberty there is usually rapid deterioration in the curve with a marked increase in curve magnitude and structurality. Any additional growth will produce a spine that is not longer but is more curved, stiffer, and shorter overall.

Orthotic management of neuromuscular scoliosis is more demanding than that of idiopathic scoliosis. The duration of bracing is longer, there are more skin problems because of the prevalence of insensate skin among these patients, and full-time bracing is not always necessary. In cases of very flexible curves that are well controlled in an orthosis, bracing is necessary only when the patient is upright under the effect of gravity. At night during sleep, bracing is not necessary, because gravity is not loading the spine and causing the curve to collapse.

Operative Treatment

The operative management of neuromuscular scoliosis differs markedly from that of idiopathic scoliosis. Traction rarely is necessary in idiopathic scoliosis, but it plays a role in the care of paralyzed patients either to improve preoperative pulmonary status or to aid in postoperative care by providing upright support.

The preoperative evaluation differs in that many more areas have to be evaluated for patients with neuromuscular scoliosis. Pulmonary status is important, but in many cases pulmonary function testing is impossible because of lack of patient cooperation or because of paralysis of the intercostal muscles. In such cases, the test results are inaccurate and give a false impression of the pulmonary function of these patients. A good assessment of pulmonary function can be obtained with the history of upper respiratory infection or pneumonia. A good nutritional assessment is important, especially for patients with swallowing or feeding problems.

Overall ambulatory function is assessed, as is the functional level of the patient. Sitting ability, hand use, mental ability, presence of seizures, vision, and functioning in activities of daily living are documented. These areas are critical and can be adversely affected by an increase in spinal deformity. It must be remembered, however, that in many cases the underlying neuromuscular disease is not static and that a change in the patient's examination or functional status may be caused by progression of the disease rather than the spinal deformity. In the patient assessment, information from the patient's family, caregivers, school staff, and physical therapist is invaluable.

The surgical principles in the management of neuromuscular scoliosis differ from those in idiopathic scoliosis. Fusion is necessary at a younger age, and the fusions are longer. Fusion to the sacrum is fairly common, because many of these children do not have sitting balance or there is pelvic obliquity. With idiopathic scoliosis in an adolescent, fusion to the sacrum is never needed. Combined anterior and posterior fusion is common in the treatment of patients with neuromuscular scoliosis either because posterior elements are absent, as in myelodysplasia, or because it is necessary to gain correction in a rigid lumbar or thoracolumbar curve and achieve a spine fused in balance over a level pelvis. Vertebral bone is osteopenic, so segmental fixation with the Luque system is preferred. Autogenous bone graft usually is insufficient because the small pelvic size or the need to fuse to the sacrum with the use of the Galveston technique or iliac screws. Blood loss is greater because the bone is osteopenic, the muscles are poor, and the procedures take a long time. In assessing blood loss, the absolute volume lost is of less importance than the proportion of blood lost from the patient's circulating blood volume. Intraoperative blood salvage with a cell saver is fairly routine in these procedures.

Anterior fusion and instrumentation alone play no role in the management of neuromuscular deformities. Combined anterior and posterior fusion and posterior fusion alone are used in neuromuscular spinal fusion. Combined fusion is used when there are no posterior elements (myelodysplasia) or when there are large, stiff curves and an anterior release and fusion is necessary to achieve a balanced spine over a level pelvis. Achieving a level pelvis is essential in the management of a sitter with neuromuscular spinal deformity and insensate skin. Pelvic obliquity among these patients causes unequal pressure distribution and pressure sores. Combined fusion usually is performed sequentially under the same anesthesia rather than as a staged procedure (9).

The child is positioned on the spinal frame (Hall-Relton or similar design) for the posterior fusion. Positioning often is difficult when hip flexion contractures are present (Fig. 3). In these cases, the pelvic positioning blocks are placed at the lower end of the holding board to allow the hips to be flexed to the required degree. When the contractures are great (more than 60 to 70 degrees), it is necessary to raise the lower end of the board on a sandbag so that the hips can be adequately flexed. Hip flexion after positioning has to be such that when the hips are extended, there is no pelvic tilt and induction of more lumbar lordosis. Sufficient padding is placed under the knees, which are flexed with pillows or rolls. As the board and patient are tilted with the head down, the operating table is tilted in a reverse manner to place the back horizontal.

The extent of posterior fusion depends on the curve pattern and the ambulatory status of the patient. For patients with neuromuscular spinal deformities who can walk, the guidelines for the selection of the fusion area follow those of idiopathic scoliosis. For patients who cannot walk and have pelvic obliquity, fusion extends to the sacrum and cranially to the upper thoracic area (T2 or T3). For patients who cannot walk who have a level pelvis, I fuse to the sacrum, but some surgeons fuse to the lower lumbar spine (16). The instrumentation used is segmental with either (a) a multiple hook-rod system with or without addition of sublaminar wires or (b) a Luque rod and sublaminar wires or a Unit Rod device (5). When fusion to the sacrum is necessary, it can be performed with the Luque-Galveston technique or with iliac screws (2 ,8 ,14).

Blood loss is monitored during the procedure by means of weighing the sponges and measuring the cell-saver return. In operations on children with neuromuscular deformities, it is important to relate any calculation of blood loss and replacement to a percentage of the calculated circulating blood volume, not to the volume of loss alone. The use of intraoperative blood salvage techniques is common in these spinal fusions. It is not unusual for these small children to have loss that equals or exceeds a circulating volume. It is imperative in cases of extensive blood loss to replace clotting factors with fresh frozen plasma and platelets with the addition of calcium.

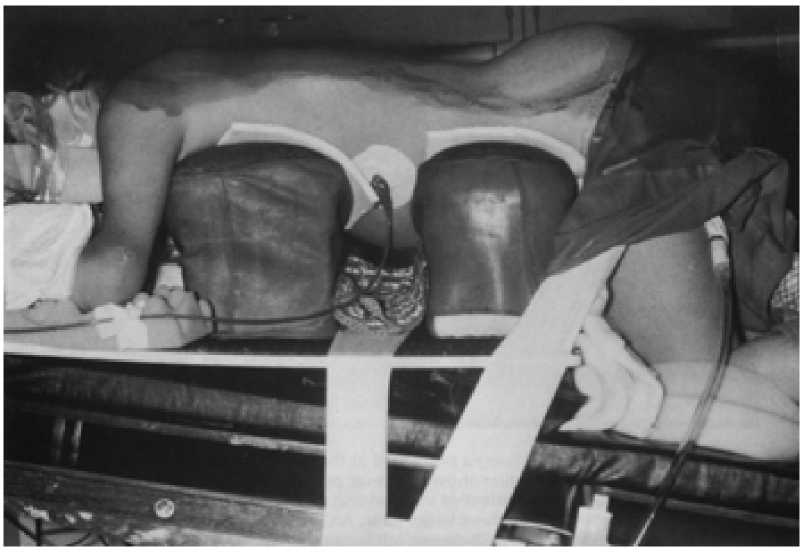

FIGURE 3. Positioning of a patient with hip flexion contractures. The child is positioned on the four-poster frame with the lower posts at the edge of the wooden board. The lower edge of the board is elevated with a sandbag to allow accommodation of full hip flexion. Padding is placed under the knees, which are flexed with a pillow. The operating table is tilted head up until the patient's back is horizontal.

Because in many of these operations inadequate iliac autograft is available, either because a small iliac crest or because of the use of iliac fixation, there is a need for graft augmentation with allograft or a bone graft substitute. Unlike operations on adults, spinal fusion with allograft use in the treatment of children is successful with good incorporation and a low pseudarthrosis rate. Crushed cancellous allograft is the easiest to use and has an excellent success rate (19).

Postoperative care of these patients is demanding. Attention has to be paid to pulmonary support, fluid status, and nutrition in addition to routine postoperative monitoring. The patients are mobilized as rapidly as possible for a return to preoperative ambulatory and functional status. Because of the secure fixation afforded by segmental fixation systems (multiple hook-rod or Luque segmental wiring) and the lower functional demands of these patients, postoperative immobilization is rarely needed.

Postoperative Complications

Postoperative complications among patients with neuromuscular spinal deformities are the same as those that affect any children undergoing spinal fusion. Because of the multitude of other problems these patients have, the complication rate after surgery is high, especially the rate of pulmonary, fluid balance, and skin problems. Some complications, however, are more common or important than others. These include respiratory problems, ileus, nutritional problems, hip problems, and crankshaft phenomenon.

Respiratory Problems

A child with neuromuscular disease may have intercostal paralysis and a poor cough reflex. As a result, the incidence of postoperative respiratory complications (atelectasis or pneumonia) is high. To minimize or prevent this problem, attention to postoperative respiratory care is essential. It is common to leave the endotracheal tube in place for 1 or 2 days after the operation and to use ventilator assistance. When prolonged support is anticipated, the tube is placed through the nasotracheal route. Secretions are handled with repeated suctioning, which is continued after tube removal. Any cough reflex present will be stimulated by suctioning. Postural drainage and chest percussion are also used to manage atelectasis.

Ileus

Ileus is common among these children after the retroperitoneal approach is used. It also occurs after the posterior approach is used because narcotics are used for pain control. Intestinal hypomotility may persist, necessitating prolonged parenteral support. Because many of these children have nutritional problems before the operation, this inability to resume oral or gastrostomy feeding is important. In these cases, hyperalimentation by the central intravenous route is necessary until adequate gastrointestinal feeding can be resumed. When there is postoperative return of intestinal motility but the child cannot tolerate oral feedings, a small feeding tube can be passed into the stomach or duodenum to allow nutritional support until oral feeding is tolerated.

Hip Problems

Hip problems—subluxation, dislocation, and contracture—are frequent among patients who do not walk. Their hips must be assessed preoperatively, and the parents and caretakers must be told that the hip position may appear worse after the operation when contractures are present. When there are postoperative hip contractures and the child is supine, the legs need to be supported on pillows with 90 degrees of hip and knee flexion. This prevents windswept abduction and adduction contractures from worsening. The forces on the pelvis are reduced, protecting the Galveston pelvic fixation.

The question arises as to when hip range of motion and stretching of contractures can be resumed after fusion to the sacrum. The danger in these cases is torque on the pelvis, which puts sacral and pelvic fixation in jeopardy. Gentle range of motion, short of the extremes, is advised in the healing phase, and stretching is not allowed. These restrictions are in effect until the fusion is solid, which usually takes 4 to 6 months. At that time, the full preoperative hip program of range of motion and stretching can be resumed.

Fusion Too Short

Incorrect selection of the fusion area can cause problems. Failure to fuse to the sacrum, when indicated, leads to a lack of sitting balance and a tilted torso. Failure to include the entire thoracic kyphosis in the fusion area increases the kyphosis immediately above the fusion as the spine falls forward over the top of the fusion.

Crankshaft Phenomenon

Because a large percentage of these children need fusion at a young age, continued anterior growth in the presence of a solid posterior fusion can occur (crankshaft phenomenon) (6). This can increase rotational deformity and even cause torquing of the fusion. Crankshaft phenomenon can be prevented with anterior fusion, which eliminates the anterior growth potential. In these children, the crankshaft phenomenon is a change in appearance only and has not been shown to have any functional effect. The decision to perform anterior fusion to prevent this phenomenon should be seriously considered in light of the added operative time, blood loss, and complications of additional surgery, especially because the functional benefits of the anterior approach in these cases have not been shown. The prospect of adding an anterior approach to an operation on a patient with respiratory compromise must be considered.

Summary

Spinal deformities are an important problem among children with neuromuscular diseases. These children can have spasticity or flaccidity. Multisystem involvement includes contractures, insensate skin, mental retardation, and respiratory problems. A detailed evaluation of all these areas and of the child's nutritional status and functional ambulatory level is essential. Nonoperative treatment plays a role in following scoliosis for progression. Active treatment involves the use of sitting supports to improve sitting function. Use of an orthosis (TLSO) plays a small role in the treatment of these children.

The two main indications for surgery are curve progression and deterioration in sitting function. A traction radiograph is the best radiographic determination of the flexibility of the spinal deformity. Leveling of the pelvis and the balance of the torso over the pelvis also are evaluated on this traction radiograph. A posterior approach alone is used for “idiopathic like” curves and for curves that balance over a level pelvis on a traction radiograph. Most fusions are long (T2 to the sacrum), the Luque-Galveston technique being the instrumentation of choice. For curves that do not balance or show pelvic obliquity on a traction radiograph, combined anterior and posterior fusion is indicated. This approach also is indicated in the care of patients with myelodysplasia when there are no posterior elements.

Postoperative care is concentrated on the respiratory system and on early implementation of nutritional support. With care in surgical technique and adequate postoperative care, complications can be minimized. The child can be returned to preoperative functional level with a successful surgical result—a solidly fused spine in balance in the coronal and sagittal planes over a level pelvis.

Spine Deformities Due to Cerebral Palsy

John E. Lonstein

J.E. Lonstein: Department of Orthopedics, University of Minnesota, Twin Cities Spine Center, Minneapolis, Minnesota 55317.

The term *cerebral palsy* originally referred to birth anoxia or trauma that caused cerebral dysfunction and spasticity. Today it is more of an all-inclusive term for static encephalopathy whether it is caused prenatally, perinatally, or postnatally (23). It includes all the nonprogressive brain disorders such as genetic demyelination, intrauterine cerebral infection (toxoplasmosis), perinatal anoxia, cerebral trauma or hemorrhage, and postnatal trauma, hemorrhage, or infection.

Because of the generalized brain involvement, all cerebral functions are affected, and there are many associated features—mental retardation, seizures, delayed motor and mental development, and vision and hearing problems (2 ,3). Mental retardation occurs with motor involvement in 71% of cases, but it can also occur alone. It was present among 29% of patients in a recent surgical series (16). Associated with the motor involvement is the development of contractures, hip dislocation, spinal deformities, pelvic obliquity, and ischial, sacral, and trochanteric pressure sores. Patients with cerebral palsy motor involvement can be divided into groups depending on muscle tone—flaccid, spastic, athetoid, or mixed—the most common problem being spasticity. In addition, the involvement can be symmetric or asymmetric, ranging from spastic monoplegia to spastic quadriplegia with lack of head control—what some have called *spastic pentaplegia* or *total body involvement.* It is important to realize that the motor and intellectual involvement can be independent. There can be major motor involvement with spastic quadriplegia but normal intelligence. The latter is difficult to recognize and appreciate, however, because of the presence of expressive aphasia.

Spinal Deformities

The spinal deformities of these patients can be divided into postural curves (caused by lack of sitting balance) and structural curves. The curves of cerebral palsy can be scoliosis, kyphosis, or lordosis. Kyphosis alone occurs fairly commonly among patients who lack sitting balance and is managed nonoperatively, as discussed later. Lordosis is rare and occurs among patients who can walk and have hip flexion contractures. Lordosis also occurs among patients with severe extensor muscle overactivity, which is an unusual spinal problem. Scoliosis is the most common spinal deformity among patients with cerebral palsy.

At first glance, the cause of the structural scoliosis appears to be easy to explain on the basis of muscle imbalance on the two sides of the body and an overall incidence of spinal deformity in cerebral palsy of 20% to 25%. There is, however, a low incidence of scoliosis (5%) in spastic diplegia and a high incidence (65% to 70%) in spastic quadriplegia. Other factors that have been correlated with the incidence of scoliosis, including degree of spasticity, ambulatory status, home or institutional setting, and other system involvement. There also are other factors, some of which may be related to the brain stem and balance.

Course of Disease

In considering the course of the spinal deformities of cerebral palsy, one must ask two questions: What are the effects of the disease if uncontrolled? How commonly does curve progression occur? In cerebral palsy, a progressive or large curve that is uncontrolled affects the patient's functional abilities and pulmonary function. Because scoliosis is more common among patient who cannot walk, the effects are more marked in this group. The scoliosis affects sitting ability, necessitating constant repositioning by the patient, parent, or caregivers. A high incidence of pressure sores on the ischium, sacrum, or trochanter accompanies this loss of sitting ability. Eventually sitting becomes difficult and limited, and the patient loses all sitting ability. Patients with severe cerebral palsy have frequent respiratory infections because they have difficulty clearing oral secretions and have problems swallowing. When scoliosis is added to this, especially accompanied by reduced pulmonary space and a raised diaphragm, pulmonary infection and pneumonia become more common.

Progression of scoliosis in a person with cerebral palsy differs from that in a person with idiopathic scoliosis. Among persons with idiopathic scoliosis, puberty occurs predictably at the age of 10 to 14 years among girls and 12 to 16 years among boys. Progression of scoliosis, when it occurs, is mainly during the rapid growth spurt of puberty. Among persons with cerebral palsy, the onset of puberty is variable and can occur as early as 8 years of age or as late as the early twenties. Progression continues into adulthood in a high percentage of cases (15 ,20 ,21 ,29). This means that the patient must be kept under observation for a long time, well into adulthood.

Patient Evaluation

The history obtained for a patient with cerebral palsy is extensive. It covers not only the spinal deformity but also the mother's pregnancy, the delivery, and the growth and development of the patient. This background provides the cause of cerebral palsy and elucidates the child's neurodevelopmental status. The effect of the spinal deformity on the child's function is evaluated with information from the child whenever possible aided by information from parents, attendants, teachers, and therapists. Has there been any change in the back? What changes have been noticed in ability to get around—walking or sitting? What associated problems are present—seizures, contractures, hearing or visual difficulties, pressure sores? Information is sought regarding feeding, nutrition, drooling, and previous respiratory infections. Inquiries are directed at the child's growth and maturity. Questions are asked to evaluate the growth pattern and, in the second decade of life, to determine whether the child is in the growth spurt.

The physical examination is divided into the three areas described in Chapter 44 : general patient evaluation, orthopaedic evaluation, and evaluation of the spinal deformity. The patient's overall size, height, weight, and nutritional status are documented. Because of the delayed development that accompanies severe cerebral palsy, patients often are below the twenty-fifth or even the fifth percentile for age. Signs of puberty, such as development of breasts or pubic hair, are documents and graded with the Tanner system (28). It is important to remember that among these children puberty can be premature or delayed. The general evaluation must include hearing, vision, intelligence, communication, and hand function, as well as assessment of any seizures and their control. The orthopaedic examination emphasizes assessment of all extremities and joints for contractures with emphasis on the hips for dislocation, contractures, and windswept status. Ambulatory status is documented and classified (see Chapter 44). The spinal deformity is documented, as are decompensation and shoulder balance. The flexibility of the scoliosis is evaluated clinically with supine assessment and passive side bending of the patient to judge the rigidity of each curve. Is there any pelvic obliquity? If there is obliquity, which side is high? Can the pelvis be leveled in the supine and sitting positions (14)?

A general medical evaluation is performed with emphasis on nutrition and swallowing (9). A history of feeding is obtained. Does the child feed him or herself, or must the child be fed? How long does it take to feed the child, and is positioning or food consistency a factor? What does the diet consist of? What is the child's height to weight ratio? Swallowing is assessed with the feeding history, history of drooling, and history of episodes of aspiration pneumonia. For a complete assessment, swallowing studies are performed to assess the child's ability to handle foods of different consistencies. A full assessment of nutritional status is necessary for surgical patients. This includes nutritional history, feeding history, and a battery of blood tests to evaluate current nutritional status. These include hemoglobin, total lymphocyte count, red blood cell mean corpuscular volume, total protein, albumin, electrolytes, serum blood urea nitrogen, creatinine, and transferrin (30).

Radiographic Evaluation

Upright frontal and lateral views, either standing or sitting, form the basis of the radiographic evaluation of the spine. The radiographs are obtained with minimal or no support, so that a true appreciation of the spinal deformity under the effect of gravity can be obtained. The posteroanterior position is used for patients who can stand, and the anteroposterior position is used for those sitters. All the curves present are identified and measured. To evaluate the flexibility of the curves (scoliosis or kyphosis), a traction radiograph is obtained. This can be done in the radiology department with manual distraction with a head halter and leg traction, but it is not very effective in cerebral palsy because of spasticity and spastic reflexes and the presence of hip flexion contractures. A better method is to obtain a traction radiograph on a Risser-Cotrel frame. The patient is positioned on the frame with the hips flexed if there are flexion contractures. Traction is applied with a head halter and pelvic straps. Every effort is made to level the pelvis; gradual forces are used so that there is minimal stimulation of any spastic reflexes. A Cotrel side strap can be applied to the convexity of the scoliosis. Anteroposterior and lateral radiographs are obtained so that the flexibility of the curves can be evaluated.

An anteroposterior hip radiograph is routinely obtained to show the status of the hips. Additional radiographs sometimes are necessary to evaluate the lumbosacral area. Spot radiographs are obtained if there is a congenital spinal abnormality.

Treatment

The treatment options are the same as those for patients with any spinal deformity–observation, nonoperative, and operative. The choice depends on the problem (curvature, loss of sitting or function, pressure sores) and the child's age and maturity.

Observation

Observation alone plays a small role in the treatment of patients with cerebral palsy. When the curve causes no loss of function and there is no documented progression, the patient is observed. The magnitude of the curve is not a factor; even large curves in patients with severe spastic quadriplegic need not be managed if there is no definite evidence of progression and no change in sitting ability. The exception is a curve greater than 25 to 30 degrees in an immature, still growing child who can walk. Such a patient would be treated for the curve. Depending on the age and maturity of the patient, the examination and radiographic evaluation are repeated in 4 to 12 months. In all cases that are followed for progression, the current radiograph is always compared with the previous and with the initial radiographs.

Nonoperative Treatment

There are two roles of nonoperative treatment: seating support and curve control.

Seating Support

Because a large percentage of patients with cerebral palsy cannot walk, the use of seating supports is important. There are many choices, and the appropriate type of seating support depends on the patient's sitting balance. Sitting balance is evaluated by means of seating the patient on the side of the examining table to see whether he or she can sit unaided. When this not possible, support is given in a progressive way until the patient can sit upright. First the pelvis is supported, then the lateral and anterior thorax, and then the head. The seating support needed for each child is determined in this evaluation. The seating supports available are a firm seat and back, upholstered sitting supports, molded sitting supports, and commercial seating systems (see Chapter 44).

Some experts have questioned the benefits of sitting to patients with severe spastic quadriplegic cerebral palsy. They state that there is no benefit in sitting someone who has no ability to respond to the environment and that the results are not worth the time, cost, and effort involved. A study conducted at Gillette Children's Hospital on the effect of the molded sitting support orthosis showed that these supports did not control curves, but they improved hand function among those able to use their hands. For the others, the greatest effect was in nursing care. Patients in sitting supports needed less repositioning. This left more time for other children in a family setting or more time for other duties in an institutional setting. Transportation was facilitated, and feeding time decreased.

Curve Control

A thoracolumbosacral orthosis (TLSO), either back opening or bivalved, is used to control scoliosis during the growing years. In most instances, this control is temporary. Curve control is achieved during the juvenile years, but the curve progresses during the adolescent growth spurt (32). One small study, however, found that bracing did not help these patients (22). Most of these children do not walk. They have long, flexible curves that are not controlled by means of sitting support alone. They need a TLSO for curve control and a sitting support for sitting balance. Among my patients with more structural curves, a TLSO has not been able to control the curve. The TLSO has proved to be effective in the management of curves (scoliosis or kyphosis) in patients with cerebral palsy who can walk. The scoliosis in these cases has the same curve patterns and response to bracing as idiopathic scoliosis. In these cases, nonoperative treatment is successful in controlling the curves during adolescence, and surgery rarely is necessary.

Operative Treatment

The indication for surgery in the treatment of patients with cerebral palsy who have nearly normal intelligence is generally not difficult. In these cases, surgery is indicated for curves greater than 45 to 50 degrees in a growing child or when there is documented progression of the curve. The role of surgery in the treatment of patients with severe disabilities and spastic quadriplegia, however, is controversial (16). These patients should be given every opportunity and not be pushed into a corner and ignored. The two main indications for surgery are documented progression of the curve and deterioration in function. An increase of a minimum of 10 degrees is considered progression, because achieving a comparable and repeatable position for radiographs is difficult. This is a more liberal definition of progression. In most other causes of scoliosis, in which dependable and reproducible radiographic positioning is possible, a 5-degree increase constitutes progression.

The other indication for surgery is a change in functional level due to the curve. This is usually a loss of or change in sitting ability. The child's caregivers (parents, attendants) report more difficulty in positioning and that constant repositioning is necessary. In addition, the child becomes fussy and may even have pressure areas over the sacrum, ischium, or greater trochanter. Information from all caregivers (parents, attendants, teachers, and therapists) is necessary to gain a full appreciation of changes in the child's functional level.

In the preoperative assessment, evaluation of the child's health is important. The two areas of greatest importance are the respiratory assessment and an evaluation of nutritional status (see Chapter). When the nutritional status is not optimal, a feeding gastrostomy tube often is placed and surgery postponed until nutrition is improved.

Once a decision has been made that surgery is indicated, the next decision concerns the extent of fusion (19). Which curve or curves should be fused? What vertebrae form the fusion limits? The curve patterns in cerebral palsy have been divided into two patterns: group I and group II curves (16) (Fig. 1). Group I curves are single or double curves that resemble the patterns of idiopathic scoliosis with a level pelvis. They occur most often among children who can walk. Group II curves occur among children who cannot walk and are long thoracolumbar or lumbar curves with pelvic obliquity. The high side of the pelvis is on the side of the concavity of the curve. There are two subgroups of this pattern. In type IIA, the curve continues into the sacrum, which thus forms the caudal extent of the curve. In type IIB, there is a short fractional curve in the lumbosacral area, and the sacral vertebrae are not part of the thoracolumbar or lumbar curve.

For group I curves among children who can walk, the fusion-level criteria are the same as those for idiopathic scoliosis (Fig. 2). In group II curves, the fusion should extend to the sacrum, because this forms part of the curve, although some surgeons prefer to stop at L5 (26). This places the fusion on a solid base and helps achieve the surgical objective in these cases—a solidly fused spine in balance over a level pelvis. The head and thorax must be balanced over the pelvis in the sagittal and coronal planes with normal thoracic kyphosis and lumbar lordosis.

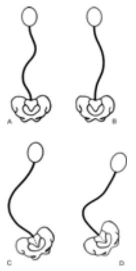

FIGURE 1. Curve patterns in cerebral palsy scoliosis. Group I curves are double curves with thoracic and lumbar components. There is little pelvic obliquity; the child may be well balanced **(A)** or, if the thoracic curve is more extensive, there may be some imbalance **(B)**. Group II curves are large lumbar or thoracolumbar curves with marked pelvic obliquity. There may be a short fractional curve between the end of the curve and the sacrum **(C)**, or the curve may continue into the sacrum, the sacral vertebrae forming part of the curve **(D)**.

Questions often arise about the cranial extent of the fusion. The upper extent of the main thoracolumbar or lumbar curve usually is in the midthoracic area with perhaps a small compensatory curve above, but the latter curve often is absent among patients who have very poor sitting balance. If the fusion stops in the midthoracic area in these cases, there is a tendency for the spine to bend over the top of the fusion, and the result is thoracic hyperkyphosis. Therefore the fusion should extend to the upper thoracic level. Thus the general fusion level for group II curves is from T2 to the sacrum.

What is the management of a group I curve in a child who cannot walk but has a level pelvis and good sitting balance? The first inclination is to fuse to L4 or L5 and not fuse to the sacrum, but I have found that this usually fails. During the growth spurt, a curve develops below the fusion. The result is pelvic obliquity and a subsequent loss of sitting balance. Because of this, I recommend fusing to the sacrum for all sitters regardless of the curve pattern.

The next question is whether to perform posterior fusion alone or combined anterior and posterior fusion. For group I curves, posterior fusion alone is performed. The question of approach generally applies to group II curves, and this decision is made with the use of a traction radiograph. Evaluation of the flexibility of the curve is performed with a Risser-Cotrel casting frame. The child is placed on the frame, and traction is applied with a head halter and muslin waist straps. More tension is placed on the high hip when pelvic obliquity is present. This maneuver is an attempt to achieve maximum correction of the pelvic obliquity. A Cotrel side strap is added over the convexity of the curve to maximally correct the scoliosis. With hip flexion contractures, the hips are placed in flexion on the leg frame on the table. Traction is gradually applied so that any spastic response is minimized. Anteroposterior and, when necessary, lateral radiographs are obtained with a long film (36 inches [90 cm]) so that the entire spine and pelvis can be included on one radiograph. The anteroposterior radiograph shows the flexibility of the scoliosis, the correction of the pelvic obliquity, and the balance of the thorax over the pelvis. A balanced thorax is a nontilted thoracic cage positioned over the pelvis. When this traction radiograph shows a level pelvis and the thorax in balance over the level pelvis, a posterior fusion alone achieves the surgical aim—a solidly fused, balanced spine (the thorax balanced in the coronal and sagittal planes over a level pelvis) (Fig. 3). When the traction radiograph shows pelvic obliquity or an unbalanced thorax (tilted or not positioned over the pelvis), anterior and posterior fusion is necessary to achieve the surgical aim (Fig. 4). No imbalance can be accepted on the traction radiograph, but a minimal amount of pelvic obliquity (less than 10 degrees) is permissible. The other indication for combined anterior and posterior fusion is the rare case that balances on the traction radiograph but still has a large lumbar or thoracolumbar curve.

Posterior Fusion

A posterior fusion alone is performed for group I curves (Fig. 2) and for the group II curves that balance on a traction radiograph (Fig. 3). For patient who can walk, the principles of treatment—selection of fusion levels, use of autograft, and selection of instrumentation—are the same as for idiopathic scoliosis (Fig. 2). When there is osteopenic bone, the Luque system with sublaminar wiring has proved to be effective and secure, because it distributes the forces over all the laminae.

Group II curves, which occur among patients who do not walk, are markedly different from idiopathic scoliosis. The fusions are long, extending on average from T2 to the sacrum. There is greater blood loss, and the bone is extremely osteopenic and soft. The pelvis is small and is used for fixation, so it is not a source of autograft. The surgical technique and planning address these issues. Intraoperative cell salvage is performed with a cell saver. The instrumentation of choice in these cases is a Luque rod with sublaminar wires and Galveston pelvic fixation technique or with iliac screws (1 ,4 ,5 ,7 ,8 ,12 ,13 ,16 ,17 ,18 ,24 ,25 ,27). I prefer 16-gauge wire (0.048 mm) with a double strand around each rod at each level. Thick wire is less likely to cut through the lamina. Whenever possible a ¼-inch (6.4 mm) Luque rod is used. A 3/16-inch (4.8 mm) rod is used when the pelvis is thin and cannot accept a larger rod. For the fusion, all the local bone from the spinous processes and laminae is placed in the lumbosacral area, and allograft cancellous cubes are added for the rest of the fusion (31).

The child is positioned on a spinal frame (Hall-Relton or similar design) as described in Chapter 44 . The techniques of

posterior instrumentation using multiple hook-rod system (1a ,15a ,23a ,23b), Luque rod and sublaminar wiring (9a), Luque-Galveston pelvic fixation (9a), and insertion of iliac screws (1a) are described elsewhere. The steps in the surgical procedure differ from surgeon to surgeon. I use the following steps: (a) exposure of the spine, (b) exposure of the iliac crests, (c) facet excision and flavectomy, (d) drilling of the iliac crest, (e) rod bending, (f) passage of the sublaminar wires on the concavity of the curve, (g) insertion of the rod on the concavity of the curve, (h) passage of the wires on the convexity of the curve, (i) insertion of the rod on the convexity of the curve, (j) decortication and bone grafting, (k) closure.

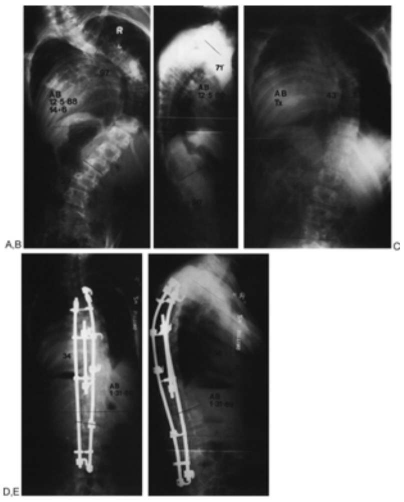

FIGURE 2. Images of a patient first evaluated at the age of 14 years 6 months with cerebral palsy, spastic quadriplegia, a right thoracic curve of 97 degrees **(A)**, and thoracic kyphosis of 71 degrees **(B)**. He could walk with hand holding and had marked visual impairment. The curve was flexible. **C:** Traction radiograph shows the curve corrected to 43 degrees. The patient underwent a posterior spinal fusion from T3 to L4 with Cotrel-Dubousset instrumentation and the three-rod technique. Postoperatively there was correction of the scoliosis to 34 degrees **(D)** and of the kyphosis to 56 degrees **(E)**.

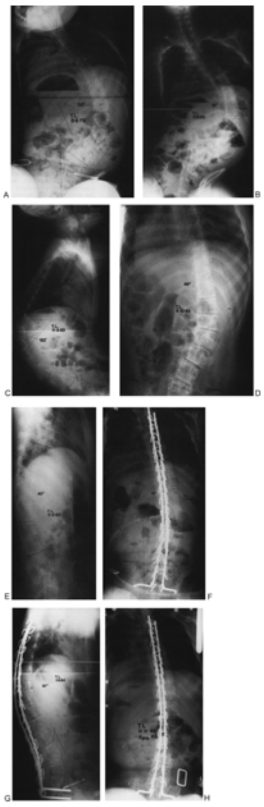

FIGURE 3. A: A 12-year-old girl with cerebral palsy and spastic quadriplegia had a 58-degree long C curve and difficulty sitting. She was placed in a molded sitting support orthosis. The curve progressed. **B:** Unsupported sitting radiograph obtained 4 years after **A** shows a level pelvis and a compensatory curve below the 81-degree thoracolumbar curve. **C:** Lateral radiograph shows a 122-degree thoracolumbar rotatory kyphosis. **D:** Traction radiograph obtained on a Risser-Cotrel frame shows a balanced torso over a level pelvis and correction of the scoliosis to 46 degrees and of the kyphosis to 40 degrees. **E:** Because of this correction, posterior fusion alone was performed with Luque-Galveston instrumentation. **F:** Postoperative radiograph shows correction of the scoliosis to 48 degrees. **G:** Lateral postoperative radiograph shows restoration of thoracic kyphosis and lumbar lordosis. Evident are the balanced torso and the smaller 3/16-inch (4.8 mm) rods used because of the thinness of the pelvis. Two years later the fusion was solid with no change. **H:** Sitting posteroanterior radiograph shows excellent lumbar fusion mass.

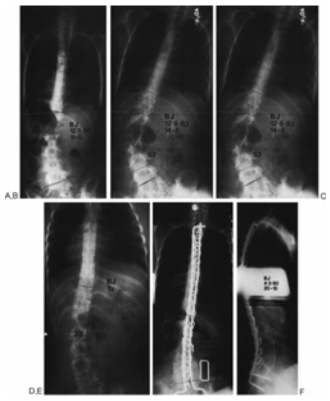

FIGURE 4. Girl with spastic quadriplegia first evaluated presented at the age of 11 years 5 months had difficulty sitting. **A:** Unsupported sitting radiograph shows level pelvis and a small left lumbar curve. A molded sitting support orthosis was fitted and was effective in providing sitting support until the beginning of puberty and the adolescent growth spurt 3 years later. **B:** Unsupported anteroposterior radiograph obtained 3 years after **A** shows pelvic obliquity and a 53-degree left lumbar curve, the sacrum forming part of the curve. **C:** Lateral view shows 74-degree thoracic kyphosis and loss of lumbar lordosis. **D:** Traction radiograph shows curve correction to 33 degrees, but the pelvis did not become level and the torso was not in balance. The patient underwent anterior fusion from T12 to S1 and posterior fusion from T2 to the sacrum with Luque-Galveston instrumentation. Six years after the operation the fusion was solid, the pelvis level, the torso balanced, and sagittal contours restored. Posteroanterior **(E)** and lateral **(F)** views show excellent fusion mass in the lumbar areas.

Blood loss is monitored during the procedure by means of weighing the sponges and measuring the cell saver return. In operations on children with cerebral palsy, it is important to relate any calculation of blood loss and replacement to a percentage of the calculated circulating blood volume, not to the volume of loss alone. It is not unusual for these small children to have a loss that equals or exceeds circulating volume. It is imperative in cases of large blood loss to replace clotting factors with fresh frozen plasma and platelets with the addition of calcium.

Postoperative care is concentrated on fluid balance, blood replacement, and pulmonary care. Operations on these children differ from other pediatric procedures in that children with cerebral palsy do not have a well-developed cough reflex. Postoperative suctioning is necessary to stimulate any cough reflex and to control oral and respiratory secretions. For pulmonary care it often is useful to leave the endotracheal tube in place for the first night after the operation and to use a respirator to aid pulmonary function in the immediately postoperative period. Because of the excellent fixation afforded by the Luque system, no postoperative immobilization is needed. The child should be returned to the preoperative sitting position as soon as possible, and appropriate adjustments should be made to sitting support.

When hip flexion contractures are present, careful positioning is necessary in the postoperative period. The legs are supported on pillows when the child is supine, and the hip and knees are placed in flexion. Any hip flexion or hip windswept deformity appears worse after surgery, because the possible compensation by pelvic flexion or rotation is eliminated with the fixation of the pelvis in the Galveston technique. It is important to be aware of this possible side effect of spinal fusion and to warn family and caregivers of this before surgery. The question always arises whether the hips should be operated on before the spinal fusion. It is easier, however, to perform spinal fusion first and then to assess the hips. Because most of these children are sitters, hip surgery is indicated only when an extremely windswept position or painful dislocation interferes with sitting. Once the child is returned to preoperative ambulatory status, a decision regarding the need for hip surgery can be made.

Anterior and Posterior Fusion

Combined anterior and posterior fusion is indicated when the traction radiograph does not show a level pelvis and balanced spine. The imbalance can be caused by a tilt of the thorax in relation to the pelvis or lack of balance of the thorax over the pelvis. When the curve is large, even with a balanced spine on a traction radiograph, combined fusion gives a better result than posterior fusion alone. Because it shortens the convexity of the curve, the anterior release corrects the thoracolumbar or lumbar curve and helps balance the spine (6 ,8 ,10). The technique of anterior discectomy and fusion is described by Herring (14a).

After the anterior procedure is concluded, the patient's condition is assessed and the timing of the posterior fusion is discussed with the anesthesiologist. In most instances, both procedures are performed under the same anesthesia. That is, when the patient's condition is stable, blood loss minimal, and the anterior procedure not prolonged, posterior fusion is performed immediately (11). After anterior fusion, the patient is turned prone and positioned on the spinal frame, and the posterior procedure is performed. In cases of large blood loss, a long anterior procedure, or suboptimal patient status, posterior fusion is delayed for 7 to 10 days to allow the patient to recover from the anterior procedure before the second-stage posterior fusion is performed. During this time, nutrition is of utmost importance. A central intravenous catheter is inserted at the conclusion of the anterior procedure and used for hyperalimentation between the two stages.

If fusion is staged, the question of traction between the stages arises. It has been found that any improvement—either improved correction or improved thoracopelvic balance—is due to the anterior release and not to any traction used. Anterior release allows additional curve correction by making the spine more flexible. Traction provides no additional correction or flexibility. If the patient is uncooperative, halo traction can be used between the stages to help control the patient, but this situation is rare.

After anterior fusion with either a concurrent or staged posterior procedure, the most important part of postoperative care is focused on the respiratory system. After thoracotomy, hypoventilation and atelectasis are common, often making respiratory support necessary in the immediately postoperative period. Bronchial secretions are handled with repeated suctioning, which also has the benefit of stimulating any cough reflex that is present. This helps minimize or prevent atelectasis and thus reduce the likelihood of superimposed pneumonia. Routine care of the chest tube is performed with daily chest radiographs to monitor the presence of air or fluid in the pleural space. The tube is removed when the drainage is minimal, usually on the third or fourth postoperative day.

After posterior fusion, whether performed on the same day or as a second stage, the aftercare regarding positioning and return to the upright preoperative ambulatory status is the same as described earlier. When the procedures are performed on the same day, postoperative recovery is a day or two longer.

Postoperative Complications

Postoperative complications among patients with cerebral palsy are the same as those for any child undergoing spinal fusion for neuromuscular spinal deformities. There are, however, specific complications that are more common or important for children with cerebral palsy. These include respiratory problems, nutritional problems, hip problems, and pseudarthrosis.

Respiratory Problems

Children with cerebral palsy have a poor cough reflex and difficulty swallowing, the latter causing inability to handle normal salivary secretions. As a result, the incidence of postoperative respiratory complications (atelectasis and pneumonia) is high. To minimize or prevent this problem, attention to postoperative respiratory care is essential (see Chapter 44).

Nutritional Problems

Nutrition is important among children with cerebral palsy undergoing surgery. A good preoperative nutritional assessment is essential, and preoperative nutritional counseling and a feeding gastrostomy are provided when necessary. Whenever surgery is performed in two stages 7 to 10 days apart, parenteral hyperalimentation is essential, regardless of how well the child tolerates the first stage. The hyperalimentation should be planned at the time of the first anesthesia, and an appropriate central line is inserted so that a portal for nutritional support is available. When posterior fusion is performed alone or in combination under one anesthesia, nutritional support sometimes is necessary. This may be accomplished through the parenteral route in the case of prolonged ileus or with a feeding tube when intestinal motility has returned but the child does not tolerate oral feedings.

Hip Problems

Hip problems—subluxation, dislocation, and contractures—are frequent among patients who do not walk. Their hips must be assessed preoperatively, and the parents and caregivers must be told that postoperatively the hip position may appear worse when contractures are present. When there are hip contractures and the child is supine, the legs need to be supported postoperatively on pillows with 90 degrees of hip and knee flexion. This prevents the windswept abduction and adduction contractures from worsening. In addition, the forces on the pelvis are reduced to protect the Galveston pelvic fixation.

Question arises about when hip range of motion and stretching of contractures can be resumed when fusion has been performed to the sacrum. The danger in these cases is torque on the pelvis, which puts the sacral and pelvic fixation in jeopardy. Gentle range of motion, short of the extremes, is advised in the healing phase, and stretching is not allowed. These restrictions are in effect until the fusion is solid, which usually takes 4 to 6 months. At that time, the full preoperative hip program of range of motion and stretching can be resumed.

Another important question concerns the need for and timing of hip surgery in relation to spinal fusion. Assessment of the need for release of hip contractures is best made after the spinal fusion, when the pelvis is fixed in position and no spinal compensation for the contracture can take place. Only if the hip contractures prevent standing (ambulators) or sitting (nonambulators) is release indicated. This is rare, because flexion contracture of the hips up to 90 degrees does not interfere with sitting. In this case, good leg support is essential when the child is supine. Alteration of the child's position in the chair often is necessary. Placing the seating support at a slight angle to the chair may give a better-appearing seated position. If hip surgery is planned, usually for dislocation or subluxation, the operation should be performed after spinal fusion. The pelvis is fixed in the final position to allow better assessment of hip position.

Pseudarthrosis

Pseudarthrosis is an important complication of operations on the spines of patients with cerebral palsy. It is related to the type of curve and the fusion technique. In a review of mainly Harrington instrumentation, the overall rate of pseudarthrosis was 17% to 25% with a posterior approach and 4% with a combined approach (16). With the introduction of Luque instrumentation with more secure internal fixation, the pseudarthrosis rate for posterior fusion has fallen dramatically. The pseudarthrosis rate for group I curves has fallen from 20% to near zero. The rate for group II curves and for combined fusions has not changed greatly. The most common sites of pseudarthrosis are the lumbosacral and thoracolumbar areas.

The fusion is evaluated with supine oblique radiographs, and defects are identified if present. Nine to 12 months after surgery, the fusion is more mature and the defects are more easily identified, often on anteroposterior or lateral radiographs. In some cases the instrumentation can fracture, and correction can be lost. It must be remembered that the defect can be difficult to identify, and the rods may remain intact and fracture many years after the original fusion procedure. There also can be associated pain, but this is rare and difficult to identify.

The need for reoperation is rare, even when a pseudarthrosis is present. Only with loss of correction and definite pain is pseudarthrosis repair indicated. Thus most pseudarthroses in these children are radiographic defects that do not necessitate surgical repair.

Summary

Spinal deformities are important orthopaedic problems among children with cerebral palsy. As with all neuromuscular diseases, multisystem involvement includes spasticity, contractures, hip dislocation and subluxation, seizures, mental retardation, vision and hearing deficits, and respiratory and feeding problems. A detailed evaluation of all these areas when the patient first arrives for treatment is essential, as is evaluation of the nutritional status and functional ambulatory level. Nonoperative treatment plays a role in following scoliosis for progression. Active treatment involves the use of sitting supports to improve sitting function. Orthoses (TLSO) play a small role in the treatment of these children.

Surgical treatment of patients with cerebral palsy, especially patients with spastic quadriplegia, is controversial in both indications and approach. The two main indications for surgery are curve progression and deterioration in sitting function. Findings on a traction radiograph are the best radiographic determinants of the flexibility of the spinal deformity. Leveling of the pelvis and balance of the torso over the pelvis also are evaluated on a traction radiograph. A posterior approach alone is used for “idiopathic-like” curves and for curves that balance over a level pelvis on a traction radiograph. Most fusions are long (T2 to the sacrum). The Luque-Galveston technique is the instrumentation of choice. For curves that do not balance or show pelvic obliquity on a traction radiograph, combined anterior and posterior fusion is indicated.

Postoperative care is concentrated on the respiratory system and early implementation of nutritional support. With care in surgical technique and adequate postoperative care, complications can be minimized. The child can be returned to the preoperative functional level with a successful surgical result—a solidly fused spine in balance in the coronal and sagittal planes over a level pelvis.

Spinal Deformities in Friedreich's Ataxia

Hubert Labelle

H. Labelle: Department of Orthopaedic Surgery, Sainte-Justine Mother-Child University Hospital, University of Montreal, Quebec, H3T 1C5 Canada.

Nicolaus Friedreich was born on July 31, 1825, in Wurtzburg, a small city in Germany. He studied biology and medicine in his hometown. At the age of 32 years, Friedreich accepted the directorship of the medical clinic and the chair of internal medicine at the nearby University of Heidelberg, where he worked for the next 25 years (4). Few eponyms in neurology are as closely identified with a specific condition as the one Friedreich described in a series of five papers published between 1863 and 1877 (4 ,18). The term *maladie de Friedreich*, or Friedreich's ataxia, was coined by the French School of Neurology in 1882, the year of Friedreich's death (4). Friedreich's original clinical and pathologic observations and ideas are still up to date and were the basis for all subsequent knowledge of hereditary spinocerebellar degeneration.

Definition and Classification

Friedreich's ataxia is the most common hereditary and progressive spinocerebellar degenerative disease characterized by ataxia. To date, more than 57 hereditary ataxic syndromes have been identified. To facilitate differentiation of these various syndromes, Barbeau et al. (9) proposed a clinical classification that is user-friendly, flexible, and based on the natural order of questions asked by a clinician (Table 1). First, the genetic mode is established. Is the pattern observed in the family autosomal dominant, autosomal recessive, or sex-linked recessive? Second, the pattern of progression is obtained from the history—nonprogressive, intermittent, or progressive ataxia. Age at onset of the first symptom further divides the syndrome into infantile (onset birth to 2 years), early (onset 2 to 25 years of age), or adult (onset after 25 years of age). Next, the state of deep tendon reflexes is recorded as either hyperactive or normoactive (positive reflexes, recorded with +) or hypoactive or areflexic (negative reflexes, recorded with a -). Finally, the type of ataxia present is recorded as either “pure ataxia” (predominant spinocerebellar or cerebellar incoordination) or “ataxia plus” (spinocerebellar or cerebellar incoordination with other central nervous system involvement).

According to this classification, Friedreich's ataxia is defined as an autosomal recessive ataxia of a progressive nature, of early onset, with weak or absent reflexes, and with predominant spinocerebellar incoordination.

Epidemiology

The prevalence of Friedreich's ataxia is approximately 1:100,000 population (38 ,40). The incidence has been reported to be between 1:25,000 and 1:50,000 with a heterozygote frequency of 1:110 (38 ,41). The sexes are equally affected. Although it is rare, the syndrome appears to have a worldwide geographic distribution. Most series described have been in Europe and North America (8 ,13 ,17 ,19 ,22 ,35 ,38).

Etiology

Since Friedreich's original description (18), it has been known that the disease is genetic in origin and inherited as an autosomal recessive trait, but it was only in 1988 that Chamberlain et al. (15) mapped the gene on chromosome 9 by means of genetic linkage. Since then, with linkage mapping techniques, the classic form of Friedreich's ataxia has been localized to 9q13-q21, a region on the long arm of chromosome 9, and the interval for the defective gene has been narrowed to a few hundred thousand base pairs (24 ,25 ,34). It is likely that the Friedreich's ataxia gene will be cloned soon. This confirms the suspicion that there is no evidence of genetic heterogeneity, despite the clinical variations encountered in the syndrome. These variations are probably caused by mutations at the same locus (25).

Extensive genealogic studies have been performed in the province of Québec, which is ideal for such investigations because most of its inhabitants (5 million of 6.5 million total) are of French extraction, originating from a pool of 70,000 immigrants who crossed the Atlantic before 1760. Most of these immigrants are known, and their descendants can easily be traced through church or civil records. Barbeau et al. (8) traced most cases of Friedreich disease in French Canada to one common ancestral couple arriving in New France (Québec) in 1634: Jean Guyon, a mason, and his wife, Mathurine Robin, both born in Perche (northwest of France). It is probable that these ancestors are also responsible for cases reported among the Cajuns of Louisiana (25). The Cajuns' ancestors came from the French colony of Acadia, which includes the territory of Canada now known as Nova Scotia and New Brunswick. The area was first colonized in 1604 by fishermen from the northern coastal regions of France.

TABLE 1. Classification of Hereditary Ataxia

Heredity	Progression	Onset	Reflexes	Ataxia	Entity
1.0 Dominant	1.1 Nonprogressive	1.1.1 Infantile			
		1.1.2 Early			
		1.1.3 Adult			
	1.2 Intermittent	1.2.1 Infantile			
		1.2.2 Early			
		1.2.3 Adult			
	1.3 Progressive	1.3.1 Infantile			
		1.3.2 Early	1.3.3.1 + Reflexes	1.3.2.1.1 Pure ataxia	Dominant spastic ataxia
		1.3.3 Adult	1.3.3.2 - Reflexes	1.3.2.1.2 Ataxia plus	
2.0 Recessive	2.1 Nonprogressive	2.1.1 Infantile			
		2.1.2 Early			
		2.1.3 Adult			
	2.2 Intermittent	2.2.1 Infantile			
		2.2.2 Early			

2.2.3 Adult					
2.3 Progressive	2.3.1 Infantile				
	2.3.2 Early	2.3.2.1 + Reflexes	2.3.2.2.1	Pure ataxia	Friedreich ataxia
	2.3.3 Adult	2.3.2.2 - Reflexes	2.3.2.2.2	Ataxia plus	
3.0 X-linked	3.1 Nonprogressive	3.1.1 Infantile			
		3.1.2 Early			
		3.1.3 Adult			
	3.2 Intermittent	3.2.1 Infantile			
		3.2.2 Early			
		3.2.3 Adult			
	3.3 Progressive	3.3.1 Infantile			
		3.3.2 Early			
		3.3.3 Adult			

Overall scheme of classification (9). The coding procedure is subdivided progressively from left to right as heredity, progression, onset, reflexes, and ataxia are determined. To date, more than 57 syndromes have been identified, but for clarity, only two examples are shown: dominant spastic ataxia coded 1.3.2.1.1 and Friedreich ataxia coded 2.3.2.2.1, which translates into autosomal recessive ataxia of a progressive nature, early onset, diminished or absent knee jerks, and without major involvement of other systems within the brain.

Unfortunately, the biochemical abnormality underlying the disorder has not yet been identified. Four areas of metabolic disturbances have been investigated: a taurine retention defect, abnormality in the pyruvate dehydrogenase complex, defective incorporation of linoleic acid in fatty acids, and disturbance of pyruvate-malate metabolism (6 ,7).

Diagnosis

Because of the large number of ataxic syndromes identified, it is of utmost importance to establish a clear diagnosis for every patient believed to have Friedreich's ataxia. Geoffroy et al. (19) proposed the following classification system, later modified by Harding (20), which is now universally accepted:

- Group I: Typical Friedreich's ataxia
- Group Ia: Complete picture
- Group Ib: Incomplete picture
- Group IIa: Atypical Friedreich's ataxia
- Group IIb: Not Friedreich's ataxia

Typical Friedreich's ataxia (groups Ia and Ib) can be characterized by a number of primary, constant symptoms and signs that are present in all cases and are essential for diagnosis. There also are secondary signs that are present in more than 90% of cases. Finally, there are a large number of accessory symptoms and signs that cannot be used to establish a diagnosis. Patients with group Ib Friedreich's ataxia are identical to those with group Ia ataxia except that they lack any evidence of pes cavus. Patients with group IIa ataxia differ from those in group I mainly through lack of progression of the ataxia and a very mild degree of scoliosis. Group IIb is heterogeneous; specifically, dysarthria, posterior column signs, and muscle weakness are lacking.

The primary symptoms and signs needed for diagnosis of Friedreich's ataxia are onset of symptoms before 25 years of age, progressive ataxia of limbs and of gait, absent knee and ankle jerks, extensor plantar responses, decreased motor nerve conduction velocity in upper limbs with small or absent sensory action potentials, and dysarthria. The secondary symptoms and signs are present in most cases but are not essential for diagnosis. These are scoliosis, pyramidal weakness in lower limbs, absent reflexes in upper limbs, distal loss of joint position and vibration sense in lower limbs, and abnormal electrocardiographic findings.

Finally, the accessory symptoms and signs present in less than 50% of cases are optic atrophy, nystagmus, distal weakness and wasting, partial deafness, pes cavus, and diabetes.

Pathologic Anatomy

The anatomic lesions of the peripheral and central nervous system found at autopsy or biopsy of persons with typical Friedreich's ataxia are remarkably similar among published reports (23 ,32 ,33). There is moderate to marked loss of large myelinated fibers and limited loss of small fibers in the peripheral nerves. Degeneration does not affect unmyelinated fibers, and there is limited evidence of myelin breakdown at the periphery. There is extensive degeneration of large neuron cell bodies in the posterior root ganglia with segmental demyelination and remyelination. This suggests dying-back axonopathy whereby axonal degeneration slowly progresses from the distal portion of the fiber toward the cell body.

In the spinal cord, anterior horns and cranial motor nerves appear normal, but there is marked loss of large myelinated fibers in the posterior columns. In the cerebellum, the most striking alterations are moderate to marked loss of dentate neurons and myelinated fibers in the dentate nucleus. Pathologic changes in the brain stem are variable, and the cerebral cortex and white matter are normal.

Laboratory Studies

Nerve conduction studies (14 ,36) reveal markedly decreased or absent sensory action potentials in the digital and sural nerves. Conduction velocity along the motor and sensory fibers of the median and tibial nerves is moderately slowed. Somatosensory evoked potentials (35) show a marked reduction in amplitude along all registration levels and a prolonged latency of the first cortical event. At electromyography, most patients have a moderate to severe loss of motor units, an increase in mean duration of motor unit potentials, and an increase in incidence of polyphasic potentials (14 ,36).

Pulmonary function studies show evidence of restrictive lung disease that is proportional to the severity of scoliosis (12). These findings are comparable with the alterations found in adolescent idiopathic scoliosis. Electrocardiography, echocardiography, angiography, and cardiac catheterization all reveal findings consistent with progressive hypertrophic cardiomyopathy but without any clear correlation between the degree of abnormal findings and the severity of neurologic impairment (16). All results of routine hematologic and biochemical laboratory tests are normal except for an increased prevalence of clinical and chemical diabetes (around 40%) with an abnormal glucose tolerance test result and hyperinsulinemia (7).

Course of Scoliosis

Since the original description in 1863, very little has been published on the behavior of the scoliosis that is so intimately associated with Friedreich's ataxia. Earlier reports (21) were mostly anecdotal and based on the personal experience of the authors, who had treated a limited number of patients. Furthermore, many unrelated ataxia syndromes probably were mistaken for typical Friedreich's ataxia before Geoffroy's classification was accepted. This may explain why scoliosis in Friedreich's ataxia was previously considered a neuromuscular curve pattern similar to the curve of muscular dystrophy or spinal muscular atrophy, characterized by a relentlessly progressive, predominantly *C*-shaped thoracolumbar pattern associated with pelvic obliquity and severe muscle weakness.

More recent evidence based on larger retrospective series of 42 patients (13), 19 patients (17), and a pool of 56 patients with typical Friedreich's ataxia observed for an average of 9 years (1 ,2 ,3 ,29 ,31) does not support many previous beliefs. The results of these studies suggest that scoliotic deformities in this disease follow a distinct pattern of behavior that is important to understand to plan treatment.

The prevalence of scoliotic deformities is close to 100% (13 ,31). This figure is higher than that generally reported in the orthopaedic literature, which probably reflects exclusion of other closely related syndromes through strict adherence to the criteria of typical Friedreich's ataxia. Scoliosis appears to be a constant finding, although it is not always present at the time of diagnosis.

The sexes are equally affected, and left-sided curves are as frequent as right-sided curves, as is the case in many neuromuscular deformities. The curve pattern, however, is more closely related to that of idiopathic scoliosis with a clear predominance of double structural thoracic and lumbar curves (57% of cases at my institution [1 ,2 ,3 ,29 ,31]) followed by single thoracic or lumbar curves. The classic *C*-shaped thoracolumbar curve pattern occurred in only 18% of cases in Cady and Bobechko's (13) series, 25% of cases reported by Daher et al. (17) series, and 14% of cases at my institution (1 ,2 ,3 ,29 ,31) (Fig. 1). In a comparison between subjects with cerebral palsy, Friedreich's ataxia, and adolescent idiopathic scoliosis, Aronsson et al. (5) found that the scoliosis curve patterns among children with Friedreich's ataxia and adolescent idiopathic scoliosis were similar. In contrast, the curve pattern among children with cerebral palsy was distinctly different. The cerebral palsy pattern had more rotation of the apical vertebrae into the convexity of the scoliosis curve (transverse plane deformity) in relation to the amount of lateral deviation of the apical vertebrae from the spinal axis (coronal plane deformity).

Nonstructural curves with a Cobb angle less than 20 degrees and little or no vertebral body rotation are frequent among immature patients and are a reflection of the postural abnormality caused by ataxia. These curves are highly variable and can change dramatically between follow-up visits. Eventually a more definite structural curve pattern with vertebral body rotation is established as the syndrome progresses (Fig. 2).

My colleagues and I (31) studied progression of structural curves by assigning patients to one of three groups according to behavior of scoliosis during a follow-up period. Group I, comprising approximately one third of the patients, included those with clearly progressive curves and Cobb angles greater than 60 degrees. Group II, comprising one third of patients, included those with nonprogressive curves and Cobb angles less than 40 degrees at skeletal maturity after more than 10 years of follow-up evaluation. Group III comprised the last one third of patients, among whom the presence or absence of progression could not be established because of insufficient follow-up evaluation.

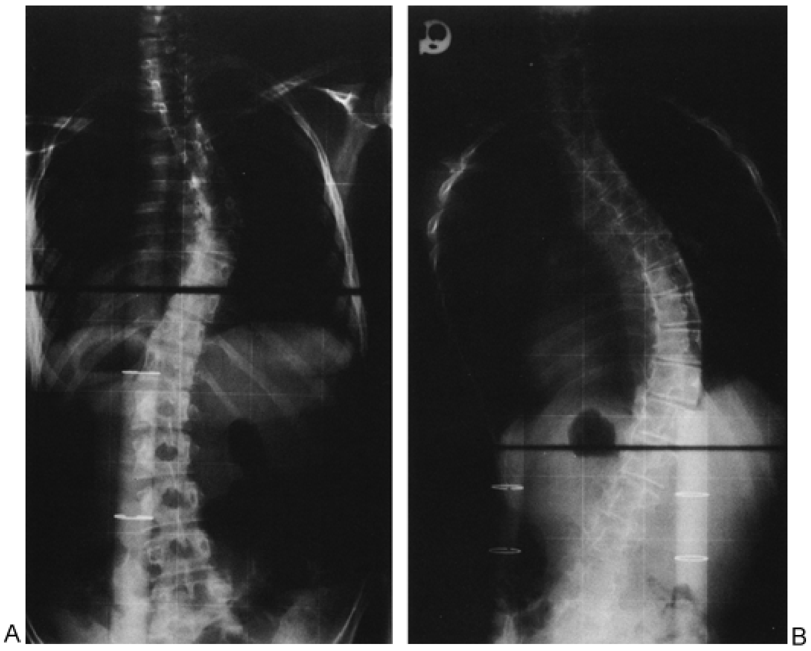

FIGURE 1. Structural scoliotic curve patterns. **A:** Double structural thoracic and lumbar curve pattern that occurs among most patients. **B:** *C*-shaped thoracolumbar curve pattern with pelvic obliquity that occurs among approximately 20% of the population.

It thus appears reasonable to state that scoliotic deformities are not always relentlessly progressive and that at least one third of the population does not need treatment. Because patients with Friedreich's ataxia die, on average, early in the third decade of life (22), many do not live long enough to experience scoliosis progression that necessitates treatment. It is also clear that many patients have curves that deteriorate rapidly and necessitate some form of treatment.

Early recognition of these two distinct patterns of progression is important. Although a pathognomonic sign has yet to be identified, many risk factors have been studied (31). Age, sex, type of curve, pelvic obliquity, trunk alignment, and duration of disease are similar for both groups and do not appear to influence the prognosis. There is, however, a statistically significant correlation between progression of the scoliosis and age at onset of disease or age at recognition of scoliosis.

The maximum growth spurt of patients with Friedreich's ataxia occurs between 10 and 15 years of age for girls and between 12 and 17 years for boys (1). For most patients with a progressive curve pattern, onset of the disease or recognition of scoliosis occurs before this growth spurt. Progression of the curve is more severe while the growth spurt continues, suggesting that skeletal immaturity is a key factor in development of the deformity. Few patients with late-onset disease have severe scoliosis.

My colleagues and I have studied muscle weakness as a possible prognostic factor (10 ,26 ,29 ,31). No significant correlation was established between overall muscle weakness and curve progression, as would be expected in neuromuscular scoliosis such as muscular dystrophy or spinal muscular atrophy. The muscle weakness is symmetric, slowly progressive in the first decades of the disease, and rapidly progressive when functional walking is lost. First and mainly, it involves the proximal rather than distal lower limb muscles, whereas the upper limbs and trunk remain relatively spared. There is no apparent correlation between extent of muscle weakness and level of functional walking, suggesting that muscle weakness is not the primary cause of gait deterioration (10).

Although not proved beyond doubt, it is probable that ataxia

is the other prime determinant of curve progression, just as severity of ataxia and not muscle weakness is primarily responsible for gradual loss of the ability to walk during the second decade of life. It is tempting to postulate that the pathogenesis of scoliotic deformities in this disorder is mainly ataxia, which causes a disturbance of equilibrium and postural reflexes—a disturbance that more and more investigators are suggesting is operative in idiopathic scoliosis. The effect of early-onset ataxia coupled with an immature and rapidly developing spine might explain the progressive curves.

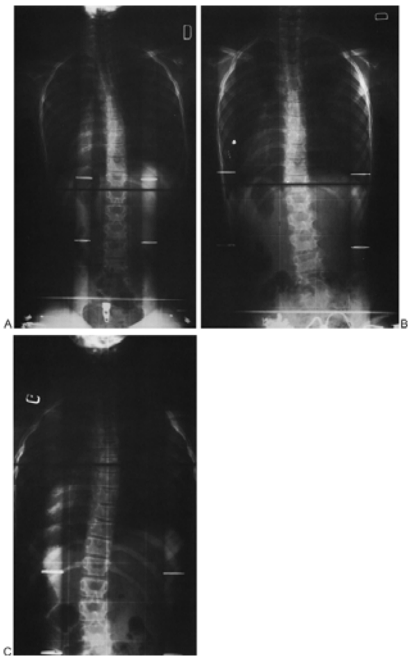

FIGURE 2. Nonstructural scoliotic curve patterns. **A:** Small, nonstructural right thoracic curve with little or no vertebral body rotation in a 10-year-old boy. **B:** Same patient 6 months later. The curve pattern has changed to a left thoracolumbar curve. **C:** Same patient 1 year later. There is now a right thoracic and left lumbar curve. Small nonstructural curves are highly variable among young patients and probably reflect the postural abnormality present before a definite structural curve is established.

In summary, scoliosis among patients with Friedreich's ataxia usually does not have the typical pattern of neuromuscular scoliosis. It appears to behave as an idiopathic curve in the following respects. The curve patterns are similar, many curves are not progressive or slowly progressive, there is no relation to muscle weakness, and early onset of the disease and the presence of a scoliosis before puberty are major factors of progression.

Sagittal Plane Abnormalities

Clinical studies (13 ,17 ,29 ,31) have shown a 40% to 66% incidence of increased thoracic kyphosis and a frequent decrease in lumbar lordosis during clinical and radiologic evaluation of patients with Friedreich's ataxia. The decrease in lumbar lordosis is easily explained by the sitting position of patients who cannot walk. The increased thoracic kyphosis, however, is somewhat controversial, because it implies that a kyphoscoliotic deformity is present. This would be an argument against the statement that the course of these deformities tends to resemble, in some respects, that of idiopathic scoliosis. It is now well recognized that idiopathic curves are lordoscoliotic and not kyphoscoliotic.

Investigations by our research group (1 ,28 ,30) using three-dimensional reconstructions of thoracic and thoracolumbar scoliosis deformities in Friedreich's ataxia have shed some light on this apparent contradiction. These studies demonstrated that both kyphotic and lordotic segments can coexist in the same person (Fig. 3). The thoracic or thoracolumbar scoliotic segment is most frequently associated with hypokyphosis or even lordosis as in idiopathic scoliosis. Many kyphotic segments seen on lateral radiographs are really pseudokyphotic from vertebral body rotation. Stagnara calls this kyphosis due to vertebral rotation *kyphosing scoliosis* (see Chapter 44).

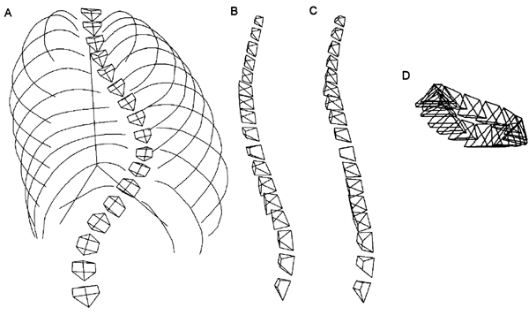

FIGURE 3. Example of a three-dimensional computer-generated graphic representation of a scoliotic deformity reconstructed from standardized anteroposterior and lateral radiographs of a patient with Friedreich's ataxia (27,28,30). **A:** Posteroanterior view of the spine from T1 to L5 shows a right thoracic curve pattern. **B:** Lateral view of the same deformity shows thoracic kyphosis, but it is located mostly above the scoliotic segment between T1 and T5. The thoracic scoliotic segment between T6 and L1 is not visible in a true lateral view because of the associated vertebral body rotation. **C:** True lateral view of the thoracic scoliotic segment. The same model has been rotated en bloc to show the lateral aspect of the thoracic scoliosis centered on T10. The scoliotic segment between T6 and L1 is clearly hypokyphotic. **D:** Apical view of the same spinal deformity shows high thoracic kyphosis from T1 to T5. The rest of the spine is straight or lordotic.

True kyphotic segments do occur, but they are usually located above the scoliotic segment in the upper thoracic area or sometimes at the thoracolumbar junction between two curves. Kyphotic deformities tend to appear later in the course of the disease, many years after the appearance of a scoliotic deformity. These deformities often are supple, compensated for by an upper cervical lordosis, and tend to progress when the patient uses a wheelchair full-time and has acquired considerable muscle weakness.

Treatment

The earlier discussion of the course of this condition shows that although scoliosis in Friedreich's ataxia can certainly be classified as neuromuscular scoliosis, it should be considered more “neurologic” than “muscular.” This implies that the scoliotic deformity is not a collapsing spinal disorder such as that of Duchenne muscular dystrophy or poliomyelitis. Except for true thoracic kyphotic deformities that appear later in the course of the disease and are somewhat related to muscle weakness, the behavior of the scoliotic deformity has many similarities to adolescent idiopathic scoliosis. Treatment principles should take these facts into consideration.

Nonoperative treatment has generally been unsuccessful and is not recommended (13 ,17 ,21 ,31). In particular, attempts at holding curves with various types of bracing have repeatedly been shown to be of limited value. Bracing often is poorly tolerated and may impair walking ability at a time when patients are struggling to continue walking. Bracing may be indicated for skeletally immature patients with progressive curves to delay surgery and allow maximal growth of the spine. Electrospinal instrumentation has been tried in the treatment of a limited number of patients and has failed in every case (13).

There are no data on the efficiency of physical therapy, but it probably does not alter the natural course of the deformity. Similarly, among patients who use a wheelchair full-time, various positioning devices are routinely prescribed, but it is doubtful that they have any solid effect in preventing curve progression. They are, however, useful for improving sitting ability and correcting flexible scoliotic or kyphotic deformities.

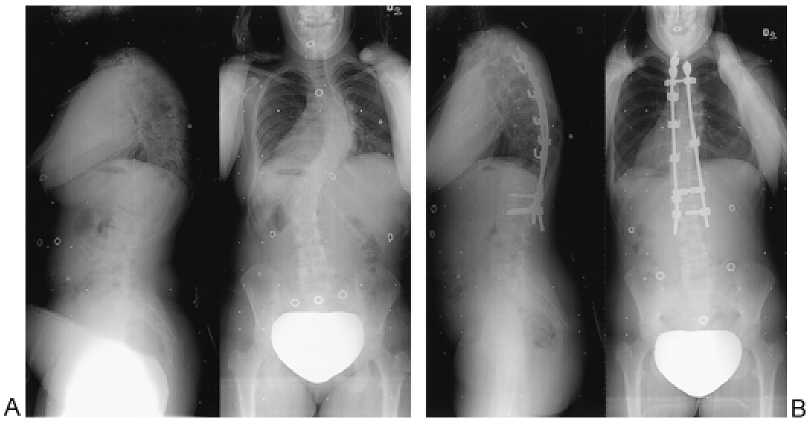

FIGURE 4. Preoperative and postoperative posteroanterior and lateral digital radiographs of a 12-year-old girl with Friedreich ataxia. **A:** Fusion and instrumentation were done with combined anterior thoracic release and posterior instrumentation and fusion with a multiple-rod, hook and screw system. **B:** The instrumentation was extended high in the thoracic area to include the upper thoracic kyphotic segment.

Surgery is the only treatment that can clearly alter the prognosis by providing curve correction and stabilization of a progressive curve (13 ,17 ,31 ,39). An adequate preoperative investigation is important. Careful evaluation should be conducted for cardiomyopathy. Pulmonary function tests are mandatory. Because muscle weakness usually is not severe when a surgical procedure is performed in the adolescent period (10), respiratory complications are less likely than with other neuromuscular disorders. Screening for diabetes also should be routine. During anesthesia, careful monitoring of cardiopulmonary function should be instituted, because Friedreich's ataxia has been reported to cause marked sensitivity to nondepolarizing muscle relaxants and to cause hyperkalemia, with resulting cardiac arrhythmias after administration of succinylcholine (suxamethonium) (11). Because somatosensory evoked potentials are markedly reduced or absent, spinal cord monitoring should be done with motor evoked potentials (37) and the Stagnara wake-up test.

The indications for surgery are similar to those for adolescent idiopathic scoliosis and include all scoliotic deformities with a clearly progressive curve and a Cobb angle greater than 40 degrees in the frontal plane. On the basis of the data available in the literature, the following treatment protocol is recommended. Curves less than 40 degrees should be followed, curves more than 60 degrees should be managed surgically, and curves between 40 and 60 degrees can be either followed or managed surgically. In the latter case, treatment decisions are based primarily on the patient's age at onset of the disease, age when the scoliosis is first recognized, and evidence of curve progression. A 50-degree thoracic curve with no further evidence of progression in a young adult probably does not necessitate treatment, whereas a 45-degree curve in a skeletally immature patient with early-onset disease should be managed by means of surgical stabilization and fusion.

Most series dealing with treatment have reported good results of spinal fusion with Harrington, Harrington-Luque, or Luque instrumentation (13 ,17 ,21 ,39). Because of the ataxia and the balance problems associated with the disease, postoperative bracing with a thoracolumbosacral orthosis (TLSO) may be useful for a few months after the operation to decrease the risk of early implant failure, particularly among patients who walk. Although there are no reports in the literature, the use of the newer-generation of multiple rod, hook and screw systems that allow improved three-dimensional correction of scoliotic curves appears logical and is recommended (Fig. 4).

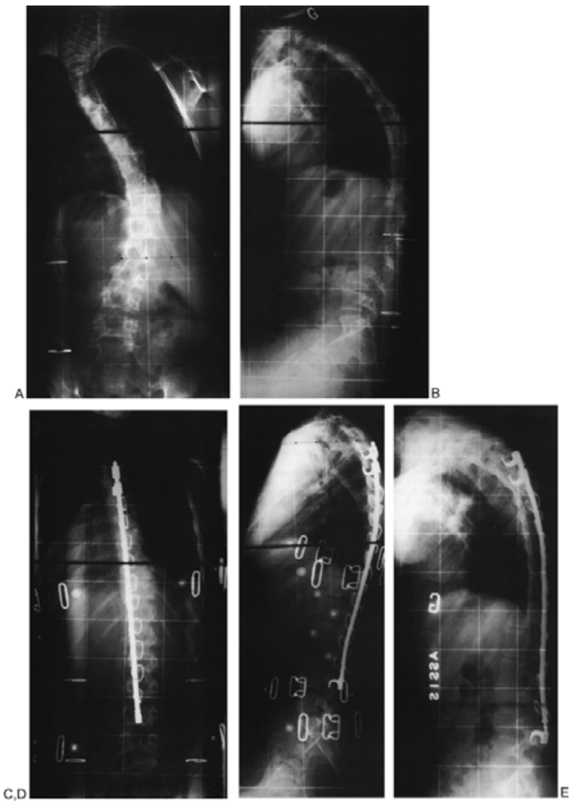

FIGURE 5. A: A 10-year-old boy with a progressive neuromuscular-like thoracolumbar curve pattern. In this case, progression of the disease was rapid, with early loss of ambulation and severe muscle weakness. **B:** Lateral radiograph of same patient as **A** in the sitting position. Associated high thoracic kyphosis is evident. When present, such kyphosis should always be considered in surgical planning. **C, D:** Results soon after Harrington-Luque instrumentation and fusion. A lightweight bivalved orthosis has been added for further protection during walking because of the severe ataxia and frequent falls. Fusion to the sacrum was not done, because there was no associated pelvic obliquity. **E:** Late postoperative result at 17 years of age. There has been recurrence and deterioration of the kyphosis above the instrumentation. In retrospect, instrumentation and fusion should have been extended higher in the thoracic area, as suggested by the preoperative lateral radiograph.

It is not necessary to extend fusion and instrumentation to the sacrum except for *C*-shaped thoracolumbar curves with associated pelvic obliquity. In all other curves, the lower level of instrumentation should be selected with the same criteria as for idiopathic scoliosis. On the other hand, fusion and instrumentation should be extended high (T2 or T3) in the thoracic area to prevent the development or deterioration of kyphosis above the scoliotic segment (Fig. 5). Anterior surgical release with or without instrumentation, usually followed by posterior instrumentation, should be limited to rigid curves greater than 60 degrees associated with poor sitting balance.

Summary

Friedreich's ataxia is a relatively rare disorder, but it is by far the most frequent ataxic syndrome and deserves particular attention, because a scoliotic deformity is nearly always associated. The course of scoliosis in this disorder is different from that of other types of neuromuscular scoliosis and tends to behave as idiopathic scoliosis in many respects. The curve patterns are similar, many curves are nonprogressive, there is no relation between muscle weakness and the scoliotic deformity, and onset of the scoliosis before puberty is a major factor in progression. In most cases, the scoliotic segment is associated with hypokyphosis or lordosis, but kyphotic deformities frequently occur in the high thoracic area above the scoliotic segment.

So far, nonoperative treatment has been unsuccessful in preventing curve progression. Surgical stabilization with fusion is the only treatment that can clearly alter the prognosis of progressive curves. The following treatment protocol is recommended. Curves less than 40 degrees should be followed; curves more than 60 degrees should be managed surgically; and curves between 40 and 60 degrees should be either followed or managed surgically. Treatment decisions should be based primarily on the patient's age at disease onset, the age when the scoliosis was first recognized, and evidence of curve progression.

Duchenne and Becker Muscular Dystrophy

For many years, the Duchenne and Becker forms of muscular dystrophy were described as two distinct diseases. They are now considered to be mild and severe forms of the same disease. They occur mainly among boys, are characterized by proximal muscle weakness, and have an X-linked recessive inheritance pattern (women are carriers). Children with Duchenne muscular dystrophy have more severe clinical manifestations than do those with Becker muscular dystrophy.

The gene defect has been isolated to the Xp21 locus of the X chromosome. The protein product, dystrophin, is a large (427 kd), intracellular, structural component of the plasma-membrane system in normal muscle fibers (17 ,54). It is also found in the neural tissues of the cerebrum, cerebellum, and peripheral axons. The exact biologic function of dystrophin remains unknown. At the genetic level, both forms of muscular dystrophy are caused by mutations of the X-linked gene encoding dystrophin. However, at the biochemical level, Duchenne muscular dystrophy is caused by a deficiency of dystrophin, and the Becker form occurs when dystrophin is present but is abnormal in either amount or molecular structure (54).

Portions of the coding sequences of the gene (c-DNA) have been used to produce polyclonal antiserum directed against the protein product of the normal gene. The polyclonal antibodies have been used to assess the quantity and quality of dystrophin in muscle biopsy specimens from patients believed to have Duchenne or Becker muscular dystrophy. According to the dystrophin level in the muscle biopsy specimen, clinical categories are defined as follows: Duchenne dystrophy, less than 3% of normal; severe Becker dystrophy, 3% to 10% of normal; and moderate to mild Becker dystrophy, 20% or more of normal dystrophin levels. Most patients with Duchenne dystrophy have undetectable levels of dystrophin, and most of those with Becker dystrophy have nearly normal levels of an altered form of dystrophin (54).

The diagnosis of Duchenne muscular dystrophy usually is made between the ages of 3 and 5 years. Motor milestones may be delayed by a few months but tend to occur within the normal range. Running is found to be awkward by the age of 18 months to 2 years, although often only in retrospect. Stair climbing becomes progressively more difficult. Some children are seen first by an orthopaedic surgeon with a main symptom of toe-walking or flat-feet. Other clinical findings of the condition that usually are apparent by 3 years of age include enlarged calf muscles, mild iliotibial band and Achilles tendon contractures, proximal weakness, and a positive Gowers sign, which indicates gluteus maximus and quadriceps weakness (Fig. 1). Later, a wide-based, lordotic stance and waddling Trendelenburg gait become apparent.

The diagnosis has traditionally been confirmed with the laboratory finding of a massively elevated level of creatinine phosphokinase (50 to 100 times normal), an electromyogram showing myopathy, and a muscle biopsy characterized by variations of fiber size in internal nuclei, split fibers, degenerating or regenerating fibers, and fibrous tissue deposition (17). Often a family history of muscular dystrophy can be elicited. Diagnostic evaluation includes DNA analysis to identify the specific mutation and protein analysis to determine the quantity and quality of dystrophin in the muscle tissue. This allows for quick and accurate differentiation between Duchenne and Becker muscular dystrophy.

Many advances have been made in prenatal testing. Reliable prenatal diagnosis can be made with chorionic villus biopsy, although this procedure carries some inherent risk. Other options include immunologic analysis of dystrophin expression obtained from fetal amniocytes or fibroblasts. Noninvasive prenatal DNA diagnosis of fetal cells in maternal blood is being studied but is not yet clinically available (47).

Clinical Course

After 5 years of age, walking gradually becomes more labored for patients with Duchenne muscular dystrophy. A typical preadolescent patient stands with anterior pelvic tilt and increased lordosis. Gluteus maximus and quadriceps weakness makes independent walking precarious generally by 8 to 10 years of age. As a result of increasing muscle weakness and decreasing activity level, children have hip and knee flexion contractures and equinovarus deformities of the feet. At this stage, patients are treated with iliotibial band release and Achilles tendon lengthening coupled with anterior transfer of the posterior tibialis muscle and the introduction of knee-ankle-foot orthoses. This combined surgical and orthotic approach prolongs walking for about 1.5 years for most patients. The patients typically stand in lordosis, which protects them from kyphoscoliosis until early in the second decade, when standing with orthoses becomes limited. These patients generally begin using a wheelchair full-time by 11 to 13 years of age and then have progressive thoracolumbar scoliosis. Other clinical findings include cardiomyopathy and decreased mental capacity. A relentless progression of spinal deformity and associated decline in pulmonary function contribute directly to early death. Death usually occurs in the late teens or early twenties as a result of cardiopulmonary failure and respiratory infections.

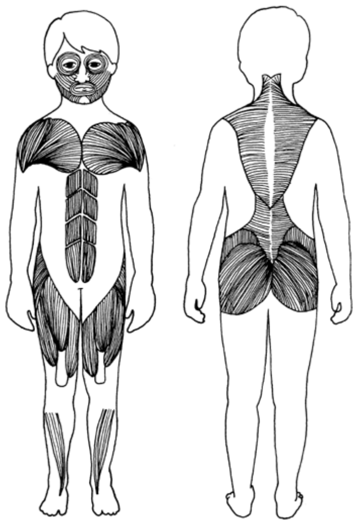

FIGURE 1. Patients with Duchenne muscular dystrophy have a characteristic, symmetric pattern of muscle weakness that involves the facial muscles, shoulder and pelvic girdles, spinal extensors and abdominals, and tibialis anterior.

Becker muscular dystrophy has symptoms similar to those of Duchenne muscular dystrophy. The onset of symptoms occurs later, however, and the condition is less severe, so ability to walk often persists into the twenties and beyond. In the past, the most dependable differentiation between the Duchenne and Becker types was the clinical course. In the Becker variant, similar electromyographic and creatinine phosphokinase abnormalities are seen, and only subtle distinctions may be evident in a biopsy specimen. Cardiac involvement and mental retardation are much less frequent in Becker muscular dystrophy. Most patients do not need surgical intervention to maintain ambulation until the adolescent years. The clinical presentation of Becker dystrophy tends to overlap with that of other non–sex-linked neuromuscular disorders, such as limb-girdle dystrophy and some metabolic and mitochondrial forms of myopathy.

Course of Spinal Deformities in Duchenne Muscular Dystrophy

Wilkins and Gibson (53) theorized two pathways of spinal deformity in Duchenne muscular dystrophy—a stable pathway characterized by a position of extension and an unstable pathway exhibiting progressive thoracolumbar kyphosis and scoliosis. A prophylactic electric wheelchair spinal support system was proposed to guide the early straight spine into a stable extended posture, thereby averting the need for operative intervention (13). Although there is a relation between extension of the lumbar spine and severity of scoliosis at the time of final follow-up examination, maintenance of lumbar lordosis is difficult and rarely prevents development of severe scoliosis even when support systems and braces are used (18 ,43 ,51).

The incidence of progressive scoliosis is about 95% among patients with Duchenne muscular dystrophy (8 ,32). The course of these curves is progression to more than 100 degrees. This usually occurs within 5 years of the beginning of full-time use of a wheelchair and greatly interferes with sitting comfort and proper positioning in the wheelchair, upper-extremity function, caloric ingestion, respiratory function, and appearance.

Smith et al. (43) reviewed the clinical charts and spinal radiographs of 51 boys who had Duchenne muscular dystrophy, no surgical management of the spinal deformity, and follow-up evaluation until death. All had scoliosis. However, the rate of progression of the curve was a determinant of the magnitude of the final curve ($P < .001$). The age at death correlated inversely with the rate of progression of the curve ($P < .01$). None of the following were useful factors in predicting which curves would become severe: age when walking began, age when walking ceased, age at onset of spinal collapse, surgical release of the iliotibial bands, or age at death. The authors found that when a curve exceeded 35 degrees, vital capacity usually was less than 40% of the predicted normal value. Hsu (18) found that the curve progressed 0.3 to 4.5 degrees each month in all eight of his patients, who were between the ages of 13 and 22 years at the time of follow-up evaluation.

In a study performed at Children's Hospital San Diego, investigators found an average 10-degree increase in thoracic scoliosis for each year of life once the child began using a wheelchair full-time (26). Cambridge and Drennan (8) found that in 95% of patients, some of whom were observed until death, the curve had progressed to an average of 75 degrees at the last examination. Curve progression was found even in the 32 boys with curves of more than 30 degrees who wore braces.

Oda et al. (37) classified the course of spinal deformity into three types: unremitting progression of scoliosis with kyphosis (type I), transition from kyphosis to lordosis before 15 years of age (type II), and mild deformity without prominent longitudinal changes (type III). The authors found that all patients with type I deformities had a Cobb angle greater than 30 degrees by 15 years of age and that the deformity progressed to a condition of “a collapsing spine.” Patients with type II deformities had a less predictable progression of scoliosis, especially those with double curves. Patients with Type III deformities had a more benign course that was associated with improvement in pulmonary function. In the series of 46 patients, 21 (46%) were classified as having type I deformity, 18 (39%) as having type II, and only seven (15%) as having type III deformity. The authors recommended surgical intervention for all patients with type I deformities and selected patients with type II deformities.

Pulmonary Function in Duchenne Muscular Dystrophy

Duchenne muscular dystrophy produces a restrictive pulmonary disease pattern, but the mechanics that cause this restriction are not well defined. Muscle weakness, muscle contractures, and severe spinal deformities that affect respiratory mechanics are important factors. A decline in respiratory function with increasing age in association with Duchenne muscular dystrophy is well recognized (7 ,15 ,19 ,21 ,22 ,38 ,39 ,48). Decreased respiratory function leads to pulmonary infection and respiratory failure. The forced vital capacity is the best prognostic factor in evaluating pulmonary function (26). Monitoring the rate of decline of forced vital capacity is necessary to ensure that the patient has sufficient pulmonary reserve to safely undergo spinal stabilization.

In idiopathic scoliosis, the degree of scoliosis shows a strong linear correlation with a decline in percentage of predicted forced vital capacity and total lung capacity (23 ,50 ,52). There is general agreement that the degree of thoracic scoliosis is the most important causative factor in declining pulmonary function in idiopathic scoliosis. In contrast, among patients with paralytic scoliosis there is a multifactorial influence on declining pulmonary function, increasing scoliotic deformity being only one of these factors (22).

Although numerous studies had described the pulmonary function abnormality among patients with Duchenne muscular dystrophy, none had showed a correlation with scoliosis until 1983, when investigators at our center conducted a study with 25 patients with this condition (26). We found that forced vital capacity peaked at approximately the age when standing ceased then declined rapidly. Percentage of forced vital capacity was found to be the measure of pulmonary function most strongly correlated with age and thoracic scoliosis measurements. Age and thoracic scoliosis together were better predictors of forced vital capacity than either one alone. Once patients were using a wheelchair full-time, each year of age had approximately the same negative influence on percentage of forced vital capacity as each additional 10 degrees of thoracic scoliosis; both decreased forced vital capacity approximately 4%. A regression equation for percentage of forced vital capacity was used to develop the theory that a patient with scoliosis, the progression of which is halted by spinal instrumentation and fusion, would after the surgery show a slower rate of decline in percentage of forced vital capacity and that this rate is quantifiable and predictable and depends solely on the patient's advancing age.

Our conclusions were supported by Galasko et al. (11), who reported results of the treatment of 55 patients with Duchenne muscular dystrophy observed for scoliosis and pulmonary function. All patients were offered surgical stabilization when the scoliosis measured 20 degrees. Thirty-two accepted, and the 23 who refused were used as the control group. The investigators found that in the group that underwent surgical treatment, forced vital capacity remained static during the first 36 months after the operation and then decreased slightly. In the group that did not undergo surgical treatment, forced vital capacity progressively diminished. Peak expiratory flow rate increased considerably among the group that underwent surgical treatment but remained the same among the controls. The survival data showed a significantly higher mortality among those who declined surgical treatment, indicating that spinal stabilization can improve survival for several years after the operation, provided the procedure is performed promptly before marked progression occurs.

Results of several other studies have contradicted these observations. Miller et al. (32), from the Hospital for Sick Children, Toronto, found that patients who underwent spinal fusion and instrumentation had the same decline in respiratory function postoperatively as the untreated group. Miller et al. (33), of Children's Hospital, San Francisco, described patients with Duchenne muscular dystrophy. These investigators also found no significant difference between the group that underwent surgical treatment and the group that did not in terms of declining respiratory function. Kennedy et al. (24), in Australia, compared pulmonary function and survival rates for 38 patients with Duchenne muscular dystrophy, 17 of whom underwent surgical stabilization of the spine and 21 of whom were treated nonoperatively. These authors also found no difference in pulmonary function or survival among the two groups and reported the decline in forced vital capacity to be 3% to 5% per year. All of these studies, however, were comparisons of patients who underwent surgical stabilization at a relatively advanced stage. The surgical group in all three studies had a mean preoperative Cobb angle greater than 50 degrees. Pulmonary function may be too poor at this stage to benefit from surgical correction. In addition, when patients with larger curves undergo instrumentation full postoperative correction often is not achieved. The residual curve may further compromise pulmonary function.

In summary, percentage of forced vital capacity remains the best test for monitoring the pulmonary function of patients with Duchenne muscular dystrophy. This percentage begins to decline rapidly (approximately 4% a year) once patients begin to use a wheelchair full-time and stabilizes at approximately 25% of normal until death (24 ,26). The benefit of early surgical correction of scoliosis in regard to pulmonary function remains unclear. It appears that once the curve reaches 40 degrees, surgical correction does not influence pulmonary function. Tracheostomy and mechanical ventilation are treatment options to be considered in the more advanced stages of the disease.

Options in for Management of Scoliosis

Nonsurgical

Scoliosis and kyphosis rarely develop while a patient with Duchenne or Becker muscular dystrophy is able to walk. During the later stages of walking, marked lordosis develops, but it is rarely fixed. This is a functional position to compensate for weakness of the gluteus maximus muscle and the subsequent anterior pelvic tilt. It should not be considered a spinal deformity (40). If scoliosis does develop while the child is still able to walk, bracing will be ineffective and will probably end the ability to walk.

Among most patients who have Duchenne or Becker muscular dystrophy, severe spinal deformity develops once the patient begins using a wheelchair full-time. Patients with the Becker type have fewer problems, because the scoliosis usually develops after maturity. Severe scoliosis makes comfortable sitting difficult; even frequent and elaborate position adjustments often cannot prevent pressure sores and pain. Thus some patients become bedridden years before they die, even if prophylactic bracing or positioning in a spinal support system has been used. Braces and spinal support systems may slow the rate of progression of the curve but do not halt it (8 ,18 ,45 ,51).

Gibson et al. (13) initially reported good control of scoliosis with their wheelchair spinal support system. Among 17 patients observed an average of 27.5 months, the average rate of curve progression was held to 0.7 degree per month, or 8.4 degrees a year. Gibson et al. also found that if the curve progressed to 20 to 30 degrees, an anterior-opening spinal orthosis or an anteroposterior bivalved body jacket could be used. For curves greater than 60 degrees, the pressure of the brace was uncomfortable, and effective correction could not be obtained. Further follow-up information from this center showed that the spinal support system only delays the progression of scoliosis; it does not prevent it (51).

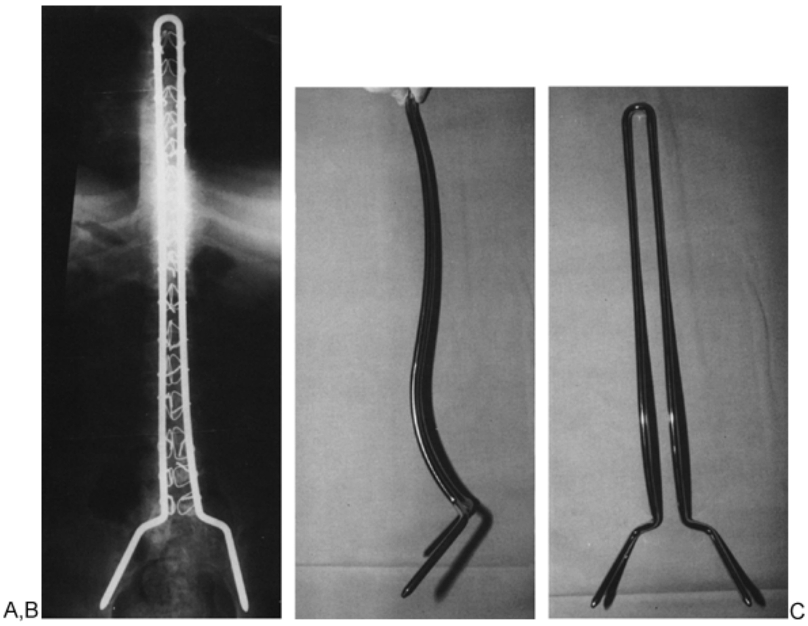

FIGURE 2. A 13-year-old boy with Duchenne muscular dystrophy and progressive scoliosis underwent posterior spinal fusion and instrumentation with a unit rod and sublaminar wires. **A:** Anteroposterior radiograph 2 months after the operation. **B:** Prebent sagittal plane contours of the Unit Rod. **C:** Unit Rod. (Courtesy of Stuart L. Weinstein, M.D.)

It is now generally believed that orthotic management is inappropriate because curve progression is only slowed. The systemic manifestations of the disease continue and cause further deterioration in cardiac and pulmonary function. The braced spinal deformity eventually progresses rapidly. By this time, the patient's may be too debilitated by decreases in pulmonary function to withstand surgery. All these patients should use well-fitting wheelchairs with solid, cushioned seat, back, and lateral trunk supports until spinal fusion is indicated. Patients with power-driven wheelchairs should use a midline control.

Surgical

Posterior spinal instrumentation with fusion is the therapy of choice for scoliosis among patients with Duchenne muscular dystrophy once they are no longer able to walk. This treatment is indicated to improve quality of life and upright wheelchair positioning.

In 1982, Luque (29) revolutionized the surgical management of paralytic scoliosis when he introduced his segmental spinal instrumentation. This procedure eliminated the need for prolonged postoperative immobilization, which is characteristic of Harrington instrumentation. Segmental instrumentation has the advantage of allowing immediately postoperative mobilization without a Risser cast or spinal orthosis. Later, the addition of the Galveston technique of pelvic instrumentation allowed stable spinal instrumentation to the pelvis to manage paralytic scoliosis (1). An additional modification in instrumentation is the unit II rod described by Moseley et al. (34), which allows improved control over pelvic obliquity and tilt to prevent relative translation and rotation (Fig. 2).

It is generally agreed that fusion must be extended into the upper thoracic area to avoid cephalic progression of the curve due to progressive trunk and neck muscle weakness. However, the caudal extent of the fusion continues to be debated. It is essential to center the patient's head over the midpelvis in both the coronal and sagittal planes to prevent the upper body weight from acting as a pendulum, which could lead to loss of head control and cephalic extension of the curve. Because of these concerns, it was initially recommended that instrumentation and fusion be performed to the sacrum to prevent or correct pelvic obliquity (27). However, as Allen and Ferguson (1) pointed out, pelvic fixation is technically demanding, increases operative time, and poses increased risk of complications. In 1984, Sussman (45) suggested that fusion and fixation to the level of L5 may be sufficient for Duchenne muscular dystrophy, but the follow-up period of the study was limited.

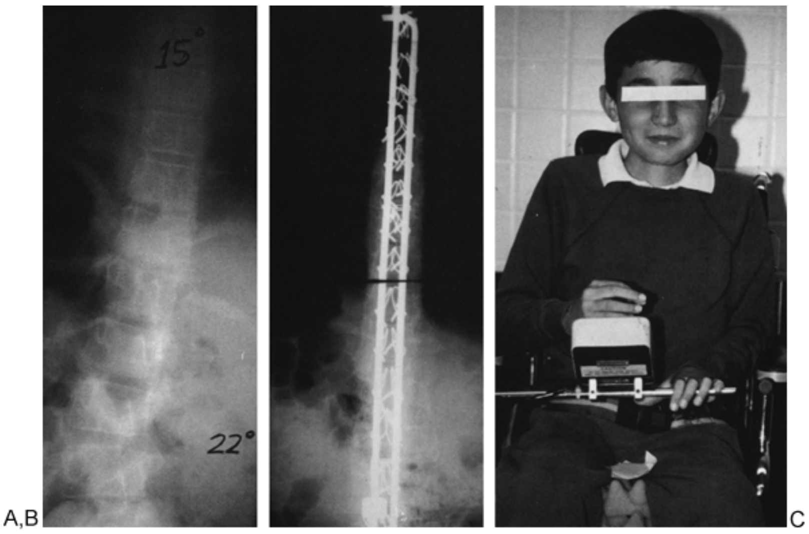

FIGURE 3. A 13-year-old boy with Duchenne muscular dystrophy had 15-degree right thoracic, 22-degree left lumbar scoliosis **(A)**. **B:** Five years after Luque segmental instrumentation to L5, the spine is straight with no substantial residual lumbar curve or pelvic obliquity. **C:** Clinical appearance 5 years after the operation.

To better define this issue, Mubarak et al. (35) conducted a prospective study with two groups of patients: 12 undergoing instrumentation and fusion to the sacrum and ten undergoing to L5 only. For all patients, instrumentation and fusion were performed cephalad to the high thoracic level, generally T2–3. The average follow-up period was 7 years. The minimum was 5 years for all living patients. There were no significant differences in estimated blood loss or length of stay in the intensive care unit and hospital between the two groups. The operative time was approximately 30 minutes longer among patients who underwent fusion to the sacrum. Review of the patients' sitting balance and pelvic obliquity revealed only minor differences between the two groups (Figs. 3 , 4). Only one patient (with a preoperative curve of 50 degrees) had marked preoperative pelvic obliquity that was not fully corrected at surgery (Fig. 5). No other patients had substantial pelvic obliquity, and all maintained an upright or only slightly shifted sitting position postoperatively (Fig. 6). It was concluded that instrumentation to L5 is sufficient if treatment is initiated early.

Alman and Kim (2) reported a similar comparison of 48 patients with Duchenne muscular dystrophy. Ten patients underwent fusion and instrumentation to the pelvis, and 38 patients underwent fusion and instrumentation to L5. The authors reported an increase in pelvic obliquity in 32 of the 38 patients

who underwent fusion to L5 and in two of the ten patients who underwent fusion to the sacrum. They found substantial increases only when the apex of the preoperative curve was below L1. They therefore recommended fusion to the sacrum for all curves with an apex below L1.

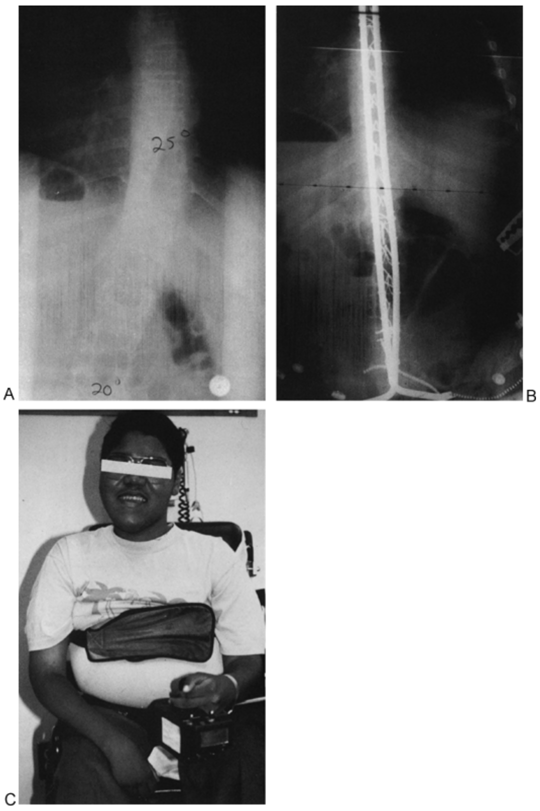

FIGURE 4. A 14-year-old boy with Duchenne muscular dystrophy. **A:** A 25-degree right thoracic, 20-degree left lumbar curve was managed with spinal instrumentation and fusion. **B:** Seven years after Luque segmental instrumentation and fusion from T2 to the pelvis, there is no substantial scoliosis or pelvic obliquity. **C:** The patient sits in a shifted position.

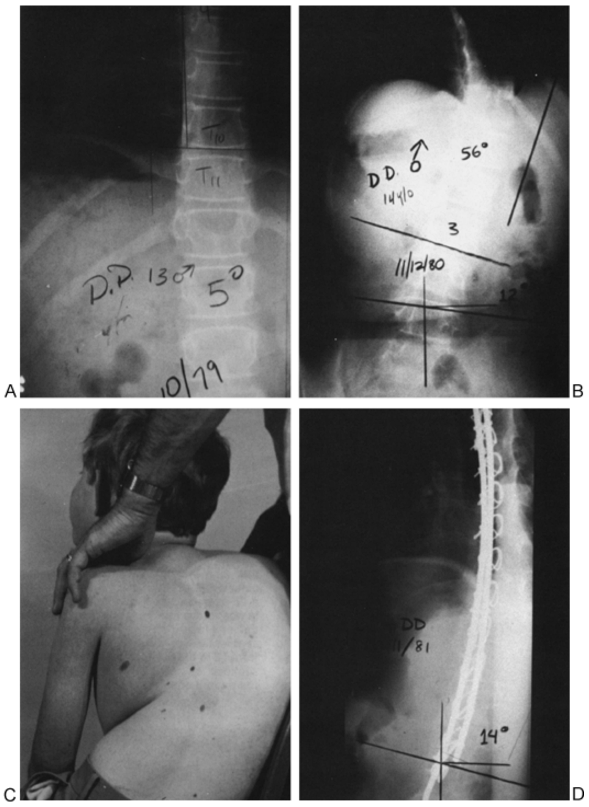

FIGURE 5. A 13-year-old boy with Duchenne muscular dystrophy. **A:** First spinal radiograph shows a 5-degree left lumbar curve. **B:** One year after **A**, a 56-degree right thoracolumbar *C*-shaped curve necessitates segmental spinal instrumentation and fusion. **C:** Preoperative appearance. **D:** Appearance 10 months after fusion from T3 to L5. The rods shifted, and the patient maintained pelvic obliquity with residual curve of 30 degrees and obliquity of 14 degrees. He was the only patient in either group with marked residual pelvic obliquity.

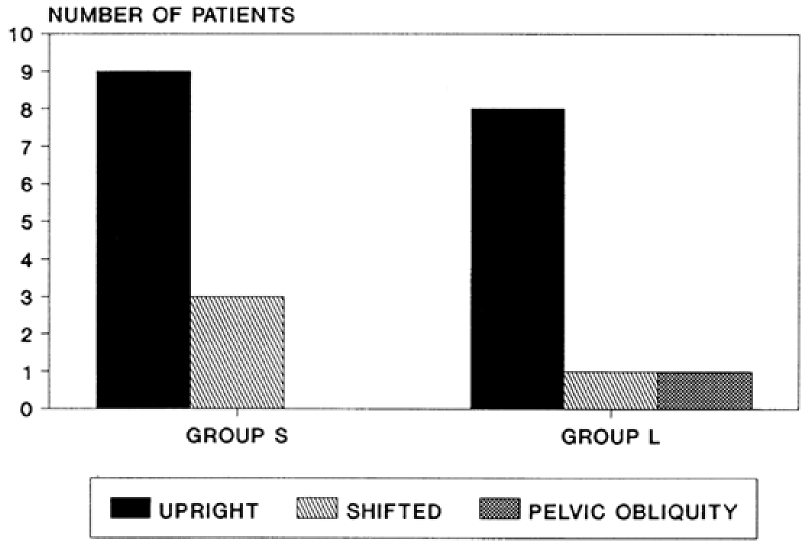

FIGURE 6. Bar graph shows clinical and radiographic categories for each of the two groups of patients. Among the 12 patients who underwent fusion to the sacrum (*group S*), nine were upright, and three had shifting. Among the ten patients who underwent fusion to L5 (*group L*), eight were upright, one had shifting, and one had pelvic obliquity (35).

In a series described by Brook et al. (5), results for ten patients who underwent fusion above the pelvis were compared with those for seven patients who underwent Luque-Galveston fixation to the pelvis. The authors found marked sitting imbalance or progression of scoliosis among six of the ten patients who underwent fusion above the pelvis and recommended fusion to the pelvis in all cases. However, three of the ten patients underwent fusion only to L4, and 1 patient underwent fusion to L3. The preoperative curves of eight of the ten patients exceeded 40 degrees, and preoperative pelvic obliquity was not recorded for any of the 10 patients who underwent fusion above the pelvis. We agree that marked preoperative pelvic obliquity or a curve greater than 40 degrees necessitates fusion to the sacrum and pelvis.

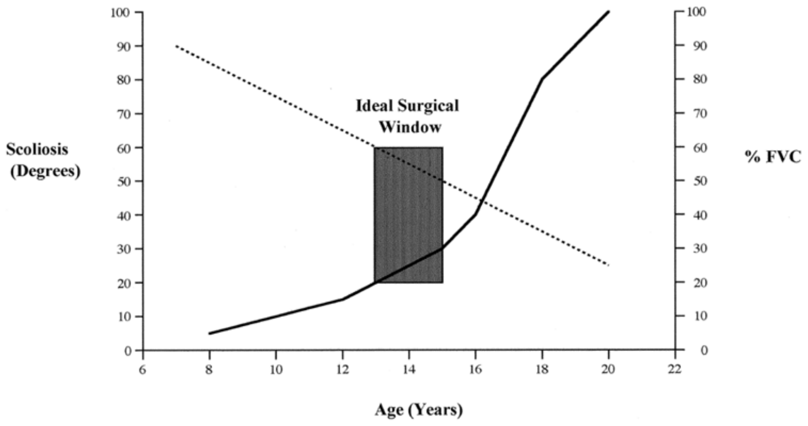

FIGURE 7. Line graph shows the natural progression of scoliosis (*solid line*) plotted against age and declining pulmonary function (*dotted line*) measured as percentage forced vital capacity (*%FVC*) plotted against age. The *shaded area* represents the ideal surgical window for correction of scoliosis—the curve measures between 20 and 30 degrees and the %FVC is greater than 40%.

We have found the following surgical treatment plan to be successful for patients with Duchenne muscular dystrophy and for those with Becker muscular dystrophy who need surgery. Spinal fusion is performed when the curve reaches 20 degrees, and forced vital capacity is still greater than 40% (Fig. 7). For patients with curves greater than 40 degrees, an operation usually can be performed without difficulty if the vital capacity is more than 35%. For patients with a smaller vital capacity, complications increase, and postoperative tracheostomy may be needed. We generally decline to operate on patients with vital capacities less than 30% because of the high incidence of pulmonary complications. At some centers, however, such patients do undergo surgery (24).

The recommended surgical technique is Luque segmental instrumentation and posterior fusion from the high thoracic level (T2 or T3) down to L5. If the preoperative pelvic obliquity is greater than 10 degrees or the scoliosis curve is greater than 40 degrees, one should consider instrumentation to the pelvis to correct this obliquity and ensure a level pelvis (Fig. 8). Texas

Scottish Rite Hospital cross-links also can be used for additional stability between the two Luque rods. The intensive care unit stay usually is 2 days, and the average hospital stay is about 7 days. Use of a lightweight Orthoplast body jacket for 6 months is recommended for both comfort and safety when the patient is upright or being transferred.

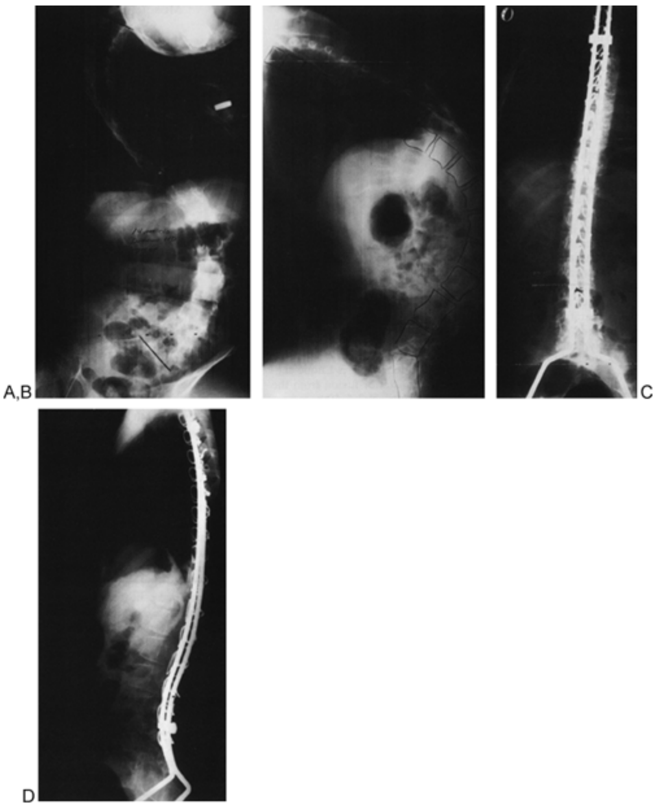

FIGURE 8. A 14-year-old boy with Duchenne muscular dystrophy had a 75-degree scoliosis with pelvic obliquity and a severe kyphotic deformity. The patient was successfully treated by means of posterior spinal fusion from T2 to the sacrum with Luque-Galveston instrumentation and Texas Scottish Rite Hospital cross-links. Preoperative sitting anteroposterior **(A)** and lateral **(B)** radiographs. Anteroposterior **(C)** and lateral **(D)** radiographs 6 months after the operation (Courtesy of Stuart L. Weinstein, M.D.)

A recent modification of the original Luque technique was described by Marchesi et al. (31). Two sacral screws are used to supplement the pelvic fixation. They found no instrumentation failure or loss of correction greater than 3 degrees among 25 patients (mean follow-up period 36 months). Intraoperative anaphylaxis to an antibiotic was the only complication recorded. This appears to a reasonable surgical alternative.

The goal in the management of spinal deformity in Duchenne muscular dystrophy is maintenance of upright sitting posture and maximal pain-free function. Many of our patients who have undergone surgical treatment are now older than 20 years, have an upright posture, can operate a power-driven wheelchair, have minimal positioning difficulties, and have an improved quality of life.

Facioscapulohumeral Dystrophy

Facioscapulohumeral dystrophy (Landouzy-Dejerines disease) is a more mild form of muscular dystrophy involving the shoulder girdle and facial muscles to varying degrees. The molecular defect has been localized on chromosome 4, but the gene has not yet been identified. The disease is transmitted in an autosomal dominant pattern with variable expression, and the prevelence is estimated at five cases per 100,000 persons (46). In most cases of facioscapulohumeral dystrophy, the onset of symptoms occurs in late childhood or adolescence. Clinical signs generally develop slowly and progressively, often with periods of arrest. Functional disability may not occur until late in the course of the disease.

In some instances the disease course is severe and rapidly progressive, symptoms beginning in infancy or early childhood. This presentation is associated with greater morbidity and higher mortality at a younger age and until recently was believed to be a distinct genetic defect (3 ,16 ,46). The parents of children with facioscapulohumeral dystrophy may have no symptoms or have minimal clinical evidence of the disease.

In all cases of facioscapulohumeral dystrophy, facial weakness occurs early in the disease course. Patients have a characteristic stare and may lack the ability to whistle, blow out the cheeks, or completely close the eyes. The usual facial creases may be absent. Weakness of the muscles of the shoulder girdle develops bilaterally, and, as is not true of any other form of muscular dystrophy, the weakness may be asymmetric. Involvement of the trapezius, serratus anterior, and rhomboid muscles is characteristic, and there is later and more variable involvement of the latissimus dorsi and pectoralis major and minor muscles (Fig. 9). Glenohumeral motion is initially preserved, and the deltoid muscle is spared until late in the disease.

With this typical pattern of muscle involvement, patients lose the ability to stabilize the scapula against the thorax and thus cannot fully abduct or flex the shoulder. Without a stable fulcrum, attempts at shoulder abduction generate scapulothoracic, rather than glenohumeral, motion. Activation of the deltoid causes winging of the scapula as it rotates superiorly and internally unrestrained.

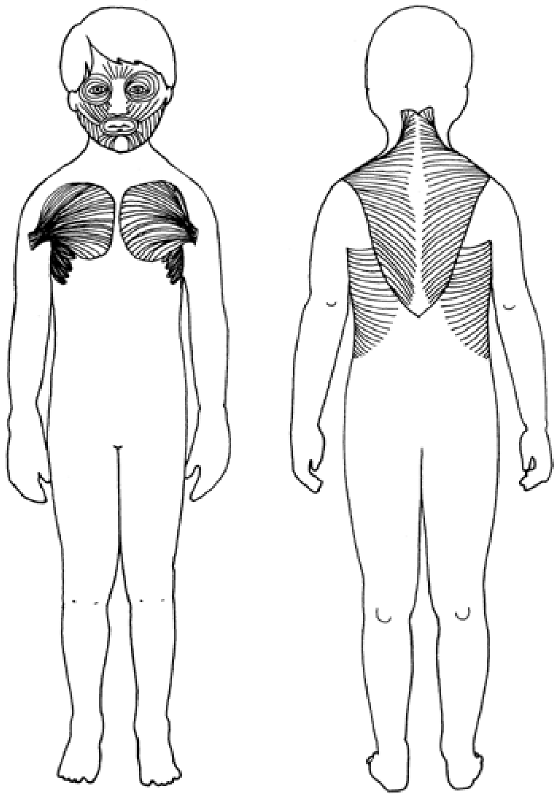

FIGURE 9. Diagram shows initial muscle involvement in facioscapulohumeral dystrophy.

Ketenjian (25), Copeland and Howard (9), and Letournel et al. (28) described methods of scapulothoracic stabilization to improve the upper-extremity function of patients with facioscapulohumeral dystrophy. Ketenjian (25) described a method of scapulocostal fasciodesis. With fascia lata, polyester mesh (Mersilene), or polyester (Dacron) strips, the scapula is secured to the underlying ribs in a position of 20 degrees of external rotation. Five shoulders evaluated over an average of 34 months had improved appearance and an average increase of 33 degrees (37%) in active shoulder abduction. Critics of such procedures, which rely on soft-tissue stabilization, claim that the improvement in active shoulder abduction gradually deteriorates (28). Letournel et al. (28) described an alternative method of stabilization consisting of arthrodesis with a wire-plate construct. Among nine patients who underwent 16 arthrodesis procedures, the authors found a mean increase in shoulder abduction of 25 degrees. With an average follow-up period of 5.7 years, they found substantial and enduring improvement in ability to perform activities of daily living. Patients with facioscapulohumeral dystrophy also may have pelvic girdle weakness as the disease progresses. Weakness of the hip extensors contributes to an increase in lumbar lordosis, which may become severe and symptomatic among some adults (Fig. 10). It may necessitates bracing, hip flexor release, or spinal fusion if the lordosis impairs the ability to walk (6).

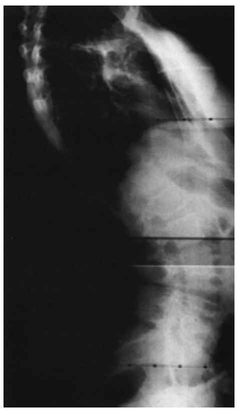

FIGURE 10. Radiograph shows a patient with facioscapulohumeral dystrophy and characteristic increase in lumbar lordosis.

Scoliosis is rare in facioscapulohumeral dystrophy because growth usually is nearly complete at the onset of disease (10 ,12 ,41). Among 16 adult patients with facioscapulohumeral dystrophy, Siegel (41) found no structural scoliosis. Patients with earlier onset of facioscapulohumeral dystrophy, however, may have marked structural scoliosis. Among these children, asymmetric muscle involvement contributes to curve progression. These patients usually respond well to bracing and surgery. Segmental instrumentation and fusion as described for Duchenne muscular dystrophy are used. The intelligence and life span of patients with facioscapulohumeral dystrophy are normal.

Limb-Girdle Muscular Dystrophy

Limb-girdle muscular dystrophy represents a group of autosomal disorders characterized by proximal muscle weakness with predominant involvement of the pelvic and shoulder girdle musculature. Both autosomal dominant and recessive forms are described, and at least six distinct chromosomal abnormalities have been identified (16 ,30). Symptoms of limb-girdle dystrophy are similar to those of facioscapulohumeral dystrophy except that the facial muscles are not involved. The symptoms may follow one of several patterns of muscular involvement, shoulder girdle muscles affected first followed by pelvic girdle weakness, or vice versa. In the scapulohumeral type (49), the muscles of the shoulder girdle constitute the primary area of involvement (Fig. 11). Symmetric weakness of the trapezius, serratus anterior, rhomboids, latissimus, and pectoralis major develops with variable subsequent involvement of the fingers and wrists. The deltoid muscle usually is spared early in the course of the disease. Patients with the pelvifemoral type (Leyden-Möbius) have hip extensor and abductor weakness, which increases in lumbar lordosis, gait abnormalities, and hip instability (Fig. 12). The distal musculature eventually is affected, specifically the tibialis anterior and peroneal muscles. The gastrocnemius and soleus muscles are not affected until late in the course of disease.

The onset of symptoms in limb-girdle dystrophy is variable, ranging from the first through fourth decades of life, but symptoms usually occur in mid to late adolescence. Symptoms progress slowly and symmetrically, but marked disability usually is present 20 years after onset. Significant structural scoliosis rarely develops in limb-girdle dystrophy because the onset of disease usually occurs during adolescence, and progression is slow and symmetric. When it is present, scoliosis usually occurs after completion of growth and is rarely severe enough to necessitate treatment (10 ,42).

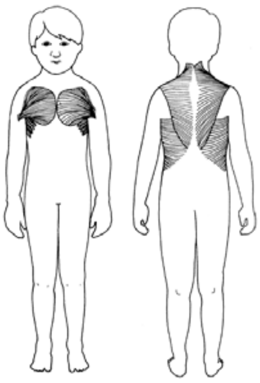

FIGURE 11. Diagram shows muscle involvement in scapulohumeral type of limb-girdle muscular dystrophy.

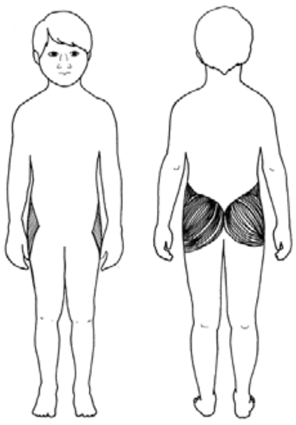

FIGURE 12. Diagram shows muscle involvement in the pelvifemoral type of limb-girdle muscular dystrophy (Leyden-Möbius).

Myotonic Muscular Dystrophy

Myotonic muscular dystrophy (dystrophia myotonica, Steinert disease) is characterized by myotonia and progressive muscular weakness. It is the most common form of muscular dystrophy among adult, affecting one in 7,000 to 8,000 persons. Myotonic dystrophy is transmitted in an autosomal dominant pattern with variable penetrance through a defective gene segment on chromosome 19 (16 ,44). Myotonic dystrophy causes progressive weakness in an initially distal distribution (Fig. 13). Symptoms may be apparent in early childhood, but the classic form manifests in late adolescence or early adulthood.

The disease is characterized by facial weakness with ptosis and the inability to whistle or close the eyes. Patients may have myopathic facies—a long, narrow face lacks expression. Speech and swallowing may be affected. Unlike the pattern of proximal limb weakness in facioscapulohumeral and limb-girdle muscular dystrophy, muscle involvement in myotonic dystrophy is in the distal limbs. In the upper extremities, intrinsic hand function and wrist and forearm strength are affected early. In the lower extremities, tibialis anterior and peroneal weakness occurs, leading to progressive footdrop deformities in adults. In addition to muscle weakness, myotonia occurs early in the disease course. Persistent involuntary muscle contraction occurs when a patient is unable to release a grasp.

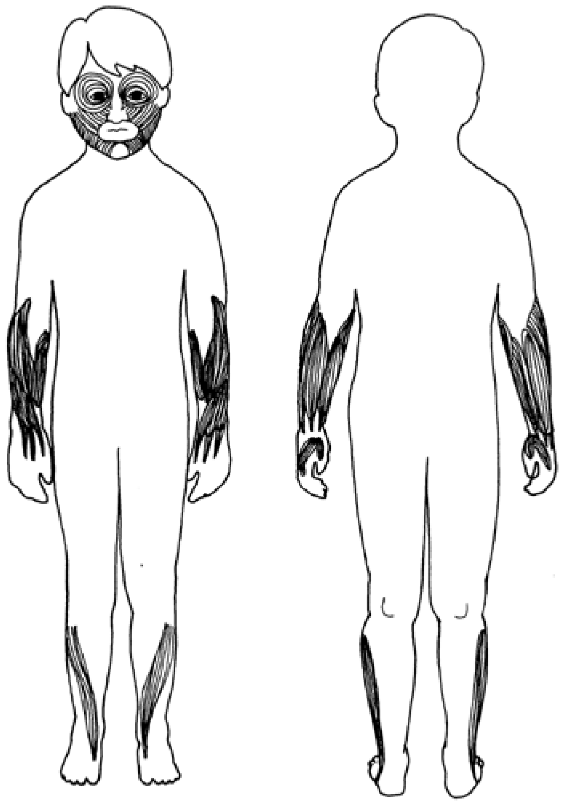

FIGURE 13. Diagram shows muscle involvement in myotonic dystrophy.

In the congenital form of myotonic dystrophy, patients are not myotonic at birth but are hypotonic. They display the classic facial diplegia with a dull, expressionless face. Fifty percent have rigid equinovarus deformities similar to those of arthrogryposis (4). The clubfoot deformities initially respond well to serial casting but eventually recur and necessitate soft-tissue release in later childhood or triple arthrodesis at skeletal maturity. Congenital myotonic dystrophy often is associated with respiratory and feeding problems at birth and with psychomotor retardation. Patients with congenital and childhood forms of myotonic dystrophy also may have cardiac problems, cataracts, frontal balding, and testicular atrophy (4 ,36). Because the axial and proximal limb muscles are spared until late in the disease, scoliosis rarely develops in myotonic dystrophy (41 ,42). Myotonic dystrophy is a progressive disorder that usually causes marked disability within 20 years of onset and often diminishes life span. Subsequent generations may be more severely affected.

Malignant Hyperthermia

Malignant hyperthermia is a potentially catastrophic series of events associated with general anesthesia and, on occasion, with local anesthesia or even stress unrelated to surgery (14 ,20). It tends to occur among otherwise healthy persons, but there is an increased incidence among persons with myopathy. The condition is genetic, but both recessive and dominant patterns with variable penetrance have been reported. It is thought to be associated with a defect in skeletal muscle that allows a marked rise in intracellular calcium levels. The syndrome results in a rapid increase in temperature (above 105°F [40.6°C]), tachycardia, muscle rigidity, especially of the masseter muscle, but often becoming generalized, hypoxemia, acidosis, hyperkalemia, and rhabdomyolysis. If not reversed, this syndrome is fatal. The mortality rate has been estimated to be 28%. Malignant hyperthermia occurs soon after induction of general anesthesia; succinylcholine and halothane are the anesthetic agents usually implicated. Once recognized, prompt intervention is required: immediate discontinuation of anesthesia and surgery, administration of oxygen, body cooling for patients with temperatures greater than 40.6°C, administration of sodium bicarbonate, frequent monitoring of acid-base and arterial blood gas values, and administration of dantrolene, which is thought to be specific for reversing the effects of malignant hyperthermia.

If malignant hyperthermia occurs, a neuromuscular evaluation should be performed that includes a detailed family history of response to surgery and anesthetic agents. Creatine kinase levels should be determined. A muscle biopsy sample can be assessed for excess reactivity to halothane, caffeine, or both. If a personal or family history of malignant hyperthermia is established, safe anesthetic agents for susceptible patients are nitrous oxide, opiates, thiopental, and pancuronium. Patients with known or suspected malignant hyperthermia also can be treated with dantrolene before undergoing required surgery (35a).

Spinal muscular atrophy is a rare autosomal recessive disorder in which the anterior horn cells of the spinal cord and the neurons of the lower bulbar nuclei undergo degeneration. Clinically common to all variants of the disease is symmetric limb and trunk weakness and muscular atrophy that affects the lower extremities more than the upper extremities and the proximal muscles more than the distal muscles. Muscle fasciculation is common in the tongue and deltoid muscles, and trembling of the hands also occurs (20 ,49). Sensibility is not affected, and pyramidal long-tract signs are absent. Intelligence usually is normal (39). Scoliosis, contractures, and hip dislocation are the most common orthopaedic conditions associated with this disease.

Epidemiology

Spinal muscular atrophy is a common group of fatal recessive diseases and is one of the most frequently occurring neurodegenerative diseases (25 ,27 ,53). The incidence is 1 in 15,000 live-births, and 1 in 40 to 80 persons is a carrier of a gene for spinal muscular atrophy (53). It was initially reported that women have less severe disease, and this has been refuted by other investigators. More recent studies, however, suggest that women do have a less severe disease course (20 ,38 ,50 ,53).

Scoliosis is the most common spinal deformity among patients with spinal muscular atrophy, yet the reported incidence varies. Benady (3) found that 31 of 54 (57%) patients with spinal muscular atrophy had scoliosis. In that report, however, only one of the patients who did not have scoliosis had reached skeletal maturity. The mean age of the skeletally immature patients without scoliosis was 6.3 years (3). Phillips et al. (57) reported that 34 of 57 (60%) patients had scoliosis diagnosed at an average age of 9 months and had an average follow-up period after diagnosis of 8.8 years. Schwentker and Gibson (66) studied the records of 50 patients with an average age of 11.5 years (range 2 to 29 years). They found 35 (70%) patients had scoliosis. In a long-term study by Evans et al. (29), 45 of 49 patients had scoliosis. All four patients without scoliosis had better motor function than those with scoliosis. Russman et al. (63) found that 48 of 48 patients had scoliosis greater than 15 degrees; only 50% were observed for more than 10 years. In all these studies many of the patients were not observed to skeletal maturity or the usual maximum age for the onset of scoliosis. Most patients with spinal muscle atrophy who survive into adulthood eventually have scoliosis.

Etiology

Spinal muscular atrophy among children is an autosomal recessive disorder. Genetic mapping has shown that the chronic childhood onset of spinal muscular atrophy is linked to a region of chromosome 5 (ql2-ql4) and that the acute childhood onset form of the disease is linked to the same or lower region of the chromosome at the 5q position (8 ,43). Results of some studies suggest that different clinical presentations are allelic and caused by different mutations of the same gene (75 ,77). Other studies, however, have shown that this condition may be heterogeneous. They challenge the character of autosomal recessive inheritance, which does not explain atypical families and the male predominance without additional hypotheses, such as the Becker allelic model, incomplete penetrance of the gene, or X-linked inheritance (35 ,40 ,77 ,78). A group with autosomal dominant inheritance has been reported but is still under discussion (40 ,52 ,76).

Results of current studies suggest reduced levels or mutations in the survival of motor neurons protein has been implicated as the cause of the Werdnig-Hoffman form of the disease (spinal muscular atrophy type I). In 98% of the patients with the Werdnig-Hoffman form of the disease, the gene (5q13) for the survival of motor neurons protein was deleted or mutated. The gene product usually is present in nucleus and cytoplasm of cells from all tissues; especially high levels are present in motor neurons. In patients with the Werdnig-Hoffman form of the disease, the gene product has been found at barely detectable levels (12 ,43 ,44 ,56).

Pathogenesis

The pathogenesis of spinal muscular atrophy is largely unknown. Insidious glial proliferation in motor roots of the brain stem and spinal cord and deficiency of vitamin E in the plasma have been reported among infants with Werdnig-Hoffmann disease (11 ,67). The spinal deformity of spinal muscular atrophy develops because of muscle weakness. Severe and diffuse weakness frequently causes collapse of the spine and a progressive deformity that may involve the entire spine and pelvis. The deformity usually is progressive and is independent of the patient's remaining growth in that the curve may progress despite skeletal maturity. In a less severely compromised patient, the deformity can start in a limited area and involve only part of the spine. However, many of these patients eventually have more extensive and severe involvement of the spine. The presence of contractures in the pelvis and lower limbs, hip subluxation or dislocation, and the lack of equilibrium may contribute to progression of the spinal deformity. Shapiro and Bresnan (68) and Eng et al. (28) suggest that dislocation of the hip causes a pelvic tilt, which complicates the developing scoliosis.

Pathologic Anatomy

In most cases of spinal muscular atrophy, the cranial nerves are involved. Cranial nerves V, VI, and VII may be affected without clinical manifestations. Cranial nerves IX, X, and XI may be affected with clear neuronal loss. Cranial nerve XII also may be affected. The range of degeneration of the lesions can include central chromatolysis, neuronophagia, nerve cell loss, and gliosis. The process is always symmetric. Reports have shown abnormalities of the cerebrum and cerebellum, marked hypoplasia, a decrease in the number of astrocytes and microglia in the cortex, and cell loss. The Betz cells at area 4 are normal (32).

Examination of the spinal cord shows anterior horn cell loss. The injury is found in the large anterior cells, markedly in the ventromedian group. Besides diminution in the number of cells, pyknotic and neuronophagia cells are found (71 ,72). Secondary changes occur in the roots and nerves with wallerian degeneration. Although clinical sensory involvement is not detected, microscopic studies developed by Carpenter et al. (10) and Marshall and Duchen (46) show alteration of the posterior columns. There is loss of myelin, especially at nerve fibers from the lumbar area, and involvement of sensory lumbar ganglia.

The muscles that usually are spared are the diaphragm, sternothyroid, sternohyoid, and the involuntary muscles of the intestine, bladder, heart, and sphincters (53). Microscopic examination shows normal groups of muscles mixed with groups showing denervation atrophy. The affected fibers are smaller in diameter, and there is more adipose and fibrous tissue between the fiber bundles than normal.

Clinical Features

Spinal muscular atrophy is a spectrum of disorders. The characteristics common to all types of spinal muscular atrophy are symmetric muscular atrophy and weakness, predominance in the lower limbs, and greater involvement in the proximal muscles than in the distal. Fasciculation of the muscles, especially the tongue, and trembling of the hands are common. Most persons with this disorder have no trembling during relaxation or sleep. Fatigue and stress may cause trembling to increase. Deep tendon reflexes usually are decreased or absent. Although both sensibility and intelligence are unaffected in most patients, the pyramidal long tract is not involved.

Because of the wide range of the clinical course, the most practical method for consideration of treatment is to divide patients into two groups: those with the acute infantile form (acute Werdnig-Hoffmann disease or spinal muscular atrophy type I) and those with the chronic childhood forms of disease. The chronic forms of disease are further divided into chronic Werdnig-Hoffmann disease (spinal muscular atrophy type II) and Kugelberg-Welander disease (mild spinal muscular atrophy type III).

Type I: Acute Infantile, Acute werdnig-Hoffmann Disease

Patients come to medical attention with severe involvement of the disease. The onset is noticed within the first 2 months of life. Pearn (53) pointed out that 30% of cases have a prenatal onset. The mother often recalls lack of movement of the fetus, and after birth, the cry is of low volume and not sustained. The infant manifests severe, generalized weakness. This patient never walks, turns over, or sits alone, and there usually is lack of head control and bulbar paralysis. The only spontaneous movement of the extremities may be of the fingers and toes. Areflexia is universal. There is intercostal weakness with severe collapse of the ribs and a bell-shaped lower chest. Respiratory movements are paradoxic, and respiratory insufficiency can lead to pneumonia and atelectasis (26). Nasogastric tubes may be needed for feeding. Involvement of the cranial nerves is present but not easily detected clinically. Bland facial expressions and a striking facial resemblance are noticed because of facial weakness. Dysphagia, aphonia, and stridor also may be present (16 ,21 ,23 ,37 ,55).

Almost all patients have a spinal deformity, and many lie in a characteristic posture with the hips flexed, abducted, and externally rotated; the shoulder abducted and externally rotated; and the hands elevated to the level of the head. The knees and elbows are flexed, and the forearms are pronated. The posture is flaccid, and the child can be moved easily. With rare exception, these children do not survive beyond the age of 3 years. Therefore orthopaedic intervention is rarely warranted (22 ,73).

Some patients who appear to have the acute infantile of spinal muscular atrophy variety can have a more benign course. In such cases, the disease is not rapidly progressive, and the clinical behavior is similar to that of the chronic disease.

Type II: Chronic Childhood, Chronic Werdnig-Hoffmann Disease

In spinal muscular atrophy type II, chronic Werdnig-Hoffmann disease, the onset of symptoms occurs between 2 months and 2 years of age. These children have less disease involvement than do patients with spinal muscular atrophy type I; however, they are never able to walk independently. Weakness is not generalized at first. It starts in the legs more often than the arms, and the proximal muscles such as the gluteals and quadriceps are affected initially. Fine tremor in the hands and fasciculations of the tongue can occur but do so less frequently than in the acute form. Fasciculation of the eyelids also can occur (69). Chest collapse is uncommon, and respiratory impairment develops after a variable initial asymptomatic period (21 ,27 ,55).

Some patients can sit if placed in position, and some can walk. These patients have a waddling gait, lumbar lordosis, genu recurvatum, a protuberant abdomen, and scoliosis. Their walking becomes progressively impaired until they have to use a wheelchair full-time, usually by the second decade of life. Life expectancy also varies widely, ranging from 18 months to adulthood. Most patients live longer than 10 years and may live up to the fifth decade. The principal cause of death is pulmonary compromise (24).

Type III: Chronic Childhood, kugelberg-Welander Disease

In spinal muscular atrophy type III, Kugelberg-Welander disease, the onset of symptoms occurs after 2 years of age but usually manifests itself before the age of 10 years. The patient has normal or slightly delayed motor milestones (42 ,74) and usually can walk, run, or climb stairs. These patients usually are able to walk independently until late childhood and sometimes into early adolescence. However, motor capability decreases. A positive Gower sign occurs in which the patient has difficulty in rising from the floor because of weakness in the pelvic girdle. There is atrophy in the lower limbs, and pseudohypertrophy of the calf develops because of sparing of the gastrocnemius muscle. Hypotonia is present, and the reflexes are hypoactive or absent. Muscles innervated by the cranial nerves usually are not affected. The capability to walk can be present for at least 8 years after the diagnosis is made and usually continues until the third decade. Life expectancy can reach the fifth decade.

Functional Classification

A functional classification relating progression of deformities to prognosis is based on the maximum physical function achieved by an individual patient (29 ,47 ,61 ,63 ,66). The classification divides the patients into the four following groups:

- Group I: Patients never have the strength to sit independently, even when placed in optimal position. Head control is poor. They have early and progressive scoliosis.
- Group II: Patients have head control and can sit but cannot stand or walk.
- Group III: Patients can stand by themselves and have a limited walking ability.
- Group IV: Patients can walk, run, or climb stairs. The mean age at diagnosis of scoliosis in this group is 8 years.

Diagnosis

The diagnosis of spinal muscular atrophy is based on the clinical features and genetic evidence in the family. Diagnostic studies include electromyography, conduction velocity, muscle biopsy, and nerve biopsy.

The electromyographic signs of spinal muscular atrophy increase in frequency incidence and magnitude in relation to the duration of the disease. Fibrillation potentials associated with denervation are the best diagnostic sign. Regular spontaneous motor-unit activity occurs frequently and is specific for this disease. This occurs at all ages (9). Conduction velocity in motor fibers usually is normal with a slight decrease among severely affected children and a faster than expected velocity among less severely affected children (17 ,49 ,59). Findings of a muscle tremor defect may be present on an electrocardiogram (62).

Muscle biopsy should be performed on only moderately affected muscle. Compromised areas of musculotendinous junctions, scars or sites of recent trauma, injections, or electromyographic needle insertion must be avoided. The vastus lateralis portion of the quadriceps usually is the best muscle for biopsy. Open biopsy is preferable for correct quantity and orientation of muscle fibers. Local anesthesia should not penetrate the muscle, and atraumatic technique should be used. The specimen is maintained in the lengthened position for histologic tests and the contracted position for electron microscopic evaluation. Part of the specimen must be rapidly frozen to preserve the enzymes and prevent artifacts for histochemical evaluation (6). Histologic findings include loss and atrophy of fibers within normal groups of fiber bundles and no evidence of primary myopathy. Proliferation of perimysial connective tissue and groups of giant fibers (usually type 1) also are present. Among neonates, the only finding is perimysial fibrosis and nonspecific variation in muscle-fiber diameter. At a few months of age, the characteristic findings are present. The same pattern is maintained in adulthood, yet there is a progressive recent denervation and necrosis of fibers within the groups of hypertrophic fibers (48 ,64).

Differential diagnosis should include all conditions that characterize a floppy baby. Congenital myopathy manifesting as an autosomal dominant pattern should be considered. Dislocation of the hip and torticollis are common, and electromyographic studies show myopathic findings. Patients with infantile myasthenia gravis may recover within 12 weeks without relapse. Cerebral palsy can manifest as a stage of hypotonia and flaccid paralysis. Congenital muscular dystrophy is rare but has signs and symptoms similar to those of spinal muscular atrophy. Further, chronic disease should be differentiated from Duchenne muscular dystrophy.

Spinal Deformity

In the forms of spinal muscular atrophy in which survival into adolescence is anticipated, the occurrence of spinal deformity should be expected. Scoliosis occurs among almost 100% of the patients with type II spinal muscular atrophy and among most patients with type III spinal muscular atrophy (7 ,29 ,34 ,57 ,61 ,66). Scoliosis is the most common and severe orthopaedic problem among children with spinal muscular atrophy and usually appears before 10 years of age. The deformity usually is a progressive *C*-shaped right-sided thoracolumbar paralytic curve. In almost all investigations, scoliosis is the principal spinal deformity, and its association with kyphosis is reported in about one third of cases (34 ,60). In addition several cases of a solitary kyphotic deformity have been reported. Some authors suggest the kyphosis appears earlier than the scoliosis, collapsing kyphosis occurring among patients younger than 3 years (60). The pulmonary function of patients with spinal muscle atrophy often decreases, and the decrease is attributed to the primary muscle weakness and the developing scoliosis and kyphosis. Some authors have reported pulmonary function less than 50% of normal among patients with moderate to severe scoliosis (26 ,61).

Factors Affecting Deformity

The age at onset and the severity of spinal deformity have been the subject of many studies, and there appears to be a relation between maximal motor function obtained and scoliosis. Russman et al. (63) found that the mean age at diagnosis of spinal deformity ranged from 6 years for patients with severe deformity to 18 years for patients who could run before the onset of the disease. Benady (3) reported that, the diagnosis of scoliosis was made after 1 year of age, most cases being diagnosed before the patients were 4 years of age. Other authors (2 ,13 ,60) have reported a mean age at diagnosis of 6 to 8 years, curve progression occurring in most patients. Kyphosis develops in 20% to 30% of the patients. In a study conducted at the Rizzoli Institute, all 13 patients with mild spinal muscular atrophy (type III) who had stopped walking had scoliosis that ranged from 30 degrees to 153 degrees (34).

The strongest factor related to the occurrence and severity of scoliosis seems to be the retained level of motor function (29 ,47 ,61 ,63 ,66). Factors related to the severity and progression of the disease, such as age at onset, type of spinal muscular atrophy, and presence of familial cases, also can be associated with spinal deformity. Controversy exists regarding the relation between motor development and age at onset and severity of the scoliosis. Aprin et al. (2) conducted a study with 22 patients who underwent spinal fusion. The investigators found no differences in the age at onset of scoliosis between the group of patients who could walk and the group who could not. In contrast, Schwentker and Gibson (66) found that seven of 15 patients able to walk had scoliosis and that only one patient had a curve greater than 60 degrees. Evans et al. (29) reported the existence of a direct relation between motor function development and age at onset and severity of the spinal deformity. Patients with more severe muscle weakness had a deformity as early as 2 years of age, whereas patients with less involvement had deformities at a mean age of 8.4 years (range 4 to 14 years). Only in the group who could walk or run were there patients with no spinal deformity. However, even in this group, seven of the 11 patients had spinal deformity. In the other three groups, spinal deformity developed in all patients. The results of these studies (29 ,34) show that patients who retain the ability to walk are unlikely to have early and severe scoliosis, whereas patients who have more severe involvement have early and more progressive scoliosis.

Radiographic Features

Even for patients who can stand, we suggest that radiographic studies be performed with the patient in the seated position. This avoids compensation to keep the patient standing and eliminates the decrease in the real value of the deformity when the patient is supine. Posteroanterior and lateral radiographs should include the entire spine from the occiput to the pelvis. This allows analysis of pelvic obliquity and alignment of the head over the pelvis.

Type and Localization of Curves

The pattern of scoliosis is similar to that in most cases of neuromuscular scoliosis: a single, large, collapsing *C*-shaped curve involving the thoracolumbar spine. Usually at least six segments are involved and more frequently between eight and ten segments are involved. The area involved ranges from the low or midthoracic region to the low lumbar region and often produces pelvic obliquity.

Approximately 90% of patients have single curves, and more than 60% have thoracolumbar curves. Eighteen percent of curves are reported as thoracic curves, lumbar curves alone and double curves being less frequent (2 ,13 ,58 ,66). Single thoracic curves usually are right-sided. In the small number of patients who lose the ability to walk, double curves are common, usually with a right thoracic and left lumbar pattern. Among patients with severe asymmetric involvement, no relation between the direction of the convexity of the curve and the side of greater muscle weakness has been shown (66). The curve in patients with spinal muscular atrophy tends to remain more flexible than comparable idiopathic curves; however, rigidity and structural changes may eventually occur. As these curves progress, more segments become involved and pelvic obliquity occurs, the process being hastened among patients who do not walk.

Kyphosis of varying degrees of severity can be associated with the scoliosis. The kyphotic curve usually compromises the upper thoracic to lower lumbar area. In most instances the kyphotic component is not severe. However, in one study, among 18 patients observed without treatment, five had severe kyphosis associated with the scoliosis with four patients had a kyphotic deformity greater than 100 degrees (60).

Treatment

Orthotic Treatment

We believe orthotic treatment will not stop development or progression of the deformity but may lend support to the spines of select patients who need the support to perform activities of daily living. Careful attention must be paid to brace tolerance and respiratory function. If vital capacity decreases markedly or if the brace is poorly tolerated, orthotic treatment should be discontinued. Orthotic treatment may be prescribed with the objective of reducing the rate of progression of the spinal deformity or of helping to maintain the sitting posture. Among adult patients with severe deformity, orthotic treatment can be used to avoid painful impingement of the lower ribs on the iliac crest (29).

Studies have shown the use of a brace does not halt the progression or prevent the development of scoliosis among patients who used a brace before scoliosis developed (66). Most reports state that an orthosis can decrease the rate of progression of scoliosis. In the study of Aprin et al. (2), 15 patients received conservative treatment before spinal fusion. Most of the patients had the orthosis applied after the curve reached 40 degrees. Five patients had this treatment discontinued because respiratory difficulty was caused by the lateral pressure of the brace. The rate of progression in the other ten patients was not reported, except to state that the deformities soon progressed and necessitated spinal fusion. Shapiro and Bresnan (68) suggested a brace be prescribed when a curve reaches 15 or 20 degrees to minimize the rate of progression of the scoliosis. They reported the brace was uncomfortable for patients who walked because of the force of the brace against the patient's thighs and torso. Savini et al. (65) found that an orthosis had an effect in preventing scoliosis among patients who could stand or walk, but they did not mention the patients' comfort level. Riddick et al. (60) reported on 20 patients who received conservative treatment. Although half of the patients were observed 2 years or less, the data suggested the use of a brace was effective in slowing curve progression.

In one series (29), the success of orthotic treatment was related to physical function of the patient. Patients who could stand or walk benefited more from brace use. Patients with severe weakness tolerated the brace poorly, and it did not avoid progression of the deformity. Bracing was recommended for use in the care of young children when the deformity reached 20 degrees to decrease the rate of progression. This treatment allows delay of spinal fusion until the child is 10 years or older. Granata et al. (34) did not find braces useful in preventing progression of scoliosis, but the orthosis was believed to improve the functional performance of all children.

A review of the aforementioned studies reveals more opinions and impressions regarding orthotic treatment than it does conclusive data. The different forms of presentation and severity, the relatively small number of patients treated with braces, the absence of description of the course of disease and the characteristics of progression, and the lack of control groups in the studies make it difficult to assess the effectiveness of orthoses in the management of scoliosis in spinal muscular atrophy.

For young children with severe involvement and poor control of the neck, a sitting-support orthosis is used. A molded plastic posterior shell with control from the head to the pelvis is useful and can have a separate removable anterior shell or straps (17 ,19). The purpose is to support the spine to provide sitting ability. Walking may be promoted by early fitting of lower-limb orthoses (33).

For a child, a lightweight three-point pressure brace can be used. For most patients, the thoracolumbosacral orthosis (TLSO) is a good option. The Wilmington and Boston braces are recommended for their ease of application and light weight. The Milwaukee brace is not recommended because of its heaviness and poor tolerance by children with spinal muscular atrophy. The cervical ring of the Milwaukee brace causes problems for a child with poor neck control, and the chin pad may cause severe dental deformities (29). The Milwaukee brace also may decrease pulmonary function and respiratory difficulty owing to lateral pressure to the thoracic cage.

Orthotic management of scoliosis is indicated to help maintain posture or to slow curve progression among children younger than 9 years with a deformity between 20 and 40 degrees. If the deformity progresses to more than approximately 50 degrees, conservative treatment should be discontinued, and spinal fusion should be considered. Orthotic treatment may be attempted in the care of a child younger than 9 years with a curve greater than 40 degrees if the deformity remains flexible. If the curve becomes rigid or progresses 15 degrees or more, operative treatment should be considered.

Spinal Fusion

The indications for operative treatment are based on the following considerations: (a) in most cases spinal deformity develops and progresses independently of conservative treatment; (b) severe scoliosis causes poor sitting posture, which diminishes the patient's functional and pulmonary capacities; and (c) deterioration of pulmonary function proceeds with increasing curve magnitude and disease progression, which may lead to death. The goal of operative treatment is to have a normally positioned, fused spine over a level pelvis (36 ,66 ,68 ,70).

With these considerations, posterior spinal fusion should be performed before the deformity becomes severe and pulmonary function becomes compromised. At this stage, the operation should not require anterior release or traction. In addition, better correction may be achieved and less postoperative complications occur if the spine is fused before a large-magnitude curve develops that necessitates a more aggressive procedure. With severe deformity, the rate of complications increases with the severity of the curve. The goal of achieving a stabilized spine centered over the pelvis in a severe deformity must be assessed with consideration of the risks involved. Attention should be given to the increased muscular weakness, decreased vital capacity, and the need for anterior release (60).

Most authors recommend posterior spinal fusion at moderate deformity after 10 years of age. Some authors recommended operative intervention when the curve is between 40 and 60 degrees and anterior release if the curve is greater than 100 degrees (18 ,29 ,68). Others recommend earlier fusion for curves of approximately 35 degrees or greater (8 ,57). Still other authors suggest the operation not be performed on a routine basis or for preventive reasons but should be performed only after the development of a severe curve of approximately 85 degrees (47). In consideration of the risk versus the benefits, we recommend posterior spinal fusion for patients with moderate deformity of approximately 50 degrees. If possible, arthrodesis should be performed after the age of 10 years for the benefit of growth. Fusion should not be delayed if delay necessitates anterior release or will cause substantial increase in risk.

Patients scheduled for an operation benefit from a comprehensive evaluation by a pulmonologist, a neurologist, an anesthesiologist, and a physical therapist. Evaluation of pulmonary function a few weeks before the operation provides a useful and relatively simple baseline of preoperative condition. In a study conducted at the Alfred I. du Pont Institute involving patients who underwent posterior spinal fusion for neuromuscular scoliosis, it was found that patients with a vital capacity of 50% or less of predicted value were at risk of development of pulmonary edema or atelectasis. Patients with a vital capacity of more than

60% did not have pulmonary complications after the operation (51). Patients with a vital capacity of less than 25% are at severe risk of pulmonary complications and need extensive therapy (30).

The use of preoperative halo-dependent traction in an attempt to improve pulmonary function is controversial. Although it has some reported benefit, this treatment is not routine, and the limited effect on the pulmonary function should be counterbalanced with the inconvenience and complications for the patient, family, and medical team. In reviewing the records of our patients who underwent halo-dependent traction before surgery, we found a small increase in vital capacity (in most less than 10%). Although physical and respiratory therapy techniques have improved in the last few years, no reports have shown data about improvement in the preoperative pulmonary condition.

Spinal Instrumentation

In spinal muscular atrophy, as in the many other forms of neuromuscular scoliosis, the function of instrumentation is to produce safe correction of the deformity, allow fixation from the upper thoracic spine to the pelvis, and provide rigid fixation that eliminates the need for postoperative casting or traction.

Use of the Harrington system to manage scoliosis in spinal muscular atrophy has been reported (2 ,5 ,41 ,53 ,66). This system has an increased risk of failure, because it fixes the spine at only two points and fails to restore normal alignment of the spine in the sagittal plane. In addition, cast immobilization is needed after the operation, This is detrimental to children with spinal muscular atrophy. There is greater loss of correction with the use of the Harrington system of fixation (7 ,13).

Segmental fixation with Luque rods or a Unit Rod is the current standard in the management of neuromuscular scoliosis (Fig. 1). These systems provide good rigid fixation and usually do not necessitate postoperative external immobilization. Correction of pelvic obliquity and decompensation of the torso are controlled through the intrailiac fixation (1 ,15). This is important because pelvic obliquity places excessive force on a single ischium, and the ability to sit for long periods becomes limited. Physiologic realignment in the sagittal plane is another advantage provided by these systems. When a single Unit Rod (Fig. 1) cannot be used, a connection link between rods, such as the device for transverse traction or the Texas Scottish Rite Hospital cross-link, provides better rigidity in the Luque system. No major neurologic deficits have been related to the correction or to the use of sublaminar wires. However, high blood loss often occurs (5 ,15).

We recommend spinal fusion from T1 or T2 to the sacrum using a Unit Rod for fixation of the spine. The Unit Rod provides the best correction, stability, and sitting balance with fusion to the pelvis. In addition postsurgical care is easier, and no immobilization is needed. This facilitates early and complete physical therapy. Luque rods may be used in place of a Unit Rod, but the two Luque rods should be connected as previously mentioned to provide better stability and decrease the likelihood of occurrence of the “windshield wiper” effect (Fig. 2).

Anterior Spinal Fusion

The usual indication for an anterior procedure to manage neuromuscular scoliosis is a severe and rigid curve with a pelvis that cannot be leveled or a torso that cannot be placed in balance over the pelvis with external maneuvers (5 ,15). In the care of children with spinal muscular atrophy, other factors should be considered. Because of weakness of the muscles in the neck and thorax, these children are more dependent on the diaphragm and abdominal muscles for breathing. An anterior approach and fusion, especially through a thoracoabdominal approach, decreases the respiratory and coughing capacities of these patients and increases the risk of pulmonary complications. At our institution, such complications occurred among five of six patients who underwent anterior spinal fusion. Three patients needed endotracheal intubation and ventilatory assistance for an average of 5 days. Other reports have shown similar data. Patients who need an anterior procedure have more severe imbalance and more pulmonary constriction preoperatively, which makes them more likely to have complications. Anterior release combined with posterior fusion and instrumentation may be performed only if there is a severe fixed lumbar curve with pelvic obliquity. The disadvantage of restricting pulmonary function among these patients should be carefully considered in decision making.

Bone Grafting

The generous use of crushed allograft, approximately 100 to 120 g, is recommended in the treatment of patients with spinal muscular atrophy undergoing spinal fusion. Autograft of iliac bone is not recommended to not disturb or weaken the site of intrailiac fixation. The iliac wing often is osteopenic and provides an inadequate quantity of graft.

Postoperative Care and Results

With arthrodesis from T1 or T2 to the sacrum and the use of segmental fixation with allograft bone, postoperative immobilization usually is not necessary. A TLSO can be applied for comfort.

The most important postoperative concern is respiratory care. Coughing capacity decreases after the operative procedure, especially after an anterior procedure with involvement of the diaphragm. This, along with restriction of the patient's mobility, increases the incidence of pneumonitis and atelectasis. Patients with severe involvement (vital capacity 30% or less) may need endotracheal intubation and ventilatory assistance for several days after the operation. Pulmonary therapy with respiratory and postural exercises and mobilization of the patient are fundamental to minimize respiratory complications (14). In extreme conditions, tracheostomy can be performed to maintain respiratory support for a longer time.

No significant functional gain should be expected after spinal fusion. One team of investigators (2) found no difference in the ability to perform tasks of daily hygiene and self-feeding. Eighty-six percent of the patients were happy with the results, although only three patients had improvement in the performance of daily activities. The main reason for increased patient satisfaction was that patients no longer needed to use their arms to support their trunks and could therefore sit better. Other investigators have reported improvement in function after spinal arthrodesis (41 ,58 ,60). In contrast are reports (7 ,31) of a decline in motor activity, including bathing, toileting, transferring, feeding, and self-feeding, after the operation. Additional mobile arm supports, lapboards, and reachers were necessary after the operation. The upper-extremity activities of these patients had declined at the 2-year follow-up evaluation but had improved slightly 5 years after the operation. However, the patients never reached preoperative levels of function. Physical therapy should begin as soon as possible after the operation to maintain the maximum amount of motor function possible (28).

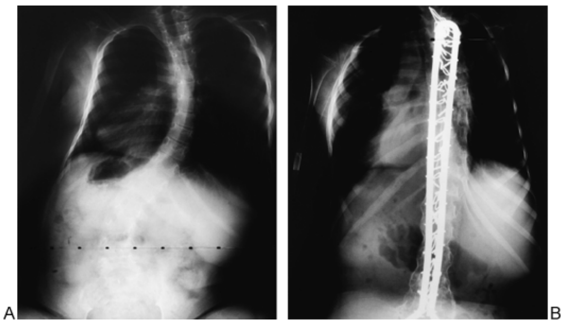

FIGURE 1. A: Patient with spinal muscle atrophy had 78-degree neuromuscular scoliosis that was fused and instrumented with a Unit Rod. **B:** Two and one-half years after the operation the correction is maintained at 22 degrees with good balance.

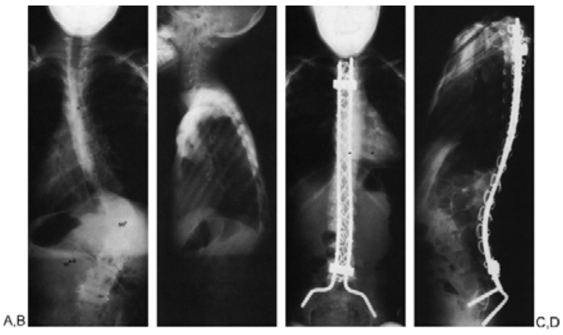

FIGURE 2. A boy 10 years 6 months with spinal muscular atrophy and progressive scoliosis measuring 50 degrees was treated surgically. **A:** Sitting anteroposterior preoperative radiograph. **B:** Sitting lateral preoperative radiograph. **C:** Sitting anteroposterior radiograph 10 months after insertion of Luque rod from T1 to the sacrum by means of the Luque-Galveston technique. **D:** Sitting lateral radiograph 10 months after the operation. (Courtesy of Stuart L. Weinstein, M.D.)

The fusion mass should be evaluated with periodic postoperative radiographs. If back pain develops several months after the operation, loss of internal fixation occurs, or the the deformity progresses, investigation with radiographs and bone scintigraphy should be performed to localize a possible pseudarthrosis.

Postoperative Complications

Complications occur among approximately 40% of patients who undergo surgery, especially older patients and those with severe curves (57). Respiratory insufficiency and atelectasis are the most common postoperative complications. Patients with severe complications may need endotracheal intubation and ventilatory support for several days or, in rare cases, a tracheostomy if the respiratory insufficiency is prolonged. Brown et al. (7) reported that tracheostomy was needed by 30% of their patients. The need for tracheostomy has been related to use of the anterior approach (2). Patients with a preoperative vital capacity less than 50% are at risk of pulmonary complications, but patients with vital capacities as low as 25% of normal can tolerate the procedure (58). Postoperative pneumonia, rupture of the diaphragm with severe loss of pulmonary function, pulmonary embolism, and acute gastric volvulus and late narrowing of the diameter of the chest have been reported after spinal arthrodesis and instrumentation (2 ,45 ,58 ,60).

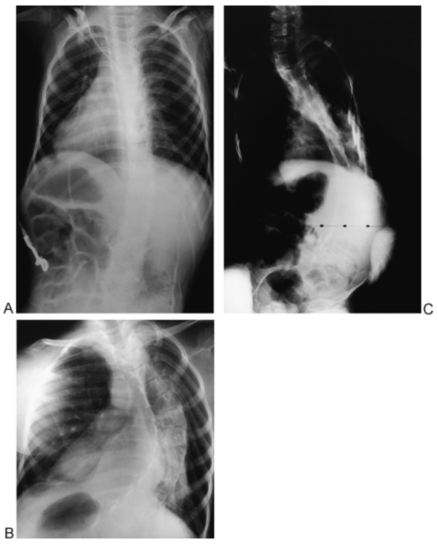

FIGURE 3. A: A patient with spinal muscle atrophy had a preoperative deformity of 64 degrees. The curve was initially instrumented with a Unit Rod. During the operation, the sublaminar wires pulled through the lamina, necessitating removal of the rod for loss of fixation. The patient underwent fusion in situ with 6 months of immobilization. **B:** Pseudarthrosis developed, and an operation was performed to repair the pseudarthrosis and to bone graft the nonfused mass. **C:** Postoperative radiograph shows a poor result due to uncontrolled crankshaft deformity.

Complications with the use of spinal instrumentation have been reported. Luque instrumentation for neuromuscular scoliosis has been associated with an index of complications as high as 15% (4). Complications of spinal fusion among patients with spinal muscle atrophy include rod breakage, pull-out of the sublaminar wires, dislocation of the sacral hooks, and painful prominence of the Luque rod (Fig. 3) (2 ,57 ,60). Manifestations of pseudarthrosis are pain, progression of the deformity, and breakage of the instruments, although results of some studies suggest that pseudoarthrosis can be asymptomatic (29). The reported incidence of pseudarthrosis after spinal fusion for all kinds of neuromuscular scoliosis ranges from 6.5% to 27% (4 ,5 ,60).

Other complications include wound infection and postoperative urinary tract infection (58). Weakness of the neck muscles associated with traction or cast immobilization also occurs. Support with a soft collar and neck-muscle exercises gradually improve the strength of the neck muscles. Narrowing of the chest diameter as a major late complication has been attributed to postoperative cast immobilization (2).

Regression of the functional status of the patient can be considered a complication of operative treatment. This complication may be associated with the use of postoperative traction or a cast. Another cause of regression of the functional status of the patient may be neurologic complications. In the study by Boachie-Adjei et al. (4), this complication was verified for 6.5% of patients with all forms of neuromuscular scoliosis who underwent Luque instrumentation. No studies involving patients with spinal muscular atrophy have addressed this issue. It is important to observe for manifestations that can be caused by neurologic complications after spinal fusion. These include such as paresthesia, progressive weakness, deterioration of pulmonary function, and autonomous dysreflexia.

Summary

Posterior spinal arthrodesis of T1 or T2 to the sacrum is indicated in the care of patients with spinal muscular atrophy with a curve greater than approximately 50 degrees, regardless of age. At this stage, the deformity usually is quite flexible, and pulmonary function is relatively preserved. Therefore, excellent correction and results are expected with a low incidence of complications. For patients with a more severe curve, posterior fusion is still the best option until the curve reaches approximately 80 degrees. For curves greater than 80 degrees, careful evaluation is performed to determine the most appropriate treatment. If the curve is flexible and can be corrected to give relatively good balance with the spine over a level pelvis and a pelvic obliquity of 25 degrees or less, posterior fusion with a Unit Rod is the procedure of choice. Combined procedures with both anterior and posterior fusion are indicated for severe cases of spinal muscular dystrophy with a rigid curve in which a balanced spine is not possible or when the torso cannot be placed over the pelvis. Total correction of pelvic obliquity is not always necessary; however, some correction is preferred.

In the care of patients who are candidates for spinal fusion, pulmonary function is the principal issue. Vital capacity is a guideline for the preoperative condition. If vital capacity is greater than 25%, the planned operation may proceed. However, respiratory therapy rehabilitation should be performed to minimize the risk of pulmonary complications. The therapy should include passive and assisted cough techniques, breathing exercises, postural drainage, and vibration. Patients should be taught to perform breathing exercises that maintain chest-cage expansion and ventilatory capacity, but excessive exercise that causes fatigue should be avoided (28 ,30).

Posterior spinal fusion with segmental spinal instrumentation should include the entire spine from T1 to the sacrum. The Luque rod or Unit Rod technique is suggested. We believe the Unit Rod system yields superior correction and maintenance of the correction. Blood loss usually is substantial, even when the operation is performed by an experienced surgeon. Most patients have a blood loss of 1,000 mL or more. Respiratory and positional exercises are started immediately after the operation.

Myelomeningocele Spine

Richard E. Lindseth

R. E. Lindseth: School of Medicine, Indiana University, Indianapolis, Indiana 46202.

Spinal deformity is so common in myelomeningocele that it should be considered part of the disease complex. It is rare for a child with myelomeningocele to reach adulthood without undergoing some treatment of the spine (30). The spinal deformities are usually progressive and may cause severe disability, interfere with rehabilitation, and negate previous treatment to maintain ambulation. They may also resemble other, more common congenital and developmental spinal deformities, with angulation and displacement of the vertebral column in the sagittal, coronal, and transverse planes. However, spinal deformities in myelomeningocele exhibit unique characteristics that must be considered during treatment if the results are to be satisfactory.

The most obvious and consistent abnormality that sets myelomeningocele spinal deformity apart from other spinal deformities is the incomplete posterior arch in the lumbar spine. This abnormality affects many aspects of treatment for scoliosis and kyphosis. Other congenital malformations may also be present (5). Hemivertebrae, diastematomyelia, or unsegmented bars may occur at any level along the spine. Unsegmented bars are particularly difficult to identify and evaluate if they occur in the area of the spina bifida where the facet joints, laminae, and spinous processes are difficult to identify on standard radiographs.

Another consistent problem is the abnormal nervous system. In addition to paralysis, which may be asymmetric, the central nervous system may show abnormalities of the upper spinal cord and brain stem, producing spasticity or increased muscle tone. The central nervous system abnormalities are often the cause of the scoliosis and must be dealt with before or at least concurrent with any orthopaedic treatment of the scoliosis (6 ,16 ,17).

The spinal curvature often appears at a younger age than is typical for most developmental abnormalities. It may be present by 2 to 3 years of age, becoming severe by 7 years of age. Because of the early onset of the deformity, treatment plans need to anticipate growth of the spine. However, the projections for growth in children with myelomeningocele are different from those for children with normal growth potential. Children with myelomeningocele have slow growth because of growth hormone deficiency, and they mature earlier than usual, often by 9 to 10 years of age in girls and 11 to 12 years of age in boys.

Another factor that needs to be considered in the surgical treatment of these patients is the high infection rate (9 ,23 ,41 ,48). These patients are subject to septicemia from urinary tract infections and skin ulcerations. Also, the skin in the area of the meningocele repair is often of poor quality and gives minimal coverage to the instrumentation.

These children also have deformities of the pelvis and hips that affect spine balance. For example, asymmetric hip contractures may cause lumbar scoliosis, pelvic obliquity, and abnormal lordosis in the standing or sitting position. Likewise, correction of the spine in the treatment of scoliosis can position the legs in such a way as to prevent functional sitting, standing, or walking.

As with all children with spinal deformities, the goals of treatment are the prevention of further deformity and the creation of a stable, balanced spine. Children with myelomeningocele, however, require more precise correction of their deformities; because of their paralysis, they are unable to compensate for any residual deformity, which may prevent them from sitting or from standing and walking. Pressure sores are likely to develop if pelvic obliquity remains, and their sagittal plane alignment must allow them to perform intermittent self-catheterization.

Three types of spinal deformity occur with myelomeningocele: scoliosis, usually associated with severe lordosis; congenital malformation of the spine secondary to lack of segmentation or formation; and kyphosis, which is usually congenital in nature and centered in the upper lumbar spine. The sagittal plane deformities are often of greater significance than the coronal plane deformities.

Scoliosis and Lordosis

Scoliosis is common, particularly in the higher levels of paraplegia (3 ,13 ,24). Almost 100% of patients with thoracic-level paraplegia develop scoliosis (37), and 85% of these curves are greater than 45 degrees. As the paralysis level lowers, so does the incidence of scoliosis. At the fourth lumbar level of paraplegia, the incidence of curvature decreases to about 60%, with only 40% requiring surgical intervention (37). Lordosis without concurrent scoliosis is rare and is usually caused by hip flexion contractures. Historically, it has been seen after spinal-peritoneal shunting for hydrocephalus. However, this procedure is rarely performed today.

Several causes have been identified for the scoliosis. A *C*-shaped scoliosis is usually caused by muscle weakness associated with high-level paraplegia. It may also be associated with asymmetric levels of paralysis or a spastic hemiplegia due to the hydrocephalus. This type of scoliosis may be associated with kyphosis rather than lordosis. Typically, this curve pattern occurs at a young age, often in infancy, and it is almost always progressive.

Hydromyelia or hydrosyringomyelia associated with uncompensated hydrocephalus can cause scoliosis (15 ,16 ,17 ,25). The scoliosis is usually in the thoracic or the thoracolumbar region. It is typically *S* shaped and resembles idiopathic scoliosis. Because of stiffness in the area of the myelomeningocele in the lumbar spine, the compensation for the major curve may be incomplete and associated with pelvic obliquity. Scoliosis may be the only clinical sign of shunt malfunction or progressive hydromyelia and may occur at any age, even early in childhood. Headache, nausea, vomiting, and vision changes—the usual signs of hydrocephalus—may be absent. Other symptoms of hydromyelia are back pain, weakness of the upper extremities, and increasing paralysis of the legs (25). It has been shown that reinserting a functional shunt may decrease the scoliosis if it is less than 50 degrees (17).

Another cause of scoliosis is the tethered cord syndrome (6 ,12 ,45). This abnormality is caused by attachment of the spinal cord to the area of the myelomeningocele, preventing its upward migration with growth. This syndrome may be associated with other intraspinal pathology such as dermoid tumors, lipomas, or diastematomyelia. In my experience, the tethered cord usually causes a dorsolumbar or lumbar scoliosis with a marked increase in lumbar lordosis. Other associated symptoms are increased spasticity in the legs, increasing level of paralysis, and back or leg pain. Results of releasing the tethered cord are variable, but in 75% of cases, curve progression stopped or improved 10 degrees at 1 year (45). If the curve is more than 50 degrees, the scoliosis should be corrected and stabilized with spinal fusion at the time of the tethered cord release or shortly thereafter.

Spasticity is another cause of scoliosis that interferes with attempts at nonoperative and operative treatment. If the spasticity is not caused by hydromyelia or a tethered cord, intraspinal rhizotomy and cordectomy may be necessary (35).

Congenital malformations, including the lack of formation and the lack of segmentation (5 ,51), may exist in combination with hydromyelia, tethered cord, or muscle paralysis. When evaluating a child with scoliosis, the physician must consider each component of the scoliosis in the treatment program. It may be necessary to reinsert the shunt, detether the spinal cord, and treat the congenital scoliosis, if all are present.

Diagnostic Studies

The spine should be evaluated by physical examination each time the patient is seen—from newborn to adult. Note should be made of the coronal and sagittal plane alignment. The examination should be carried out with the child seated without support of the arms. Because of weakness of the legs, standing without the use of arm support is difficult and gives inaccurate results. This eliminates the problems related to hip flexion contracture and asymmetric abduction and adduction. In the coronal plane, balance is the most important consideration. The occiput should lie over the midsacrum, and the pelvis should be level (41). In the sagittal alignment, particular attention should be paid to increased lumbar lordosis and to the appearance of kyphosis at the thoracolumbar junction. In an ambulatory child, any changes in the lumbar lordosis between sitting and standing should be noted.

Hip range of motion should be carefully documented. Particular note should be made of hip flexion contractures and of asymmetry between abduction and adduction.

A thorough neurologic examination of muscle strength, levels of sensation, and reflex activity of the upper and lower extremities should be carefully documented. If scoliosis is developing, the documented changes in neurologic function are of major diagnostic importance regarding the etiology of the scoliosis.

An assessment of the overall growth of the child should be made. If the child is dropping below the fifth percentile in length, the child is probably suffering from growth hormone deficiency. Note should be made of this for future assessment of anticipated skeletal growth. Likewise, evaluation of the relative maturity of the child should be made. Early onset of puberty is common and decreases the overall length of the spine.

Radiographic evaluation should be carried out annually from the age of 1 year. These radiographs should be taken while the child is sitting as soon as the child is able to do so. If there is documented progressive scoliosis, additional radiographic examination is indicated. Magnetic resonance imaging (MRI) probably gives the most information without requiring invasive studies. MRI of the head and cervical spine evaluates the hydrocephalus and the degree of Arnold-Chiari malformation. The cervical, thoracic, and lumbar spine should also be scanned. The cervical spine and thoracic spine are evaluated for the appearance of syrinx or hydromyelia. The scan of the lumbar spine provides information on the posterior displacement of the conus and the presence of intraspinal tumors, such as lipoma or dermoid cysts. The MRI studies must be interpreted in association with the clinical findings to determine the cause of the scoliosis. The presence of a tethered cord is common, and it alone may not be the cause of the deformity.

Computed tomography (CT) can also be used. To achieve the maximal benefit from the study, however, contrast material is usually necessary for evaluation of the spinal cord. Both MRI and CT usually require sedation or anesthesia in young children.

Treatment

The treatment of each child is individualized and depends on the level and type of curve, the level of paralysis, the age of the patient, and the patient's ambulatory status. The first step is to determine whether there are neurologic causes for the scoliosis. Fortunately, it is often possible to treat the etiology of the scoliosis rather than the curve itself. A prompt referral to a neurosurgeon should be made at the first sign of scoliosis, before the curve becomes severe. Minor curves may correct spontaneously without orthopaedic treatment.

Orthoses

If the scoliosis continues to progress after neurologic problems have been corrected, orthopaedic treatment is indicated. If the spine is balanced and the curve is 30 degrees or less, observation is probably indicated. If the curve is unbalanced or greater than 30 degrees, however, the spine will be unstable, and progression of the deformity is almost assured. A trial of bracing is indicated in children younger than 7 years of age if the curve is supple and can be corrected easily. Because bracing in paralytic scoliosis is passive, however, the brace has a tendency to deform the rib cage and produce pressure sores in the area of insensate skin. In infants, special care is needed to avoid abdominal compression, which may make it difficult for the child to breathe and eat. Although the use of a brace is only temporary, it may delay the need for surgery until the child is 8 or 9 years of age, when many of these children are beginning adolescence and a satisfactory surgical correction can be made (4 ,5).

The most effective spinal orthosis is a two-piece, polypropylene, bivalved, molded body jacket. This design allows the brace to be expanded or contracted throughout the day to permit eating and also allows some adjustability for growth. With a body jacket, meticulous skin care is required because pressure sores are common; after pressure sores develop, it is almost impossible to continue using the brace for control of the curve. Therefore, prevention is the rule. In general, the child begins orthosis wear slowly, starting at 1-hour intervals, after which the skin should be inspected. If any redness does not disappear within 4 hours, the orthosis must be modified. The time in the brace is gradually increased over a period of 2 to 3 weeks until the child is wearing it throughout the day except for naps and at night. If the family or caregivers are unable to provide this degree of care, an orthosis is probably not indicated.

Spinal Fusion

Most of these children require surgical correction and spinal fusion. Levels of fusion depend on the age of the child, location of the curve, level of paralysis, and ambulatory status. Generally, the same guidelines for instrumentation and fusion of idiopathic scoliosis are applicable to the myelomeningocele spine. The fusion should go from neutral vertebra to neutral vertebra, and the end vertebra should be located within the stable zone. This holds true for thoracic and thoracolumbar curves. In double curves, uncompensated curves, or primary lumbar curves, however, the decision becomes more difficult. Here, the guidelines for fusion and instrumentation differ from those for idiopathic scoliosis. In general, it is a mistake to fuse short; if there is any question, fuse long. This is particularly true in compensatory thoracic curves, in which reoperation is most common because of progression of the compensatory curve in the thoracic spine (26). In general, a compensatory thoracic curve should be fused for its entire length.

The selection of the level at the distal end is usually complicated by the open vertebral arch, which prevents attachment of the instrumentation to the end vertebra. There is a decreased stability in the vertebral column if the spinal fusion ends in the middle of the spina bifida. Lumbar hyperlordosis is usually present, compounding the problem of deciding on the distal level of fusion. In the past, the instrumentation was extended to the pelvis because of the difficulty of getting a firm attachment to the lower lumbar vertebra (1). With the newer methods of pedicle fixation, it may be possible to control some curves without fusing the lumbosacral joint. At the present, the indications for extending the fusion mass to the sacrum are not well established. Lumbosacral arthrodesis is difficult to obtain because of the lack of posterior vertebral arch to fuse to. Consequently, pseudarthroses and instrumentation failures are common (48). Attempts to correct these problems require repeated surgical procedures and have an uncertain outcome. If a successful fusion to the sacrum is obtained, it may deprive ambulatory patients of the ability to walk (39). For this reason, extending the fusion to the pelvis in an ambulatory child should be avoided, if possible. Even in wheelchair-bound patients, a lumbosacral fusion may cause difficulty as a result of increased occurrence of pressure sores, if the residual pelvic obliquity is 15 degrees or greater. Movement in the lumbosacral spine absorbs much of the angular and rotational movements of the trunk during wheelchair activities. If the lumbosacral spine is fused, these torsional movements are transmitted to the pelvis, creating increased shear between the pelvis, skin, and wheelchair seat. Unless the lumbar scoliosis can be corrected to less than 20 degrees and the pelvic obliquity to less than 15 degrees, however, the scoliosis will continue to progress if the lumbosacral spine is not fused (26). Therefore, it is important to treat the scoliosis while the curve is small and can be corrected to less than a 40-degree lumbar curve and a 15-degree pelvic obliquity, whether or not fusion to the sacrum is planned. Delaying surgical correction of the scoliosis to allow the spine to grow may lead to an unsatisfactory correction. After spinal correction, residual pelvic obliquity greater than 15 degrees can be corrected by a bilateral posterior iliac osteotomy with transfer of a wedge of bone from the long side to the short side (27) (Fig. 1).

The sagittal deformity must also be evaluated because increased lumbar lordosis is a common deformity. Assessment of sitting, supine, and standing posture must be made before correcting the lumbar lordosis. These children often require a greater degree of lordosis than normal. Bringing the lumbar lordosis back to the normal range may uncover a hip flexion contracture and prevent the child from standing or walking. If too much lordosis is fused into the lumbar spine of a female patient, she may not be able to carry out intermittent self-catheterization. The degree of lordosis left in the spine after fusion needs to be individually tailored to each patient. In general, it is best to treat the hip contractures before correcting the spine. It is difficult to maintain the correction of the hip when there is an uncorrected spinal deformity. If the hip deformity is not corrected first, however, positioning of the spine on the operating table will be difficult and will torque the spine postoperatively, leading to instrument failure and pseudarthrosis.

Ischial pressure sores should also be treated before spinal fusion to lessen the chance of infection. This is often difficult to do because the pelvic obliquity is a major cause of the ulceration, and unless it is corrected, pressure cannot be relieved from the ulcer. In this circumstance, a gluteus maximus myocutaneous flap can be used to promote primary healing. The patient is maintained on an air-mattress bed until the spinal correction can be performed. This may seem extreme, but it is much less of a problem than an infected spinal fusion that requires instrument removal.

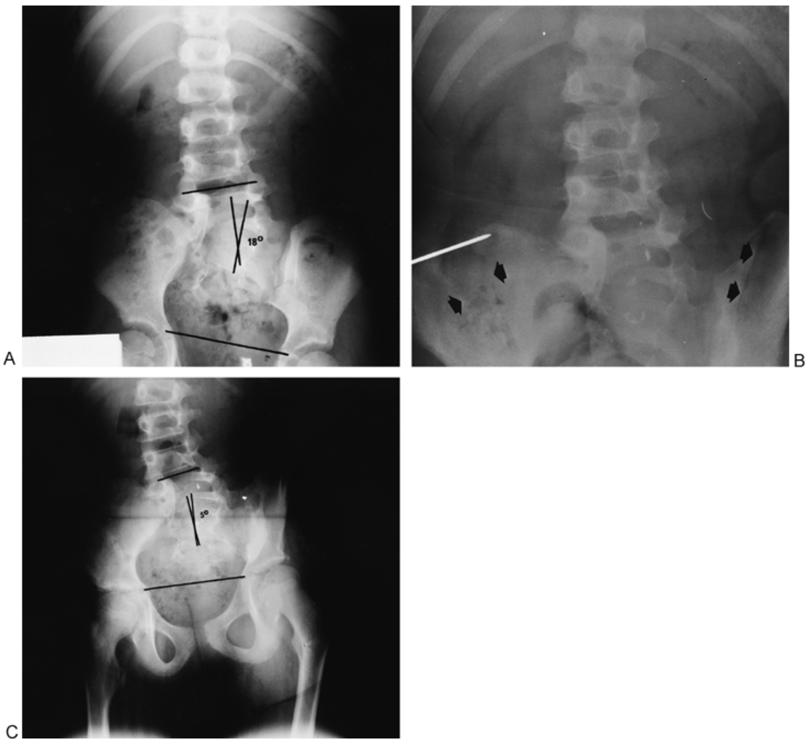

FIGURE 1. Eleven-year-old girl who has 18 degrees of pelvic obliquity because of congenital malformation of the lumbosacral spine. This deformity was stable without progression for 5 years. Her level of paralysis was L4 on the right and S1 on the left. **A:** Anteroposterior radiographs show the 18-degree pelvic obliquity. **B:** Postoperative radiographs show the wedge of bone that has been transferred from the long side to the short side. The graft is shown by the opposing *arrows*; the donor site by the *parallel arrows*. **C:** Follow-up radiographs show correction of the pelvic obliquity to 5 degrees.

The age of the child at the time of surgery is an important consideration. If the child has not yet reached adolescence, there is an almost 100% assurance that the curve will continue to progress despite posterior fusion unless the anterior spine is fused to the same level (10). The lumbar spine will almost always be fused anteriorly as well as posteriorly because of the deficient posterior vertebral arch, but if the posterior fusion extends up into the thoracic spine, it must be fused anteriorly as well.

In a child with a progressive curve that cannot be controlled by a brace who is too young to have the entire thoracolumbar spine fused, the preferred treatment is extraperiosteal segmental Luque instrumentation without spinal fusion (Fig. 2). Postoperative brace treatment is still indicated, and complications from this approach include rod breakage, wire breakage, and spontaneous fusion. To provide a definitive solution, reoperation is often necessary when the child reaches maturity. In the interim, however, valuable spine growth often occurs.

There is a growing belief that before surgical correction of the scoliosis, the tethered spinal cord should be surgically released. As yet, there are no control studies to support or contradict this belief. Certainly, the correction of the scoliosis lengthens the posterior column of the spine and puts stretch on the cord. Whether this causes changes in neurologic function is unproved and probably varies on an individual basis. My approach is to have the child evaluated by neurosurgeons and abide by their recommendation. If a release is to be done, I prefer that it is performed before the spine surgery as a separate procedure.

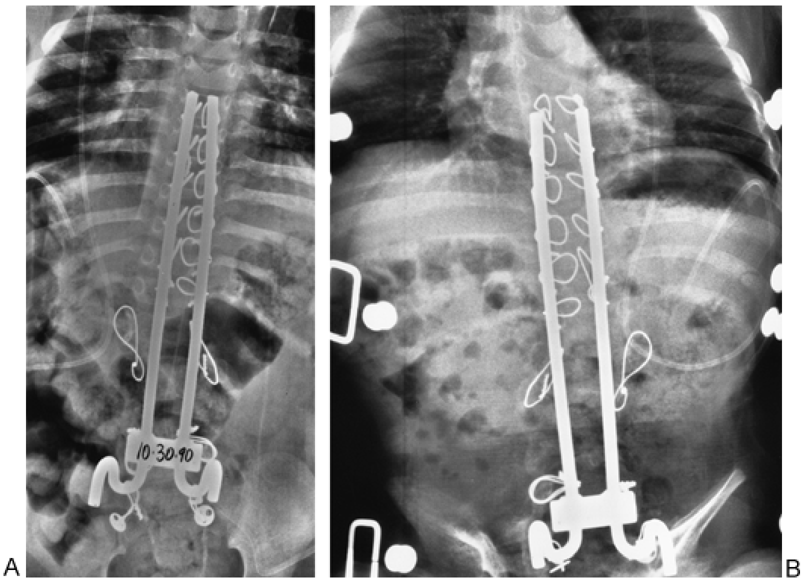

FIGURE 2. Segmental fixation of a spine without fusion in a 2-year-old. **A:** Anteroposterior radiograph after surgery showing the relationship of the sacral wrap rod to the sacrum. A spinous process wire is used to prevent upper migration of the rod. **B:** Radiograph 1 year later showing growth along the rod. Instrumentation

Spinal fusion is still the most important part of the surgical treatment of scoliosis despite the recent advances in spinal instrumentation. The role of the instrumentation is to improve spinal alignment, improve the fusion rate, and reduce the need for recumbency or postoperative immobilization. Regardless of the instrumentation used, the degree of correctability of the curve is limited. It is, therefore, important to carry out an early fusion when the deformity is still manageable. The amount of correction that is possible is probably limited to about 60 degrees, regardless of the size of the curve. Occasionally, it is possible to produce truly amazing degrees of correction, but this is not the rule. It is better to correct a 60-degree curve completely than to correct a 120-degree curve to 60 degrees.

It is generally agreed that anterior and posterior fusion is necessary in the area of the lumbar spine (36 ,37 ,39 ,41). There is no agreement, however, about whether the anterior spine needs to be instrumented. In general, the more severe the deformity to be corrected, the greater the indication for using anterior instrumentation. Anterior instrumentation has recently gone through considerable development. Dwyer and Zielke instrumentation corrected frontal plane deformity but had little control of the sagittal deformity. They usually required external support until healing, a problem in asensate skin. Recent instrumentation using thicker rods up to $^1/_4$ inch appear able to control the spine in frontal and sagittal planes (21). Experience is still too short, however, to determine whehter the results are lasting. Instrumentation to the sacrum is difficult, and fusion of L5 to S1 anteriorly should not be attempted unless posterior instrumentation is to be used. Normally, this is a stable joint, and adequate posterior fusion can be obtained by grafting from the lamina and transverse process of L5 to the sacral ala. When the anterior longitudinal ligament is destroyed along with the annulus fibrosus, however, instability and severe deformity of this joint may occur if the child develops a pseudarthrosis of the lumbosacral joint. Because repair of this deformity and pseudarthrosis can be exceedingly difficult, it is preferable to end the anterior instrumentation at L4 in those patients who have a dorsolumbar curve that ends or is stable at L3 to L4. If it is necessary to extend the fusion down to the pelvis, perform an anterior fusion only down to L5 and do not use anterior instrumentation. If the primary curve is less than 60 degrees, use only posterior instrumentation; if the primary curve is more than 60 degrees, instrument anteriorly to L4 and posteriorly to the pelvis.

Posterior instrumentation has evolved considerably. Initially, Harrington instrumentation was used, but because of the lack of posterior vertebral arch, distal fixation of the fusion was difficult unless the instrumentation was extended down to the sacral ala. The alar hooks frequently became displaced, and the pseudarthrosis and complication rates were unacceptably high (40 ,41). The child also required postoperative immobilization, which increased the occurrence of pressure sores.

Luque instrumentation has probably become the standard instrumentation for these children (1). Because of the segmental fixation to each vertebra, there is much better control over the spine, and postoperative immobilization is not required. However, it does not fix to the length of the spine as a rod with hooks does; therefore, the spine may settle or collapse along the rod, with loss of some of the correction in the immediate postoperative period. If the rod is contoured to maintain a normal sagittal alignment, there is a tendency for the rod to twist into the coronal plane deformity, with loss of correction. This is lessened somewhat by the use of the unit rod or multiple transverse rod connectors. Fixation to the open posterior spine in the lumbar area is weak, and extension of the instrumentation to the ilium is usually necessary. Even this distal attachment of the Luque rods is weak because there may be significant osteoporosis of the pelvis. Loosening of the instrumentation and pseudarthrosis of the lumbosacral joint are common.

The development of instrumentation that allows segmental fixation, distraction, and compression on the same rod along with the use of pedicle screws may solve many of the problems of instrumentation of the distal spine. The pedicle screws allow the end vertebra to be positioned in three planes and provide stable segmental instrumentation. This instrumentation may lessen the desirability of anterior instrumentation. Long-term studies have not yet been performed, but early reports indicate that satisfactory results can be obtained.

Whatever the instrumentation used posteriorly, it should be low profile in design. In the area of the meningocele sac, there is poor skin and soft tissue coverage. Prominence of hardware will invariably lead to ulceration over the hardware, eventual infection, and the need to remove the instrumentation.

Surgical Techniques

Luque Instrumentation Without Fusion

A midline incision is made from the midsacrum to the upper dorsal spine. The upper level of instrumentation should include the compensatory curve. Cephalad to the meningocele, the incision is carried down to the fascia. In the area of the meningocele, the skin and subcutaneous tissues that may be present are carefully dissected off the dural sac laterally until a strip of lumbar dorsal fascia 1 inch wide is exposed. Between the upper level of instrumentation and the first open spinal arch, the spine is approached by carefully dissecting the paraspinous muscles off the periosteum of the spinous process. Bleeding vessels must be carefully coagulated. Injury to and elevation of the periosteum are to be avoided. In the area of the myelomeningocele, the dura is carefully dissected away from the periosteum and ligamenta flava on the inside of the open canal. On the outside of the canal, the paraspinous muscles are carefully dissected extraperiosteally down to the transverse process. At each interspace along the length of instrumented spine, the interspinous ligament and the ligamenta flava are carefully removed with a narrow rongeur to expose the epidural space. Care is taken to avoid removing any bone from the spinous processes. It may be necessary to place a small towel clip in the spinous processes above and below the area of dissection; this can be used to spread the spinous processes to provide sufficient space so that the ligament can be removed without damaging periosteum or bone. A small angled rongeur may be necessary to remove enough ligamenta flava to permit sublaminar wire passage. In the area of the meningocele, wires can be looped around the pedicle or lamina.

The distal fixation point for the rod can be determined in two ways. If the child has intact neurologic function at the lower lumbar and upper sacral levels, an *S*-shaped rod can be looped around the sacral ala (Fig. 2). To keep the rod from displacing proximally and losing control over the sacrum, it is necessary to wire the rod to the sacrum with a sublaminar or spinous process wire. Bone should be grafted between the L5 transverse process and the ala. The rod should be relatively straight, with no contouring, and should be as large as possible. Unless the child is very small, $^1/_4$-inch rods are preferable. If possible, the two rods should be connected at the sacrum with some type of transverse rod-connecting device. This anchors the pelvis and prevents the occurrence of pelvic obliquity in relationship to the rods (Fig. 3). The rods should be as long as possible to allow for growth. It is common for these children to grow at least 6 cm after the rod has been inserted, and they will probably grow off the end of the rod. If this becomes a major problem, a longer rod may need to be inserted at a later date.

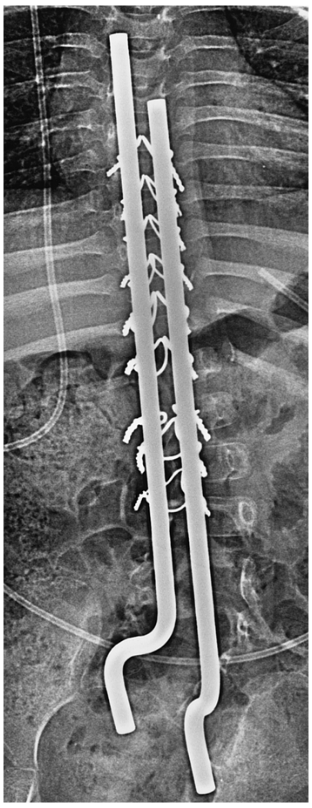

FIGURE 3. Luque rods that were bent to insert into the first sacral foramen. A transverse rod-connecting device was not used, resulting in shift of the rods and recurrence of the pelvic obliquity.

If the child has an upper lumbar level of paraplegia, an alternative method of fixation to the sacrum is possible, making use of the L5 to S1 or S1 foramen for the point of fixation (50). The distal end of the Luque rod is bent in two angles. The first, about 1 inch from the end, is bent at an angle of about 120 degrees. About half an inch proximal to this bend is a right-angle bend going in the opposite direction (Fig. 4). The segmental nerve and vessel are ligated and divided at the selected foramen anchor site. With blunt dissection, the foramen is freed of soft tissue, and the rod is inserted. Even in a 3- or 4-year-old child, a $^1/_4$-inch rod fits nicely into this foramen. A transverse rod-connecting device should be used to secure the rod in relationship to the pelvis (see Fig. 4C, D). If this rod system is used, care must be taken to bend a slight outward bow in the rod to follow the contour of the meningocele and then back to midline, as the intact spine is approached. This prevents undue pressure on the dural sac. Lordosis should also be bent into the rod so that the end of the rod is against the anterior surface of the sacrum.

With the Galveston technique, it may be extremely difficult to anchor the distal rod to the pelvis. The pelvis in an infant or small child is small and osteoporotic and provides an inadequate anchor site. Loss of fixation and eventual protrusion of the rods through the skin have been common.

Postoperatively, the patient is placed in a body jacket for day activities; night protection is not necessary.

Anterior Instrumentation and Fusion

If only thoracolumbar fusion is necessary, a standard thoracolumbar approach removing the tenth rib is appropriate. The diaphragm is usually detached about 1 inch from its lateral border, and a retroperitoneal approach is made to the lumbar spine. If anterior discectomy and fusion without instrumentation are anticipated, it is possible to retract the soft tissues carefully around the disc space so that the disc can be removed and bone graft inserted into the disc space without ligation of the segmental vessels. If instrumentation is required, the segmental vessels are ligated and retracted, exposing the lateral vertebral body. The vertebral screws should be placed as far posteriorly as possible to avoid producing kyphosis in the lumbar spine. A $^1/_4$-inch rod is able to correct the frontal and sagittal deformities (Fig. 5).

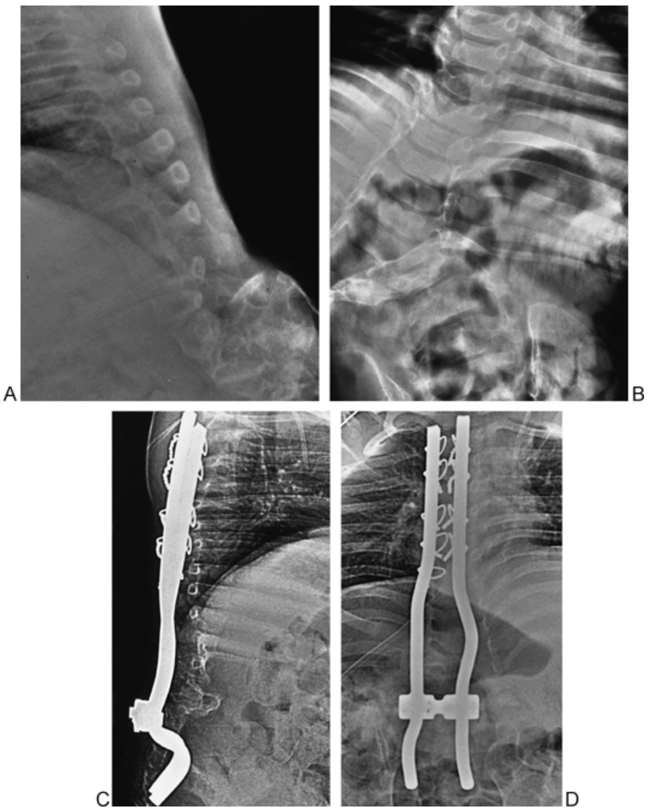

FIGURE 4. A 2-year-old T12-level paraplegic child with a form of medial spinal aplasia and severe kyphosis. **A:** Lateral radiograph showing severe kyphosis that is unmeasurable because of the disorganized anatomy. The proximal lordosis is also severe and rigid. The deformity resembles the more common *S*-shaped kyphosis. Treatment consists of excision of the vertebrae between the thoracic lordosis and the apex of the lumbar kyphosis. **B:** Anteroposterior radiograph showing the presence of scoliosis as well as the absence of several lumbar vertebrae. **C:** After excision of two vertebrae in the lordotic segment, satisfactory reduction of the deformity was achieved. This lateral radiograph shows lordosis of the remaining lumbar spine. The Luque rods are bent to enter the L5 to S1 foramen and lie along the anterior border of the sacrum. **D:** Anteroposterior radiograph showing correction of the scoliosis. A transverse rod-connecting device is maintaining the relationship of the rods. The bend in the rod is to avoid compression of the dural sac.

Anterior spinal fusions that extend proximal to T10 require more than one rib excision. The spine is approached from the direction of the major deformity, particularly if instrumentation is anticipated. The compensatory curve can be approached from the concave side using this approach. The skin incision extends along the proximal rib to be excised from the posterior rib angle to the costochondral junction, where it then curves distally along the lateral border of the rectus abdominal muscle. The incision is carried down through the subcutaneous tissue, exposing the chest musculature. The skin and subcutaneous tissue are carefully removed by sharp dissection from the chest musculature distally to the tenth rib and proximally to the upper rib to be excised. The incision in the latissimus dorsi is made at the level of the tenth rib. The latissimus dorsi is detached along its anterior border from the chest wall along with the origin of the serratus anterior, preserving the nerve supply. This flap is elevated to expose the entire rib cage from T4 down to T10. Any rib, typically the tenth, may be removed at this point to allow access to the spine. The rib at the uppermost level of the fusion or instrumentation is also removed.

At the termination of the procedure, the wound is closed in layers. The latissimus dorsi can easily be brought down and repaired, and the origin of the serratus can be reattached.

Posterior Fusion and Instrumentation

A standard midline approach can be used, with a subperiosteal approach to the spine. The skin is carefully removed from the dural sac. If a tethered cord is present and there is any function in the lumbar cord, the tether should be released at the time of spinal fusion. Otherwise, there may be a change in nerve function, including bowel and bladder control. If the skin over the meningocele is poor and scarred to the dural sac and the neurosurgeon is not performing a simultaneous tethered cord release, an inverted *Y* incision is made (38). Segmental instrumentation is preferred—either a Luque rod or one of the newer types (e.g., TSRH, Moss-Miami) of instrumentation. If the compensatory curves are fused, they must not be overcorrected and must provide a balanced spine. The rods are bent to provide sagittal alignment of the spine, with special care given to the lumbar lordosis.

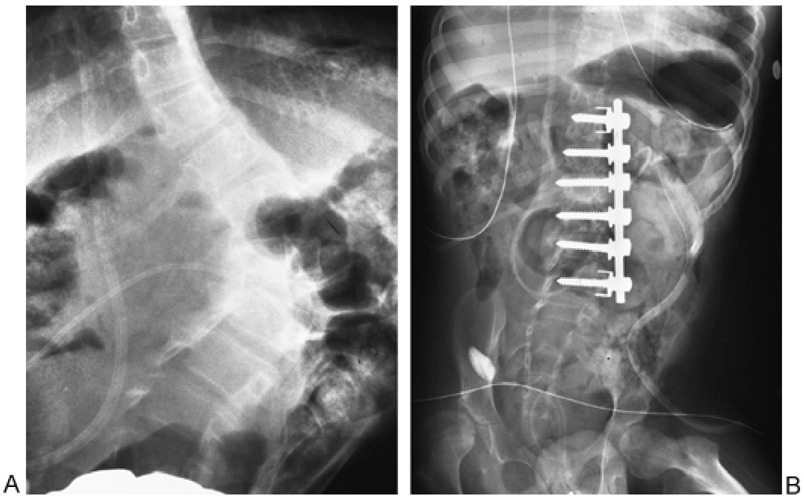

FIGURE 5. A 12-year-old girl with a motor level paralysis at L4. **A:** 80-degree scoliosis. **B:** Correction to 10 degrees with anterior instrumentation from T11 to L4. The ¼-inch rod also controls sagittal alignment.

Segmental fixation of the rods to the dorsal spine usually presents little difficulty because of adequate anchor sites for hooks or wires, but rod fixation in the lumbar spine may be quite difficult. If the distal end of the fusion ends in an area of an intact posterior arch, only routine hook, wire, or screw fixation is necessary. This is not usually the case, however, and the fusion usually ends in the area of the meningocele. If the spine has been instrumented anteriorly, wire fixation to the pedicle is sufficient, but if anterior instrumentation has not been used, pedicle screws in the end vertebra are probably the best choice (Fig. 6). However, care must be taken when attempting to use pedicle screws. Although the pedicle is easily identifiable under direct vision after retracting the dural sac, it is occasionally too small in diameter to accept even a 5.5-mm screw. If adequate fixation cannot be obtained in the area of the meningocele, the fusion should be extended to the sacrum. The instrumentation is carried down and fixed to the ilium using the Galveston technique. Additional fixation at L5 with pedicle screws attached to the rod gives additional fixation to the sacrum and the lower lumbar spine (Fig. 7).

A meticulous lateral mass fusion from the lumbar vertebrae is essential. This must be performed with the same care as one would use for a lumbosacral fusion for spondylolisthesis. The bone graft is then placed along the lamina and transverse process. Care must be taken to curet and bone graft the facet joints in the lumbar vertebrae, which is somewhat difficult because of their abnormal orientation.

Postoperatively, the patient is mobilized as soon as possible to prevent problems with osteoporosis and pressure sores. If the neurosurgeon has performed a tethered cord release, mobilization depends on the adequacy of the dural repair and the possibility of dural leak. Activities are restricted for the first 3 months. If the child is ambulatory and the fusion ended at L3, resumption of ambulation with assistance and the use of crutches or a walker is allowed after 2 or 3 weeks. If the child is a thoracic-level paraplegic and the fusion included the sacrum, activity is limited for at least 3 months. These children are not allowed to transfer themselves without assistance or to participate in activities that would torque the pelvis in relationship to the spine. They must not be transferred to the bathtub (necessitating sponge baths), and they must have assistance getting on and off the toilet and with their intermittent catheterization. They are allowed to wheel their wheelchairs by themselves. After the spine has shown evidence of fusion, usually at 3 months, activities are gradually

increased. Unrestricted activities are not allowed for at least 6 to 9 months.

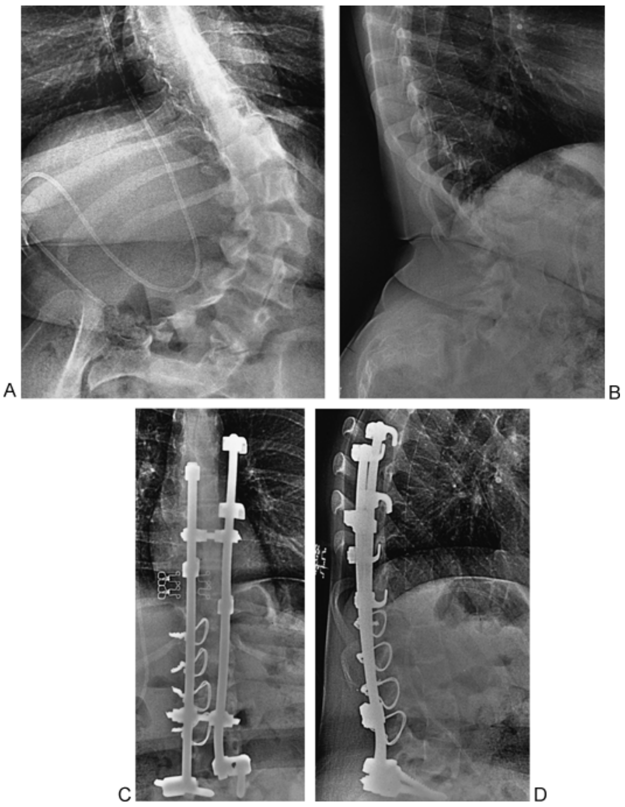

FIGURE 6. A mature 12-year-old girl with progressive lumbar scoliosis. She has an L4 level of paraplegia and is a community walker with ankle-foot orthoses and crutches. Neurologic evaluation showed a functional ventriculoperitoneal shunt and the presence of a tethered spinal cord. **A:** Anteroposterior radiograph showing a 55-degree lumbar scoliosis from T9 to L3. There is a 20-degree compensatory curve from L4 to the sacrum, but because this is insufficient, there is a residual 30-degree pelvic obliquity. The last intact vertebral arch is L2. **B:** Lateral radiograph showing a severe 120-degree lordosis, which is typical of the deformity associated with a tethered cord. **C:** Anteroposterior radiograph showing correction of the scoliosis and pelvic obliquity. Pedicle screws are used to fix the distal end vertebra at L5. The lumbosacral joint was left unfused to allow the patient enough pelvic mobility to continue walking. A release of the tethered cord was performed at the same time as the spinal fusion. An anterior interbody fusion was also performed from T9 to L5. **D:** Lateral radiograph showing correction of the lordosis to 45 degrees and the achievement of a normal sagittal alignment.

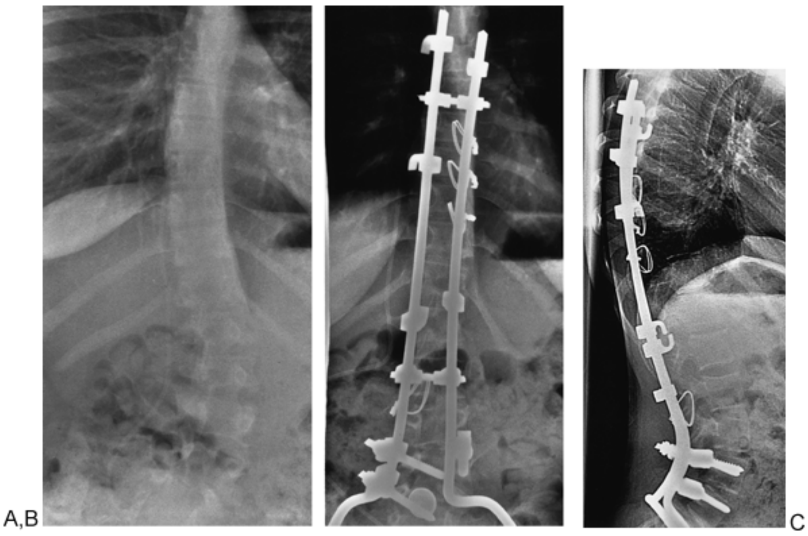

FIGURE 7. A 13-year-old girl who has an L3-level paraplegia but is not ambulatory. She is obese and has a progressive lumbar scoliosis and increase in pelvic obliquity. A tethered spinal cord was released previously. **A:** Anteroposterior radiograph showing a 50-degree uncompensated lumbar scoliosis resulting in 35 degrees of pelvic obliquity. There is also excessive lumbar lordosis. **B:** Postoperative anteroposterior radiograph showing complete correction of the scoliosis. The fusion included the sacrum because the lumbar scoliosis included the first sacral vertebra and the child was not ambulatory. Pedicle screws were used to secure the segmental instrumentation to L4 and L5. Anterior interbody fusion was performed from T10 to the sacrum. **C:** Postoperative lateral radiograph showing restoration of normal sagittal alignment. Lumbar lordosis now measures 55 degrees. She has full extension of her hips and is able to perform intermittent self-catheterization.

Congenital Scoliosis

Congenital scoliosis may occur anywhere along the spine, including the cervical, thoracic, and lumbosacral spine. Congenital malformations may be caused by the lack of formation, the lack of segmentation, or a combination of the two. If the malformation occurs in the lumbosacral area, the progression of deformity is usually rapid and uncompensated, causing severe pelvic obliquity. Nonoperative methods of treatment do not correct congenital scoliosis or prevent it from worsening. Because of their neurologic abnormalities, these children are unable to tolerate an unbalanced spine. Therefore, it is important that treatment be carried out in infancy when the deformity is small rather than waiting until the child is older and heroic measures are needed to obtain satisfactory alignment.

Posterior fusion of the malformation is rarely successful in preventing progression (49). This is particularly so in the lumbar spine, where there is an incomplete posterior arch. Anterior and posterior fusion appears to be the procedure of choice, and it should be performed as soon as a diagnosis of progressive scoliosis is made, usually at about 1 year of age. An alternative to approaching the spine in staged or separate procedures, the anterior and posterior interbody fusions may be performed through a posterior approach, using the pedicle as the access conduit to the anterior spine (18 ,28). This is especially true when the malformation is in the upper thoracic spine, where the anterior approach is very difficult. If the lumbar curve is already so severe that the pelvic obliquity is greater than 15 degrees, an osteotomy of the spine to correct the deformity should be considered. Another possibility in a child older than 10 years of age is to perform a bilateral posterior iliac osteotomy to balance the pelvis after the spine has been fused (28).

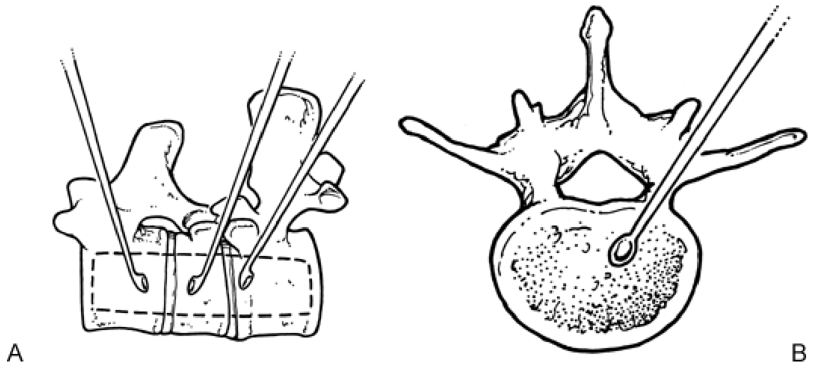

FIGURE 8. Transpedicular anterior fusion of congenital scoliosis. **A:** Lateral view showing the curet in the pedicles clearing out a trough of the vertebrae that cross the disc space. **B:** Transverse view showing the position of the curet in the pedicle and the vertebral body.

Surgical Techniques

Anteroposterior Spinal Fusion: Posterior Approach

Preoperative evaluation includes tomograms to identify correctly the anatomy of the vertebral abnormality. Occasionally, a CT evaluation is also indicated to look at cartilaginous abnormalities that may not be visible on conventional radiographs. If there is a suspicion of a diastematomyelia in association with the congenital malformation, an MRI is useful to look at the dural contents. If a diastematomyelia is present, it should be addressed at the same time as the fusion. Pulmonary function tests are indicated if the congenital curve involves the thoracic spine and a thoracotomy is anticipated to perform the anteroposterior fusion.

The child is placed in the prone position on an operating table that allows either radiographic or fluoroscopic examination to be performed during the surgical procedure. The longitudinal incision is centered over the congenital malformation. A subperiosteal dissection is made of the abnormal vertebrae, including the vertebrae above and below the anticipated level of fusion. Only the convex side of the spine is exposed. Minimal exposure is made above and below the intended fusion site to prevent spontaneous fusion from occurring as a result of dissection in areas where fusion is not wanted.

After the spinous process, lamina, and transverse process have been dissected free, the area of the pedicle is identified and confirmed by radiograph. The posterior cortical bone is removed from the lamina overlying the pedicle. It may be necessary to remove part of the inferior facet joint from the vertebra above. Using a small 3-0 or 4-0 straight curet, the cancellous bone is removed from the pedicle (Fig. 8). It is important to use a toggling motion rather than a pushing motion to identify the canal of the pedicle. Some resistance may be met in the area of the pedicle physis. However, with care, this area can be traversed without breaching the cortical margins of the pedicle. After this resistance has been overcome, the curet will pass easily into the vertebral body. Again, it is important not to push, but rather to use a toggling motion to allow the curet to advance. A tapping motion can be used to confirm that the curet has not perforated the cortex of the vertebral body. With an ever-expanding toggle to the curet, most of the cancellous bone can be removed from the convex half of the vertebral body. Care is taken not to penetrate cortical bone. If bleeding is encountered, small patties can be packed into the pedicle for a few minutes and then removed. An angled 3-0 curet is then used to continue the removal of the cancellous bone up to and including the subchondral bony plate of the vertebral end plate. A similar procedure is performed at each vertebra for the length of the intended fusion (Fig. 9). This includes the abnormal vertebrae plus the vertebrae above and below. Using angled curets, one from above and one from below, the disc can be penetrated and carefully removed. When dissecting posteriorly, it is important not to penetrate the annulus, which would injure the segmental nerve and vessel. The dissection should be checked at frequent intervals using radiographic control.

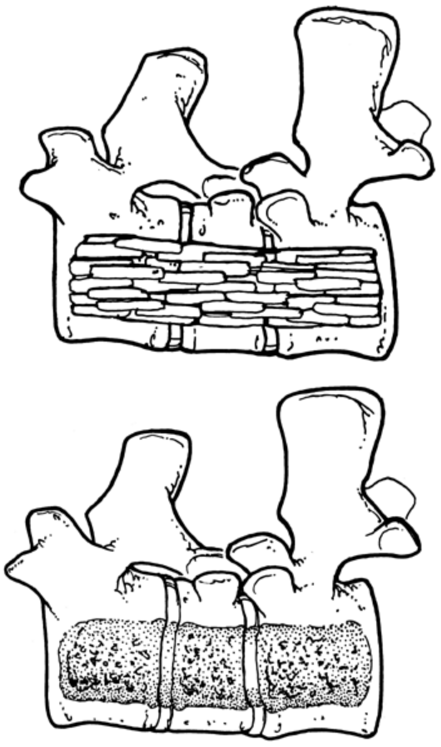

FIGURE 9. *Bottom:* The anterior trough has been completed along the length of the congenital curve. *Top:* Bone graft has been inserted through the pedicles into the trough to promote the anterior spinal fusion.

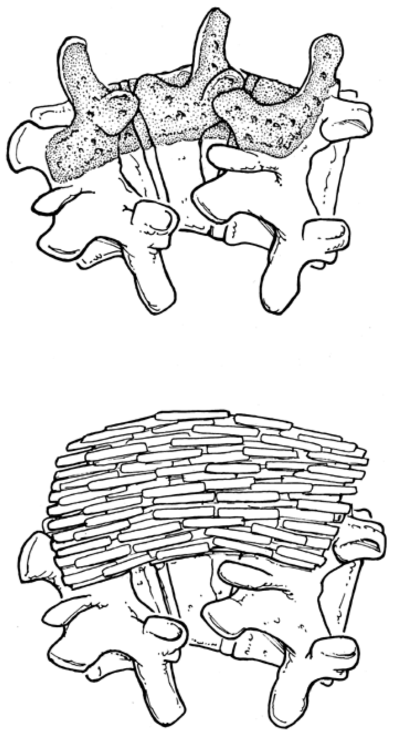

FIGURE 10. The posterior fusion is performed on the convex side of the scoliosis.

After a satisfactory trough has been created in the lateral vertebra from the top to the bottom of the fusion mass, small strips of cortical cancellous autogenous graft are removed from the ilium. They are fitted through the pedicle into the anterior trough in the vertebra. The entire trough is packed with bone extending from one vertebra to the next (Fig. 9). The facet joints and the laminae are then decorticated along the convex side of the curve, and additional bone graft is added posteriorly (Fig. 10). Wound closure is carried out in layers.

Rarely, a pedicle is too small to accept a curet. In this situation, a posterior fusion is performed.

The child is then rolled into the lateral position, a standard anterior approach to the vertebra is made, and an anterior interbody fusion is performed.

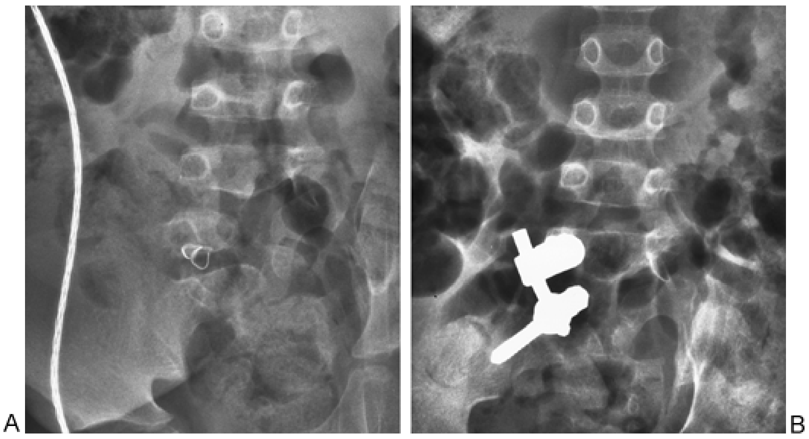

FIGURE 11. A 6-year-old child with severe congenital scoliosis due to hemivertebra. **A:** Radiograph shows the hemivertebra at L5 and an unsegmented bar on the concave side. **B:** Postoperative radiograph shows excision of the hemivertebra and osteotomy of the unsegmented bar. The vertebrae on each side of the hemivertebra were opposed by means of a pedicle screw and a connecting rod. This technique was used instead of a wire because of her age.

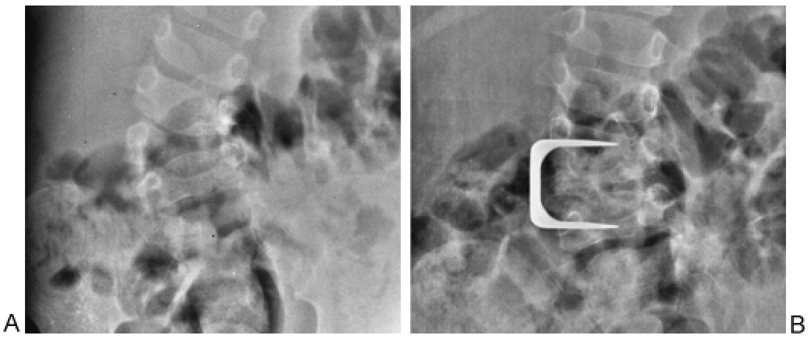

FIGURE 12. A 3-year-old child with congenital scoliosis due to hemivertebra at L4. Posterior excision of the posterior arch of L4 was followed by an anterior excision of the hemivertebra and fixation with a staple. A staged procedure was used because the neurologic level was below S1. **A:** Preoperative radiograph showing the hemivertebra. **B:** Postoperative radiograph shows correction of the deformity.

Typical blood loss from the anteroposterior fusion is about 100 to 150 mL. Operative time averages about 3 hours, which is considerably less than the traditional separate anterior and posterior fusions.

Postoperatively, the child is allowed to resume preoperative activities without restrictions. No brace or cast is used.

Excision of Hemivertebra in the Lumbar Spine: Posterior Approach

This procedure is limited to the lumbar spine in the area of the spina bifida or where neurologic function is intact at the level of the deformity (Fig. 11). It is not appropriate for the dorsal spine, where a more traditional anterior and posterior excision of the hemivertebra in a staged procedure is appropriate.

A longitudinal incision is made in the lumbar spine. Skin and subcutaneous tissue are carefully dissected off the dural sac and lateral to the paraspinous muscles. The dural sac is carefully freed extraperiosteally from the convex side of the curve. The paraspinous muscles are stripped subperiosteally from the convex side of the curve to the transverse process. The hemivertebra is then exposed by a dural retractor retracting the dural sac medially. The spinous process, lamina, and transverse process are removed with a rongeur, exposing the pedicle. Using a small curet, the cancellous bone is removed from the hemivertebra. The cortical bone can then be removed laterally and posteriorly, exposing the anterior cortex. Under direct vision, it is also removed. The disc space and subchondral bone are removed with a curet and rongeur superiorly and inferiorly to the hemivertebra. The deformity can then be reduced by bringing the opposing surfaces together. Bone from the removed hemivertebra can be used for bone graft. Reduction is held by a wire around the pedicle of the vertebra above and below the excised hemivertebra or by pedicle screws and rod. Postoperatively, the patient is placed in a pantaloon cast for 3 months (Fig. 12).

Kyphosis

Lumbar kyphosis is a major deformity that occurs in 8% to 15% of patients with myelomeningocele (8 ,12 ,22 ,29 ,43 ,46 ,47). It often measures 80 degrees or more at birth and usually progresses with growth. Children with extensive kyphosis have difficulty wearing braces and sitting in a wheelchair and often have ulcerations over the prominent kyphos. Progression of the kyphosis may lead to breathing difficulty because the abdominal contents are crowded into the chest cavity by increasing upward pressure on the diaphragm. These children also have difficulty eating because of loss of abdominal size, which results in a failure to thrive. They are underweight and short in stature. The increased flexion of the trunk may also interfere with drainage of urine and cause technical difficulties with urethrostomy, vesicotomy, or ileostomy.

Kyphosis is almost always progressive, and attempts to delay definitive treatment until the child is older lead to a more severe deformity (2). Unfortunately, the aorta and vena cava do not follow the anterior border of the spine across the kyphosis (32); they take the short route like a bowstring. Therefore, the amount of surgical correctability is limited. For this reason, it is important to carry out treatment early, even though it may be only a temporizing procedure. A more definitive procedure can be performed later.

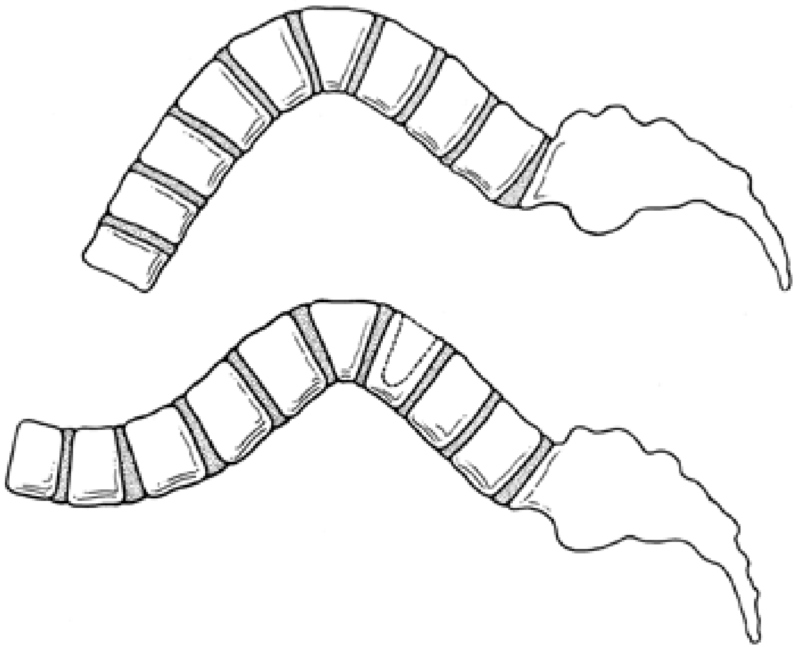

FIGURE 13. Two types of lumbar kyphosis: the *C*-shaped collapsing curve (*top*) and the *S*-shaped curve (*bottom*).

The goal of treatment is to increase abdominal height to allow more room for the abdominal contents and relieve pressure on the diaphragm and the lungs. In addition, the kyphosis must be minimized to lessen the incidence of pressure sores, and the center of gravity must be moved posteriorly to center it over the ischium. This improves the child's ability to sit without using the arms for support.

The kyphosis deformity can be divided into three types (Fig. 13). The first type is a collapsing kyphosis; it is often *C*-shaped and supple, at least during the initial stages. The apex may occur anywhere from the lower dorsal spine to the lumbosacral joint. The second is a rigid *S*-shaped lumbar kyphosis with a proximal dorsal lordosis. The kyphosis is usually centered at L2 and the proximal rigid lordosis at about T10. This is the most common variety of congenital kyphosis in the older child. Some children progress from the *C* type to the *S* type as they grow. The third type of kyphosis is rare and is associated with partial aplasia of the lumbar spine (7) (Fig. 4). It can exist in either the proximal or distal portion of the lumbar spine and is distinguished from sacral agenesis by the presence of a sacrum. Because the treatment of this type is similar to that used for the rigid *S*-shaped deformity, they are discussed together.

Collapsing Kyphosis

Conservative treatment, which consists of observation, is usually futile. The curve progresses rapidly, and it is not unusual to see a 2- or 3-year-old child with a kyphosis greater than 100 degrees. In those few instances in which the collapsing curve does not progress rapidly and is less than 20 to 30 degrees, an initial period of observation may be worthwhile. At the first sign of progression, however, treatment is indicated. If the curve is very small and the skin is in excellent condition, a brace can be used. However, because any orthotic device must push over the apical vertebra posteriorly and against the protuberant abdomen anteriorly, this leads to pressure sores over the gibbus and increased pressure on the abdominal contents. This pressure decreases the child's appetite and pulmonary reserve, jeopardizing survival. The kyphosis almost always requires surgical correction; this should not be delayed if brace treatment is unsatisfactory.

Collapsing scoliosis in an immature child is difficult to treat. Posterior spinal fusion without instrumentation usually fails because of tension forces in the fusion mass. When instrumentation is used, instrument failure is common. Attempts to provide stability by anterior strut fusion with a strut graft also tend to fail in young patients. The fusion creates an anterior unsegmented bar, with growth potential remaining posteriorly. As the child grows, the kyphosis increases. If the surgeon waits until the child is older to carry out anteroposterior fusion with instrumentation along the dorsolumbar spine, the curve is often so severe that satisfactory correction is difficult, if not impossible, to obtain. If the anteroposterior fusion is carried out in infancy, the resulting spine is too short to allow sufficient room for abdominal volume and respiratory sufficiency.

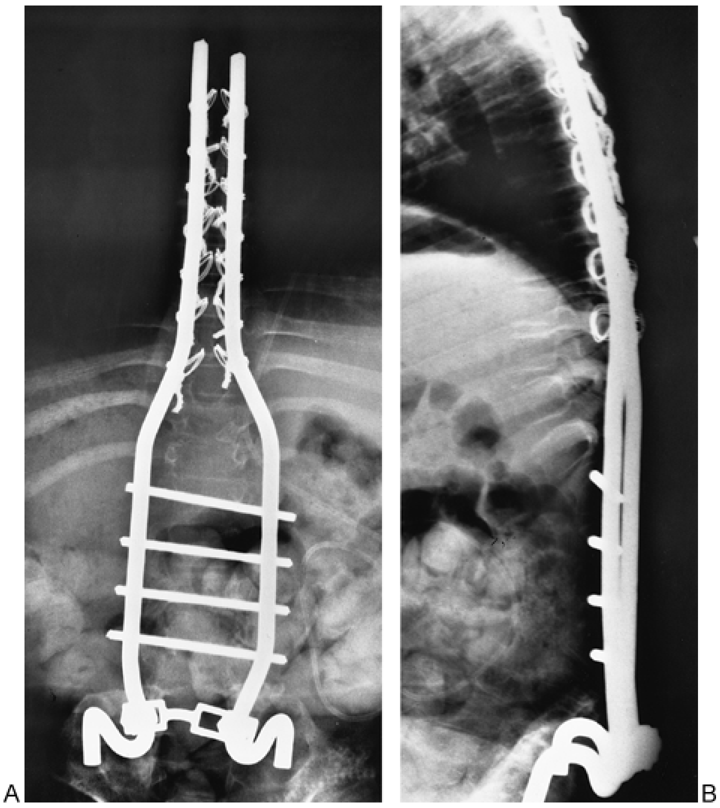

FIGURE 14. Postoperative radiograph showing the instrumentation used for the procedure performed by McCarthy (34). **A:** Anteroposterior radiograph showing the bend of the rod around the dural sac. The pins through the vertebrae are present in the area of the kyphosis. **B:** Lateral radiograph shows a good alignment of the trunk, with the dorsal spine over the sacrum despite a residual kyphosis of 70 degrees. The flexion of the pelvis remains despite the sacral wrap rod. (Courtesy of R. E. McCarthy, M.D., Arkansas Spine Center, Little Rock.)

Satisfactory treatment of this deformity requires that the spine be brought into normal sagittal alignment. McCarthy (34) has developed a technique of incising the disc space anteriorly and laterally using a posterior approach (Fig. 14). This is performed at about five levels centered at the apex of the curve. A catheter is placed in one of the foot arteries and hooked to a monitor to watch for a pressure wave as the spine is gradually corrected by pressure over the apical vertebra. Steinmann pins are drilled crosswise through the vertebral body to act as a fixation point for specially contoured Luque rods, which maintain the reduction. In 14 patients, McCarthy has had no vascular compromise (32).

Most authors, however, found that the anterior structures, including the abdominal wall, aorta, and vena cava, are of insufficient length to allow correction to occur without shortening the spine to remove tension from these structures (32). Many different procedures have been described to shorten the posterior spine to allow it to be straightened and put into more normal sagittal alignment. Most of these techniques require fusion of the spine to maintain correction and should therefore be performed only in a mature child; otherwise, the spine will be too short. The most common technique uses an excision of the apical vertebra and a variable amount of the neighboring vertebrae. However, because the deformity usually extends over three or more vertebrae, it is difficult to obtain satisfactory correction; recurrence of the deformity and failure of instrumentation are common.

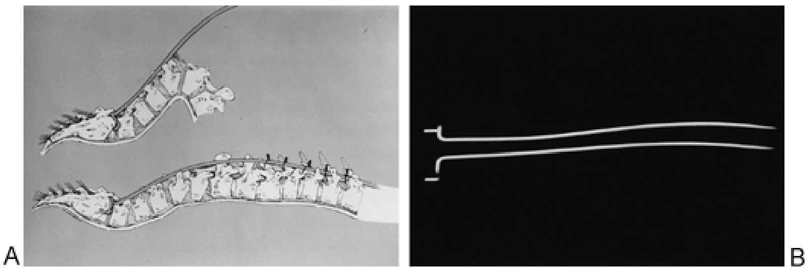

FIGURE 15. Correction of the spine using multiple disc excision and a rod fixation described by Dunn (11). **A:** Lateral diagram showing the rod attachment to the sacrum and thoracic spine. **B:** The rod is bent with three right-angle bends so that it can pass through the L5 foramen and into the sacral ala. (Courtesy of H. K. Dunn, M.D., University of Utah Medical Center, Salt Lake City, Utah.)

The procedure described by Dunn (11) has been successful in obtaining satisfactory correction. In this procedure, the disc space and end plate are removed from each vertebral space over the entire length of the deformity. This gives sufficient mobility of the spine to correct most deformities. If additional shortening is needed, bone can be removed from each interspace as well. This procedure destroys all stability of the spine, and rigid segmental fixation is needed until the fusion is complete. Dunn (11) uses a specially contoured Luque rod (Fig. 15). Because the procedure requires transection of the segmental nerves and vessels at each level and elevation of the spinal cord, it can be used only in patients with thoracic-level paraplegia.

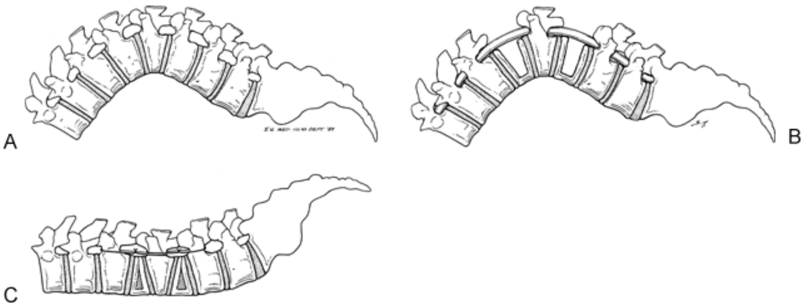

FIGURE 16. Correction of the *C*-shaped curve by removing the ossific nuclei of the vertebrae above and below the apical vertebra. **A:** The *C*-shaped kyphosis before removal of the ossific nuclei from the vertebrae. **B:** Spinous processes, laminae, pedicles, and ossific nuclei have been removed from the vertebrae above and below the apical vertebra. The growth plate disc and anterior cortex are left intact. **C:** The deformity is reduced by pushing the apical vertebra forward. Tension band wiring around the pedicles maintains the reduction. (From

Lindseth RE (1991): Spine deformity in myelomeningocele. *Instr Course Lect* 40:276

, with permission.)

Another method used to shorten the spine is to remove the ossific nuclei from the vertebrae above and below the apical vertebra, which is left intact (Fig. 16A, B). The pedicle and posterior arch are, likewise, removed from these two vertebrae. The apical vertebra is pushed forward, correcting the kyphosis (Fig. 16C). Segmental wiring is used to create a tension band between the pedicles of the apical vertebra and the vertebrae above and below the osteotomy in the newborn child. In a child older than 1 year of age, rods without fusion maintain the correction (Fig. 4). Because the vertebral body growth centers are left intact, the growth of the spine continues, often producing a gradual increase in the lordosis. The spine is not fused; hence, the procedure can be performed at any age, even in newborns (Figs. 17 and 18). It is also possible to perform this surgery without mobilizing the spinal cord or dividing any of the nerve roots. Therefore, it can be performed when nerve function is intact below the level of the kyphosis. About 100 degrees of kyphosis can be corrected in this fashion. If the spinal cord is resected, there may be a detrimental change in urologic control (42).

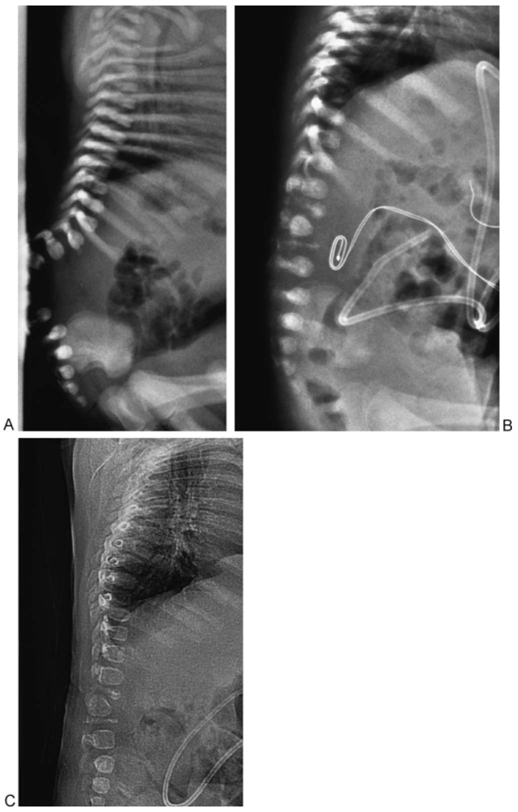

FIGURE 17. Newborn infant with severe kyphosis and myelomeningocele that extends from T12 to the sacrum. Correction was obtained at birth at the same time as the meningocele closure. **A:** Lateral radiograph showing a 100-degree kyphosis. Although there was a proximal lordosis of the distal thoracic spine, it appeared to be supple upon examination, and the decision was made to treat this as a *C*-shaped curve. **B:** Postoperative radiograph showing that the kyphosis has been reduced to 10 degrees. Nonabsorbable suture was used instead of wire to hold the correction because of the weakness of the infantile bone. After reduction of the kyphosis, the paravertebral muscles could be closed behind the dural sac. Also, the skin was closed primarily without the need for skin flaps. The resected vertebrae are visible as narrow bands of bone on each side of the apical vertebrae. **C:** One-year postoperative lateral radiograph shows further correction of the kyphosis to 2 degrees. Reformation of the excised vertebrae is beginning, as shown by the increased width of the bone above and below the apical vertebrae.

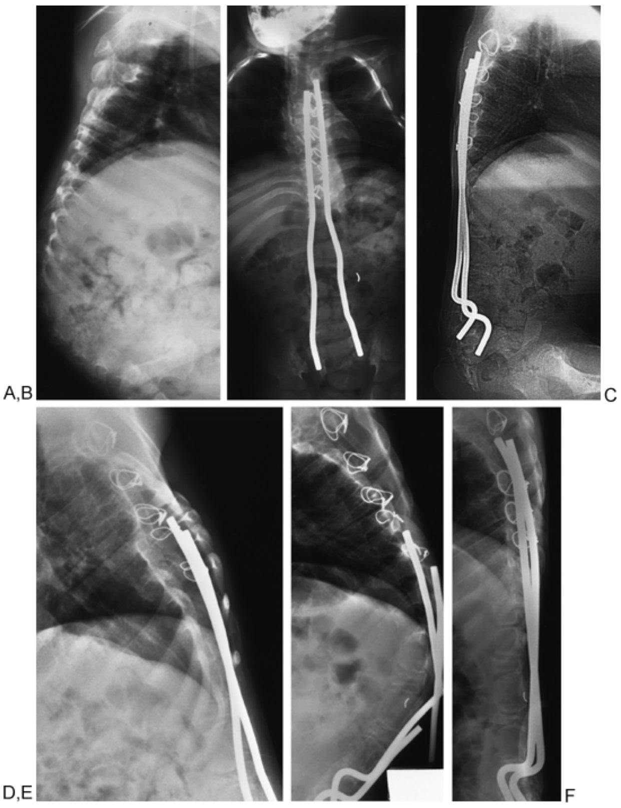

FIGURE 18. A 5-year-old male with 95-degree lumbar kyphosis. **A:** Lateral radiograph showing the 95-degree kyphosis with the apex at L2. **B:** Postoperative anteroposterior radiograph shows the contour of the rod at the lower thoracic spine to avoid pressure on the dura. The upper ends of the rod extend beyond the proximal wires. Because of his young age, fusion was not performed. **C:** Lateral radiograph taken 2 years later shows growth off the proximal wire. The distal end of the rod shows its placement into the first sacral foramen. **D:** By 12 years of age, the spine has grown off three of the proximal wires. **E:** At 14 years of age, the 3/16-inch rods have broken, and the kyphos has recurred. **F:** The broken rods have been replaced with ¼-inch rods and the spine has been fused because he has reached maturity.

Skin coverage is often a problem. If the skin is exceedingly scarred or ulcerated over the kyphosis, wound breakdown and infection are likely. The problem with skin coverage should be addressed before the spinal correction. A myocutaneous flap should be planned and prepared beforehand (33).

Surgical Technique

Newborn

In newborns, it is ideal to correct the kyphosis in association with the sac closure by the neurosurgeon. This facilitates postoperative treatment of the child and decreases the need for flap closure and sacrifice of remaining spinal cord function.

After the neurosurgeon has closed the dura, the approach to the spine is performed. By extraperiosteal dissection, the paraspinous muscles are carefully removed from the turned-out spinous process, lamina, and transverse process down to the pedicle. This is performed from the beginning of the spina bifida down to the attachment of the paraspinous muscles to the ilium. The vertebra that is closest to the apex of the kyphosis is identified, and the vertebra above the apical vertebra is approached. The spinous process, lamina, transverse process, and pedicle are removed with a rongeur at the level of the pedicle physis. Working from each side of the spine, the cancellous bone of the vertebral body is removed using the base of the pedicle as a conduit (19) (Fig. 8B). The bone in the newborn infant is soft and is easily removed with a curet. The dissection is carried out between the nerve roots and anterior to the cord so that the spinal cord and peripheral nerves are not injured. After the cancellous bone has been removed entirely from the vertebral body, the posterior cortex is removed from the posterior longitudinal ligament. The lateral cortex is also removed with a rongeur, preserving the anterior cortex.

An identical procedure is then carried out on the vertebra below the apex. Bleeding during this dissection is minimal, although there may be some bleeding as the cortex is taken away from the posterior longitudinal ligament. Care must be taken during this part of the procedure to avoid injuring the venous plexus.

A heavy 0-0 or 1-0 nonabsorbable suture or wire is placed around the pedicle of the vertebra above the proximally excised vertebra and around the pedicle of the apical vertebra. Another suture is placed around the pedicle of the apical vertebra and the pedicle of the vertebra below the distally excised vertebra. The kyphosis is reduced by pushing the apical vertebra forward and tying the sutures, which act as tension band wiring (Fig. 16).

The paraspinous muscles are closed behind the dural sac. This is an important part of the procedure in the newborn. If the muscles are under excessive tension, they may need to be freed from the quadratus lumborum anteriorly. The paraspinous muscles can usually be approximated to the level of L4, at which point they begin to attach to the ilium. As the muscles are closed over the dura, the skin moves with the muscles from lateral to posterior, and primary closure of the skin is usually possible without the elevation of skin flaps.

Postoperatively, the patient is nursed in the prone position until primary wound healing has occurred and the child is ready to be discharged from the hospital. At that point, the child is placed in a posterior body shell to be used whenever the child is not lying prone. The child is kept prone or supine until 2 months of age, at which time the child is allowed to assume a sitting posture to develop head control and hand-eye coordination. A two-piece polypropylene body jacket is worn for all activities other than sleeping until the child is at least 1 year of age. The bone forms rapidly in the ossific nucleus in the areas of the resected vertebrae and can stabilize the spine quickly (Fig. 16). After the patient reaches 1 year of age, bracing of the spine is used only for functional activities such as standing. In some cases, the kyphosis returns and repeat surgery is needed. However, valuable time has been gained until a more definitive procedure can be performed.

One Year or Older

The child is placed in the prone position. A midline incision is made from the upper dorsal spine down to the midsacrum and carried down through the subcutaneous tissue to the lumbodorsal fascia. In the area of the previous meningocele repair, skin and subcutaneous tissue are carefully dissected off the dural sac laterally to the bony prominences of the turned-out lamina. Proximal to the meningocele, the spine is approached through an extraperiosteal approach for a distance of at least four or five vertebrae above the last intact spinous process. The surgeon dissects the paraspinous muscles off the periosteum of the spinous process, lamina, and transverse process, taking care not to injure the periosteum. Bleeding is carefully controlled to avoid postoperative hematoma. The interspinous ligament and ligamenta flava are carefully dissected to provide access to the extradural space. It may be necessary to place a towel clamp in the spinous process to spread the spinous process for exposure. Care should be taken not to remove bone from the spinous process.

The paraspinous muscles in the area of the meningocele are removed subperiosteally from the turned-out spinous process, lamina, and transverse process to the pedicle, from the level of the beginning of the spina bifida to the sacrum. If the child is paraplegic at the level of the kyphosis, the segmental roots and vessels of the spinal cord are divided and ligated starting at the sacrum. Each root and neurovascular bundle is ligated, working proximally until the vertebra above the apical vertebra has been reached. The spinal cord is elevated as a tube to provide exposure to the posterior spine. Bleeding vessels are cauterized. The ossific nucleus, posterior cortex, and lateral cortex of the vertebrae above and below the apical vertebra are then removed, similar to the procedure in the newborn (Fig. 15). Care is taken not to damage the epiphysis or the disc space. The spine is reduced by pushing the apical vertebra forward. Fixation is obtained by inserting a specially formed Luque rod into the foramen of L5 to S1 or the first sacral foramen (50) (Fig. 18). In a 1-year-old child, a $^3/_{16}$-inch rod is probably satisfactory; in an older child, a $^1/_4$-inch rod often fits into this foramen. The $^1/_4$-inch rod should be used if possible. The $^3/_{16}$-inch rod usually breaks after several years and needs to be replaced. The rod is bent, with the first bend of about 135 degrees being made 1 inch from the end. Half an inch proximal to this, a right-angle bend is made in the opposite direction. The prebent rod is available commonly from AcroMed (325 Paramount Drive, Raynham, MA 02767-0350). The rods are then inserted carefully into the foramen and should be positioned so that they are tight up against the anterior surface of the sacrum. If possible, a transverse loading device should be used to hold the rods separated at the sacrum. The rods are bent to allow a place for the spinal cord as the rods pass through the midline and for the sublaminar wiring proximally. If the spinal cord is pinched between the rods, a spinal cord reflex may develop. Sublaminar wires are then placed in the proximal vertebrae that have already been prepared for their passage. At least three wires are needed for each rod proximally. The sublaminar wires are tightened, correcting the deformity. Because of the bend in the rod at the sacrum, there is usually about 40 degrees of lordosis at the lumbosacral joint. This establishes normal sagittal alignment in this area. The paraspinous muscles are then closed over the rod, and the subcutaneous skin is closed in the routine manner. The rod is cut about 2 inches above the most proximal wire to allow for growth.

Postoperatively, no splint or body cast is needed. The child is allowed to sit after 1 week. When the child is ready to resume physical therapy and standing, a two-piece body jacket may be worn for protection during periods of increased activity.

If the child has intact nerve function, the ossific nuclei of the vertebrae are approached as in the newborn procedure, with care taken to avoid injury to the spinal cord and the segmental nerves. Tension band wiring similar to that in the newborn is used. Because the wiring is of insufficient strength for an older child, however, and the tension band wires will cut through the pedicle when the child begins to sit, the osteotomy must be protected with instrumentation. The distal instrumentation to the pelvis or sacrum is performed as described previously with sacrifice of the S1 nerve root so that the rod can be inserted in the S1 foramen. The sacral wrap rods, similar to the McCarthy (34) and Dunn (11) techniques, may allow the pelvis to tip forward, causing kyphosis at the lumbosacral joint (Fig. 14). The Galveston technique has been unsuccessful in obtaining satisfactory control of the spine for the treatment of kyphosis. The direction of the rods makes it difficult for them to resist the forward flexion that occurs in the treatment of kyphosis.

In children who have reached adolescence, the procedure is further modified by performing a spinal fusion that is instrumented for the entire length of the spine.

Rigid S-Shaped Kyphosis

Treatment of the rigid form of upper lumbar kyphosis is difficult and controversial. Conservative nonoperative treatment invariably leads to an increased deformity and difficulty in later correction. In 1968, Sharrard (44) first described resection of the apical vertebral body for the treatment of kyphosis; since then, most authors have recommended vertebral excision as part of the operative treatment (20). Most of these reports also showed that excision of the apical vertebra may lead to initial correction of the deformity. However, the deformity has a tendency to recur, often to a worse degree than the initial kyphosis (28), leading to feelings of futility and frustration.

Treatment of the rigid form of kyphosis requires a different approach. Because both the kyphosis and the proximal lordosis are rigid, it is necessary to correct both deformities at the same time. This can be accomplished by excising the vertebrae (usually two) between the kyphosis and lordosis (14 ,29) (Fig. 19) and fusing the apical vertebra to the distal end of the thoracic spine at the level of the resection. In a young child, this is the only area fused, and the osteotomy is held in position by tension band wiring around the pedicle above and below the resected vertebrae (29) (Fig. 18). It is important that the paraspinous muscles be sutured behind the area of the spine to add a corrective force, decreasing the likelihood of recurrence of the deformity (Fig. 18).

An evaluation of 39 patients who underwent this resection of the lordotic segment proximal to the apical vertebra, with a mean follow-up of 11 years, showed that most patients maintained at least 50% of the correction demonstrated on the postoperative radiographs (31). Even though this long-term follow up showed satisfactory outcome, I now use the S1 sacral spinal rod described in the collapsing kyphosis in all patients older than 1 year of age.

Occasionally, there is an associated congenital scoliosis in the same area of the congenital kyphosis. In most instances, resection of the two vertebrae proximal to the apical vertebra allows correction of both the scoliosis and the kyphosis. There is also an increased incidence of diastematomyelia at the proximal end of the myelomeningocele. This should also be addressed at the time of the vertebral excision.

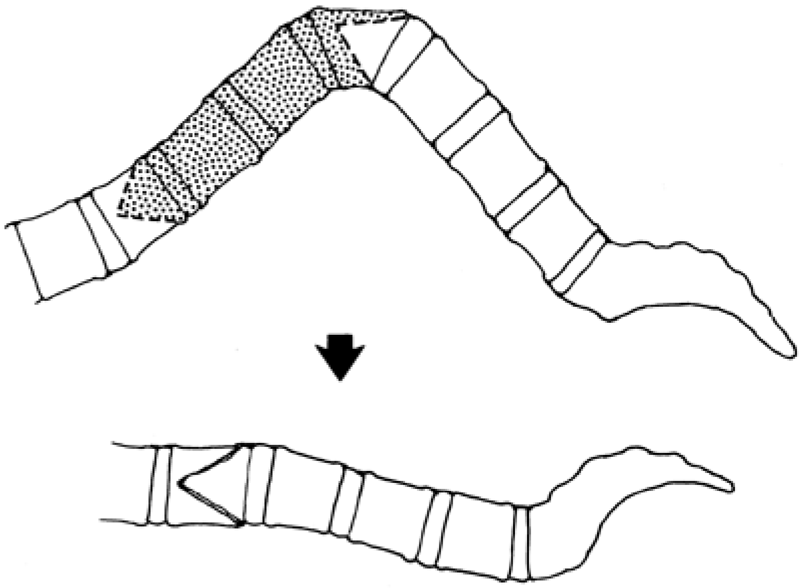

FIGURE 19. Stippled area shows the bone removed for correction of a rigid *S*-shaped lumbar kyphosis. It usually includes one or two vertebrae proximal to the apical vertebra in the area of the fixed lordosis. The vertebrae proximal to the resection and the apical vertebra are shaped to receive each other in a tongue-and-groove joint to provide stability until bony union is achieved. (From La Marca F, Herman M, Grant JA, et al. (1997): Presentation and management of hydromyelia in children with Chiari type-II malformation. *Pediatr Neurosurg* 26(2):57–67, with permission).

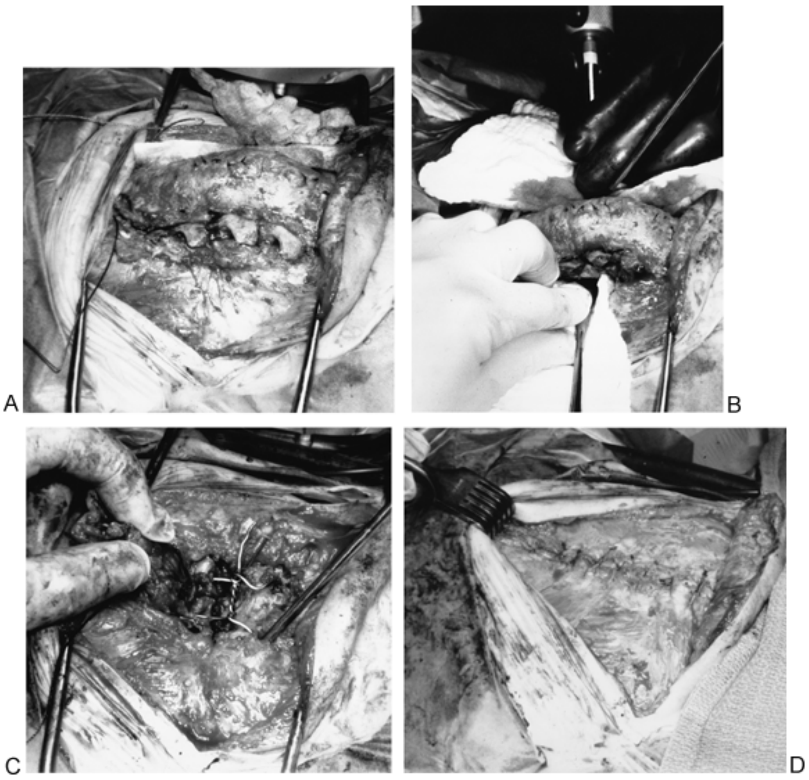

FIGURE 20. Operative photographs of resection of the proximal vertebrae in an *S*-shaped kyphosis. **A:** The head of the child is at the left. A transverse skin incision has been used. The dural sac can be seen posterior to the spine. The paraspinous muscles have been stripped from the spinous process and the lamina. This shows the anatomy of the turned-out lamina and spinous process. The paraspinous muscles are anterior to the spine. **B:** The segmental vessels and nerves have been divided. Soft tissues are stripped from the front of the spine from each side. A lap sponge is used to protect the soft tissues from the periosteal elevators. **C:** Two vertebrae (T12 and L1) have been removed above the apical (L2) vertebra. The apical vertebra has been pushed down to the proximal vertebra (T11). The reduction is held by two stainless-steel wires around the pedicle of T11 and L3. These wires are visible in place. The spine now lies anterior to the paraspinous muscles. **D:** The paraspinous muscles have been closed behind the dural sac and the spine.

Surgical Technique

Newborn

A technique similar to the procedure described for a collapsing kyphosis in newborns should be performed. In most cases, the proximal lordosis is not rigid in newborns, and satisfactory alignment can be obtained (Fig. 17). If the proximal lordosis is rigid, correction of the kyphosis should be delayed until the child is at least 1 year of age.

One Year or Older

If the kyphosis is not corrected at the time of the sac closure in the newborn period, the procedure should be delayed until the child is at least the size of a 1-year-old, although the child may be considerably older than 1 year chronologically. A midline incision is made from at least three vertebrae proximal to the last complete neural arch to the midsacrum.

The dissection is started proximally three levels above the last intact vertebral arch and carried distally along the everted spinous process and lamina. The incision is made in the periosteum overlying the posterior surface of these vertebrae and by extraperiosteal dissection. The paraspinous muscles are removed from the undersurface of the spinous process, lamina, and transverse process (Fig. 18). This dissection extends from the last intact arch to the sacrum. The dural sac is freed from the lamina and the inner border of the pedicle, exposing the segmental nerves and vessels. The segmental nerves and vessels are ligated and divided, starting distal to the apical vertebra and extending a distance of at least two segments above the apical vertebra.

The everted spinous process, lamina, and transverse process of the apical vertebra and the two more proximal vertebrae are removed by rongeur. Using careful dissection with a Cobb periosteal elevator, the surgeon dissects the front part of the vertebra free of soft tissue attachments (Fig. 18). The anterior abdominal structures are protected by a sponge during the dissection, which is carried out from both sides. After dissection is complete, a malleable retractor is passed anterior to the vertebral bodies, protecting the soft tissues from injury. The neurotube is divided at one segment level distal to the apical vertebra, and the distal segment is oversewn for hemostasis. The proximal end is opened, and the neuroplate is dissected free of the dura and allowed to fall back into the sac. The sac is closed with a watertight closure with 6-0 silk dural suture. The surgeon then elevates the dural sac, cauterizing bleeding vessels, and retracts it proximally to expose the apical vertebra and the vertebra just proximal to the apex. The disc space between these vertebrae is incised with a scalpel. The anterior soft tissues are protected by the previously inserted malleable retractor. The disc space proximal to this vertebra is incised with a scalpel, and the entire vertebra is removed. This provides considerable relaxation to the spine and allows for additional exposure. The next most proximal vertebral end plate can then be seen. With careful dissection, it is possible to free this proximal vertebra circumferentially and excise it through the proximal disc space. Rarely are more than two vertebrae excised. The end plate of the proximal vertebra is denuded of disc and growth plate, and a transverse groove is cut into the vertebral body about 1 cm deep and 1 cm high. The apical vertebra is shaped into a wedge by removing the disc and subchondral bone from its undersurface. This wedge-shaped vertebra fits into the groove of the proximal vertebra (Fig. 19) and is held in position by tension band wiring looped around the pedicle of the proximal vertebra and around the pedicle of the vertebra just distal to the apical vertebra (Fig. 20). Bone graft obtained from the excised vertebrae is placed around the osteotomy site. The dura is allowed to fall back into its normal position.

The S1 nerve root and artery are ligated and divided. The prebent sacral rod is carefully inserted through the S1 foramen, similar to the procedure described previously for a collapsing *C*-shaped kyphosis. Proximally, the rod is held by at least three sublaminar wires and the rod cut 2 inches longer than the most proximal wire. In a child older than 10 years of age, a fusion is performed along the instrumented spine.

Paraspinous muscles are freed of attachments to the quadratus lumborum and, if necessary, from the lateral abdominal musculature. The paraspinous muscles are closed over the dural sac posterior to the vertebrae (Fig. 20) to the level of about L3 to L4, where they begin to attach to the ilium. A hemovac drain is placed for drainage, and the skin is closed.
Typical blood loss during this procedure is 50% or more of blood volume (28). It is therefore necessary to perform blood replacement and to maintain blood volume during the procedure.

Postoperatively, the child is kept flat for 24 hours to avoid cerebrospinal fluid leakage. Thereafter, the child may sit up and move with assistance to wheelchair. No cast or brace is used. Activities are limited to avoid bending, twisting, reaching, or lifting for a period of 3 months. The child may then begin his or her usual activities.

Revision Surgery

Occasionally, the deformity recurs as the child matures. This does not represent a failure of the initial surgery. In most instances, growth has occurred, increasing the length of the spine, and the deformity is still less than it would have been without treatment. If it becomes necessary to reoperate, a procedure similar to that described for a collapsing kyphosis can be performed. The instrumentation is anchored to the pelvis in the same fashion, and a fusion is carried out throughout the length of the instrumented spine. The area of increase in the kyphosis is usually distal to the previous osteotomy and fusion, forming a collapsing *C*-shaped type of curve (Fig. 18).

Poliomyelitis Scoliosis

Po-Quang Chen

Young-Shung Shen

P-Q Chen: Department of Orthopedic Surgery, College of Medicine, National Taiwan University, Taipei, Taiwan.

Y-S Shen: Po-Cheng Orthopedic Institute, Kaohsiung, Taiwan.

Acute poliomyelitis is an infectious disease caused by one of the three polioviruses known as Leon (type 3), Lansing (type 2), and Brunhilde (type 1). Humans and monkeys are the only hosts for polioviruses. In humans, these viruses have a specific affinity for nervous tissue and, in particular, for the large motor neurons of the anterior horn of the brain stem and spinal cord. Most poliovirus infections have a benign course, with no or only mild gastrointestinal symptoms. Less than 1% develop into the severe paralytic form.

Poliomyelitis was recognized as a clinical entity in the first half of the nineteenth century. Large epidemics occurred in Europe and North America until the first half of the twentieth century. There have been no large-scale epidemics since the immunization programs using both the Salk and the Sabin vaccines (57 ,58), but endemic outbreaks are still reported in third-world countries, where sanitary conditions are poor and large-scale immunization has not been accomplished. In 1988, the World Health Assembly adopted the goal of worldwide poliomyelitis eradication by the year 2000. Despite substantial progress in that direction, there remain multitudes of postpolio patients in need of scoliosis surgery. In China alone, about 60,000 of these patients need scoliosis surgery (71).

Poliomyelitis is primarily an intestinal infection. The virus gains entrance by way of the oropharynx and can be isolated from the pharynx and feces in both the preparetic and postparetic stages. The virus can be discovered from the blood of abortive cases of poliomyelitis and from chimpanzees after oral feedings (2). However, once the central nervous system is invaded, the motor neuron cells of the anterior horns of the spinal cord and brain stem are destroyed or temporarily lose the ability to function. This loss of function in the motor neuron may be either reversible or irreversible, which is reflected clinically by the recovery of some muscle power in certain patients.

The true incidence of scoliosis in poliomyelitic patients cannot be determined precisely. Colonna and Vom Saal (11) found that of 600 patients with poliomyelitis, 150 developed scoliosis. An island-wide survey of 840 polio victims was conducted during 1986 and 1987 in Taiwan. Scoliosis with Cobb angle larger than 10 degrees was found in 144 children (17.14%) (65). Kuo and colleagues (31) stated that in a long-term follow-up of 118 adult polio victims in southern Taiwan, the most common deformity was scoliosis (67.8%), followed by limb length inequality (54.1%) and foot deformity (51.7%).

Curve Patterns in Polioscoliosis

The type and severity of the scoliotic curvature depends on the level of involvement of the spinal cord, extent and residual power of the involved trunk muscles, and pelvic obliquity (20 ,24 ,36 ,41 ,42). Thus, the curve may be in the high thoracic, thoracolumbar, or lumbar area, depending on which groups of muscles are paralyzed.

Roaf (56) classified the curve patterns into four types:

1. The thoracolumbar *C*-shaped curve is supposed to occur in patients with relatively slight paralysis and who have been allowed to get up too early. The deformity becomes more evident on standing.
2. The general “collapse” type, or combined thoracic and lumbar curve, is usually caused by extensive spinal weakness. The curves are mobile, and head suspension usually produces marked correction. Rotational deformity is moderate.
3. The primary lumbar curve is caused by a combination of pelvic obliquity resulting from limb length inequality and imbalance of the trunk muscles. Compensatory thoracic curves of less magnitude are often noted. This is the common type.
4. The primary thoracic curve is often associated with weakness of the scapular muscles, and there are secondary compensatory curves above and below.

In a series of 144 children among the 840 polio victims, as surveyed by the Cheng Hsin Rehabilitation Center, lumbar scoliosis was found in 71 patients (49.31%), followed by thoracolumbar curve in 34 patients (23.61%), double major thoracic and lumbar curve in 26 (18.06%), and thoracic curve in 13 (9.03%) patients (65). Mayer and associates (43), in a study of 118 cases of polioscoliosis, found that the most common deformity was the double major thoracic and lumbar curve (92 cases), followed by the thoracic, or thoracolumbar curve (20 cases). Long *C*-shaped curves were infrequent. From 1977 to 1988, 404 patients with polioscoliosis were operated on to correct the spinal deformity at Pingtung Christian Hospital. The curve patterns were classified as double major thoracic and lumbar, 223 cases (55.2%); thoracolumbar (C type), 95 cases (23.5%); lumbar, 68 cases (16.8%); thoracic, 17 cases (4.2%); and double thoracic, 1 case (0.3%). Pelvic obliquity was noted in 339 patients, with 207 patients having a pelvic tilt angle of more than 30 degrees.

Because of severe rotation of the spine, kyphosis in the lumbar spine and lordosis in the thoracic spine are frequently noted in these patients. Rotation of the thoracic spine also produces a prominent rib hump and significant thoracic cage deformity. For these reasons, surgical exposure of the spine and implant placement is difficult. If the spine is left untreated, the disc spaces become narrow, the vertebral bodies and the laminae become hypoplastic and osteoporotic, and adjacent spinal segments on the concave side may coalesce. Therefore, the corrective spinal surgery is more difficult in polio patients than in patients with idiopathic scoliosis.

Patient Evaluation for Scoliosis

The principles of evaluation of scoliosis secondary to polio are basically the same as those for idiopathic scoliosis or scoliosis of other etiologies. Unfortunately, polio patients often present for surgical correction of the spine when curves are severe and progressing. Because the natural history of polioscoliosis is not as clear as that of idiopathic scoliosis, it is difficult to predict outcome and eventual severity of the curve. Fortunately, most scoliosis secondary to polio appears be mild and nonprogressive.

Patients must be followed annually with a careful examination and the orthopedic conditions recorded in detail. The extent of muscle involvement, degree of motor power, and any deformity, joint contracture, or limb length inequality must be measured and recorded. The presence of pelvic obliquity and the ambulatory status of the patient (independent walking, crutch-assisted walking, or wheelchair use) are significant for determining the optimal methods and time of treatment of the joint and spine problems. The degree of limb length inequality and the presence of pelvic obliquity accentuate the deformity in the lumbar region. Pavon and Manning (53) noted that leg length inequality was present in about half of their patients with pelvic obliquity.

The severity and location of the spinal deformity in three dimensions may modify the treatment plan. The age of the patient and growth potential at the onset of scoliosis are also important factors in determining management and predicting the outcome of treatment. In young patients, in whom the spine is relatively flexible, surgical correction may be easier. In more mature patients in their late 20s to early 30s with severe curves, the bone stock may be very porotic, and the spine may be severely rotated. Disc spaces become narrow, and the facet joints fuse together; these may render the spinal segments more rigid. Serial casting, brace application, and surface electrical muscular stimulation are ineffective in controlling or correcting spinal deformity in this group of patients. Physiotherapy or muscle training also fails to reduce or even maintain curve magnitude (5 ,48 ,55). Braces can be used in young children with collapsing spines, but it is not effective in the long-term (13).

Correction of Limb Deformities

Perry and coauthors (54) considered the postpolio syndrome to be the result of overuse of muscles in adulthood. Modification of lifestyle and use of orthosis or other passive devices are important for these patients. Surgical procedures to correct and stabilize deformities are often necessary.

Irwin (28) believed that abduction contracture of one side hip was a major etiologic factor in producing an oblique pelvis and secondary scoliosis. In teenagers, hip or knee contracture may cause difficulty in ambulation. A soft tissue procedure, such as the Campbell (6) or Wilson (69) procedure, can easily release the deformities caused by such contracture. Hip dislocation may occur if pelvic tilting becomes severe. Complete release of abduction contracture of the hip (18) or pelvic osteotomy and muscle transfer (32) is helpful in stabilizing the hip joint. Lee and associates (33) classified two types of pelvic obliquity resulting from poliomyelitis, according to the level of the pelvis relative to the short leg. In the subtype D, in which moderate to severe paralytic scoliosis was noted, appropriate spinal fusion was usually necessary. Lumbar lordosis and anterior tilt of the pelvis may aggravate flexion contracture of the hip (18). In this circumstance, unless the flexion contracture is severe enough to interfere with the spinal approach, the spinal deformity should be corrected first; otherwise, further release may be necessary.

Foot deformities are corrected by various procedures, such as Achilles tendon lengthening for the equinus deformity and tendon transfer for varus or valgus deformities of the foot. Bony procedures are reserved for patients older than 12 years of age and when soft tissue procedures are not sufficient to maintain stability or provide good function. Osteotomy of the lower femur or upper tibia can be done to correct the valgus or varus deformity of the knee. Triple arthrodesis is often necessary for the correction of foot deformities. Limb length inequality can also be corrected with modern leg lengthening devices. A balanced and stable trunk is crucial for performing daily activities.

Pulmonary Function

Nickel and colleagues (46) demonstrated that respiratory paralysis due to poliomyelitis results from severe involvement of the muscles in the trunk and extremities; however, the breathing ability of these patients does not dictate their ability to tolerate surgery. It merely indicates their relative need for mechanical respiratory assistance during and immediately after surgery.

Werner and coauthors (68) found that vital capacity was significantly restricted in some patients with extensive respiratory muscle paralysis. Mackley and associates (39) studied pulmonary function in both paralytic and nonparalytic groups and found that pulmonary function was significantly impaired if the Cobb angle was greater than 66 degrees in the thoracic spine. Preliminary cast correction of the curvature reduced vital capacity, whereas halo traction had no influence on it. There was also no significant improvement of pulmonary function after spinal fusion. Swank and associates (63) reported a series of 20 severe scoliosis patients (curves ranging from 90 to 200 degrees) who had overt cor pulmonale. The results of preoperative halo traction showed that, in polioscoliosis patients, there was an average increase of vital capacity and PaO_2, whereas $PaCO_2$ was reduced. Bradford (4) recommended preliminary halo traction to facilitate the evaluation of the reversibility of pulmonary dysfunction and to improve the patient's general cardiopulmonary status before surgery.

In our experience of 38 adult patients with severe polioscoliosis, 35 were found to have impaired pulmonary function. Single-staged or multiple-staged surgery did not result in exacerbation of the patients' cardiopulmonary status. However, the patients were taught to perform pulmonary exercise long before surgery. On admission, patients should be taught to use the respirator; this will reduce the morbidity if overt respiratory insufficiency occurs immediately after surgery.

Modern anesthetic techniques and improved monitoring devices, such as right heart catheterization, continuous arterial monitoring, and serial blood gas studies, enable the detection of subtle changes in cardiopulmonary status and allow early correction. Tracheotomy is rarely needed either before or after surgery.

Indications for Surgical Correction

Curve Progression

Curve progression is the main reason patients seek treatment. In progressive thoracic curvatures, the deformity can be severe. The thoracic cage becomes prominent, with secondary pulmonary function impairment. In patients with lumbar scoliosis, pelvic tilting can be relentless, causing severe trunk deviation and unilateral ischial sitting. The goal of treatment of spinal deformity is to obtain a vertical torso centered over a level pelvis. This permits stable sitting on level buttocks and helps prevent ischial pressure callosities and paralytic dislocation of the hip on the high side of the pelvis. The patient does not have to use the arms for support and is able to use both hands freely to perform other activities. When the spinal curvature is severe or is collapsing, the lower costal margin sometimes impinges against the upper margin of the iliac crest, causing pain. Respiratory capacity and ambulation are also hampered. In this situation, a straight and stable spine can relieve symptoms and facilitate walking. Back pain may be a major problem in adult polioscoliosis patients.

Curve Magnitude

Surgery should be considered only when the Cobb angle is larger than 40 degrees or when the spine is collapsing. The indications for posterior instrumentation only are thoracic and long *C*-shaped curves with minimal pelvic obliquity or thoracolumbar or lumbar curves of less than 60 degrees. If the curvature is larger than 60 degrees, whether flexible or rigid, or pelvic obliquity is severe, a two-staged anterior and posterior surgery should be recommended because this results in better correction of the deformity and less pseudarthrosis (8 ,34 ,43). This combined approach may be performed in single or separate occasions.

Procedures for Surgical Correction of Scoliosis

Application of Halo Traction

The halo was developed by Nickel and colleagues (47). DeWald and Ray (12) and O'Brien and associates in Hong Kong (52) popularized the application of halo-pelvis traction in ambulatory patients, such as polioscoliosis and the spinal deformity caused by spinal tuberculosis. The apparatus is mounted on patients with severe scoliotic curves or kyphoscoliotic deformity before definitive surgery. Clark and coauthors (10) found that the maximal effect was achieved about 1 week after initiation and that a 2-week period was usually sufficient to release the viscoelastic properties of muscular and ligamentous tension. The advantage of the apparatus is that it provides effective, controlled distraction of the spine.

Because of possible neurologic and pelvic pin complications (16 ,30 ,35 ,66) and inconvenience of ambulation after femoral pin insertion, halo gravity traction is now used when traction is deemed necessary (Fig. 1). Traction can be exerted anytime to the halo, with the patient either lying in bed, sitting on the bed or on a wheelchair, or even walking with the imposed weight attached to the wheelchair. Preliminary traction is used when the scoliotic spine in a child is stiff and severe or the Cobb angle is greater than 100 degrees (57 ,58). However, the use of preliminary halo traction has been challenged. Flierl and Carstens (19) claimed that halo gravity traction only accounted for 16.9% improvement in six patients with severe polioscoliosis. This method can also be used between staged surgery to reduce the severe curvature, when no implant is added after the completion of anterior spinal release. This is our preferred method. If an anterior implant is placed, halo traction becomes superfluous. The maximal load should be about one third of the body weight. The load should be determined by the patient's tolerance. Daily evaluation of the pin tightness and pin care are mandatory. Repeated neurologic evaluations are also mandatory.

Posterior Instrumentation of the Spine

Bunch (5) considered orthotics to be effective in preventing curve progression in young children with paralytic scoliosis. The number of patients under study was small, however, and the follow-up period was only 2 years. Present concepts exclude the use of orthosis in polio scoliosis (13).

The introduction of Harrington instrumentation in the early 1960s revolutionized the treatment of scoliosis (25 ,26 ,27). The experience of Rancho Los Amigos Hospital using halo-femoral traction and posterior Harrington instrumentation showed that the best result for paralytic scoliosis was a 57% correction; the pseudarthrosis rate was 27% (3). Gui and colleagues (23), using Harrington instrumentation, showed that the curve correction rate was 37% for thoracic scoliosis, 40% for lumbar scoliosis, and 28% for double scoliosis. Loss of correction is generally a result of hardware loosening or bending before fusion. After solid fusion, it does not progress.

The segmental spinal instrumentation system devised by Luque (38) is a powerful implant for the correction and stabilization of spinal deformities. Basically, it consists of two smooth, round, L-shaped rods on both sides of the spinous processes. Correction of scoliosis is accomplished by twisting stainless steel sublaminar wires to the precontoured rods at each level of lamina. By sequential twisting of the wires, the rods and laminae are approximated, and the deformed segments of the spine are gradually straightened. Bone chips are placed in the excised facet joints and the exposed bony parts of the spine (Fig. 2). This instrumentation is strong enough to resist torsional and compressive stresses (9 ,29 ,44 ,67). Luque instrumentation is suitable for the correction of small-angle curvatures, but the instrumented segments should be long enough to avoid junctional kyphosis. Instrumentation should not end at the apex of a curve in any plane.

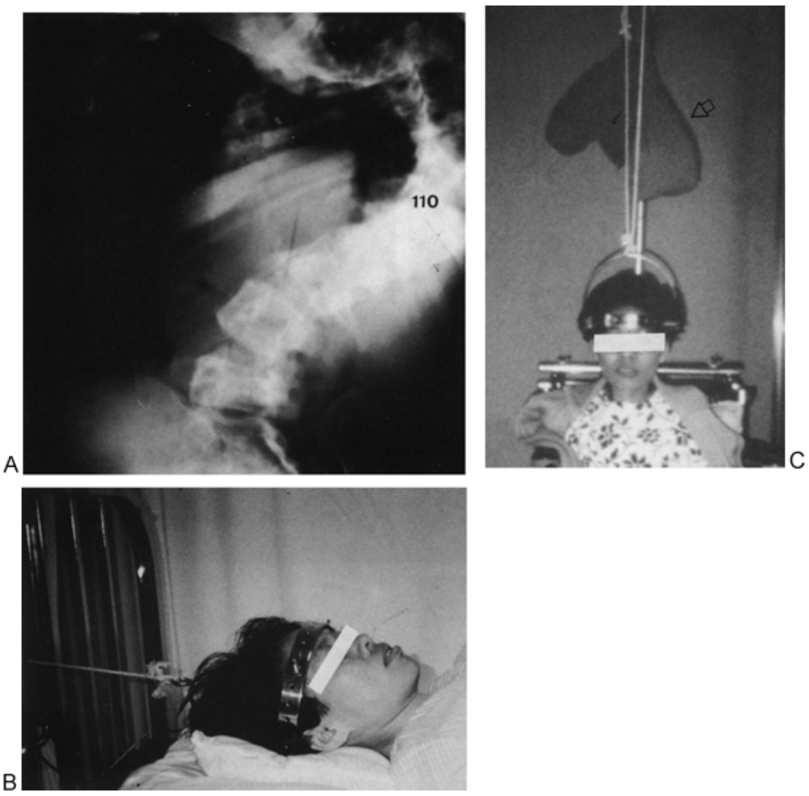

FIGURE 1. A 30-year-old woman with rigid kyphoscoliosis. She underwent two-staged surgery. A halo was also mounted between the operations. **A:** Radiograph reveals 110-degree thoracic scoliosis and 99-degree kyphosis. **B:** The patient under traction while lying in bed. **C:** The patient under halo gravity traction while sitting in a wheelchair. The traction apparatus was connected high on the wheelchair; the *arrow* denotes the sandbags. In this manner, the patient can achieve continuous traction in different positions during the entire day.

Cardoso (7), Sullivan and Conner (62), and Taddonio (64) reported that the use of Luque rods for neuromuscular scoliosis resulted in a balanced spine because of better correction in the coronal and sagittal planes. In nearly all patients operated on, external support became unnecessary; pulmonary function also improved. If fusion and correction to the pelvis are necessary, lower Harrington hooks can be placed at the sacral rim (Fig. 3). The Galveston technique, by contouring the lower end of the rods to enter iliac wings, is favorable (1 ,21).

Arthrodesis of the spine in a young child results in growth retardation of the spine (22 ,45). Luque and Cardoso (37) reported that segmental spinal fixation of the involved spine without bone grafting could be a good alternative in a growing child. The advantages include good control of the curve, expected continuous spinal growth, and elimination of the need for bracing. Eberle (17) reported a series of 16 patients with severe paralytic polioscoliosis who were between 5 and 12 years old. In 15 of the 16 patients, the segmental spinal implants failed to control the deformity. In these patients, however, the Cobb angle was the same before and after correction. Spontaneous fusion of the instrumented portion of the spine was also noted in some cases. Implant complications were noted, including rod breakage, longitudinal shifting, and rotation of the short limb of the rod out of the pelvis, which perforated the skin and resulted in infection.

In older children with paralytic scoliosis due to poliomyelitis, Harrington rods with segmental wiring or the combination of Harrington and Luque rods is preferable to Harrington rods alone (Fig. 4). A Harrington square-ended rod is placed on the concave side of the curve and inserted into the squared hole of the hooks, whereas a Luque rod is placed on the convex side.

Both rods can be bent according to the magnitude and contour of the deformity. With proper distraction of the Harrington rod and segmental wiring of both rods, this combined method is useful for the correction of cases with large Cobb angles. Both these implants should be available as a correcting device in countries where resources are still inadequate. If pelvic obliquity is to be corrected simultaneously, fixation and fusion to the pelvic region can be helpful. In the severe and rigid curves, anterior release and instrumentation are usually necessary. Many new implants have been developed, such as Cotrel-Dubousset instrumentation (Fig. 5), Isola, TSRH, or Moss-Miami. Using these modern implants, the deformity can be corrected without the need for external support.

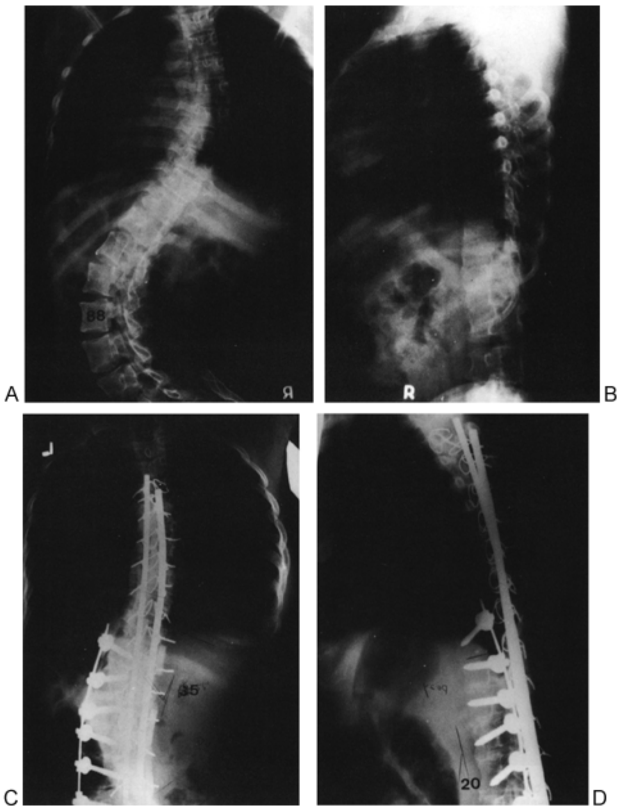

FIGURE 2. This 18-year-old girl needed crutches and pelvic shift for walking. Anterior Zielke VDS and subsequent Luque rods were implanted. **A, B:** Radiographs reveal 88-degree lumbar scoliosis and 5-degree lordosis. **C, D:** Radiographs show the spinal contour 2 years after surgery.

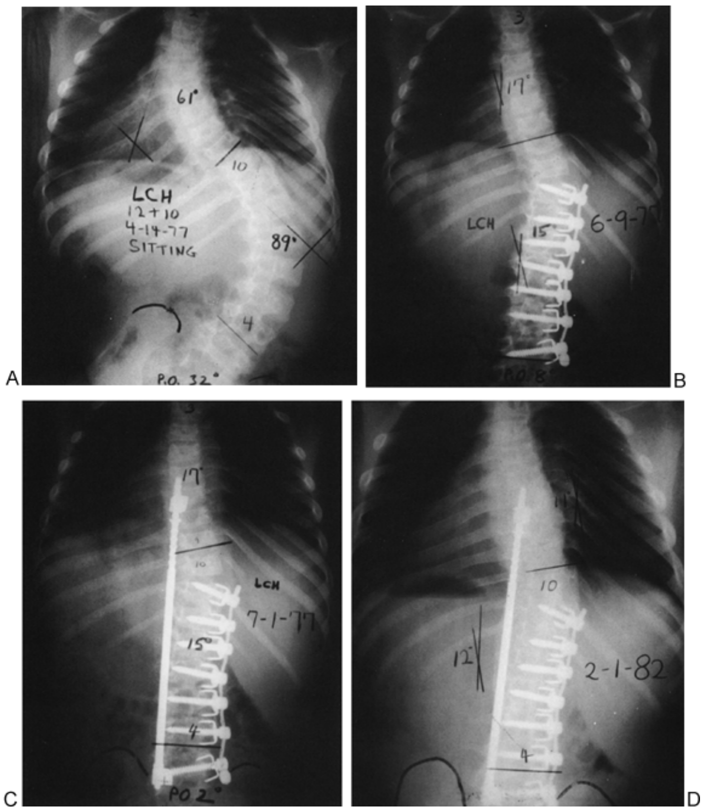

FIGURE 3. A boy 12 years 10 months with polioscoliosis. He walked with crutches. **A:** Radiograph reveals scoliosis with a 61-degree Cobb angle from T2 to T9 and an 89-degree Cobb angle from T10 to L4. Pelvic obliquity is 32 degrees. **B:** After Dwyer instrumentation, the scoliosis is reduced to 15 degrees at the lower curvature. Pelvic obliquity is now less than 8 degrees. **C, D:** The spine after Harrington instrumentation and at 56 months' follow-up. The coronal balance was well corrected and maintained. Note that the lower Harrington hook was anchored at the sacral rim.

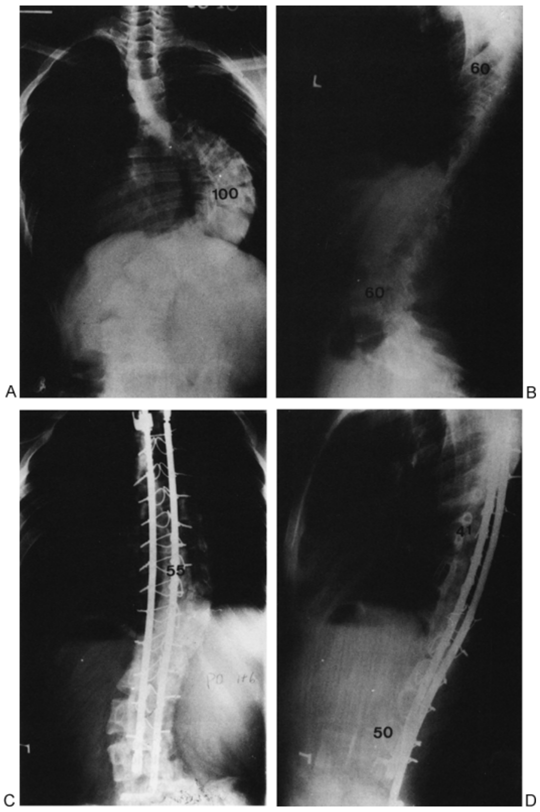

FIGURE 4. This 20-year-old woman underwent anterior release and rib grafting. Two weeks later, combined posterior Harrington-Luque instrumentation and fusion were performed. **A, B:** Lower thoracic scoliosis with a Cobb angle of 100 degrees and thoracic kyphosis of 60 degrees. **C, D:** Spinal contour 18 months after correction. Both coronal and sagittal planes were much improved.

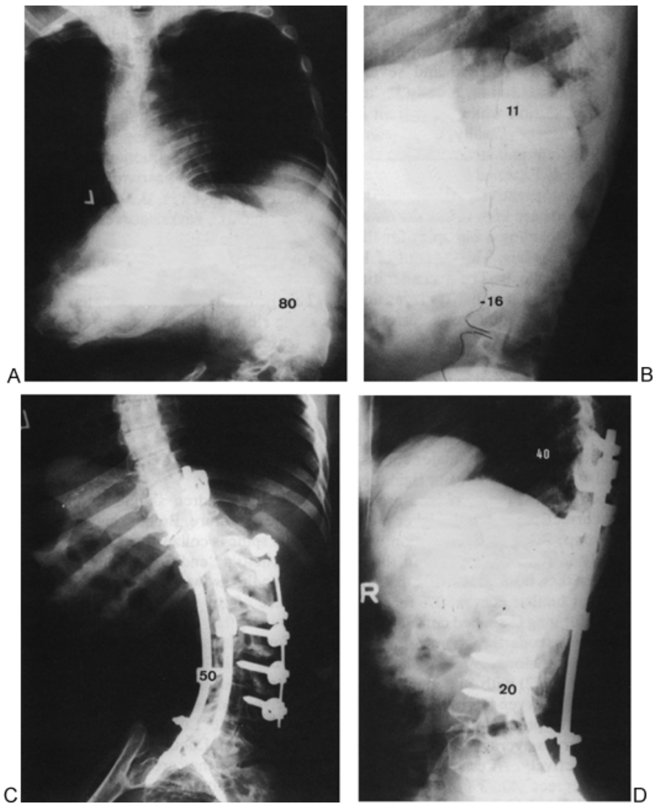

FIGURE 5. A 25-year-old woman with lumbar kyphoscoliosis. She underwent two-stage surgery: anterior Zielke VDS and posterior Cotrel-Dubousset instrumentation from T9 to S1. She had no external support after the second instrumentation. **A, B:** Lumbar scoliosis was 80 degrees, and lordosis was 16 degrees. **C, D:** The spine 3 years after surgery.

Anterior Surgery on the Spine

Dwyer (14 ,15) introduced a cable and screw system for correction and stabilization of the spine. O'Brien and colleagues (49 ,50 ,51) adopted it to correct scoliosis due to poliomyelitis. They recommended combined, staged anterior and posterior correction and fusion using Dwyer-Harrington instrumentation. Preliminary halo-femoral traction was preferred for cases with pelvic obliquity or rigid and severe curves. In a study of 110 patients from Hong Kong, Leong and associates (34) demonstrated that combined anterior Dwyer instrumentation and fusion and posterior Harrington instrumentation and fusion resulted in excellent correction. In the lumbar region, the correction rate was 79% for moderate curves and 64% for severe, major curves. Pelvic obliquity was also corrected. For rigid thoracic and long *C*-shaped curves, the combined procedure also gave better correction, but with higher morbidity in the former group. Preoperative traction was found to be useful only in rigid curves and in those with a Cobb angle larger than 80 degrees. The pseudarthrosis rate was 12.5% for long *C*-shaped curves, 7% for lumbar curves, and 0% for thoracic curves, This was in contrast to a 25% pseudarthrosis rate for patients having posterior fusion alone.

The experience in Taiwan (43) with 54 patients who had traction and combined Dwyer-Harrington procedures was also reported. The preoperative Cobb angle for the upper and lower curves averaged 79 degrees and 115 degrees, respectively. After surgery, these were reduced to 52 degrees (40.73%) in the upper curve and 60 degrees (56.2%) in the lower curve. In 20 patients operated on using only Harrington instrumentation and fusion, the correction was 43.2% in the upper curve and 44% in the lower curve. The correction of pelvic obliquity was 43.6% after the posterior fusion only procedure and 68.4% after the combined procedure. In a further study of 290 patients with double major thoracolumbar and lumbar polioscoliosis, pelvic obliquity was reduced from 35.5 degrees to 14.2 degrees (59.9%) (59).

Zielke and coauthors (70) reported the experience of anterior ventrale derotations-spondylodese (VDS) instrumentation to correct scoliosis in the thoracolumbar and lumbar regions. More recently, the more rigid implants, such as Webb-Morley, Moss-Miami, and so forth, have replaced the previously mentioned systems.

If anterior instrumentation is not used after anterior release, or if the patient has a double major curve, halo gravity traction can be applied during the waiting period for posterior surgery. In adult scoliosis, the patients usually present with a very rigid and severely rotated large curve, and the spine becomes osteoporotic and hypoplastic, the disc spaces are narrow, and the bony parts become adhered. Therefore, two- or three-staged surgery is mandatory. This generally consists of initial anterior release and fusion using rib or pelvic bone grafts, followed by posterior release, long instrumentation, and bony fusion. In some patients, the posterior bony elements are fused, necessitating release of the fused bony segments as the first procedure. Halo gravity traction can be applied between the periods of a staged operation.

Treatment Recommendations

Young children should be carefully evaluated for spinal curvature. Bracing may be necessary, especially if the spine is collapsing. If curve progression is noted, Marchetti's “end-fusion” technique may be helpful in saving the growth potential of the vertebra (40). The chance of rod breakage in this technique is so high, however, that repeated surgery is inevitable.

For adolescents, when the spine is still supple and the curve is less than 60 degrees, there are several treatment alternatives. If the deformity is in the thoracic spine or is the collapsing long C type, we recommend double Luque rods or the Harrington-Luque combination. Both rods must be bent to conform to the contour of the spine; in the sagittal plane, thoracic kyphosis and lumbar lordosis are reconstituted, and the coronal plane deformity is also corrected. This greatly facilitates the patient's ambulation. The instrumentation and fusion segments should be long enough to avoid junctional kyphosis.

Harrington-Luque combination has both mechanical and clinical advantages. It allows both axial distraction and transverse correction. The rods can be contoured according to the shape of the spinal curvature. Using a curved pusher to approximate the rod to laminae, allowing close tightening of the wire loops during manual correction can further minimize the curvature. The final step is the application of wires to link the two rods at several levels to stabilize the whole construct. The square-ended Harrington rod is superior for the segmental correction of scoliosis because it prevents rotation of the rod during wiring. In most circumstances, external support after surgery is not necessary.

In countries in which economic conditions allow, Cotrel-Dubousset instrumentation or the newer implants, such as Isola, TSRH, or Moss-Miami, are preferred (Fig. 6). Better curve correction and increased stability have been noted. These implants have been widely adopted in the surgery of scoliosis. In choosing these implants, the size of the implant parts should be considered because many of these patients are very thin.

After the hooks and the pedicle screws are placed or inserted in the proper segments of the spine, the rod is carefully mounted over the heads of the hooks and screws. The parts are distracted or compressed along the rods, as needed, to minimize the curve and obtain the normal contour of the spine. Manual rotation of the rods is not an important procedure in the polio cases, however, because the aim of surgery is to achieve truncal stability and balance. At the end of instrumentation, the lumbar spine should be corrected to be in the form of lordosis to avoid the flat-back syndrome. This is important, especially in the lumbar scoliosis with kyphotic deformity.

Bone grafting technique must be carried out meticulously; the ligaments, tendons, and capsules must be removed completely. The facets must be excised and exposed completely. Bone chips are placed in the facet regions and are extended laterally to the transverse processes in the lumbar spine and the costotransverse processes in the thoracic spine.

For rigid curves and those larger than 60 degrees, or sometimes 80 degrees, or in the presence of obvious pelvic tilting, two-stage surgery is suggested. These patients usually have large lumbar curves. The Zielke VDS system or the newer anterior implant can be used anteriorly, and bone chips are placed in the released disc spaces as the first stage in the lumbar or thoracolumbar region. This results in better balance and stability of the trunk and correction of pelvic obliquity. The lower screws placed down to L5 are sufficient. In these cases, preliminary halo traction is not necessary. If anterior release is performed without instrumentation, halo traction is preferably used. The time between the two operations is about 10 days to 3 weeks, depending on the curve magnitude and the effect of traction. At the second stage, posterior instrumentation and spinal fusion are performed. This combined approach is advantageous in that the spinal construct can be more rigid, bony fusion rates are higher, and correction is better. If the deformity is in the thoracic region, anterior release and rib grafting, followed by posterior Luque or Harrington-Luque instrumentation, are sufficient.

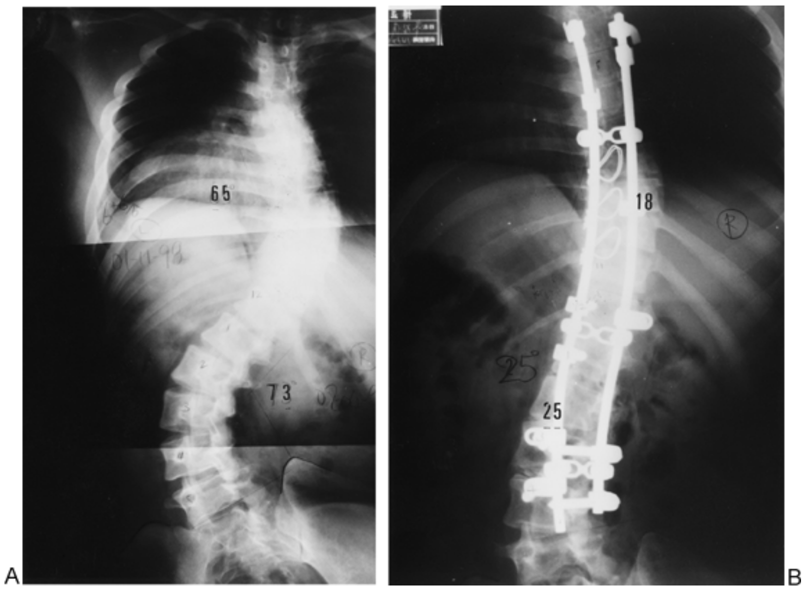

FIGURE 6. A 16½-year-old boy with double thoracic and lumbar scoliosis. He underwent two-staged surgery: anterior release of the lumbar spine from T12 to L4, followed by posterior Isola instrumentation extending from T4 to L4. **A:** The spine before surgery. The Cobb angle at the thoracic spine was 65 degrees and at the lumbar spine, 73 degrees. **B:** After Isola instrumentation, the Cobb angle in the thoracic spine was reduced to 18 degree; in the lumbar spine, it became 25 degrees.

Many polio victims present as adults with curve progression despite previous attempts at fusion or with a synostosis of the posterior bony elements. In these situations, posterior osteotomies should be considered. This is followed by traction, and possibly, further anterior release, if the disc spaces are still wide. The final stage is posterior instrumentation and fusion.

In selecting the fusion level, we should consider the conditions of the upper extremities. If the upper extremities are flaccid, fusion of both the thoracic and lumbar spine is necessary. This reflects the weakness of the upper trunk musculature. If the child had lumbar scoliosis without the presence of flaccid upper extremities, fusion of the lumbar curve down to fifth lumbar segment is enough. However, if both the thoracic and lumbar spine are deformed, fusion level depends on the magnitude of the thoracic curve. When the Cobb angle of the thoracic spine is greater than 40 degrees, both segments should be fused; otherwise, fusion of only the lumbar segment is sufficient. In any case, it is desirable to achieve lumbar lordosis by using modern instrumentation, especially in adults.

Fusion down to sacrum should be carefully considered. If a patient needs pelvic swing to facilitate ambulation, fixation at the lumbosacral region will greatly impair ambulatory activity. Thus, if pelvic tilting is not severe, lumbosacral fusion should be avoided, in cases in which fusion to sacrum is desirable, instrumentation by the Luque-Galveston technique or by double sets of sacral screws offers better stability. Fusion to the sacrum is often necessary to provide truncal balance and to correct pelvic obliquity.

External support is not used in most cases. During hospitalization, patients are encouraged to exercise to maintain their strength, prevent osteoporosis, and avoid prolonged convalescence.

Long-segment fusion for polioscoliosis is usually the rule. This necessitates large amounts of bone chips. In idiopathic scoliosis, autogenous bone taken from one ilium or both ilia is enough. But many polio patients present with a hypoplastic pelvis, making the use of bone grafts from this area impractical. Allograft is often used alone or mixed with autograft. Because anterior fusion requires less bone graft, the resected rib, the iliac bone, or both are usually sufficient. Bony fusion is dependent on providing a large amount of exposed bony areas, performing meticulous facet joint excision, selecting suitable implants, and avoiding excessive loading.

Postoperative Care

Immediately after surgery, the neurologic status of the lower limbs must be checked. Adequate fluid replacement should be administered. Patients should be carefully monitored for respiratory status and cardiac function. Patients with obvious respiratory insufficiency should be monitored in the intensive care unit and given respiratory assistance as needed. Blood gas studies and chest radiographs must be obtained as a treatment guide. Abdominal distention can be annoying, but it is usually not too severe. Menthol packing of the abdominal wall or a rectal suppository to stimulate bowel peristalsis is usually adequate. Gastric tube decompression may be necessary if the abdominal distention is significant. Sphincter training is started soon after the surgery. Patients are allowed to sit 3 or 4 days after posterior instrumentation. A well-molded plastic jacket (TLSO), if needed, should be worn before the patient is allowed to walk.

Patient Satisfaction

Some patients may have higher than reasonable expectations of the results of surgery. A thorough examination of the patient's musculoskeletal function and an understanding of his or her expectations are mandatory. Good communication between the surgeon, patient, and family must be obtained before surgery.

Shen and Cheung (60) studied patient satisfaction after combined anterior and posterior surgery in 148 polio cases. After an average of 4.7 years of follow-up, 117 patients (79.6%) were satisfied with the operative results. 53% of the patients still complained of low back pain after sitting or standing for long periods, but only three patients needed analgesics for relief; the remainder required only rest. Nearly half of the patients (49.7%) could walk more steadily and for a longer distance, but 17% of patients felt that they had more difficulty walking after spinal fusion. Daily activities were improved in 63.3% of the patients; however, 17.7% complained that after fusion their spines became stiffer, hampering their daily functions. The most gratifying result may be that patients have better sitting balance. Eighty-eight patients had to sit on one hip before the operation. At final follow-up study, 48% of the patients had achieved balanced ischial sitting, which greatly facilitates free motion of the upper extremities.

A 15-year or longer follow-up of 88 patients among this same group of patients was carried out (61). The most rewarding result was that after surgery, patients could sit on a stool without using their hands or any other support. This was noted in 54 (61.4%) cases, whereas only 12.9% of the patients could do this before surgery. Relief of back pain was also noted. At follow-up, only 19.3% complained of pain, whereas before surgery, 64% had this complaint. Interestingly, whether patients had fusion down to L5 or to the sacrum, there was no difference in terms of ambulation, daily activities, sitting balance, or back pain.

The management of spinal deformities is difficult in poliomyelitis and requires a thorough understanding of the condition, its natural history, and the alternatives of management. Realistic expectation and meticulous attention to surgical detail can lead to gratifying results.

Acknowledgments

We appreciate the financial assistance from the Taiwan Spine Research Foundation and the National Science Council, ROC. Thanks are also extended to Dr. S. L. Weinstein for his kind suggestions.

Other Neuromuscular Deformities

Michael J. Barnes

M. J. Barnes: Starship Children's Hospital, Auckland, New Zealand

This chapter discusses a miscellaneous group of neuromuscular disorders that share a propensity to produce spinal deformity. The etiologies are diverse, and it is imperative to diagnose the underlying conditions accurately and to make attempts to predict the natural course not only of the condition itself but also of any associated spinal deformities. This allows prediction of the likely effects of the deformity on the patient, which helps to guide treatment recommendations. Even so, the disorders discussed in this chapter are generally uncommon or rare, and guidelines from the literature consequently are often either lacking or taken from a historical era. Frequently, therefore, the surgeon charged with treating these patients needs to revert to the principles outlined in Chapter 46 . Many of these conditions are associated with a severe and rigid spinal deformity at a relatively early stage in spinal maturation. This dictates that the surgeon possess a thorough understanding of normal growth and maturation of the spine (see Chap. 1 , Appendix B) and the effect of evolving deformity on pulmonary parameters (see Chap. 17) and that the surgeon apply this knowledge in recommending observation, orthotic treatment, or surgical treatment.

Rett Syndrome

Rett syndrome is a progressive neurologic disorder affecting females almost exclusively (11). It is not excessively rare, with a prevalence between 0.1 and 0.15 per 1000 population (27). Rett syndrome now appears to be a developmental rather than a degenerative disorder (57). It is not, in most cases, an inherited condition, even though the overwhelming female preponderance suggests a genetic origin (1 ,64 ,87). Patients with Rett syndrome develop a characteristic cluster of clinical manifestations, including early psychomotor regression with autistic features, loss of purposeful use of the hands that is replaced by stereotypical activity, ataxia and apraxia of gait, and acquired microcephaly (27).

Rett syndrome is remarkable for a period of apparently normal initial development, although affected girls may be somewhat hypotonic from birth (46). The onset of clinical manifestations is between 6 months and 3 years of age, and affected patients progress at variable rates through four recognizable neurobiologic stages (84). Stage I (early-onset stagnation) occurs between 6 and 18 months of age. Stage II (rapid developmental regression) occurs between 1 and 3 years of age. Stereotypical hand movements develop in this stage, language is lost, and autistic manifestations appear. Stage III (pseudostationary period) follows, persists for years, and is marked by resolution of some of the autistic features but is followed inevitably by stage IV (late motor deterioration). Most patients develop seizures. Only one fourth to one third ever acquire independent ambulation; this is generally lost in stage IV, at which time muscle wasting, spasticity, and contractures become more marked (28).

The syndrome was first described by Rett in 1966 and came to clinical prominence after Hagberg's description in 1980 (26). Even so, it is only recently that most patients have been correctly diagnosed and surviving patients followed into their fourth of fifth decade. The diagnosis of Rett syndrome received attention in the orthopaedic literature in the late 1980s when reports appeared documenting the musculoskeletal manifestations. Foremost among these, and most likely to necessitate intervention, is spinal deformity, although lower limb contractures, acquired hip instability, and foot deformities (equinovarus or planovalgus) also occur (24 ,29 ,36 ,48 ,70 ,71). Because of the relatively recent recognition of this disorder, natural history data are still emerging. It is becoming apparent that most patients followed through stage IV develop a spinal deformity (7 ,14 ,35 ,36 ,39 ,47 ,48). Age of onset is variable and correlates more closely with neurobiologic stage than chronologic age (47). The incidence of spinal deformity, therefore, increases with age and is well established in many patients by 8 or 9 years of age. Patients who are hypotonic at birth may develop significant deformity during the infantile period (47). Most curves progress (39 ,47), and progression accelerates during stage III and especially stage IV. A moderate curve may quickly become severe at this time (7 ,33 ,47 ,48).

In general, these patients develop long *C*-shaped curves, and pelvic obliquity is frequently seen in association with larger curves. Single thoracic and double curve patterns are also seen (7 ,33 ,47 ,48). Often, the curve has a major kyphotic component, although a thoracic hypokyphosis is sometimes observed, particularly in association with smaller curves (48). Also apparent radiographically is the markedly diminished spine bone mineral density (34).

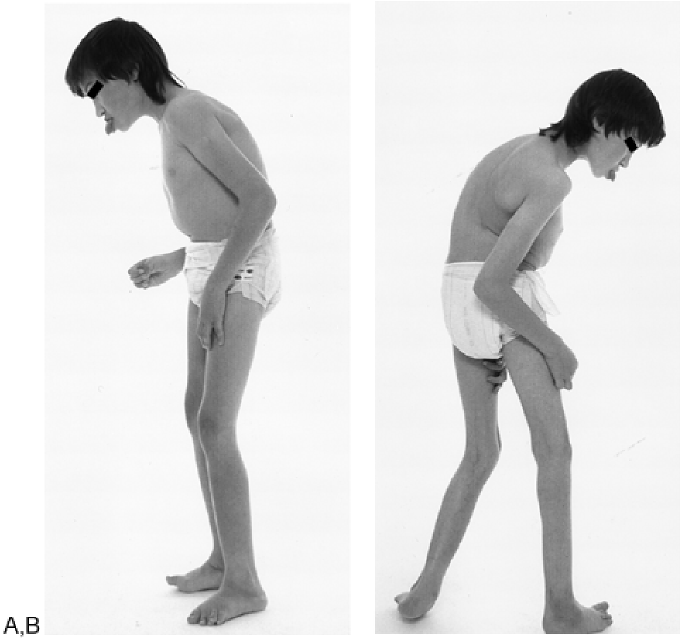

FIGURE 1. A, B: Stage III Rett syndrome in a 9-year-old demonstrating truncal imbalance disproportionate to the structural scoliosis.

Although curve progression accelerates in stage IV, moderate to severe curves are observed in ambulatory patients. In these patients, a severe truncal imbalance may be noted out of proportion to the structural component of the curve (Fig. 1).

There is no definite evidence that bracing alters the natural progression of spinal deformity in Rett syndrome or prevents a severe deformity ultimately developing (33 ,39 ,40 ,41). It is possible, however, that the use of a TLSO will delay curve progression and allow trunk lengthening through spinal growth before definitive spinal fusion. The best indication for the use of an orthosis, and the situation in which it is most likely to be accepted, is as a temporizing measure when it is found that standing or seated balance is improved with the brace in situ.

As with other, more common neuromuscular conditions (see Chap. 46), surgical treatment of spinal deformity now appears to be an accepted modality in Rett syndrome and holds benefits for both patients and their families. Unfortunately, there is a paucity of published data to allow firm conclusions regarding timing of surgery, posterior only versus anterior and posterior surgery, and fusion levels, particularly with regard to the necessity to fuse to the sacrum. For many curves in the 60- to 70-degree range, segmental posterior instrumentation can effect a correction of about 50 degrees (36). Only one author (33) has reported anterior fusion in addition to posterior instrumentation and fusion, suggesting that this will only be necessary for severe, rigid, or neglected curves or in older patients. Because these patients display what could be termed a cerebral imbalance, and ultimately become nonambulators, crankshaft is not really an issue (Fig. 2). Several authors report an improvement in gait after spinal surgery in patients with Rett syndrome (33 ,39). Loss of ambulatory function as a result of spinal fusion has not been described.

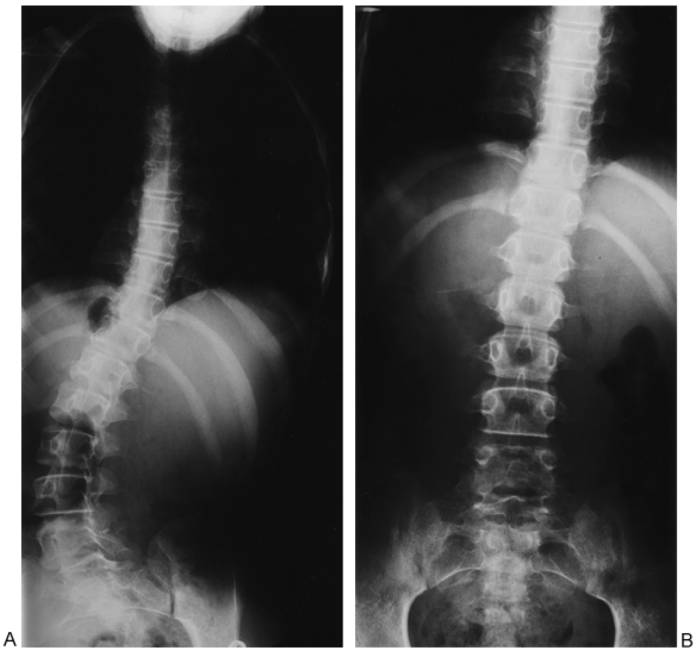

FIGURE 2. Rett syndrome in a 12-year-old ambulator. **A:** Standing radiographs demonstrate a moderate but severely unbalanced curve. **B:** Supine radiographs demonstrate the curve to be almost completely postural.

As in other neuromuscular conditions, the timing of surgery is a product of curve magnitude, stiffness, and spinal growth. As with bracing, the primary aim of surgery is to achieve truncal balance, and surgical recommendations are not dictated by Cobb angle alone. For example, a severely unbalanced 40-degree curve in an ambulatory patient may merit spinal fusion, whereas in other patients, a partially compensated and flexible curve may safely be able to progress to 60 or 70 degrees before surgery. It seems that in Rett syndrome, surgery can usually be delayed past 10 years of age and that posterior procedures alone often suffice in ambulatory patients. Because of severe truncal ataxia and imbalance, frequently associated sagittal plane deformity, and the fact that these patients ultimately become spastic, fusion for thoracolumbar or lumbar curves generally commences at T2 and extends to the sacrum (Fig. 3). Patients are certainly encountered in whom, by virtue of spinal flexibility or a fractional compensatory lower lumbar curve, it is possible to end the fusion caudally at L4 or L5 and achieve static spinal balance. However, the risks for decompensation due to truncal ataxia or late pelvic obliquity due to evolution of deformity in unfused lower lumbar segments make it prudent to fuse to the sacrum in most cases. When it is anticipated that posterior segmental instrumentation does not effect sufficient correction to restore balance, it should be preceded by anterior discectomy and, if necessary, instrumentation. In the absence of data to the contrary, perioperative management should mirror that of scoliosis surgery in cerebral palsy (see Chap. 45).

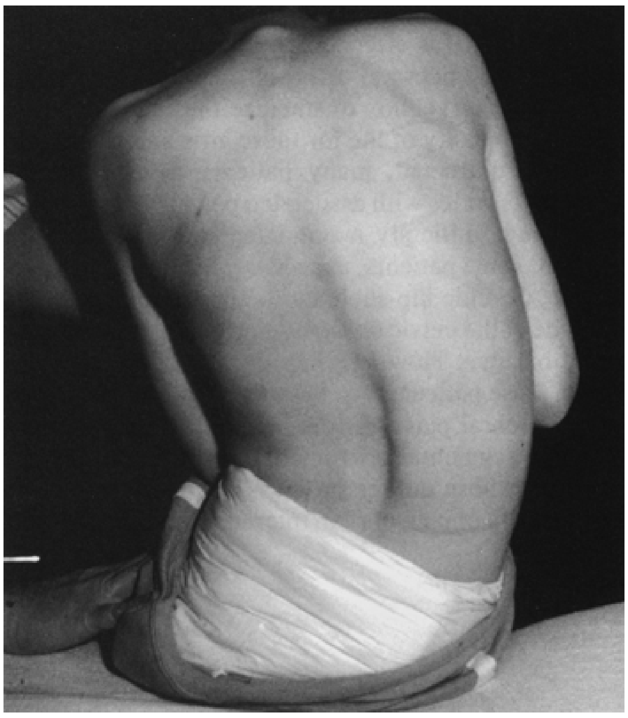

FIGURE 3. Stage IV Rett syndrome in an 18-year-old with a long thoracolumbar, “paralytic” curve pattern and associated pelvic obliquity.

Arthrogryposis

Arthrogryposis translated literally means “curved joint” and is a purely descriptive term. It was expanded to “arthrogryposis multiplex congenita” by Stern in 1923 (80) to denote a syndrome present at birth involving multiple joints. Currently, arthrogryposis is defined as a congenital, generally nonprogressive limitation of movement of two or more joints in different body regions (79). The estimated incidence is 1 per 3000 live births (79).

Animal studies support the concept that joint contractures are a direct result of fetal akinesia (55 ,82). This failure of normal in utero joint movement may be due to intrinsic causes, namely abnormal formation or function of striated muscle (myopathic origin), a neurologic process (neuropathic origin), or an abnormality of connective tissue (fibropathic origin) (6). Less commonly, it is due to extrinsic causes, including oligohydramnios, structural uterine abnormalities, or various maternal illnesses (76 ,79).

Under the descriptive umbrella of multiple congenital joint contractures, as many as 150 clinical or genetic entities have been delineated. Many specific types of arthrogryposis have now been mapped to loci on the human chromosomes (31 ,32). In any one child, it is clearly important to make a precise diagnosis if possible. The sparse orthopaedic and spinal deformity arthrogryposis literature largely predates these diagnostic distinctions. This literature has tended to focus on the common clinical and treatment-related features, specifically the unyielding soft tissues and osteopenia that are the hallmarks of this condition. Historically, the causative distinctions have been considered more important by other specialists, such as clinical geneticists and neurologists.

The term *amyoplasia* (77), itself descriptive and nonetiologic, has been used to denote the classic, extensive arthrogrypotic syndrome seen in orthopaedic services. It is predominantly these patients who form the basis of published spinal deformity series. This subgroup occurs sporadically with an incidence of 1 per 10,000 live births. Other distinct but orthopaedically recognizable syndromes include the various distal arthrogryposes, contractural arachnodactyly or Beals syndrome, the multiple pterygium syndromes, the popliteal pterygium syndromes, and the Freeman-Sheldon syndromes. According to Sarwark and colleagues (74), it is only occasionally difficult to distinguish patients with amyoplasia from those with other specific arthrogrypotic syndromes.

Patients with amyoplasia most typically display symmetric positioning of the limbs with severe equinovarus feet, deformities of all major joints, absent muscle tissue with fibrotic or fatty replacement, midfacial hemangioma, and normal intelligence. The absence of normal functioning muscle mass creates smooth, fusiform limbs (Fig. 4). The skin is glossy and atrophic, creaseless, and often dimpled over bony prominences. Most patients have all four limbs involved. Hip contractures (50%) and dislocation of one or both hips (33%) are common (79).

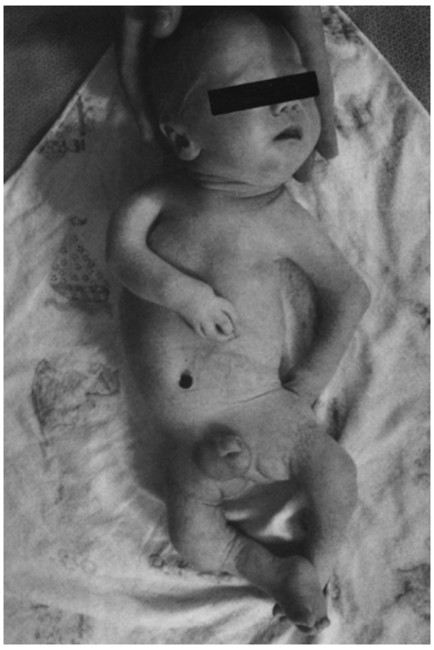

FIGURE 4. Arthrogryposis in a 4-week-old neonate. Classic features of amyoplasia congenita are present and a scoliosis already evident. (Courtesy of the Alfred I. du Pont Institute, Wilmington, DE.)

Ten percent of patients with amyoplasia are said to have abdominal structural anomalies, which may be a major factor in the genesis of early-onset scoliosis. The reported incidence of scoliosis in arthrogryposis multiplex congenita is 10% to 30% (30 ,73 ,79). The variance is accounted for by etiologic heterogeneity and patient selection under study. In amyoplasia, it is about 35% (73).

It is generally considered that patients with amyoplasia and scoliosis do not have congenital vertebral anomalies (73). In a radiographic study of 14 patients with arthrogryposis multiplex congenita and scoliosis, Poznanski and associates (66) found no congenitally anomalous vertebrae. In clinically based studies of spinal deformity in arthrogryposis multiplex congenita, the findings are similar. Herron and coauthors (38) found no such anomalies in 16 patients. Sarwark and associates (73) found no anomalies in 23 patients with scoliosis and amyoplasia but did note congenital vertebral anomalies in other contractural syndromes (74). Other authors make no mention of vertebral anomalies (10 ,13), with the exception of Drummond and Mackenzie (15), whose seven patients with congenital anomalies probably represented other diagnostic subgroups of arthrogryposis.

Excluding curves with congenital vertebral anomalies, characteristic curve patterns have been noted. Lumbar and thoracolumbar curve patterns predominate (10 ,12 ,38 ,73), frequently associated with increased lordosis and pelvic obliquity. Double (thoracic and lumbar) and single thoracic curves are also seen. Available data do not allow comment on the contribution of the ambulatory status or hip position to the development of spinal deformity, which occurs in all categories. A significant proportion (8% to 38%) of patients with scoliosis exhibit curvatures at birth. By 5 years of age, it is present in 63% of patients who will ultimately develop scoliosis. The remaining curves develop in the juvenile and adolescent periods (Fig. 5) such that the average age a curve is noted is 5 years (12 ,38 ,73).

Natural history data are limited. Herron and coauthors (38) noted curve progression in six of seven untreated immature patients, averaging seven degrees per year. No useful data exist on these patients after maturity. Progressive curves do not necessarily become severe by skeletal maturity. As might be expected, the earlier the onset of curvature, the more likely it is to become severe. Authors almost invariably comment on the inflexible, rigid nature of the curves.

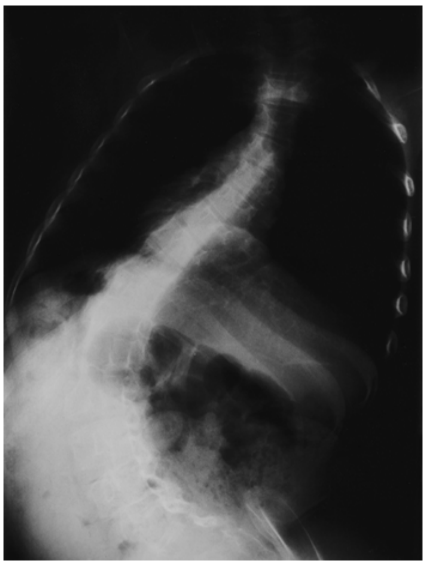

FIGURE 5. Amyoplasia in an 8-year-old nonambulator. A severe, rigid scoliosis is already present.

Nonsurgical treatment modalities consist of passive trunk stretching and orthoses. Sarwark and colleagues (73) stated that trunk contractures present at birth respond to passive stretching. Various authors document orthotic treatment with TLSOs or Milwaukee braces. No attempt was made to assess curve correction after initial brace application. Herron and associates (38) were not able to demonstrate a significant reduction in rate of curve progression over natural history in five patients braced. None of the authors reported successful bracing based on currently accepted stringent criteria.

No series documents surgical outcomes with segmental instrumentation. The available literature documents seven cases only that underwent an instrumented correction. Harrington rods were used in all cases, and treatment included preoperative halo-femoral traction in some patients. The average preoperative curve magnitude was 60 degrees, and the average curve magnitude at follow up was 48 degrees, giving a correction of only 20%. This is consistent with the impression that these are indeed relatively rigid curves.

In view of the paucity of published data, it is necessary to invoke the basic neuromuscular deformity principles when treating these patients. Hip dislocation and deformity should be treated at an early age on their own merits, although it is doubtful that this will materially alter the development or progression of any spinal deformities. Bracing is indicated for the occasional patient with a relatively small flexible curve in the 20- to 40-degree range; however, such a patient is seldom encountered. Because of the tendency for these curves to progress and become rigid at an early age, surgery is often required in the juvenile period. In determining the ideal timing of surgery, it should be recognized that, even with aggressive modern surgical techniques, correction is likely to be much less than that obtained in other neuromuscular conditions as a result of the malignant combination of soft tissue rigidity and osteopenia. Surgery should therefore be recommended before curves become severe and before substantial pelvic obliquity develops. If pelvic obliquity is present, fusion to the sacrum is generally necessary. As always, fusion to the sacrum should be recommended cautiously in ambulatory patients but probably carries little penalty in patients with stiff lumbar or thoracolumbar curves. Provided that pulmonary function is adequate, posterior segmental instrumentation and fusion frequently need to be preceded by anterior disc excision to enhance curve mobility and prevent crankshaft.

At the time of surgery, peripheral venous access is frequently limited or absent. Care should be taken in positioning the patient for surgery because the combination of stiff, deformed joints and osteopenia predisposes to pathologic fractures. Finally, difficulty in establishing a subperiosteal plane because of deficient muscle and soft tissue adherence as well as osteopenia may predispose to moderate or excessive blood loss (12).

Hereditary Motor and Sensory Neuropathies

The current classification of hereditary motor and sensory neuropathies (HMSN) is based in part on the pathology (axonal or myelinic); their electroclinical manifestations, especially the motor and sensory conduction velocities; and their mode of inheritance. Classifications are rapidly changing as a result of progression in molecular genetics (1).

For example, the term *peroneal muscular atrophy* or *Charcot-Marie-Tooth disease* was originally believed to be specific for one disorder. Dyck and Lambert (16 ,17) in 1968 were the first to suggest that peroneal muscular atrophy occurs in several inherited muscular disorders. They distinguished between the hypertrophic neuropathy variety now commonly known as HMSN type I, and the neuronal variety, or HMSN type II.

HMSN I, also referred to as Charcot-Marie-Tooth disease type I, is genetically heterogenous and has been further subdivided. According to Dyck (19), perhaps less than 10% of patients affected with HMSN I have sought medical consultation. This conclusion comes from examination of relatives of probands diagnosed with HMSN. The clinical manifestation of HMSN II are similar but with a later onset and even slower course (1).

In contrast, HMSN III, also known as *hypertrophic neuropathy of infancy* or *Déjérine-Sottas syndrome*, has a course that is more often severe, and loss of independent walking before adolescence may occur. Déjérine and Sottas' original description (cited by Dyck) pertained to two siblings with this disorder, whose clinical manifestations included kyphoscoliosis. Ouvrier and colleagues (60) noted kyphoscoliosis in two of six patients with this disorder.

HMSN IV, alternatively known as *hypertrophic neuropathy* or *Refsum's disease*, which is associated with phytanic acid excess, is rare, and although skeletal abnormalities are common in this disorder, spinal deformity has only been sporadically recorded. HMSN V is spastic paraplegia, and types VI and VII have features of HMSN I in addition to ocular manifestations. Scoliosis has not yet been described in association with these variants.

Onset of HMSN I is usually within the first decade of life, and it occasionally occurs in the neonatal period or the first year of life. Foot deformity and gait disturbance are the usual presenting manifestations. Examination reveals symmetric atrophy of the peroneal muscles, later involving the calves and eventually the distal thighs, although about half of affected children and adolescents do not display wasting (1). In the upper extremities, atrophy of the small muscles of the hand may occur, although this is usually a later manifestation. Deep tendon reflexes are often lost early. Sensory abnormalities are mild and may be difficult to evidence.

HMSN II has a later onset, during the second or third decade of life, and a slower course. Absent reflexes and foot deformities are less common. Differentiation from type I is by electrophysiologic parameters. Even in HMSN I, most patients remain active indefinitely, but some severe cases exist. The prevalence of HMSN I and II is about 40 per 100,000 population, with the disorder remaining undiagnosed in perhaps most cases (18).

Orthopaedic considerations relate to instability and deformity of the foot and ankle, occult hip dysplasia (44 ,61), and spinal deformities. Because affected patients with HMSN I and II do not always come to medical attention, the proportion of affected individuals with scoliosis is uncertain. Hensinger and MacEwen (37) noted kyphoscoliosis in 7 of 69 patients with Charcot-Marie-Tooth disease. This report appears to form the basis of the statement that scoliosis is seen in about 10% of patients with HMSN, which is widely quoted in the orthopaedic literature (76). However, Ouvrier and colleagues (60) found evidence of spinal deformity in 3 of 10 patients with HMSN I, Nukada and associates (58) in three of four patients with HMSN II, and recently Walker and colleagues (85) noted scoliosis greater than 10 degrees in 34 of 89 children examined with HMSN I and II and followed to or close to skeletal maturity. Many of these curves exhibited a kyphotic component, and pure kyphosis (greater than 40 degrees) was seen in a further three children. Spinal deformity was found in 84% of children with HMSN I and in only 19% with HMSN II. Of the 34 patients with scoliosis, single thoracic curves, more often left sided, predominated, although all curve patterns were seen (Fig. 6). Daher and coauthors (13) also noted an associated kyphosis in six of 12 patients with Charcot-Marie-Tooth disease and scoliosis. In the pediatric and adolescent group of Walker and colleagues (85), most scoliotic curves were less than 20 degrees, and only two were greater than 40 degrees. Six patients, however, had a kyphotic component of greater than 60 degrees. Similarly, Daher and coauthors (13) found an average scoliotic curve of 19 degrees only. The average ages at diagnosis of spinal deformity in these two series were 10 years and 13 years, 10 months, respectively (13 ,85).

The literature reports few orthotically and surgically treated patients, probably reflecting and confirming the relatively non progressive nature of the deformity in most cases. Hensinger and MacEwen (37) reported that a Milwaukee brace was successful in three of six patients, with the remainder coming to surgery. Likewise, bracing controlled progression in one of Daher's (13) two patients and in one of Walker's (85) three patients so treated. The two patients in Walker's (85) series who underwent spinal fusion had no complications, whereas two of Daher's (13) four patients, who had Harrington instrumentation, developed a pseudarthrosis.

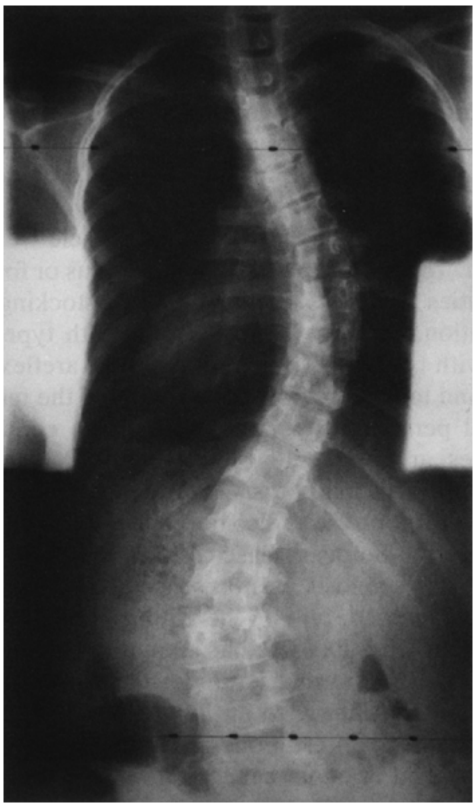

FIGURE 6. Charcot-Marie-Tooth disease in a 13-year-old. The right thoracic, left lumbar curve pattern is similar to that seen in adolescent idiopathic scoliosis.

Hensinger and MacEwen (37) believed that spinal deformity in Charcot-Marie-Tooth disease may be managed by the same techniques used for idiopathic scoliosis, including the effective use of a Milwaukee brace. Currently, it would be reasonable to apply bracing criteria and indications developed for adolescent idiopathic scoliosis, using an underarm TLSO when applicable. Because the disorder is slowly progressive and rarely leads to severe disability, adult progression would be predicted to occur only in larger curves by extrapolation from adolescent idiopathic scoliosis data. On the other hand, the occasional patient may develop late curve progression as a result of a neuropathic spinal arthropathy, as recently reported by Anand and coauthors (3) in a 45-year-old man who had been managed as a teenager in a Milwaukee brace.

Even fewer patients require surgical treatment. This most often involves a posterior spinal fusion with segmental instrumentation. The pattern of hook placement and the length of fusion should take account of the frequently associated sagittal plane deformity and the neuromuscular etiology. The occasional patient with a large, stiff curve or a major kyphotic component may require a preliminary anterior disc excision. Anterior and posterior surgery is required if there are any neuropathic features on radiograph, although these are unlikely to be present before maturity (14). As noted recently by Krishna and colleagues (43), surgeons should anticipate failure of conventional somatosensory evoked potential monitoring in these patients.

Hereditary Sensory and Autonomic Neuropathies

Inherited peripheral sensory neuropathies are rare, and their definitive diagnosis is difficult. Relative insensitivity to pain is common to all and underpins many of the clinical features. Surgeons treating patients with spinal deformity need to be cognizant of the existence of the Riley-Day syndrome or familial dysautonomia (HSAN III). Although the most common of the hereditary sensory and autonomic neuropathies, HSAN III is only rarely encountered outside Israel in several centers in the United States. Nevertheless, the disorder's protean clinical manifestations and the numerous dangers associated with surgical and anesthetic management of these patients are likely to leave an unforgettable clinical impression out of proportion to the condition's prevalence (81). Rarely, patients with other hereditary sensory and autonomic neuropathies are encountered in scoliosis clinics (Fig. 7). Their recognition may result from identification of characteristic clinical features, including anhidrosis, recurrent fractures, Charcot joints, osteomyelitis, acral and oral mutilation, autoamputation, deafness, and behavioral problems or mental retardation (1 ,19 ,25). These patients rarely present for spinal surgery as a result of deformity or neurologic compromise associated with the development of Charcot arthropathy of the spine (9 ,35 ,65) (Fig. 8).

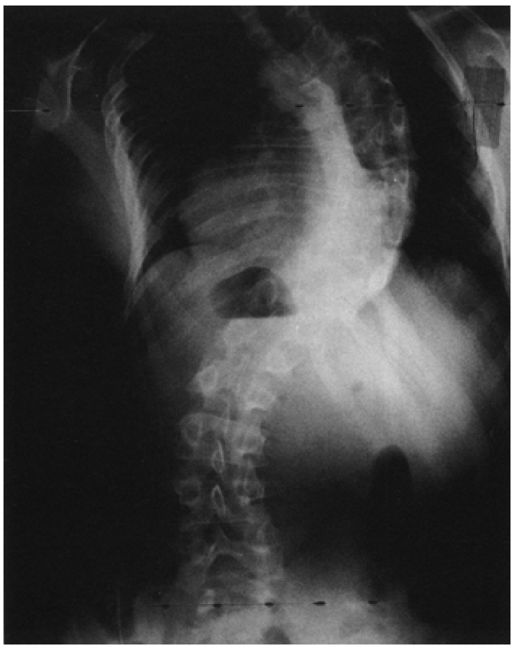

FIGURE 7. Congenital insensitivity to pain (HSAN II) in a 15-year-old demonstrating a severe thoracic scoliosis. (Courtesy of the Alfred I. du Pont Institute Wilmington, DE.)

Five types of hereditary sensory and autonomic neuropathies have been categorized. With the exception of HSAN III, in which scoliosis is almost invariable and its management well documented, reports of patients with spinal deformity are sporadic (20) and do not generally distinguish between the various HSAN subtypes.

The hereditary sensory and autonomic neuropathies are, as the name implies, inherited and are characterized by the fact that primary sensory and autonomic neurons either undergo atrophy and degeneration (HSAN I) or fail to develop (HSAN II to IV). HSAN type I typically has a symptomatic onset during late childhood or adolescence, affects predominately the lower limbs, and is slowly progressive. HSAN types II to V are congenital, the disorder is more generalized (upper limbs, trunk, and face are variably affected), and clinically the disorders are static. However, the present classification is assumed to be temporary and imperfect, and rarer forms exist (19).

Reports of HSAN in the orthopaedic literature either predate the currently accepted classification (50 ,63) or, with rare exceptions, (7 ,59) fail to take cognizance of it. Although reports of small numbers of patients exist in both the older and more recent orthopaedic literature (7 ,20 ,23 ,42 ,45), only three such reports (7 ,20 ,23) specifically describe scoliosis in patients other than those with HSAN III. These various reports highlight the particular difficulties in management of joint instability (both congenital and acquired), fractures, bone and joint infections, acral mutilation, and other orthopaedic problems imposed by the underlying sensory and autonomic neuropathies.

HSAN type III is a recessively inherited disorder seen predominantly but not exclusively in Jewish people. Although there is an overlap of symptoms and signs in this disorder with those of other varieties of HSAN, HSAN III can be distinguished by the predominance of autonomic symptoms (defective lacrimation, defective temperature control, skin blotching, extensive perspiration, hypertension, postural hypotension), absence of fungiform papillae, and occurrence particularly among the Ashkenazi Jews (18). The initial account of the disorder was published by Riley, Day, and coworkers in New York in 1949 (68). The disease has an incidence among Ashkenazi Jews of between 0.5 and 1 per 10,000 live births (51).

The presence of the disorder may be apparent soon after birth or during infancy as a result of hypotonia, poor sucking, vomiting, failure to thrive, unexplained fever, and repeated episodes of pneumonia. Presenting symptoms at an older age may include developmental delay, growth impairment, corneal abrasions, excessive sweating, blotching of the skin with emotion, emotional lability, clumsiness, decreased pain sensation, and spinal deformity (18).

The disorder affects peripheral autonomic, sensory and motor neurons, and possibly other classes of central nervous system neurons (18). Autonomic and spinal ganglia are markedly diminished in number, and significantly reduced numbers of unmyelinated fibers are found in cutaneous nerve biopsies (18 ,68). The sensory deficit is variable and increases progressively with age (4). Deep tendon reflexes tend to be lost early in the disease, ataxia develops in some patients, and mental retardation may be observed, although more often intelligence is normal. Additional diagnostic criteria include lack of an axon flare after intradermal histamine injection and a hypersensitivity to parasympathetic drugs.

The course of HSAN III is severe. Whereas in the 1960s, only 20% of patients survived to adulthood, improvements in management have seen that proportion rise to 50% (5). From an orthopaedic standpoint, acral mutilation is not a feature, and although Charcot joints do occur, spinal deformity is the leading musculoskeletal abnormality and develops in most patients. The reported frequency of either scoliosis or kyphosis ranges from 60% to 96% (72 ,86), depending obviously on the age of patients under study and selection criteria. Much of the natural history data derive from patients registered with the Familial Dysautonomia Center of New York University, and it is likely that many patients are common to chronologically successive studies (22 ,52 ,72 ,86). Additional treatment-related data come from Toronto (2) and Israel (71). Scoliosis is the most common deformity, with perhaps one half of these patients also having significantly increased kyphosis (22 ,52) and with pure kyphosis also occurring occasionally (71). Single thoracic curve patterns predominate, often left sided, although double curve patterns are not infrequent (22 ,72). The apex of the scoliotic curve is often several vertebrae cephalad to that seen in idiopathic scoliosis (86). The apex of the kyphosis may also be high, and the thoracic kyphosis may extend to the caudad portion of the cervical spine, where it may meet a rigid cervical lordosis (72).

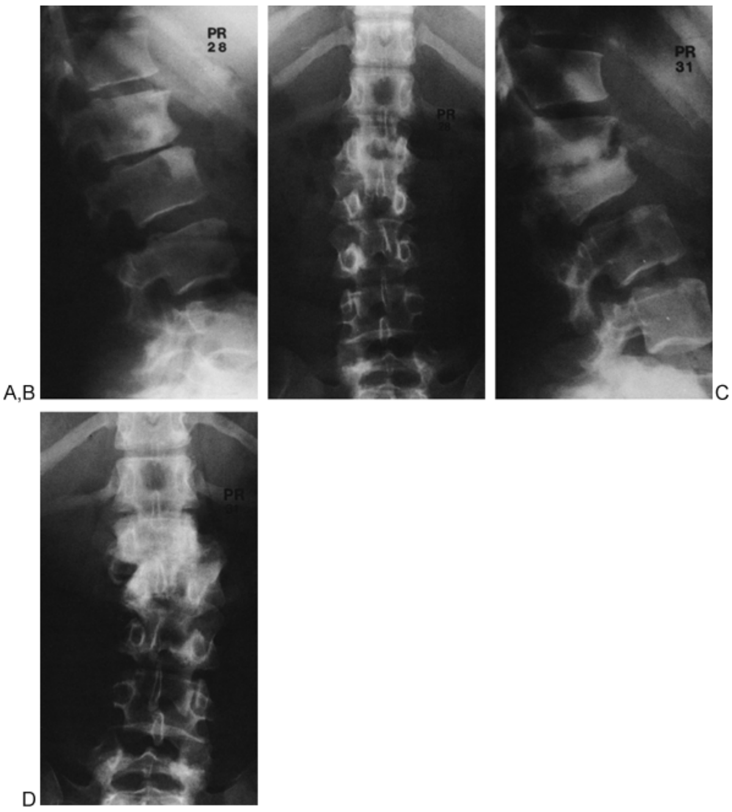

FIGURE 8. Patient with congenital insensitivity to pain and Charcot changes involving the L1 to L2 level. **A, B:** Early changes of disc space narrowing and scoliosis in a 28-year-old woman. **C, D:** Three years later, progressive destruction and instability have developed (From Piazza MR, Bassett GS, Bunnell WP (1988): Neuropathic arthropathy in congenital indifference to pain. *Clin Orthop* 236:175–179, with permission.)

Onset of spinal deformity is usually noted between 5 and 10 years of age and is progressive in most patients; frequently, moderately severe or severe curves that tend to be rigid are thought to contribute to cardiopulmonary morbidity and mortality (71 ,86).

Treatment of spinal deformity is discussed in depth by three authors (2 ,71 ,72), with by far the most comprehensive report provided by Rubery and colleagues (72). They considered that failure of bracing to prevent progression of kyphoscoliosis to 45 degrees was an indication for operative treatment. The other authors report limited success with bracing, either Milwaukee or TLSO. Brace efficacy is compromised by the high and rigid curves and the tendency to repeated pneumonia, impaired thermoregulation and hence pressure sores, gastrostomy feeding tubes, and emotional lability. Nevertheless, bracing should probably be attempted for smaller, supple curves in immature patients using modern bracing principles and techniques.

This is particularly so because surgical treatment is likewise often associated with complications of both a medical and surgical nature. Rubery and colleagues (72) reported operative treatment of 22 patients with a mean preoperative scoliosis of 70 degrees and kyphosis of 68 degrees. All patients underwent posterior spinal fusion using Harrington instrumentation with the exception of three patients treated with Cotrel-Dubousset instrumentation. Two patients had an additional anterior fusion. At the most recent follow-up, modest improvements in the scoliosis were noted, with no significant improvement in the kyphosis. Cut out of the upper hook occurred in four patients, one patient required reoperation for pseudarthrosis, and one patient died from paraplegia associated with deep infection. Severe medical complications, including pneumonia and gastrointestinal hemorrhage, were more common early in the series.

Despite these many difficulties, surgery is indicated for scoliotic curves that progress beyond 45 degrees. Fusion length may often be dictated by the extent of the frequently associated kyphosis, and preoperative planning should take into account sagittal plane deformity in cervical, thoracic, and lumbar segments to maximize sagittal balance postoperatively. Segmental instrumentation should reduce the incidence of implant failure, and combined anterior and posterior procedures should be considered for large, rigid curves, especially if there is a major kyphotic component. Unless perioperative medical, anesthetic, and intensive care management is ideal, however, complications will occur with unacceptable frequency. Preoperatively, adequate hydration and avoidance of atropine should reduce the incidence of inspissation of secretions plugging endotracheal tubes (72). Intraoperatively, the surgical practice of infiltration with epinephrine solution should be avoided (2), and blood pressure should be controlled with sedatives rather than antihypertensive medications (72). Postoperatively, cardiovascular, pulmonary, and gastrointestinal symptoms should be adequately supported and monitored.

Congenital Myopathies

The congenital myopathies constitute a group of disorders characterized clinically by hypotonia and weakness from birth and pathologically by distinctive histologic and electron microscopic findings, an absence of dystrophic features, and a normal or only mildly elevated serum creatine kinase (1 ,75). The current classification is based on histopathologic findings rather than genetic or clinical characterizations. Consequently, there is considerable clinical overlap between the various pathologic entities as well as marked variability in clinical severity within the spectrum of each pathologic class.

Central core disease was the first congenital myopathy to be described and is a rare disease with autosomal dominant inheritance as well as sporadic occurrence. The responsible gene appears to be allelic with the gene that has been implicated in malignant hyperthermia, and the two conditions frequently coexist, although they may occur discordantly (21 ,56 ,78). Histologically, the muscle fibers contain central areas that are devoid of the normal histochemical reactions for oxidative enzymes, myophosphorylase, and glycogen and that ultrastructurally consist of closely packed myofibrils that lack mitochondria, cytoplasmic reticulum, and glycogen.

Nemaline myopathy is predominantly an autosomal recessive trait, although rarely it has an autosomal dominant transmittance. Histologically, multiple small, rodlike particles, thought to represent Z-band proteins, are present within most muscle fibers. There are several patterns of clinical presentation, including a severe, usually fatal, neonatal form; a milder congenital form; and an adult-onset form (53).

The term *congenital fiber-type disproportion myopathy* is applied when biopsy samples demonstrate a disparity between type I and type II fibers in the absence of other histologic abnormalities. *Myotubular myopathy* (or *centronuclear myopathy*) produces a histologic picture of type I fiber predominance and centrally located nuclei, with or without fiber hypertrophy. Variability of both clinical severity and genetic transmittance are also hallmarks of these remaining two categories, and a large number of even rarer categories exist.

Spinal deformity has been described in patients with each of these major divisions of congenital myopathy, as have other musculoskeletal abnormalities, including congenital hip instability, various foot deformities (cavovarus, equinovarus), and contractures (75). The spinal deformity is often rigid but may, less commonly, at least in the early stages, be flexible. Double curve patterns and typical long, thoracolumbar “paralytic” curves are encountered. Within each diagnostic category, phenotypic variability may range from a severe or even fatal neonatal or infantile form to a barely detectable adult picture with little or no clinical impact. There are even cases in which an improvement in strength is noted after the end of infancy. Consequently, treatment must be individualized, but if possible, the underlying condition should be accurately diagnosed and its natural course defined.

An evolving scoliosis can add significantly to the burden of respiratory muscle weakness in these children. In the more severe forms, bracing may be contraindicated, either by virtue of the presence of a severe rigid curve or because of marginal respiratory reserves. However, patients should be kept under regular review. Occasionally a patient is encountered in the infantile period who appears to be untreatable with a grave prognosis, is oxygen dependent, and already has a well-established scoliotic or kyphoscoliotic curve. Surprisingly, at subsequent follow-up, such a child is sometimes seen to be much more robust and perhaps even a candidate for surgery.

Provided that respiration is adequate, attempts should be made to control smaller, flexible curves with an orthosis. Failing this, definitive fusion should be recommended to control progressive curves and should be applied at an age that is calculated to maximize ultimate trunk length and lung capacity and at the same time minimize deformities. This calculation should take account of thoracic vertebral rotation and lordosis, which can severely limit thoracic volume in these patients (see Chap. 46). The possibility of malignant hyperthermia must be investigated if surgery is planned in these patients. Congenital myopathy is probably one of the few diagnostic categories in which the occasional patient may warrant consideration of a growth-preserving surgical approach (49 ,54 ,62 ,69 ,83). Such a patient would generally be encountered in the infantile or early juvenile period and have a long, flexible, thoracolumbar curve that is too large or too rotated to allow bracing or for which bracing without internal fixation has already failed.

The history of mechanical devices to support or correct deformities of the spine in children is long and respectable (2 ,14). Galen (131–201), Ambroise Paré (1510–1590), and Nicolas Andry (1658–1742) (4) all used and wrote about orthotic devices. Throughout the nineteenth century, the Europeans developed a large number of devices fashioned from steel, leather, and plaster, designed to correct deformities of the spine.

The modern era of orthotic treatment for spinal deformities began with the development of the Milwaukee brace (cervicothoracolumbosacral orthosis, CTLSO) by Blount and Schmidt (9) in the late 1940s. The Milwaukee brace was first used as a postoperative device to replace plaster casts, but in the 1960s it became the mainstay of nonoperative management of spinal deformities due to the leadership of John Moe (8). The 1970s heralded a better understanding of the biomechanical function of spinal orthoses and resulted in the design of low-profile orthoses (thoracolumbosacral orthosis, TLSO), which were used on the more caudal curves and functioned through the mechanism of transverse loading.

But the 1970s and 1980s were also a time of misgivings and even nihilism concerning the efficacy of orthotic treatment. Part-time regimens, electrical stimulation, and observation until the time of surgery all had their advocates. The uncertainty about natural history and the role of orthoses is now relegated to the past, and the value of orthotic treatment has been convincingly demonstrated.

Modern orthotic treatment decision making for pediatric patients requires knowledge of biomechanical mechanisms of action combined with sound clinical procedures, adequate follow-up, proper patient instruction, and physical therapy to ensure the best result. This chapter discusses state-of-the-art biomechanics, technical parameters, indications for treatment, and treatment outcomes for orthotic treatment of the pediatric spine.

Spinal Deformity

Biomechanics of Orthotic Treatment

To understand the biomechanical principles of orthotic treatment for idiopathic scoliosis it is necessary to first understand why curves progress. Only when we understand the concepts of why and when curves progress will we understand why and how our clinical treatments will best arrest curve progression and yield a stable spine after skeletal maturity. Long-term clinical studies of children with idiopathic scoliosis have yielded a general understanding of who is at risk of progressing and when we should treat curves, and gives us expectations for the outcome of treatment (51 ,53 ,60 ,76). Understanding the conceptual framework for progression permits formulation of individually tailored clinical treatment plans to fulfill the specific requirements of each patient.

Curve Progression

Curve progression in idiopathic scoliosis may be explained theoretically by using Euler's theory of elastic buckling of a slender column (80). For a flexible column fixed at the base, free at the upper end, and subjected to an axial compressive force (Fig. 1A), there is an upper limit on the magnitude of this force at which point the column will buckle. The buckling load of a column is a function of its flexibility, length, and end support (boundary) conditions (80). For the column shown in Fig. 1A , the relationship is given by:

$Pe = \pi^2 EI/4L^2$

where Pe is the buckling load, EI is the flexural rigidity (resistance to bending), and *L* is the length.

This is an excellent analogy to show the relationship between patient growth and curve progression. In a child at a given age, the weight of the upper torso and arms may not exceed the buckling load of the spinal column. Therefore, an existing scoliotic curve may not progress. However, with height increase and weight gain of the upper trunk and arms, this relation may help explain progression of the curve. The formula for the buckling load indicates that an increase in the child's height greatly affects the capacity of the spinal column to support axial load. This formula implies that a 10% increase in height would result in about a 20% decrease in the buckling load. As a patient's height and weight increase, these two factors act together and may explain progression seen during the preadolescent growth spurt.

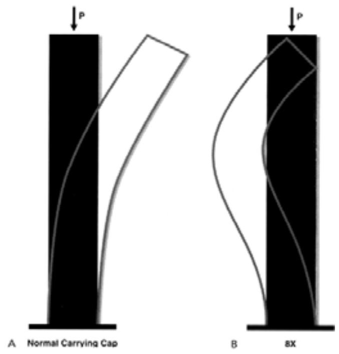

FIGURE 1. A: Flexible column fixed at the base, free at the upper end under an axial load. (Redrawn from Gavin TM, Patwardhan AG, Bunch WH, et al. [1997]: Principles and components of spinal orthoses. In: American Academy of Orthopaedic Surgeons, ed. *Atlas of orthoses and assistive devices*, 3rd ed. St. Louis: Mosby–Year Book Publishers, pp. 155–194.) **B:** Stabilizing the superior end of a flexible column by means of a “pin.” (Redrawn from Gavin TM, Patwardhan AG, Bunch WH, et al. (1997): Principles and components of spinal orthoses. In: American Academy of Orthopedic Surgeons, ed. *Atlas of orthoses and assistive devices*, 3rd ed. St. Louis: Mosby–Year Book Publishers, pp. 155–194.)

Curve progression seen in idiopathic scoliosis is not truly *elastic* buckling, which implies a *sudden* departure from the straight configuration of the column followed by total collapse (74). In idiopathic scoliosis, curve progression is a *gradual* deviation from the normal configuration of the spine over an extended period. Furthermore, in elastic buckling the critical load remains the same regardless of the magnitude of curvature.

Progression of a spinal curvature is actually a *plastic* (permanent) deformation. For plastic deformation of the spine, the upper limit of axial load that the spine can withstand without undergoing a permanent increase in curvature is termed “critical load” (74). There is a direct relationship between the magnitude of deformation and critical load. Clinical observations clearly document a strong relationship between the risk of progression and curve magnitude as the literature clearly shows that a patient with a larger curve, for any given maturity state, is more likely to experience progression than one with a smaller curve (12 ,53). With plastic deformation, the axial load may be removed *without* the spine returning to the original shape, thus yielding a permanent, or plastic, deformation.

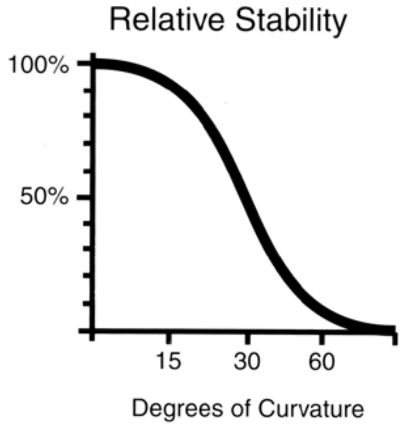

FIGURE 2. The effect of curve magnitude or degree on the stability of a spinal curve. (Redrawn from Bunch WH, Patwardhan AG (1989): Biomechanics of orthoses. In: Bunch WH, Patwardhan AG. *Scoliosis: making clinical decisions*. St. Louis: CV Mosby, pp. 204–215.)

Curve Magnitude Effect

The effect of curve magnitude or degree on the stability of a spinal curve, as reported by Bunch and Patwardhan (11), is shown in Figure 2 . This graph shows that larger curves have low critical load values and are usually progressive. However, smaller curves have much higher critical load values and therefore are usually stable, requiring observation alone. The moderate curve range has a rapidly decreasing critical load value for increasing curve magnitude. This explains why these curves are sensitive to small changes in height and weight. Moderate curves are usually the ones wherein orthotic treatment is initiated. Curves of 60 degrees or greater are severely reduced in their critical load value and are unstable. That is why orthoses usually fail to stabilize these curves and why such curves often progress after skeletal maturity.

Biomechanics of Orthoses for Spinal Deformities

Mechanism of Action

Early attempts at correcting curves with external devices led to the development of orthoses that functioned by pure distraction (2 ,8). Andry reported on “depressing bony protuberances” (4), which may have implied the use of a transverse directed force. The controversy of using distractive versus transverse force may be best explained by White and Panjabi (85), who showed that curves less than 53 degrees respond better to transverse force, whereas curves greater than 53 degrees respond better to axial distraction (Fig. 3). This has resulted in the development of the current era of orthoses wherein the mechanism of distraction has yielded to the use of orthoses that only utilize transverse forces.

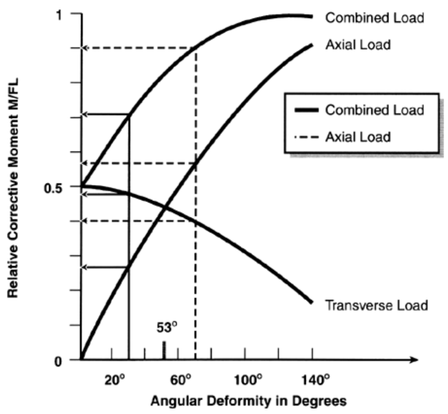

FIGURE 3. Effect of axial distractive loads and transverse loads on the curved spinal column. (From White AA, Panjabi MM (1978): *Clinical biomechanics of the spine.* Philadelphia: JB Lippincott, p. 105.)

The clinical expectation of scoliosis orthosis is that it will prevent progression of an existing spinal curve and stabilize it until skeletal maturity. Three primary mechanisms of action are utilized to achieve this goal and are considered as separate but interactive effects (11). These are end point control, curve correction, and transverse loading.

End Point Control

End point control is the column sway resistance provided by the mechanical constraints of a spinal orthosis. For example, the neck ring of the Milwaukee brace reduces the sway in all directions by keeping the head and neck centered over the pelvis. Also, to provide a stable base of support from which pad loads may be applied, the pelvic interface fixes the orthosis rigidly to the base of the spine.

End point control alone provides an initial increase in the critical load of a curved spine (11). Stabilizing the superior end of the spine by means of a hinge (Fig. 1B) results in a theoretical critical load value that is eight times that for the column shown in Figure 1A .

The mechanical analogy shown in Figure 1B is an approximation of the constraints imposed by an orthosis on the end points of the scoliotic curve. For example, even though the neck ring of the Milwaukee brace limits the lateral sway, the superior end point of the scoliotic curve (usually T5) is caudal to the neck ring and does not provide the same kinematic constraint as the Euler model (Fig. 1B). Thus, the actual beneficial effect of the neck ring on the stability of a scoliotic curve may be much smaller than that predicted by this analogy. However, this illustration of the concept clearly emphasizes the value of end point control in orthotic treatment for idiopathic scoliosis.

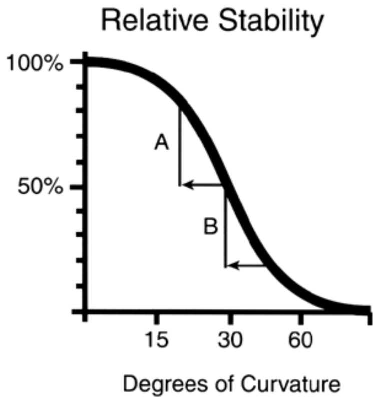

FIGURE 4. Stabilizing effect of curve correction yielded by an orthosis. (Redrawn from Bunch WH, Patwardhan AG (1978): Biomechanics of orthoses. In: Bunch WH, Patwardhan AG. *Scoliosis: making clinical decisions*. St. Louis: CV Mosby, pp. 204–215.)

Curve Correction

Curve correction produced by an orthosis has the single greatest effect on increasing the overall critical load of the spinal column. Reducing a curve of 30 degrees to 20 degrees in the orthosis, which is considered a suboptimal clinical result by today's standards, will increase the stability of the curve from 50% to about 80% of normal. This is shown in Figure 4 by the vertical bar on the left.

This effect is also significant for larger curves. A curve of 45 degrees has a critical load of about 20% of normal. If the curve can be reduced to 30 degrees, the critical load increases to about 50% of normal. This is shown in Figure 4 as the vertical bar on the right.

Transverse Load

The defining characteristic of scoliosis orthoses is some form of a transversely directed load to the curvature of the scoliotic spine, usually through accessories known as pads. A transverse load alone directed at the apex of the curve increases the critical load that the spine can carry. In Figure 5 the lower line represents the critical load for an unsupported spine of increasing degree of curvature while the upper line indicates the critical load of the spine with a transverse support applied at the apex of the curve. For curves of 25 to 30 degrees, the transverse support increases the critical load from approximately 50% to 70% of normal.

This increase is shown in Figure 5 as the left vertical bar. It may be enough to prevent the curve from progressing; however, transverse support without curve correction will usually yield a clinically suboptimal result. Orthotic treatment may only keep the curve unchanged through the growth phase while the orthosis is donned. For curves of small magnitudes, maintenance of the status quo is satisfactory but should be considered a clinically suboptimal result.

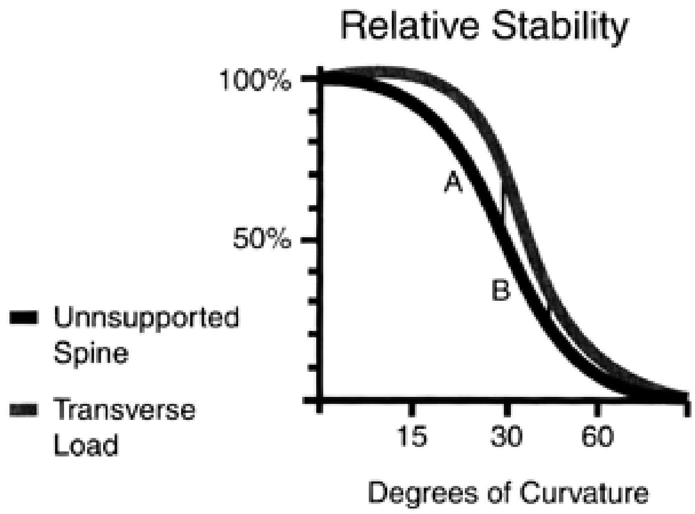

FIGURE 5. Stabilizing effect of transverse load directed at the apex of the curve. (Redrawn from Bunch WH, Patwardhan AG (1989): Biomechanics of orthoses. In: Bunch WH, Patwardhan AG, eds. *Scoliosis: making clinical decisions*. St. Louis: CV Mosby, pp. 204–215.)

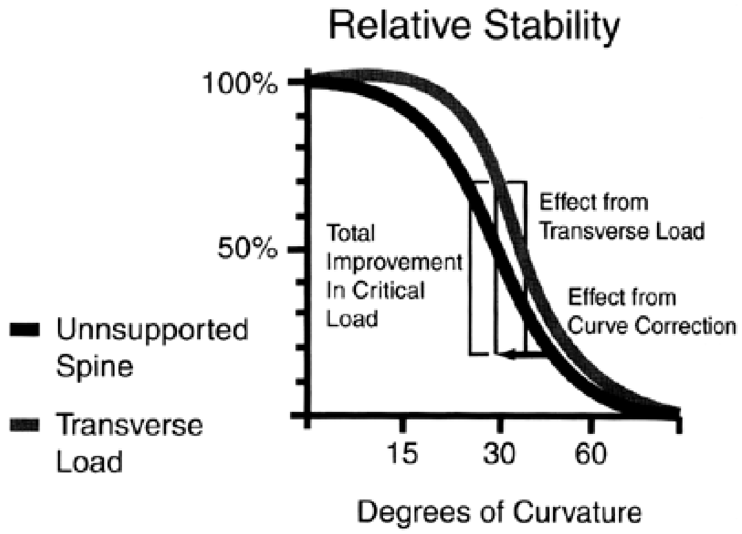

FIGURE 6. Combined effect of curve correction and transverse load. (From Bunch WH, Patwardhan AG (1989): Biomechanics of Orthoses. In: Bunch WH, Patwardhan AG, eds. *Scoliosis: making clinical decisions*. St. Louis: CV Mosby, pp. 204–215.)

However, for curves of progressively larger magnitudes, the effect of transverse support is reduced. In contrast to the smaller curves, a curve of 45 degrees would have its critical load increased from about 20% of normal to about 30%. This is shown in Figure 5 as the right vertical bar. The resultant stability may not be enough to stabilize the curve, and progression could be expected despite the use of an orthosis. This analysis suggests that orthoses that do not produce much correction should not be used on curves larger than 25 to 30 degrees.

A comparison of results shown in Figures 4 and 5 illustrates that for any given curvature, reduction of curve magnitude improves the critical load of the spine far more than transverse support alone.

Combined Effect

The effects of curve correction and continued transverse support are additive as shown in Figure 6 . Once a curve of 45 degrees is reduced in the orthosis to 30 degrees, the corrective pads of an orthosis can be tightened maximally to provide continued lateral support (transverse load) to the corrected curve to further increase the critical load. This cumulative orthosis adjustment, which usually is done three times over the first 9 months of orthosis wearing, has the potential of increasing the critical load value of 20% to approximately 70% of normal (Fig. 6). Thus, with initial response from pad tightness and subsequent pad tightening, significant curve correction in the orthosis and continued transverse load must be obtained to optimize the results of orthotic treatment.

The Milwaukee Brace

The Milwaukee brace (Fig. 7) was developed in the late 1940s as a substitute for postoperative casting (9). It was subsequently used for nonoperative treatment, and its traditional design was improved and refined (8). Several authors (3 ,8 ,11 ,51 ,59 ,74 ,72 ,70) have reported the clinical and biomechanical mechanisms of action of the Milwaukee brace for stabilizing curves. In some studies, the magnitudes of forces generated by the various components of the orthosis were measured experimentally (29 ,59). In the standing position, the average distractive force was about 10 to 20 N and the lateral pad forces were about 20 to 40 N. Removal of the thoracic pad substantially increased the distractive forces, implying that the thoracic pad plays a primary role in providing curve stability.

FIGURE 7. The Milwaukee brace.

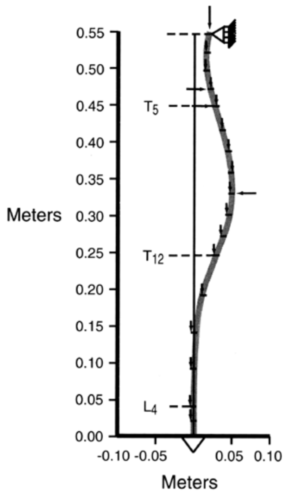

FIGURE 8. Milwaukee brace-spine model. (Redrawn from Patwardhan AG, Gavin TM, Bunch WH, et al. (1996): A biomechanical comparison of the Milwaukee brace and TLSO. *J Prosth Orth* 8(4):115–122.)

Andriacchi et al. (3) used a mathematical model of the spine to analyze curve correction achieved by various components of the Milwaukee brace. In moderate curves of 40 to 45 degrees, the lateral pad load was the predominant corrective component as compared to the distractive force due to the superstructure of the orthosis (29 ,59).

Given the spine model described above, it is possible to think theoretically about the Milwaukee brace (Fig. 8). The sacrum was first fixed in all degrees to simulate the pelvic interface (70). To simulate the neck ring, the lateral displacement of the first thoracic vertebra was constrained to prevent sway. Transverse loads were then applied at the apex of the curve and were subsequently varied to vertebra above and below the apex.

For primary right thoracic curves with T5 cephalic end point and T8 apex, axillary pad resistive forces were applied in addition to thoracic and lumbar pads to complete the force triangulation. This resists having the neck ring be pulled into the neck on the side contralateral to the thoracic pad, in response to thoracic pad force (neck ring reaction). The axillary sling force was set to minimize or eliminate the neck ring reaction (relative to the magnitude of thoracic pad force) and was placed at the most common superior end point of an idiopathic curve with a T8–9 apex (T4 and T5). The force was directed onto the concave side of the curve.

The magnitude of the axillary sling forces was found to be in the range 15 to 34 N for various combinations of the pad placements and a maximum thoracic pad load of 50 N. Addition of a lumbar pad decreased the magnitude of shoulder sling force needed to minimize the neck ring reaction.

In these simulations, as well as in the simulations of the TLSO, the stabilizing effect of the pad forces was evaluated in a two-stage manner corresponding directly to the clinical procedure used in fitting a patient with an orthosis. The loads were applied and the corrections produced were calculated. The spine was initially loaded to simulate axial load after orthosis pad loads were applied (19). Then additional force was applied to the corrected curve to simulate pad adjustments done by the orthotist during follow-up visits to regain lateral support in the orthosis that was lost when the curve responded to the initial force and was reduced. The stability of the curve was measured by calculating the critical load under these different conditions.

Primary Thoracic

This model supports much of the trial-and-error–generated clinical knowledge gained from experience. The best correction and maximum stability of the primary thoracic curve can be achieved by applying the thoracic pad load at its apex. However, incorrect placement of the thoracic pad cephalad to the apex reduces the stability of the thoracic curve and might suggest a strong sensitivity to pad placement. This reinforces the need of frequent clinical follow-ups to adjust the pads for growth, thus ensuring continual optimum thoracic pad placement. Placement of the thoracic pad two levels caudad to the apex reduces the stability achieved by the correctly placed thoracic pad by 16% (Fig. 9).

Although necessary for double curves, the lumbar pad at the apex of the lumbar compensatory curve tends to decrease the correction of the primary thoracic curve and the stability achieved by a correctly placed thoracic pad. A lumbar pad one level too cephalad causes a further reduction in the correction of the thoracic primary curve, with an even greater loss in the stability gained by the use of the thoracic pad. This is shown in Figure 9 . The loss of stability caused by having the lumbar pad one level too cephalad is about equal to that of having the thoracic pad two levels too caudad.

In midthoracic curves, placement of a thoracic pad at the apex of the curve produced maximum correction. Correction of the midthoracic curve decreased when the thoracic pad was placed two levels caudad to the apex and also with the addition of a lumbar pad. When treating primary thoracic curves, a single thoracic pad without a lumbar pad on the compensatory curve provides the maximum critical load of the curve and therefore the maximum stability. This may help us to understand why double curves with both thoracic and lumbar pads are usually less responsive to orthotic force than single thoracic curves and therefore correct less in an orthosis.

Primary Lumbar

Primary lumbar curves, which are usually not treated with a Milwaukee brace, were modeled to better understand the effect of pad forces and to be able to compare the Milwaukee brace to the TLSO (70).

The best correction and maximum stability for a primary lumbar curve treated with a Milwaukee brace can be achieved by placement of a lumbar pad on the apex of the primary curve and a thoracic pad counterforce of a sufficient magnitude to minimize the neck ring reaction. A lumbar pad alone at the apex of the primary curve without a thoracic counterforce results in about the same amount of curve correction, although the resultant critical load is nearly 25% less than that achieved when a thoracic apical counterforce is used, and therefore it is not as effective in *stabilizing* the primary lumbar curve (Fig. 10). Incorrect placement of the lumbar pad one level too cephalad reduces its stabilizing effect by about 12%. This suggests that a three-point orthosis for lumbar primary curves (1 , pelvic constraint; 2, lumbar apical load; 3, thoracic apex) is clearly more optimal than a two-point orthosis (1 , pelvic constraint; 2, lumbar apical load; 3, righting reflex) and should be used to optimize results when treating these curves.

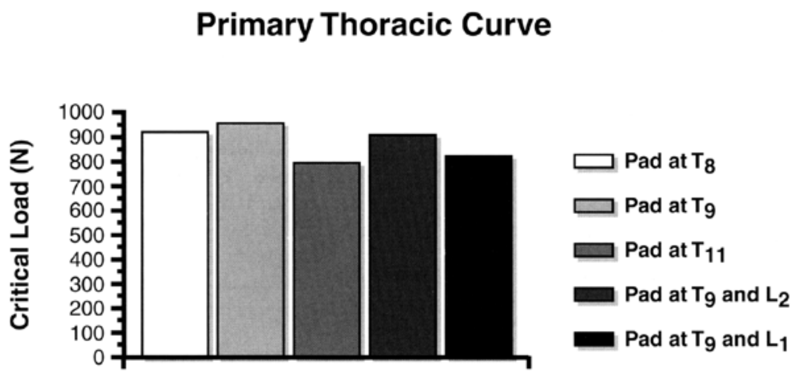

FIGURE 9. Stability yielded by thoracic and lumbar pads in the Milwaukee brace for thoracic primary curves. (Redrawn from Patwardhan AG, Gavin TM, Bunch WH, et al. (1996): A biomechanical comparison of the Milwaukee brace and TLSO. *J Prosth Orth* 8(4):115–122.)

Correct placement of the pads is of great importance. In the thoracic area, misplacement of a pad one level too high or too low greatly reduces the stabilizing effect of the thoracic pad. This effect is even more significant in the lumbar area. Placing a lumbar pad one level too high effectively eliminates any benefit of the pad. Therefore, the sensitivity of pad placement for primary lumbar curves is similar to the sensitivity for the primary thoracic curves. Thus, follow-up growth adjustments to reposition the pads are essential for optimal outcome of treatment.

The Thoracolumbosacral Orthosis

The same type of modeling has been done for the TLSO (70). The sacrum was fixed to simulate the stabilizing effect of the pelvic section. The lateral walls of the orthoses and the trim line (concave side superior endpoint counterforce) were simulated by linear springs at the appropriate vertebral levels. The springs denote the equivalent resistance of the ribs to deformation along the medial-lateral direction. As before, the procedure was to apply a load and calculate the correction. Then additional force was applied to this corrected configuration to simulate the maintenance of lateral support in the orthosis.

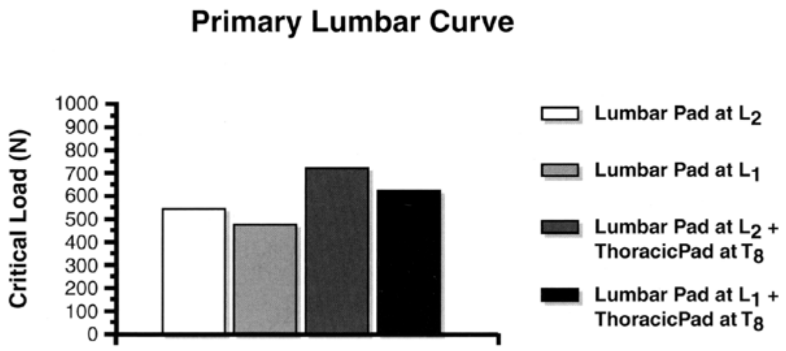

FIGURE 10. Stability yielded by thoracic and lumbar pads in the Milwaukee brace for lumbar primary curves. (Redrawn from Patwardhan AG, Gavin TM, Bunch WH, et al. (1996): A biomechanical comparison of the Milwaukee brace and TLSO. *J Prosth Orth* 8(4):115–122.)

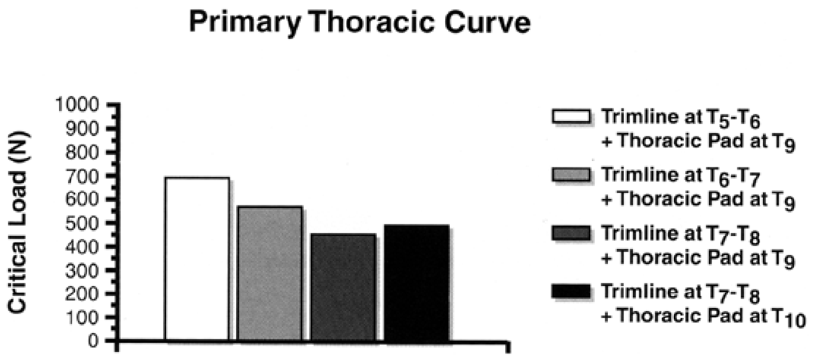

FIGURE 11. Stability yielded by thoracic and lumbar pads in the thoracolumbosacral orthosis for thoracic primary curves. (Redrawn from Patwardhan AG, Gavin TM, Bunch WH, et al. (1996): A biomechanical comparison of the Milwaukee brace and TLSO. *J Prosth Orth* 8(4):115–122.)

Primary Thoracic

For primary thoracic curves, with T5 as the cephalic end and a T8 apex, maximum stability and curve correction are achieved with the trim line at T5–6 and a pad at the apex to the thoracic curve (Fig. 11). As the trim line of the TLSO moves caudal relative to the superior end point of the curve, curve correction decreases and there is a loss of stability of nearly 18% to 20% with each level.

With the counterforce trim line set at T5–6, moving the thoracic pad one level cephalad to the apex decreases the curve correction and causes a 13% loss in stability. Placement of the thoracic pad up to two levels caudad to the apex has no appreciable effect on the curve correction and stability. Although necessary for double curves, adding a lumbar pad at the apex of the compensatory curve decreases the effectiveness of correctly placed thoracic pad because the critical load value decreases by nearly 15%. A lumbar pad one level too cephalad further decreases the correction of the primary curve and causes a 20% decrease in stability as compared to that achieved by a correctly placed thoracic pad alone. This is consistent with the behavior of the lumbar pad noted for the Milwaukee brace treatment of primary thoracic curves.

Primary Lumbar

In primary lumbar curves, the optimum result with a TLSO is achieved with the trim line at the apical level of the compensatory thoracic curve and a pad at the apex of the primary lumbar curve. Moving the trim line caudad toward the end point of the primary lumbar curve results in progressively greater loss of stability with each lower level (Fig. 12).

Comparison of the Milwaukee Brace and TLSO

Because we consider the Milwaukee brace the historical gold standard against which other orthoses should be measured, it is important to compare the stability of a TLSO with that of the Milwaukee brace (70). These comparisons are shown in Figure 13 . For primary thoracic curves, the stability gained with a TLSO is approximately 25% less than that obtained with the Milwaukee brace.

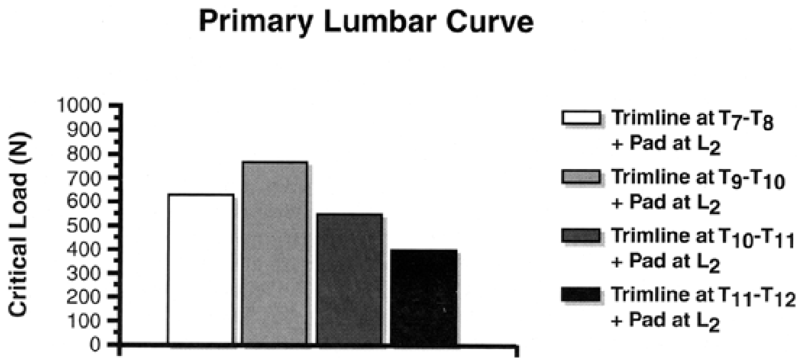

FIGURE 12. Stability yielded by thoracic and lumbar pads in the thoracolumbosacral orthosis for lumbar primary curves. (Redrawn from Patwardhan AG, Gavin TM, Bunch WH, et al. (1996): A biomechanical comparison of the Milwaukee brace and TLSO. *J Prosth Orth* 8(4):115–122.)

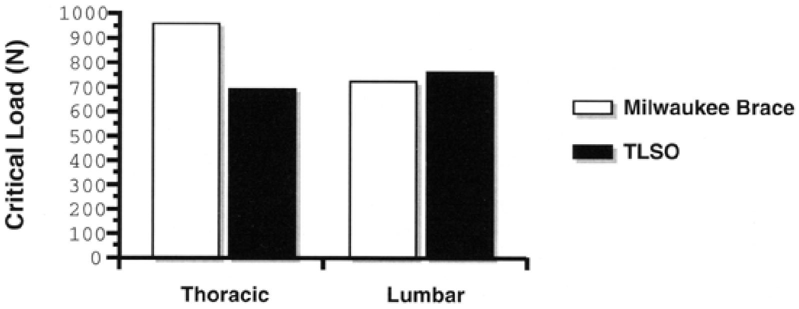

FIGURE 13. Comparison of stability yielded by Milwaukee brace and thoracolumbosacral orthosis for thoracic and lumbar primary curves. (Redrawn from Patwardhan AG, Gavin TM, Bunch WH, et al. (1996): A biomechanical comparison of the Milwaukee brace and TLSO. *J Prosth Orth* 8(4):115–122.)

This suggests that thoracic curves of larger magnitudes that are not well corrected may respond better with a Milwaukee brace than a TLSO. For primary lumbar curves, a properly fitted TLSO appears to be as effective as the Milwaukee brace in stabilizing the curve. This is consistent with clinical experience because the current use of a Milwaukee brace is usually for a thoracic primary curve whereas the TLSO is the exclusive orthosis for lumbar primary curves.

Decompensation

When most people stand, the head in the frontal plane is centered directly over the sacrum or is “compensated.” This is also true of patients with scoliosis. However, such individuals develop secondary curves or half-curves to keep the head centered while accommodating the primary curve. This secondary accommodation maintains a compensated posture.

For double curves in which the caudal lumbar end point is rotated counterclockwise, the tendency is to shift to the left of the center sacral line (CSL) or in the direction of the tilt of the lowest vertebra in the lowest curve (30). When patients are placed in orthoses for double curves, this shift, known as *decompensation*, is frequently increased. In a geometrical modeling study, Gavin et al. (30) showed that for double curves corrected in orthoses (with the upper thoracic curve geometry fixed), if there is a greater than 2:1 ratio of either thoracic to lumbar or lumbar to thoracic curve magnitudes, the patient will always decompensate to the left (Fig. 14). With the initial tendency to lean left, care must be taken to counter this to yield a balanced spine in the orthosis. Because patients will be leaning to one side or another due to the position of the orthosis and the confinement, it is important to counteract the decompensation tendency caused from the curve pattern (toward the tilt of the lowest vertebra in the curves).

Effect of Decompensation on Spinal Stability

As shown in Figure 15 , decompensation is directly related to progressive decrease in the stability of the spine (11). Correctly placed pads will increase the stability by about the same percentage as for compensated curves. However, as the initial stability was lower due to decompensation, the end result of an orthosis in which the patient is not compensated is a lower critical load of the spine. These results should encourage orthopaedists and orthotists to check brace alignment frequently and with great care in order to avoid decompensation and to make the proper timely adjustments to the orthosis to counteract the tendency to decompensate.

Pad Loading

The modeling studies described above showed that for optimal stability resultant pad forces should be directed at curve apices. Also, counterforces should be directed at the pelvis and cephalad curve end points. This leaves the question: “How should we load the curves to optimize results?”

The traditional three-point loading system for single thoracic, lumbar, or thoracolumbar curves, as reported by Gavin (34), in which a “translatory” or trunk-shifting load is applied at and inferior to the apex of the curve on the convex side, shifting against a concave side counterforce on the superior end of the curve and against an inferior, concave side counterforce on the pelvis, is ideal for single curves. This three-point system will reduce the tilt of the most inferior vertebra in the curve as well as reduce the Cobb magnitude.

However, when we consider right thoracic, left lumbar double-curve patterns in which the thoracic curve is primary, traditional experience would have us placing pads at the thoracic and lumbar apices, with the greatest magnitude of pad pressure directed at and below the primary curve apex (translatory load, or TL). The lumbar pad would be of a lesser load magnitude (constraining load, or CL), placed over the deformity of the lumbar curve, and would increase its load magnitude from the synergy of tightening the thoracic pad (Fig. 16).

Counterforces would then be applied at the pelvis opposite the lumbar pad and the axilla opposite the thoracic pad. This has been called the four-point pressure system, which is a synergistic system that utilizes two 3-point force systems: one 3-point system on the thoracic curve and one 3-point system on the lumbar curve. This yields two triangulation of force on the two curves (Fig. 16). Tightening of the thoracic pad results in the increase in force from all four points. The result is a trunk shift from right (convex side of thoracic curve) to left (concave side of thoracic curve). Therefore, the only shifting or translatory load is at the thoracic apex as depicted in Fig. 16A as TL, and the axilla, lumbar apex, and opposite pelvis becomes counterforces or “constraining” loads as depicted in Fig. 16A as CL.

Coronal Balance Possible for Given Thoracic/Lumbar Angle Combinations

FIGURE 14. Table of possible compensation/decompensation values (-25 mm, -10 mm, 0 mm, 10 mm, 25 mm) for a combination of 30 thoracic/lumbar curve magnitudes with a fixed upper thoracic geometry.

This traditional four-point loading mechanism has an inherent flaw. The translatory force creates a trunk shift to the left of CSL, toward the direction the spinal column, which already displays a tendency to decompensate (32). This may or may not increase decompensation, but it moves the entire column in the area of the curve farther left from center sacral line (CSL) and may resist correction in the orthosis.

FIGURE 17. A: New four-point curve loading system on a right thoracic, left lumbar curve. **B:** On the Milwaukee brace. **C:** On a thoracolumbosacral orthosis (Rosenberger).

We have reported a four-point force system in which the axilla and lumbar points become translatory loads and shift the torso from left to right, against the thoracic pad, thus loading these three points with a resultant overall shift of the spinal column toward CSL (32) (Fig. 17). Because of the greater magnitude of the axilla load, the orthosis tends to become unstable and rotate counterclockwise (away from the axilla), necessitating a stabilizing force at the pelvis *on the same side as the axilla and lumbar loads.* Thus, the axilla counterforce and lumbar pad become *translatory* force (TL), whereas the pelvis and thoracic sling become *constraining* forces (CL), as depicted in Fig. 17A .

This force system has only one synergistic triangulation of force that is on the primary curve only and a stabilizing force on the pelvis. Therefore, the system yields three points of force on the left side and one point on the right. The tendency of the spinal column to move left is countered first, and then the curves are corrected. This method first reduces the tilt of the lowest vertebra in the lumbar curve and then reduces the Cobb magnitude.

Natural History

Originally, the diagnosis of scoliosis was an indication for treatment. Small curves of 15 and 20 degrees, as well as larger curves of up to 60 degrees, were treated without consideration of the degree of skeletal maturity or documented progression. Studies on prevalence and natural history to provide a rationale for treatment were needed.

Lonstein and Carlson (53) provided this needed natural history and showed the relationship of age and curve magnitude to risk of progression. They found that children first seen at the age of 10 years (or younger) with curve magnitude of 5 to 19 degrees had a 45% risk of progression, whereas those with curves between 20 and 29 degrees had a 100% risk. In children 11 to 12 years of age, the risk of progression in the 5- to 19-degree range was 23%, whereas in the 20- to 29-degree range it was 61%. For children 15 years and older, the 5- to 19-degree group reduced to a 4% risk factor and the 20- to 29-degree group reduced to a 16% risk factor.

Fernandez-Feliberti et al. (26) later confirmed these findings. In their study, 33% of the patients aged 13 or younger and with a curve of less that 29 degrees progressed. However, if the curve of these patients was 30 degrees or greater, 66% progressed. Of the children older than 13 years and with a curve of less than 29 degrees, fewer than 10% needed surgery. If the curve of this group was greater than 30 degrees, 14% needed surgery. This is illustrated in Table 1 .

Long-term progression has been studied by Weinstein et al. (82 ,83). With an average follow-up of 40 years, it was found that 68% of the curves had progressed 5 degrees or more. Although some of this progression probably occurred in late adolescence, 37% had progressed in the last 10 years an average of 13 degrees. As in childhood progression, the degree of curve and the degree of progression were linked. The thoracic curves under 30 degrees did not progress, whereas those between 30 and 50 degrees progressed an average of 10 degrees, and curves of 50 to 75 degrees progressed an average of 29 degrees. This study showed that progression was not linear throughout follow-up. Curve progression was greater during the time from skeletal maturity to 30-year follow-up than from 30 to 40 years after diagnosis.

TABLE 1. Risk of Progression[a]

	Curve (Degrees)	
Age	**<30**	**>30**
<13	38%	66%
>13	10%	14%

[a] The prediction of curve progression in untreated idiopathic scoliosis during growth. Based on data presented in Brill PW, Mitty HA, Guall GE (1974): Homocystinuria and Marfan's syndrome *J Bone Joint Surg Br* 54:277–298.

These studies of the nature of curve progression and the relationships of age and curve magnitude lead directly to orthotic treatment indications and expectations.

Indications for Orthotic Treatment

Orthotic treatment is generally indicated for skeletally immature patients with curves between 20 and 40 degrees. There is no indication for treatment of curves under 20 degrees. Orthotic treatment should be started immediately for curves of 20 to 30 degrees if 2 or 3 years of growth remains (i.e., a Risser sign of 0–1 and premenarchal). Those with Risser signs of 2 or 3 with demonstrated progression in this range should also be treated.

Children with curves of 30 to 40 degrees should be treated at the first visit if they have growth remaining. A more mature adolescent with a Risser sign of 4 or 5 and who is 1.5 years post menarche should not need treatment.

There is no convincing evidence that the type of orthosis is critical as long as it is designed for the specific curve problem and corrects the curve in the brace. For optimal results in avoiding surgery, the larger curves must be reduced by at least 50% in the orthosis and maintained throughout the duration of wear (51). With the newer designs, this threshold can and should be reached for all patients.

We believe that the treatment course for all but the Charleston bending brace should be full time until growth is completed followed by a gradual weaning period. Green (37) reported that part-time orthotic treatment can yield good results and that the protocol of full-time treatment is not necessary. However, Edmonsson and Morris (22) found that patients who were not compliant with full-time wearing did not do as well as the full-time wearers. The difference was 25% correction for the full-time wearers and only 14% for the partially compliant. In the meta-analysis to be discussed below, 8 and 16 hours of wearing time were not as effective as full-time protocols. The weight of the evidence is on the side of full-time wearing until growth is completed.

The Charleston bending brace (Fig. 18A) can only be used at night. The principle is demonstrated in Figure 18B and C . Acceptable results have been reported using this orthosis (75). However, it must be noted that in the meta-analysis (76) reported below and in a comparison with the Boston brace (44), the Charleston brace did not give as good a result as others. Because it is only worn at night, the effect of part-time treatment cannot be definitively separated from the effect of brace type.

Studies of Results

Many studies have been carried out to investigate clinical outcome of patients with idiopathic scoliosis treated in the Milwaukee brace (12 ,17 ,22 ,46 ,51 ,56 ,57). However, many of these studies included patients that would not be considered for treatment today because of small curve magnitude, stage of maturity, or lack of documented progression. These inadequacies have been largely overcome in two large-scale studies of patients treated with a Milwaukee brace and one prospective study.

The first is the report by Lonstein and Winter (51) in which 1,020 patients with adolescent idiopathic scoliosis were treated with the Milwaukee brace between 1954 and 1979. Average follow-up was 6.2 years, with all greater than 2 years. Failure was defined as the need for surgery. Overall, 22% of the patients required surgery.

Curve Pattern

Persons with single right thoracic curves needed surgery only 19% of the time. Approximately 27% of patients with lumbar, thoracolumbar, or double thoracic curves required surgery.

Curve Magnitude

Six percent of patients with curves under 19 degrees needed surgery. In the 20- to 29-degree range, 7% required surgery. For curves of 30 to 39 degrees, the rate of surgery increased to 23%; for 40 to 49 degrees, 33%; and for curves greater than 60 degrees at the start of orthotic treatment, 84% of patients required surgery. This trend was constant for all curve patterns (Fig. 19).

Maturity of the Patient

The surgery rate on patients who initiated treatment at Risser 0–1 with curves of 20 to 29 degrees was 32% and for curves 30 to 39 degrees 45%. Both of these were below natural history predictions of 68% for curves over 20 degrees and Risser sign 0–1. For more mature patients with a Risser sign of 2, the comparative figures were 12% and 18%, respectively. This study showed that the incidence of surgery was lower for the more mature patient and that orthotic treatment affects the natural history of progression.

There were two findings that are important in the thinking about treatment course. First, the average time in brace was 3 years 10 months. Good results are not possible when the orthosis wear is terminated after correction is achieved but growth is incomplete. Second, all patients lost a few degrees of correction when the brace was discontinued. This implies that the best possible correction should be obtained and maintained during treatment.

The second large-scale study is a meta-analysis by Rowe et al. (76). Meta-analysis is a statistical method of pooling and analyzing data from a number of reports. Its purpose is to increase the statistical power and resolve uncertainty when the results disagree. There are several objections that can be raised to the use of meta-analysis but none apply to this paper. The application of this technique to scoliosis was long overdue (6).

The report included 1,910 patients from 22 different studies of whom 1,459 had been treated with an orthosis. (The Lonstein and Winter study was not included in this meta-analysis, so that there is no overlap between the two reports.) The authors of this study found that the use of an orthosis, particularly the Milwaukee brace, for 23 hours per day effectively halted progression of the curve. Treatment programs for 8 or 16 hours a day were significantly less effective. Electrical stimulation was completely ineffective.

Although these two papers have large numbers and convincing results, neither is a prospective controlled study. The Scoliosis Research Society, under the leadership of Alf Nachemson, designed such a study (60). This could not be randomized for a number of practical reasons but consisted of each center treating the patient as they believed best. Patients were treated with observation only (129 patients), bracing (111 patients), and electrical stimulation (46 patients). There was a 74% success rate for those treated with an orthosis; observation only and electrical stimulation had only a 33% success rate. Criteria for inclusion and for failure were standardized across all treatment centers.

There are few large long-term studies involving patients treated with TLSOs. However, many reports suggest that excellent results can be obtained. Emans (23) reported on 295 patients with idiopathic scoliosis treated with the Boston brace. Of the patients treated with curves 30 to 40 degrees, only 16% required surgery by the time of follow-up, whereas for curves greater than 40 degrees, 32% required surgery. McCollough et al. (55) reported results of a study on 100 patients treated with the Miami orthosis in which 6% of patients required surgery at the time of follow-up. Allington and Bowen (1) showed the surgery rate on a series of patients treated with the Wilmington jacket also to be 6%.

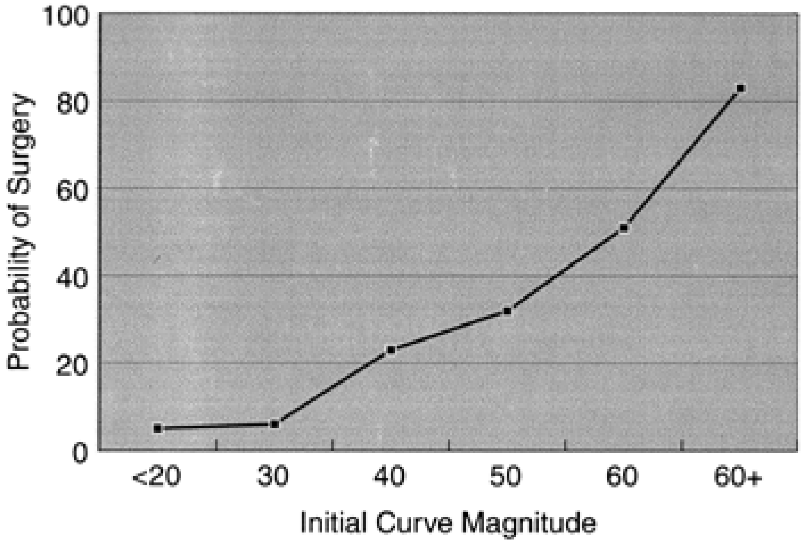

FIGURE 19. Orthotic failure

The authors are confident that these studies have convincingly demonstrated the value of orthotic treatment for scoliosis. However, doubters remain (68 ,78). In some cases the problem has been the lack of correction obtained in the orthosis. If the curve is not corrected in the orthosis, good results cannot be expected.

Some who are opposed to orthotic treatment suggest that psychological damage is a significant risk. Although there are some suggestions of this in the literature, the broad stream of reports from the 1970s (86) to the most recent (67) have indicated that psychological effects, if any, are usually mild and transient.

Idiopathic Scoliosis

The **Milwaukee Brace**

Contemporary nonoperative treatment of idiopathic scoliosis originated with Blount and Moe (8) in the 1950s. They designed a device fabricated from steel and leather extending from the pelvis to the mandible and occiput (to provide longitudinal distraction) along with a lateral pad against the most displaced ribs on the convex side of the deformity (to control scoliosis in children without resorting to surgery). In its present form, the neck ring does not provide distraction and the superstructure of the Milwaukee brace is a structure to which lateral pads are attached. The neck ring provides resistance to the sway of the vertebral column and functions as a mechanical “pin,” keeping the upper thoracic spine constrained over the sacrum (34). Thermoplastics are used for the pelvic interface, replacing leather and steel in an effort to reduce weight and improve hygiene (Fig. 20).

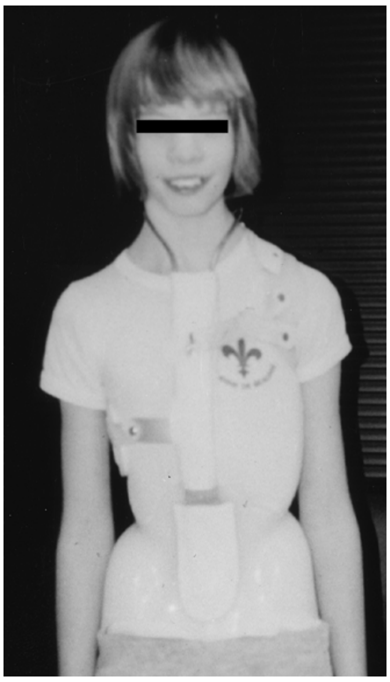

FIGURE 20. Current Milwaukee brace.

The TLSO

Low-profile or underarm-type orthoses, more commonly known as TLSOs, are not a modern concept. Crude underarm trunk supports fashioned from tree bark were found in the cave dwellings of pre-Columbian Indians (2). Modern TLSO usage for the nonoperative treatment of scoliosis began with the Boston brace (Fig. 21). The concept began as a method of treating curves with apices at and caudad to T10 with the pelvic aspect of a CTLSO, thus eliminating the superstructure (39). The Boston brace has evolved into a system of prefabricated TLSO modules, custom-fitted for specific patient needs, and is currently used to treat all curves with apices as cephalad as T8. It is the most widely known TLSO for scoliosis treatment.

Unlike the Milwaukee brace, which is still the only CTLSO for treatment of spinal deformity, several different TLSOs have been developed throughout the 1970s and 1980s. The Lyon orthosis was developed in France with modifications used in the United States (Fig. 22). The Lyon was developed for the treatment of more caudal lumbar and thoracolumbar curves (16). The Miami orthosis (55) is an orthosis similar to the Boston brace in many regards, including usage parameters with variations in trim line, and is custom-molded. The Wilmington orthosis (15) (Fig. 23) is a custom-molded TLSO fabricated from a Risser frame plaster impression taken in curve correction. The Rosenberger orthosis (35) (Fig. 24) is a custom-molded TLSO fabricated from a plaster impression taken with curvature correction and uses a Dacron thoracic sling to load thoracic curves.

Description of Thoracolumbosacral Orthoses

The Boston brace is a one-piece, posterior-opening TLSO fabricated from polypropylene that extends anteriorly from the xyphoid process to the symphysis pubis, with posterior and lateral trim lines varied for each curve pattern. This orthosis is modular and does not require a plaster impression. However, it must be custom-fitted for individual size and curve pattern. On the convex side of the curve, the Boston brace is trimmed one level superior to the apex of the curve to provide a wall to function as a thoracic or lumbar pad mount. On the concave side of the curve, an opening is cut opposite the pad to allow an open area for the concave side trunk shift on the level of the primary curve. Above the cutout a band of plastic is left intact to provide concave side superior end-point counterforce to function in the same manner as the axillary sling of the Milwaukee brace (Fig. 20).

The Lyon Orthosis

The Lyon orthosis is a one-piece, anterior-opening orthosis custom-fabricated from a plaster impression and fashioned from polypropylene. This orthosis extends anteriorly from the sternal notch to the symphysis pubis and has lateral trim lines, openings, and counterforce parameters that function similar to the Boston brace. Original fabrication utilized two lateral shells of custom-molded plastic joined posteriorly by a longitudinal aluminum bar, and steel hinges allowing for function as an anterior-opening orthosis. Recent modifications have changed this to a one-piece molded, with a posterior seam used for hinge function, which eliminates the metal structure and lightens the orthosis as seen in Figure 21 .

The Miami Orthosis

The Miami orthosis is a one-piece, posterior-opening polypropylene TLSO, custom-molded from a plaster impression. This orthosis has many of the advantages of the Boston brace, yet, unlike the Boston brace, is custom-molded and trimmed short enough to allow forward bending of the patient. Lateral trim line heights and concave side cutout areas for trunk shift are similar to the Boston and Lyon orthoses, as they are all varied according to curve pattern.

The Wilmington Jacket

The Wilmington jacket is unique in that it is casted molding the plaster impression from the Risser frame. This impression is designed to be similar to the localizer cast, as the curves are to be reduced and analyzed by radiograph before proceeding with fabrication. This orthosis was originally designed to be molded with a low-temperature orthoplast. However, many have adopted the high-temperature, vacuum-formed, low-density polyethylene, as shown in Figure 22 , as it will provide greater longevity without material degradation. This is a one-piece, anterior-opening orthosis with anterior trim line from symphysis pubis to sternal notch and bilateral heights to axilla. It does not have concave side cutouts, varied trim lines, or wall-mounted pads, as all loads, counterforces, and concave side area for trunk shift are fabricated into the orthosis.

The Rosenberger Orthosis

The Rosenberger orthosis is a custom-molded, low-density polyethylene, anterior-opening TLSO. It is fabricated from a bivalved plaster impression made on an examination table with corrective forces done in the impression. Although the impression is bivalved and does not require a Risser frame, the procedure is similar to that for the Wilmington jacket. This orthosis extends anteriorly from the pubis to the xyphoid process. The convex side trim line is one rib level superior to the apical height, similar to the Boston or Miami orthosis. However, the concave side is similar to the Wilmington jacket in that there is no cutout for trunk shift because the shift is built into the orthosis. The concave side trim line terminates at the superior end point of the superior curve being treated. This orthosis is unique in that it uses adjustable floating slings for curve loading, as is seen in Figure 23 , so that loading can exceed what is achieved by the corrected walls of the orthosis.

The Charleston Orthosis

The Charleston orthosis is unique in that it is prescribed for sleeping hours only. It is a custom-molded, one-piece, anterior-opening TLSO fabricated in a maximal side-bending position to “unbend” the primary curve. This concept is important because it is based on the concept of overcorrection during sleep. Because side bending decompensates the spine, this orthosis is not recommended for standing. Trunk shift is allowed for in the walls of the orthosis similar to the Rosenberger orthosis, and the side-bending correction is built into the orthosis walls similar to the Wilmington orthosis (Fig. 17A).

Neuromuscular Scoliosis

Orthotic treatment for neuromuscular scoliosis has traditionally been a treatment method to delay spinal fusion. Because of the pelvic obliquity and decompensation from neuromuscular scoliosis common to the nonambulatory child, seating balance is a major concern. A properly fitted orthosis will also assist this type of patient with seating balance to reduce fatigue and allow for longer periods of upper limb function. Custom-molded seating orthoses attached to the wheelchair are presently state of the art for this condition. However, these devices frequently do not incorporate continuous circumferential support and may not provide optimal function for curve reduction and maintenance of curves post reduction.

We have developed an orthotic approach to the correction of neuromuscular spinal deformity for the long *C*-shaped curves that eliminates the usage of three-point corrective forces. This replaces the three-point approach to curve correction with lateral bending toward the convexity of the curve. The primary focus of this “illiotibial band stretching” mechanism of action is to lengthen the pelvic origin and spinal insertion points of the psoas major muscle. This is coupled with a derotation force at the apex of the curve to lessen the rotational deformity. The result is greater correction of spinal deformity, resistance of deformity progression, and seating balance in the orthosis (31) (Fig. 25).

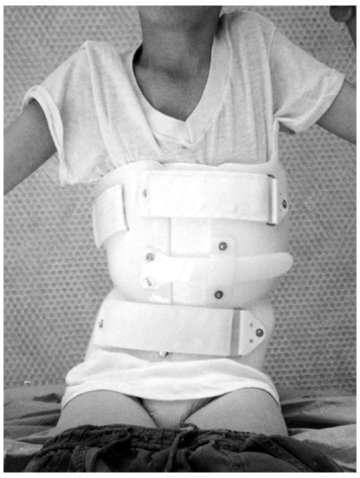

FIGURE 25. Thoracolumbosacral orthosis for neuromuscular scoliosis.

The ambulatory neuromuscular patient who frequently presents with compensatory curves benefits from the adjustability of three-point orthoses for idiopathic scoliosis, as described earlier in this chapter. Decision making for these patients must be based on primary orthotic goals. If seating stability is primary, then the patient will benefit from custom-molded seating. If, however, curve reduction and delay of fusion is primary, then the TLSO will yield the optimal result (31).

Although Bunch (13) successfully used the Milwaukee brace for paralytic scoliosis, current state of the art for the neuromuscular patient is the custom-molded, total-contact TLSO. Although some are pessimistic about the use of orthoses for neuromuscular scoliosis, the purpose of orthotic treatment is to reduce and maintain the curve until the patient is mature enough for fusion. Even though current treatment protocols call for operating on these patients at a younger age, many neuromuscular patients are either juvenile or infantile at the onset of progressive curvature and will benefit from the use of an orthosis (40). This will allow for trunk growth, which is important because the organs of the thorax and abdomen will continue to grow even if the spine does not.

Congenital Scoliosis

The patient with congenital scoliosis challenges the orthotic creativity of the clinical team. Goals for orthotic treatment of congenital scoliosis are to reduce compensatory curves and to maintain a compensated alignment of the spine during growth. Changing the segmental angulation of the congenital anomaly is not possible using orthoses; any attempt will lead to discomfort and skin breakdown.

The decision for proper choice of orthosis should include clinical requirements as well as mechanism of action. As most of these patients begin treatment at an early age and usually require surgery during the clinical course, they will require several orthoses during treatment. For families with financial difficulties the Milwaukee brace is the orthosis of choice because it is the only orthosis that has longitudinal adjustability, allows for partial refabrication, and is easily converted for postoperative use (34). The TLSO is the orthosis of choice for reasons of cosmesis.

Reduction or control of compensatory curves, compensation of the spine, and correction of any secondary deformity are the goals of orthotic treatment for the congenital patient.

Kyphosis

The sagittal plane deformity of kyphosis has many causes, such as Scheuermann disease, postural round back, neuromuscular disorders, and congenital dysplasia. The most common form to be treated with an orthosis is Scheuermann kyphosis, which manifests radiographically as anterior wedging of several consecutive vertebrae. The orthosis of choice is the Milwaukee brace because the apices of these curves are usually more cephalad than a TLSO can control. The pelvic interface and neck ring provides constraints in space that yield the counterforce to the kyphosis pads (Fig. 26). These pads are usually rectangular and are placed at and inferior to the apex of the curve, mounted on the paraspinal bars. They produce an anteriorly directed force that reduces the curvature, thus opening the wedges and allowing bony remodeling.

As the nature of kyphosis is two-dimensional in comparison with the three-dimensional aspects of scoliosis, reduction of these curves is usually an easy task. Early in the treatment course there is a tendency on the part of the patient to lean on the throat mold because of the force generated by the kyphosis pads. Physical therapy plays a role in teaching these patients thoracic hyperextension exercises so that they can retract from the neck ring, thus providing an active counterforce to the kyphosis pads (33).

For the more caudal thoracic and thoracolumbar curves, a TLSO may gain the desired result because the apex is low and the sternum is cephalad enough to be used as a counterforce without being in opposition to the kyphosis pads (52).

The goal when treating Scheuermann kyphosis is bony remodeling of the wedged vertebrae and overall reduction of the curvature. Sachs et al. (77) reviewed 75 patients who had completed an average of 34 months in the Milwaukee brace and had vertebral wedging corrected to a mean of 5 degrees. At long-term follow-up, there was an average of only 6 degrees loss of overall correction. In contrast, Montgomery and Erwin (58) reported poor results for a group of patients who were weaned from orthoses 4 to 6 months after overall correction of the kyphosis. They showed a 15-degree average loss of correction at follow-up. Because bony remodeling is the goal of orthotic treatment, weaning from the orthosis is recommended only after measurable changes have occurred in the vertebral wedging. Once again, proper follow-up for growth adjustment and increases in pad pressure along with adherence to sound clinical parameters of treatment yield the best possible result.

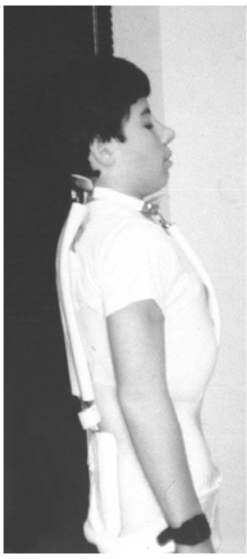

FIGURE 26. The Milwaukee brace for kyphosis.

Spinal Injury

Thoracolumbar Injuries

To classify acute thoracolumbar fractures, Denis (20) proposed that the spine is composed of three load-bearing columns. The anterior longitudinal ligament, anterior annulus fibrosis, and anterior part of the vertebral body form the anterior column. The posterior longitudinal ligament, posterior annulus fibrosis, and posterior wall of the vertebral body form the middle column. The posterior arch, supraspinous ligament, interspinous ligament, capsule, and ligamentum flavum form the posterior column. Compression fracture involves failure of the anterior column, with the middle column being totally intact. The burst fracture involves failure of both the anterior and middle columns. Seat belt-type injuries represent failure of the middle and posterior columns. Finally, the fracture dislocation injury represents failure of all three columns.

The stability of the injured spine, measured by its ability to withstand loads without causing the progression of a deformity at the injury site, is a primary biomechanical concern in the treatment of thoracolumbar injuries. The stability of a segment defined by its load displacement behavior is affected by an injury, and the extent of such effect is a function of the type of injury, that is, the anatomical components disrupted by the injury and the severity of the damage.

The axial load carrying capacity of the thoracolumbar spine as a function of injury to the three columns of the spine was studied by Haher et al. (38). Disruption of the anterior column reduced the load carrying capacity (LCC) of the spine by 20%. The reduction in the LCC of the spine was 80%, with disruption of both the anterior and middle columns of the spine. Disruption of the posterior column reduced the LCC by 35%, whereas the reduction in LCC was 60% with disruption of both the posterior and the middle columns. Ferguson et al. (25) found that a two-column injury involving disruption of the anterior and posterior columns caused a 78% loss in flexion stiffness of the T11–L1 segment as compared with the intact value. Thus, disruption of two of the three load-bearing columns led to substantial instability, whereas the three-column injury rendered the segment completely unstable.

Slosar et al. (79) investigated the three-dimensional instability patterns of L1 burst fractures. Analysis of the burst fracture in flexion and lateral bending showed stiffness losses of 71% and 75%, respectively, at low-moment load (up to 3 Nm) applications. Subsequent loss of stiffness through higher moment loads (3 to 10 Nm) showed only a 5% stiffness change in flexion and 25% stiffness loss in lateral bending when comparing intact with burst fracture. Postinjury stiffness losses for rotation were 92% and 67% for low-moment load and high-moment load applications. After the burst fracture, loss of stiffness was much larger at low-moment loads than the subsequent loss of stiffness at high-moment loads.

It may be postulated that the initial instability represents a structural collapse through the fracture itself. Once the collapse is complete, the apposition of the involved cortices limits further significant displacement. With the fracture now maximally collapsed and cortices apposed, the behavior of the injured spine is similar to that of the intact spine. The severe loss of stiffness found through both the low- and high-moment load applications in rotation may indicate that to the unprotected injured spine, rotation is potentially the most destabilizing motion. The authors also determined that posterior column involvement in the form of an isolated lamina fracture did not alter the behavior of a two-column (anterior plus middle) burst fracture. Burst fractures with extensive third-column injuries in the form of facet joint disruptions or bilateral lamina fractures were less stable than two-column injuries.

Biomechanics of Orthoses for Spinal Injuries

Orthoses for spinal injury are designed to protect the spinal column from loads and stresses that cause progression of the angular and translational deformity from the injury (71 ,84). Orthoses for thoracolumbar injuries have two primary classifications: nonoperative and postoperative. Although there is no agreement on the mechanisms of action, orthoses primarily function to provide biomechanical stability.

Nonoperative Treatment

Mild injuries, such as those that affect only a single level and a single column and are at low risk of progression, require minimally immobilizing orthoses. The more severe two-level and two-column injuries that have only marginal stability but do not require surgery need orthoses that offer maximal stabilization and resistance to further progression of the deformity.

The primary mechanism of action is that of limiting gross trunk motion. Gross trunk motion is the movement and sway of the vertebral column during activities of normal daily living. Orthoses that primarily restrict gross trunk motion provide protection to the vertebral column by minimizing bending moments. Buchalter et al. (10) and Lantz and Schultz (49) studied the effectiveness of spinal orthoses in limiting gross trunk motion in flexion-extension, lateral bending, and axial rotation. The TLSO resulted in the most motion restriction in all three planes, whereas the corset provided the least restriction of gross upper body movement.

Another mechanism of orthotic stabilization is the reduction of intersegmental motion. Orthoses that reduce intersegmental motion may be assumed to also reduce gross motion. Many investigators (27 ,54 ,65 ,69) have studied the effect of orthoses in segmental immobilization. The three-point hyperextension orthosis was fair in limiting flexion-extension motion but had little effect on the motion in lateral bending or axial rotation. The Taylor-Knight orthosis was effective in lateral bending, fair in flexion-extension, but had little effect on limiting axial rotation. The body cast performed satisfactorily in limiting motion in all three modes. In general, the orthoses were more effective in reducing motion at the upper lumbar levels than at lower levels. The canvas corset was found to reduce the segmental motion by one third. The Raney jacket and the Baycast spica reduced the segmental motion by about two thirds at the midlumbar levels, and the Baycast spica was the only orthosis that was effective in limiting motion at the lower lumbar levels.

The effects of gross motion limitation on the spine are assumed to affect all vertebrae equally. However, the studies of orthoses for reducing intersegmental motion show that the effect of motion reduction is nonlinear and affects different motion segments differently. Orthoses are less effective in reducing intersegmental motion the more caudal the motion segment is in the lumbar spine.

The third mechanism, limited to the nonoperative treatment, is “three-point” sagittal plane hyperextension. This mechanism was first reported by Chance in 1948 (18). Patwardhan et al. (73) used a finite element model to investigate the effect of the Jewett hyperextension orthosis on single- and two-level injuries. They reported that for single-level injuries that cause up to 50% loss of segmental stiffness, the Jewett orthosis can restore stability under normal gravitational as well as large flexion loads. In severe two-level injuries with loss of stiffness between 50% and 85% of normal, the orthosis can restore stability with restricted patient activity level in the brace. Beyond 85% loss in segmental stiffness, such as three-column injuries, the orthosis alone appears to be ineffective in preventing progression of deformity.

The effects of orthoses on trunk myoelectric activity, abdominal cavity pressures, and intradiscal pressures have also been investigated, but results have been inconsistent (36 ,47 ,50 ,64 ,62 ,81).

The nonoperative treatment of single- and two-column injuries must encompass the known mechanisms of action: three-point hyperextension, gross motion reduction, and intersegmental motion reduction. There is some speculation as to the possibility of load sharing as a viable mechanism of action for some spinal orthoses. This may be unique to molded TLSOs in three-point hyperextension as they increase the Cobb angle of lumbar lordosis as well as increase the height of many patients. If load sharing is a reality with these orthoses, this could indeed be the most significant mechanism of action. Further investigation is necessary to prove this theory.

The state of the art in nonoperative management of spinal injuries is the custom-molded TLSO. Figure 27A depicts a girl with a Chance-type flexion distraction injury. Figure 27B shows the patient in her first orthosis (custom-molded, bivalved TLSO in hyperextension) with only a minimal change in the segmental angle at the fracture. Figure 27C shows the patient after 10 days of gradual hyperextension in her first TLSO with the addition of hyperextension pads upon being refitted into a new TLSO in even more hyperextension. Note the decrease in segmental angle after gradual hyperextension over time. Figure 27D was taken nearly 4 months later when the patient was being weaned from the orthosis.

Postoperative Orthoses

The goal of orthotic stabilization of a thoracolumbar injury that has been surgically reduced and instrumented is to protect the surgical construct from large loads created from torso motion until solid biologic fusion occurs. Nachemson and Elfstrom (63) studied the effect of the Milwaukee brace and body cast on the loads acting on spinal instrumentation in patients with idiopathic scoliosis. Both the Milwaukee brace and the body cast reduced the axial force in the Harrington rod during standing and walking. There exist no objective data regarding reduction of stresses that an orthosis may provide for other, more modern implants.

A postoperative orthosis should protect the surgical construct from the planes of motion in which the construct is vulnerable to failure. For most surgical constructs, these motions are *flexion* and *torsion.* The Harrington distraction rod can carry the axial load in the physiologic range. However, it is vulnerable to forward flexion and rotation. Postoperative orthoses that restrict these motions will minimize the chances of hook dislodgement or fracture. Segmental fixation of the Harrington rods using wires improves the failure strength and rigidity of the construct in flexion and rotation because segmental fixation distributes the load over multiple fixation points. The Luque system benefits from this principle, but it is notably weak in axial loading. The Cotrel-Dubousset system combines the axial load carrying ability of the Harrington rods with improved torsional rigidity of segmental fixation.

The fixation devices utilizing intrapeduncular screw fixation to the spine result in the most stable construct in all modes of loading and therefore can potentially stabilize injury to all three load-bearing columns. The improved rigidity of these constructs is derived from the fixation of screws in the pedicles, which provides a greater control on the three-dimensional motion of the vertebral body. However, it should be noted that both the strength and rigidity of these constructs would be adversely affected by a loss of bone mineral density such as in osteoporotic bone.

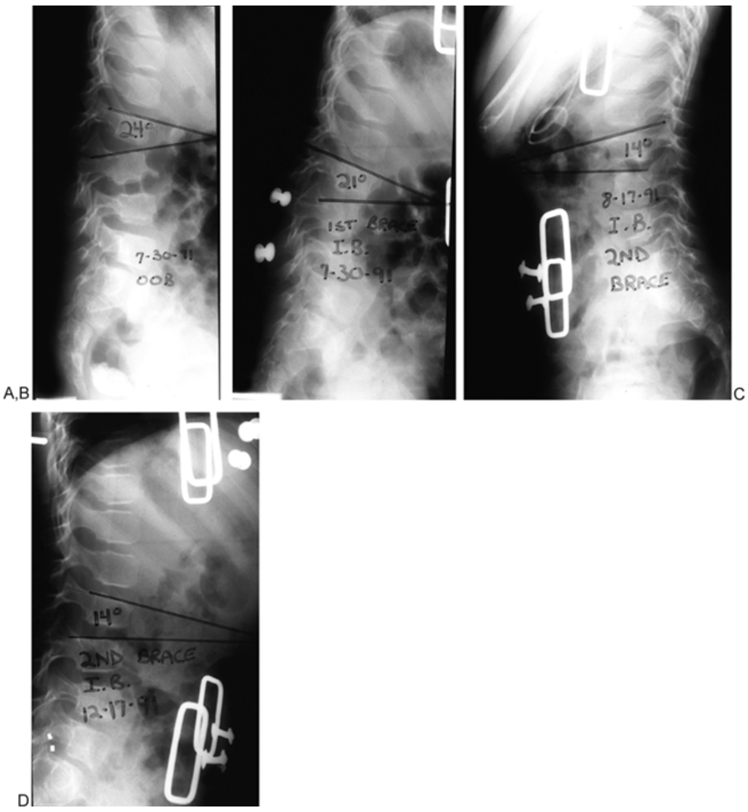

FIGURE 27. Orthotic treatment of chance fracture. **A:** Preorthosis radiograph of a girl with a Chance fracture. **B:** With the patient in her first thoracolumbosacral brace, the reduction of the segmental angle was only to 21 degrees despite hyperextension fabricated into the orthosis. **C:** After a gradual increase in extension and refabrication of orthosis, reduction was to 14 degrees. **D:** After 4 months in the orthosis, the patient maintained 14-degree angulation. (From Patwardhan AG, Gavin TM, Slosar P, et al. (1993): Biomechanics of implants and orthoses for thoracolumbar injuries. In: Lorenz MA, Akbarnia B, eds. *Spine: state of the art reviews*, Vol. 7. Philadelphia: Hanley and Belfus, pp. 261–280.)

The role of a postoperative orthosis is to protect the implant from undue loads during the process of fusion. The segmental motion limiting requirements of a postoperative orthosis are not as stringent as in the case of nonoperative treatment because the orthosis is only being used as an adjunct to protect the implant from loads, moments, and stresses.

A postoperative TLSO should have enough anterior height to resist forward bending at the sternum. However, care must be taken that it does not induce hyperextension, as this will additionally stress the implant.

When spinal fusion is performed across the lumbosacral joint, a thigh extension must be applied to the TLSO to reduce lumbosacral motion in the orthosis. A TLSO without thigh extension has been shown either to have no effect or to actually increase lumbosacral motion (54 ,69). Despite patient preferences, an orthosis must not interfere with the surgical construct.

Cervical Orthoses

Much of the motion of the upper spine is determined by the structure of the anatomy. An example is the rotation that occurs at the C1 and C2 level. White and Panjabi (84) state that the occipitoatlantoaxial complex is the most complicated series of articulations in the human body. They further state that it supports the head, allows for necessary motion of the head on the spine, and protects the spinal cord from damage. In summary, there is little or no axial rotation at the occipito-C1 joint, but much that occurs is at the C1–2 joint.

Pure flexion of the cervical spine occurs at many levels. It is generally thought that the greatest amount of flexion-extension occurs at C5–6, followed by C4–5 and C6–7. Few studies of cervical spine orthoses for the pediatric patient exist. There are only a small number of studies dealing with cervical orthoses in adults and these are reviewed here.

Nachemson (61) draws a distinction between two groups of cervical orthoses: the cervical orthosis, dealing with C1 and C2; and the cervicothoracic orthosis, dealing with C3–T1. Nachemson classifies cervical orthotics as soft, reinforced, and rigid. Most of these orthoses are prefabricated and are available in pediatric sizes.

A foam collar is an example of a soft collar. It is usually encased in a knitted material and closes in back using velcro. These collars provide very little support or control and are usually used for the mildest of conditions. Beavis (7) measured a 39% reduction in cervical flexion using a soft collar. Beavis also measured a warming effect from the collar, but it was no more than a plain wool scarf.

The Philadelphia collar is the best known example of a reinforced collar. It is made of plastazote reinforced with plastic anteriorly and posteriorly. It is available in 12 sizes, depending on the neck measurement and the distance between the chin and chest. The greater the distance, the more cervical extension given. The pediatric collar has a tracheotomy opening, which allows room for respiratory apparatus if necessary.

Beavis (7) measured a 73% reduction in flexion and a 58% reduction in extension compared to no collar. Lateral flexion was reduced by 35% and rotation reduced by 63%. Interestingly, the study concluded that the custom-fitted plastazote collars were more comfortable to wear, an important concern given the high rejection rate of patients wearing collars. Kaufman et al. (45) found that the plastazote collar immobilized better than the foam but did not control axial rotation as well.

Fisher (28) reported that because most patients loosen the cervical orthoses from the initial adjustment, the effectiveness of the orthosis is much diminished. This report suggests that there is an important fitting component as well as a compliance factor if the orthoses are to be worn effectively.

Most cervical orthoses used for long-term stability rely on fixation on the mandible and therefore cause problems in eating or opening the mouth. One that does not is the frontooccipitozygomatic orthosis (FOZY) (Fig. 28). Developed in Japan, it uses pressure on the frontal bones of the face and leaves the mandible free to move. It purportedly controls all motions of the cervical spine, including rotation. The connecting parts of the orthosis are made of aluminum and thus can be adjusted as the need arises. It weighs only 1 lb (66).

Lango et al. (48) reported success using a custom-fabricated low-temperature plastic orthosis in the treatment of the congenital torticollis patient. It was formed directly on the patient and in the opposite directions of the deformity. By incorporating a thoracic component, the necessary forces were developed from the thorax to control the head.

A second example of the reinforced type of orthosis is the sternooccipitomandibular orthosis (SOMI) (Fig. 29). The SOMI consists of three components: the sternal yoke, the occipital component, and the mandibular component. These are easily fitted and available in pediatric sizes. Johnson reported a mean percentage of normal flexion-extension restriction of 32% to 61% per level from C1–2 to C7–T1. It remains the orthosis of choice in levels C4 and above, where flexion control is critical.

Below C4, the orthosis of choice is a cervicothoracic orthosis (Fig. 30) when the extra lever is needed (41 ,42).

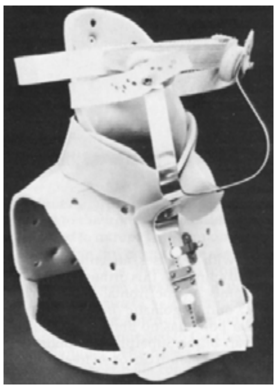

FIGURE 28. Frontooccipitozygomatic orthosis.

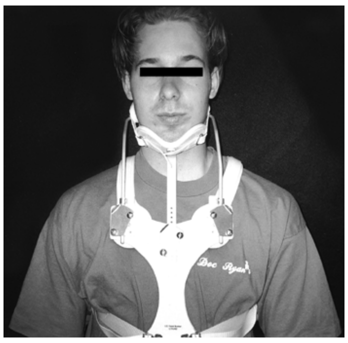

FIGURE 29. Sternooccipitomandibular orthosis.

Evans and Bethem (24) reported on 24 cases of pediatric cervical spine injuries and their treatment. They concluded that the injury is very rare (only 1.2 cases per year), but that these injuries frequently have many other associated injuries and the patients are often treated nonoperatively. Nonoperative treatment was successful 95% of the time, with 14% developing late kyphosis. Since C1 or C2 was involved only 29% of the time, there were many Minerva-type orthotic fittings (Fig. 31). Flexion injuries were recommended for surgical fixation, with postoperative use of orthoses.

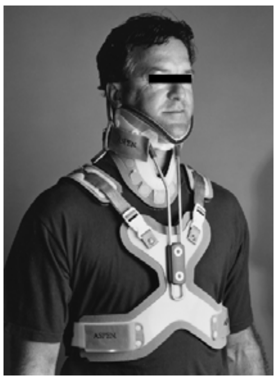

FIGURE 30. Cervicothoracic orthosis. (Photograph courtesy of International Healthcare Devices.)

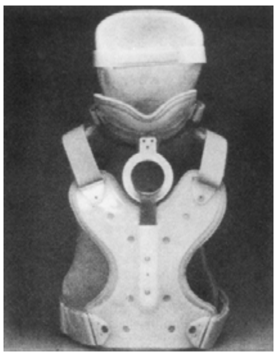

FIGURE 31. Minerva orthosis.

Ducker (21) reported on motion allowed using five collars, including the Miami J. Results indicated that the Miami J collar restrained all but 15% of flexion, 25% of extension, 37% of lateral flexion, and 24% of rotation.

Askins and Eismont (5) compared motion restriction in several prefabricated cervical orthoses and determined that the NecLoc and Miami J collars restricted motion better than the other collars tested.

International Healthcare Devices manufactures a pediatric version of their Aspen collar (Fig. 32). This collar is not a scaled down version of an adult collar but rather is designed to fit the different occipital and mandibular shape of the pediatric patient. Most of the other pediatric collars available are shaped much like a small version of an adult collar and do not conform well to the pediatric mandible. This makes immobilization unreliable and creates discomfort in wearing. Many of the newer collars, such as the Aspen, also are made from materials that keep moisture on the skin to a minimum.

An example of a rigid orthosis is the halo (Fig. 33). This provides the best control and support of any cervical orthosis and comes in pediatric sizes. However, often a vest must be customized for a small patient or for one of nonstandard size or shape. White and Panjabi (85) refer to the “low stiff viscoelastic transmitter” when describing the medium between the orthosis and the skeletal structures of the spine.

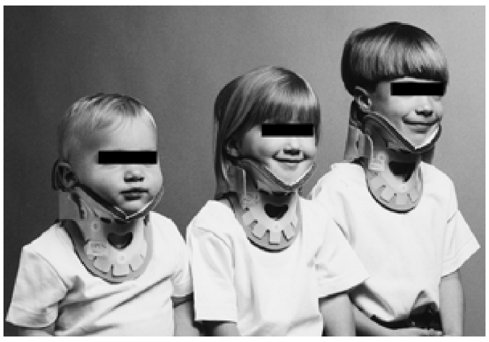

FIGURE 32. Pediatric cervical collars (Aspen). (Photograph courtesy of International Healthcare Devices.)

Two inherent flaws in the testing methodology are that the amount of exertion against these collars was not measured and controlled and that some prehospitalization collars that are considered too uncomfortable to wear long term were compared with the more comfortable long-term collars. More reliable testing parameters and better controls for cervical orthoses are needed to ascertain which collars and related devices have greatest efficacy.

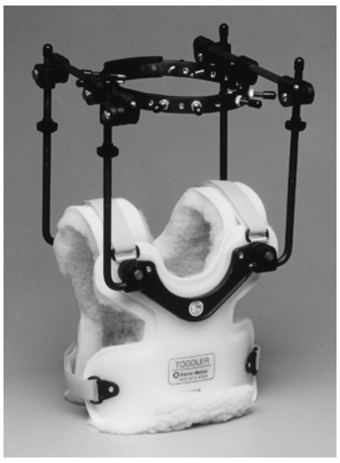

FIGURE 33. Ambulatory halo orthosis.

Custom-Molded Cervical Orthoses

As a result of the problems associated with adaptability, deformity control, and patient tolerance, Jurgutis et al. (43) described a custom-designed multiadjustable cervical orthosis. Used for the treatment of torticollis, the posterior device of a thoracic and cranial component is connected with ball-jointed steel rods, allowing adaptability and contouring. Like the FOZY, this orthosis draws purchase on the frontal bones of the face to control and derotate, as well as maintains the position of the head and neck.

Clinical Team Approach

Whereas spinal orthoses are considered to be an off-the-shelf product by some, when used properly they are much more than that. Without careful attention to detail in the design, fitting, and follow-up of spinal orthoses, the results can be disastrous. To maximize the benefit of a spinal orthosis, a well-trained spinal orthotist must communicate with the physician, the patient, the patient support group, and other health care professionals. In the current era, when large clinics with a multitude of health care specialists in attendance are becoming increasingly rare, communication among health care professionals has become more difficult. If the physician is not clear in communicating the desired mechanism of action to the orthotist, the likelihood of achieving maximal result with the least amount of orthosis decreases.

The last decade has seen a sharp decrease in the level of spinal orthotic training of physicians. Therefore, greater reliance on the knowledge and skill of the orthotist has resulted. All too often an orthosis is ordered based on nomenclature or acronym and not on mechanism of action; this frequently results in a breakdown of the clinical treatment. Also, because the increasingly limited knowledge about orthotic treatment on the part of physicians limits orthosis usage to diagnoses commonly treated with orthoses, patients with more sophisticated needs are overlooked for this treatment modality.

The increasing number of poorly trained or untrained individuals attempting to provide orthotic treatment has compounded this problem. The attitude of “if it can't be fitted off the shelf, it can't be fitted” does great disservice to patients who require a customized approach to maximize the effect of the orthosis. However, many such providers do not have the training or access to utilize the laboratory bench science of orthotics and are self-limited to the off-the-shelf modality. Also, as the manufacturing of spinal orthoses is unregulated, the off-the-shelf approach to orthotic treatment leads to a “one size fits all” attitude, which may result in poor in-brace curve reduction for scoliosis, fractures that require hyperextension being fitted in flexion, and cervical orthoses that do not immobilize properly.

The best orthosis is well fitted and delivers the desired mechanism of action to achieve an optimal treatment result with the least amount of structure, the most comfort possible, and at the lowest cost. Any deviation from this is suboptimal and may lead to failure to reach the treatment objective. The physician needs more than a cursory knowledge of spinal orthotics to be successful with their use. Also, the orthotist needs advanced training in the area of spine and must have the experience and laboratory access necessary to custom-fabricate orthoses. The clinical team approach is still the best model to ensure that one of the oldest known treatment methods for spinal maladies is carried out for the optimal benefit of the patient.

Section XIII Appendices

A

Terminology and Definitions

Aurelio G. Martinez-Lozano

A. G. Martinez-Lozano: Universidad Autónoma De Nuevo León, Monterey, Mexico.

It was the editor's intention that this text would provide the reader with the majority of information related to the pediatric spine, spinal cord and their diseases and disorders in a single location. This appendix is intended to compliment the text chapters and subject areas and to serve as a supplemental reference source for information on terminology and nomenclature, embryology, growth and maturation, laboratory data, radiographic measurements and classifications referable to the pediatric spine and spinal cord. When charts, graphs, or line drawings were available, these were reprinted; when permissions to reprint were not granted, appropriate references were instead provided to enable the reader to know where to look for this information. Each topic area in the appendix is accompanied by additional references related to measurement values and classifications for supplemental reading. The editor and the author hope that you will find the supplemental information included in this appendix helpful.

Glossary

Adolescent scoliosis

Spinal curvature presenting at or about the onset of puberty and before maturity.

Adult scoliosis

Spinal curvature existing after skeletal maturity.

Angle of thoracic inclination

With the trunk flexed 90 degrees at the hips, the angle between horizontal and a plane across the posterior rib cage at the greatest prominence of a rib hump.

Apical vertebra

The most rotated vertebra in a curve; the most deviated vertebra from the vertical axis of the patient.

Body alignment, balance, compensation

1. The alignment of the midpoint of the occiput over the sacrum in the same vertical plane as the shoulders over hips. 2. Roentgenology: When the sum of the angular deviations of the spine in one direction is equal to that in the opposite direction.

Café au lait spots

Light brown irregular areas of skin pigmentation. If they are sufficient in number and with smooth margins, they suggest neurofibromatosis.

Cervical curve

Spinal curvature that has its apex from C1 to C6.

Cervicothoracic curve

Spinal curvature that has its apex at C7 or T1.

Compensation

Accurate alignment of the midline of the skull over the midline of the sacrum.

Compensatory curve

A curve, which can be structural, above or below a major curve that tends to maintain normal body alignment.

Congenital scoliosis

Scoliosis due to congenitally anomalous vertebral development.

Curve measurement

Cobb method: Select the upper and lower end vertebrae. Erect perpendiculars to their transverse axes. They intersect to form the angle of the curve. If the vertebral end plates are poorly visualized, a line through the bottom or top of the pedicles may be used. *Ferguson method:* The angle of a curve is formed by the intersection of two lines drawn from the center of the superior and inferior end vertebral bodies to the center of the apical vertebral body.

Double structural curve

Double major scoliosis: A scoliosis with two structural curves. Two structural curves in the same spine, one balancing the other.

Double thoracic curve (scoliosis)

A scoliosis with a structural upper thoracic curve; a larger, more deforming lower thoracic curve; and a relatively nonstructural lumbar curve.

End vertebra

The most cephalad vertebra of a curve whose superior surface, or the most caudad vertebra of a curve whose inferior surface tilts maximally toward the concavity of the curve.

Fractional curve

A compensatory curve that is incomplete because it returns to the erect. Its only horizontal vertebra is caudad or cephalad.

Full curve

A curve in which the only horizontal vertebra is at the apex.

Functional curve, Nonstructural curve

A curve that has no structural component and that corrects or overcorrects on recumbent side-bending radiographic views.

Genetic scoliosis

A structural spinal curvature inherited according to a genetic pattern.

Gibbus

A sharply angular kyphos.

Hysterical scoliosis
A nonstructural deformity of the spine that develops as a manifestation of a conversion reaction.

Idiopathic scoliosis
A structural spinal curvature for which no cause is established.

Iliac epiphysis, Iliac apophysis
The epiphysis along the wing of the ilium.

Iliac epiphysis sign, Iliac apophysis sign
In the anteroposterior radiograhic view of the spine, when the excursion of ossification in the iliac epiphysis (apophysis) reaches its ultimate medial migration, vertebral growth may be complete.

Inclinometer
An instrument used to measure the angle of thoracic inclination or rib hump.

Infantile scoliosis
Spinal curvature that develops during the first 3 years of life.

Juvenile scoliosis
Spinal curvature that develops between the skeletal age of 3 years and the onset of puberty.

Kyphos
A change in the alignment of a segment of the spine in the sagittal plane that increases the posterior convex angulation.

Kyphoscoliosis
Lateral curvature of the spine associated with either increased posterior or decreased anterior angulation in the sagittal plane in excess of the accepted norm for that region. In the thoracic region, 20 to 40 degrees of kyphosis is considered normal.

Lordoscoliosis
Lateral curvature of the spine associated with an increase in anterior curvature or a decrease in posterior angulation thoracic spine where posterior angulation is normally present, less than 20 degrees would constitute lordoscoliosis.

Lumbar curve
Spinal curvature that has its apex from L1 to L4.

Lumbosacral curve
Spinal curvature that has its apex at L5 or below.

Major curve
Term used to designate the larger (largest) curve or curves, usually structural.

Minor curve
Term used to refer to the smaller (smallest) curve or curves.

Myogenic scoliosis
Spinal curvature due to disease or anomalies of the musculature.

Neurogenic scoliosis
Spinal curvature due to disease or anomalies of nerve tissue.

Osteogenic scoliosis
Spinal curvature due to abnormality of the vertebral elements or adjacent ribs, either acquired or congenital.

Pelvic obliquity
Deviation of the pelvis from the horizontal in the frontal plane. Fixed pelvic obliquities can be attributable to contractures either above or below the pelvis.

Primary curve
The first or earliest of several curves to appear, if identifiable.

Rib hump
The prominence of the ribs on the convexity of a spinal curvature, usually due to vertebral rotation best exhibited on forward bending.

Skeletal age, Bone age
The age obtained by comparing an anteroposterior radiographic view of the left hand and wrist with the standards of the Greulich and Pyle Atlas.

Structural curve
A segment of the spine with a fixed lateral curvature. Radiographically, it is identified in supine lateral side-bending views by the failure to correct. They may be multiple.

Thoracic curve
Scoliosis in which the apex of the curvature is between T2 and T11.

Thoracogenic scoliosis
Spinal curvature attributable to disease or operative trauma in or on the thoracic cage.

Thoracolumbar curve
Spinal curvature that has its apex at T12 or L1.

Transitional vertebra
Vertebra that is neutral in relation to rotation usually at the end of a curve.

Vertebral endplates
The superior and inferior plates of cortical bone of the vertebral body adjacent to the intervertebral disc.

Vertebral growth plate
The cartilaginous surface covering the top and bottom of a vertebral body that is responsible for the linear growth of the vertebra.

Vertebral ring apophyses
The most reliable index of vertebral immaturity seen best in the lateral radiographs or in the lumbar region in side-bending anteroposterior views.

Embryology, Growth and Maturation

Aurelio G. Martinez-Lozano

A. G. Martinez-Lozano: Universidad Autónoma De Nuevo León, Monterey, Mexico.

A. **Spine Development (Prenatal)**

1. **Neural Tube Development in Human Embryos**

    Lemire RJ (1969): Variation in development of the caudal neural tube in human embryos (horizons XIV–XXI). *Teratology* 2:361–70.

2. **Spinal Cord Formation**

    The cephalic and caudal portions of the spinal cord are formed by distinctly different mechanisms and are, therefore, heir to distinctly different types of malformation. The cephalic, or majority, portion of the spinal cord forms by an orderly sequence of (a) creation of neural folds, (b) flexion of neural folds, and (c) closure of the folds into a neural tube. This process is designated neurulation. The caudal, or minority, portion of the cord forms by far less well-organized mechanisms of (a) agglomeration of cells, (b) canalization of the cell mass, and (c) involution of unused portions of the distal cord. This process is designated canalization and retrogressive differentiation (Fig. 1).

    Lemire RJ, Loeser JD, Leech RW, et al. (1975): *Normal and abnormal development of the human nervous system.* Hagerstown, MD: Harper & Row.

3. **Vertebrae and Disc Development** (Fig. 2)

    Rothman RH, Simeone FA (1982): *The spine*.

4. **Ascent of the Cord**

    In the early embryo, the spinal cord extends to the distal end of the tail. By approximately 3 months postpartum, the tip of the conus medullaris lies at approximately the L1–2 interspace, this ascent results from two processes: (a) retrogressive differentiation and (b) disproportionately more rapid growth of the vertebral column (Fig. 3).

5. **Normal Curvatures of the Spine: Termination of the Spinal Cord** (Fig. 4)

    It is generally stated that the thoracic and sacral curvatures are primary curves and that the cervical and lumbar curvatures are secondary curves, developing after birth. However, it is likely that the cervical curvature begins to form prenatally. Although the vertebral column and neural tube at first grow synchronously, a difference develops in the fetal period so that the cord ends successively at the sacral and lumbar levels. The level at birth is generally the third lumbar vertebra, and that in the adult is most commonly the first or second lumbar vertebra. The "adult" level is reached at about 2 months after birth so that the vertebral column and spinal cord grow at an equal rate during childhood (Fig. 4).

    Bagnall KM, Harris, PF, Jones, PRM (1977): A radiographic study of the human fetal spine. I. The development of the secondary cervical curvature. *J Anat* 777–782.

    Barry A (1956): A quantitative study of the prenatal changes in angulation of the spinal nerves. *Anat Rec* 126:970–110.

    Barson AJ (1970): The vertebral level of termination of the spinal cord during normal and abnormal development. *J Anat* 106:489–497.

    O'Rahilly R, Muller F, Meyer DB (1980): The human vertebral column at the end of the embryonic period proper: the column as a whole. *J Anat* 136:181–195.

6. **Vertebral Ossification Centers in Human Embryos** (Tables 1, 2, 3, 4)

    Mall FP (1906): On ossification centers in human embryos less than 100 days old. *Am J Anat* 5:433–458.

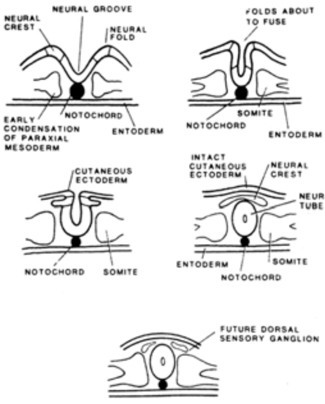

FIGURE 1. Embryonic stages 8 to 12 (18 to 27 days) in cross section showing the process of neurulation, which transforms the neural plate into the neural tube buried beneath a continuous layer of cutaneous ectoderm **(A–E)**. The paraxial mesoderm condenses to form paired segmental blocks, called comites, from which the vertebral bodies will form. If the embryo were sectioned along its length in the early stages of neurulation, all these steps would be seen, with the advanced step **(E)** in the cervicomedullary area. (From French BN (1990): Midline fusion defects and defects of formation. In: *Youman's neurological surgery*, 3rd ed. Philadelphia: WB Saunders, with permission.)

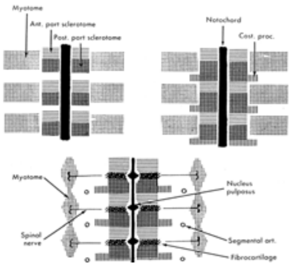

FIGURE 2. Schematic representation of development of vertebrae and discs. (From Rothman RH, Simeone FA (1982): *The Spine*, vol 1. Philadelphia: WB Saunders).

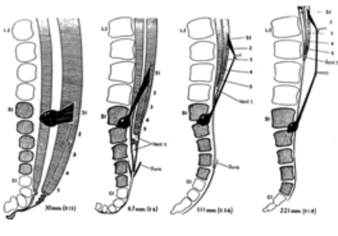

FIGURE 3. The relationship of the caudal end of the developing spinal cord to the vertebral column during the fetal period from the 8th to the 25th week. The increase in length of the S1 nerve root and the filum terminale reflects the "ascension" of the conus medullaris by a combination of regression and disproportionate elongation of the vertebral column. (From Streeter GL (1919): Factors involved in the formation of the filum terminale. *Am J Anat* 25:1–12, with permission.)

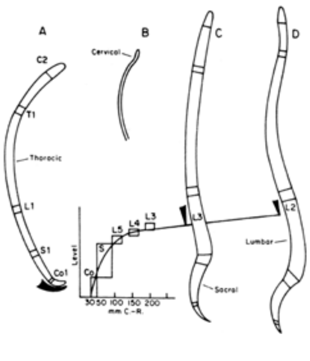

FIGURE 4. The curvatures of the vertebral column and the termination of the spinal cord. **A:** At the end of the embryonic period proper (stage 23), based on O'Rahilly and coworkers. The thoracic curvature is evident. The neural tube *(solid black)* reaches to the end of the column. **B:** An indication of a cervical curvature at the beginning of the fetal period, as illustrated by Bagnall and associates. The graph shows the level of termination of the spinal cord plotted against fetal length, as found by Barry. **C:** Newborn showing the sacral curvature. The cord ends at the third lumbar vertebra. **D:** Adult, showing all four curvatures. The spinal cord generally ends at the level of the first or second lumbar vertebra. (From O'Rahilly R, Benson DR (1985): The development of the vertebral column. In: Bradford DS, Hensinger RN, eds. *The pediatric spine*, Stuttgart: Georg Thieme, Verlag, with permission.)

B. **Spine Development (Postnatal)**

1. **Spine Ossification Centers** (Fig. 5)
2. **Normal Variations in Shape of Vertebral Bodies According to Age** (Fig. 6)
3. **Cervical Spine Development** (Figs. 7, 8, 9)
4. **Vertebral Growth** (Figs. 10, 11, 12, 13)

According to Winter (1977), the average growth of each vertebral segment is 0.07 cm per year. The most caudal vertebral have been reported (Schmorl) to show more growth than those more cephalic. Therefore, the midportion of the column in the newborn lies at the level of T7 and in the adult at T9.

Dimeglio A (1993): Growth of the spine before 5 years. *J Pediatr Orthop* 1-B:102.

Dubousset J, Katti E, Seringe R (1993): Epiphysiodesis of the spine in young children for congenital spinal deformations. *J Pediatr Orthop* 13:123.

FIGURE 9. Diagram of typical cervical vertebrae C3–7. *A*, Body: appears by fifth fetal month. *B*, Anterior (costal) portion of transverse process: may develop from a separate center that appears by the sixth fetal month and joins the arch by the sixth year. *C*, Neural arches: appears by seventh to ninth fetal week. *D*, Synchondrosis between spinous processes: usually unites by second or third year. *E*, Secondary centers for bifid spine: appears at puberty and unites with spinous process at 25 years. *F*, Neurocentral synchondrosis: fuses at 3 to 6 years. *G*, Superior and inferior epiphyseal rings: appears at puberty and unites with body at about 25 years. The seventh cervical vertebra differs slightly because of a long powerful nonbifid spinous process. (Based on the study of radiographs of the cervical spine from approximately 100 normal children ranging from newborn to 14 years of age.) (From Bailey DK (1952): The normal cervical spine in infants and children. *Radiology* 59:712–719, with permission.)

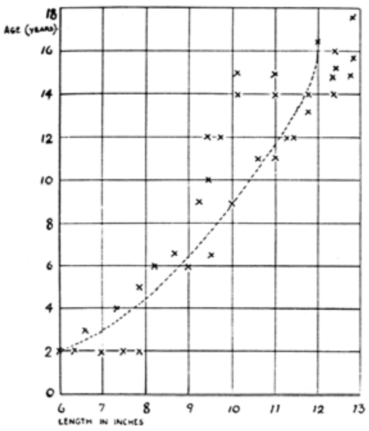

FIGURE 10. Normal growth curve for the thoracic spine. Measurements were made on radiographs obtained with standard technique. The authors did not include the relative height of the patient or the degree of kyphosis or lordosis. (From Roaf R (1960): Vertebral growth and its mechanical control. *J Bone Joint Surg [Br]* 42:40–59, with permission.)

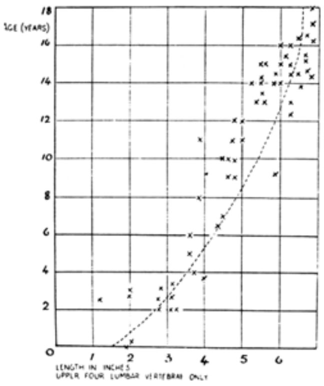

FIGURE 11. Normal growth curve for the lumbar spine (upper four lumbar vertebrae only). (From Roaf R (1960): Vertebral growth and its mechanical control. *J Bone Joint Surg [Br]* 42:40–59, with permission.)

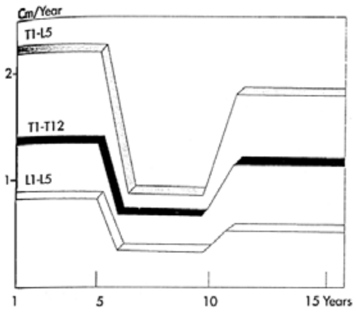

FIGURE 12. Growth velocity of T1–L5 segment, thoracic segment T1–12, and lumbar segment L1–5. (From Dimeglio A (1993): Growth of the spine before 5 years. *J Pediatr Orthop* 1-B:102.)

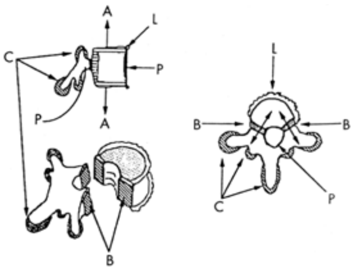

FIGURE 13. Vertebral growth. *A*, Body end plates (superior and inferior). *B*, Neurocentral cartilage (bipolar) fusion at age 7 or 8 years. *C*, Posterior elements cartilage. *P*, Periosteum. *L*, ring apophysis (begins age 7 to 9 years, closed at age 14 to 24 years) (From Dubousset J, Katti E, Seringe R (1993): Epiphysiodesis of the spine in young children for congenital spinal deformations. *J Pediatr Orthop* 13:123.)

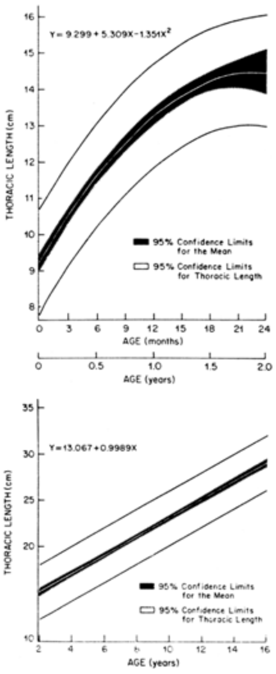

FIGURE 14. Results of statistical analysis in children from birth to 2 years and children from 2 to 16 years. The predicted values for the mean are indicated by the center curve, and the 95% confidence limits for the mean by the shaded area. The boundaries of the unshaded area (outside curves) denote the calculated 95% confidence limits for thoracic length for an individual child. In the equations shown in these figures, Y is the thoracic length in centimeters and X is the age in years. (From Currarino G, Williams B, Reisch JS (1986): Linear growth of the thoracic spine in chest roentgenograms from birth to 16 years. *Skelet Radiol* 15:628–630, with permission.)

Schmorl G, Junghanns H (1971): The human spine in health and disease, 2nd ed. New York: Grune & Stratton.

Winter RB (1977): Scoliosis and spinal growth. *Orthop Rev* 6:17–20.

5. **Thoracic Spine Length from Birth to 16 Years** (Fig. 14)

Kuhns LR, Holt JF (1975): Measurement of thoracic spine length on chest radiographs of newborn infants. *Radiology* 116:395–397.

C. Neurologic Maturation

1. **Primitive Reflexes** (Table 5)
2. **Reflex Maturation** (Fig. 15)
3. **Reflexes of Neurophysiologic Maturation** (Table 6)
4. **Developmental Milestones**

Capute AJ, Biehl RF (1973): Functional developmental evaluation. *Pediatr Clin North Am* 20:3–26.

Zausmer E (1953): Evaluation of strength and motor development in infants. *Phys Ther Rev* 33:575–581.

Zausmer E (1964): The evaluation of motor development in children. *Phys Ther Rev* 44:247–250.

Zausmer E, Tower G (1966): A quotient for the evaluation of motor development. *Phys Ther Rev* 46:725–727.

6. **Motor Maturity Tests** (Tables 9, 10)

TABLE 5. Primitive Reflexes

Reflex	Present by (months)	Gone by (months)
Intrauterine—birth reflexes		
Palmar grasp	Birth	4
Plantar grasp	Birth	9
Automatic stepping	Birth	2
Crossed extension	Birth	2
Galant	Birth	2
Moro	Birth	3–6
Tonic neck		4
Asymmetric	Birth	8
Symmetric	5	
Lower extremity placing	0.03 (1 day)	—
Upper extremity placing	3	—
Downward thrust	3	—
Late infant reflexes		
Landau (head, trunk and leg extension while prone)	3	12–24
Derotational righting	4	—
Other postural reflexes		
Anterior propping	6	—
Lateral propping	8	—
Posterior propping	10	—

TABLE 6. Reflexes of Neurophysiologic Maturation

Reflex	Test position	Stimulus	Response	Appears	Disappears	Significance of Absence	Significance of Abnormal Persistence
Palmar (hand) grasp (Fig. 1-35)	Supine; head must be midline	Introduction of a pencil or rod into palm from ulnar side; object pulled on after grasp	Finger will flex and grasp object Thumb will not oppose but will flex if extended If response is marked, infant can be suspended by object he is holding	Birth	2–4 mo	Flaccid paralysis	Flexor hypertonicity as in spastic cerebral palsy Asymmetric in hemiplegia
Plantar (foot) grasp (Fig. 1-36)	Supine	Light digital pressure on planter aspect of foot	Tonic flexion and abduction of toes	Birth	9–12 mo	Flaccid paralysis	Spasticity of leg and foot muscles
Moro's (Fig. 1-37)	Supine with both upper and lower limbs in natural extension	Sudden extension of neck by raising the head off the table, supporting head on palm of hand, then suddenly dropping hand Raising the infant by holding the hands and then rapidly releasing Sharp bang on table or sudden tap on abdomen	*First phase*: adduction and extension of all four limbs and extension of spine; extension and fanning of digits; followed by: *Second phase*: adduction and flexion of all four limbs as if embracing	Birth	3–6 mo	In flaccid paralysis, may be asymmetric in obstetric brachial plexus paralysis In generalized hypotonia or weakness of muscles, amyotonia congenita In severe hypertonicity increased flexor muscle tone prevents extension of limbs	After 6 months, delayed maturation of central nervous system as in cerebral palsy
Startle	Supine with all four limbs in natural extension	Sudden loud noise Tapping sternum	Flexion of elbows and knees, hands closed	Birth	Present through life	Severe hypotonia Asymmetric obstetric brachial plexus paralysis	—
Placing reaction							
Lower limb (Fig. 1-38)	Vertical suspension by holding at waist	Touching anterior aspect of legs and dorsum of feet on edge of table	Foot placed on table spontaneous flexion of hip and knee and dorsifiexion of ankle	Birth	2–4 mo and may persist	Brain damage if absent at birth	—
Upper limb (Fig. 1-39)	Vertical suspension (feet down) by holding at waist	Bringing dorsum of ulna against edge of table	Hand placed on table by flexion of elbow	Birth	1–2, and may persist	Brain damage if absent at birth	—
Walking or stepping (Fig. 1-40)	Upright; hold supporting trunk	Pressing (touching) soles of feet on hard surface and gently inclining and moving child forward	Altemating flexion and extension of lower limbs simulating walking (rhythmical, coordinated, needs only forward movement, no propulsion)	Birth	1–2 mo	Flaccld paralysis if absent at birth	Brain damage persists after 3–4 months
Crossed extension (Phillippson's reflex) (Fig. 1-41)	Supine, lower limbs in midline and extended at hip and knee	Firm pressure to sole of one foot by rubbing or stroking Strong pressure in inguinal region	Opposite free lower limb flexes, adducts, then extends	Birth	1–2 mo	Flaccid paralysis if absent at birth	Partial or incomplete cord lesions Brain damage
Withdrawal	Supine, lower limbs in midline and natural extended posture	Pinprick to sole	Dorsiflexion of ankle, flexion of hip and knee (withdraws limb from noxious stimulus)	Birth	1–2 mo	Flaccid paralysis as in myelomeningocele or intraspinal lesions	Spasticity of lower limbs as in cerebral palsy
Positive support or leg straightening	Upright, supported under axillae and around chest	Press soles of feet to the ground or table several times	Lower limbs and trunk go into extension, serving as strong pillars for weight bearing	Birth	4 mo	—	Reciprocal leg movements cannot appear, infant cannot walk
Extensor thrust	Lower limbs held in flexed position	Apply pressure to the sole of foot	Sudden—extension of entire lower limb (sometimes followed by flexion)	Birth	2 mo	Flaccid paralysis	Brain damage and delayed maturation of central nervous system
Trunk incurvation (Galant's reflex) (Fig. 1-42)	Prone	Strike lumbar region of back with index finger—10th rib to iliac crest—in the paravertebral area about 3 cm from midline Alternate method: prick outer side of gluteal area	Lateral flexion (incurvation) of trunk toward side of stimulus	Birth	2–2$^{1/2}$ mo	?	May cause scoliosis if dominant unilaterally
Tonic neck							
Asymmetric (Fig. 1-43)	Supine with head in midline	Rotate head to one side (without flexion of neck) to the count of 10 seconds, then rotate to the opposite side	Limbs on *chin side*—become rigid and elbow and knee go into extension Limbs on *occiput side*—elbow and knee become flexed	Birth	4–6 mo	Flaccid paralysis Severe hypotonia	Severe brain damage as in cerebral palsy
Symmetric (Fig. 1-44)	Quadriped position	Extend head-neck Flex head-neck	Upper limbs extend and lower limbs go into flexion Upper limbs flex and lower limbs extend	5–8 mo	No absolute time (1 year)	Cannot assume “four-point” kneeling position	Prevents reciprocal lower limb motion, hinders ambulation Prevents crawling Causes adduction, medial rotation flexion gait pattern

Landau's	Prone, supported under abdomen and lower thorax	First passively flex and then extend the neck-head	On flexion of neck-head, the trunk and lower and upper limbs go into flexion On extension of head-neck, the limbs and trunk extend	6 mo	24-30 mo	Motor weakness	Delayed reflex maturation, usually breaks up predominant flexion pattern
Parachute (protective extension of arms)	Prone, suspended in the air by waist	Move head suddenly toward floor by tipping or plunging downward	Sudden extension of arms and wrists to protect head	6 mo	Present through life	Brain damage Delayed maturation	—
Forward (Fig. 1-45)							
Backward	Sitting or standing in neutral position	Sudden tip or push backward with enough force to offset balance	Backward extension of both upper limbs; fingers extended and abducted, weight is born on hands	9 mo	Present through life	Delayed maturation	—
Tilting							
Prone and supine	Prone (or supine) on tilt table (flat board with all four limbs in neutral extension)	Tilt table slowly to one side	Lateral flexion of trunk with concavity upward The arm and leg on upper side go into abduction and extension Arm and leg on lower side go into protection	6 mo	Present through life	—	—
Prone and supine cont'd							
On all fours	Placed on all fours on tilt table	Tilt to either side	As above	12 mo	Present through life	—	
Standing	Supported from waist, standing on tilt board	Movement first to either side and then forward and backward	As above				
Righting							
Neck	Supine, head in midline and all four limbs fully extended	Flexion and rotation of head to one side, maintaining position to count of 10	Body rotates *as a whole* in same direction as head	Birth	6 mo	Delayed maturation	Brain damage
Body	As for neck righting	Rotation of shoulder to one side, maintaining position to count of 10	Sequential rotation of trunk	6 mo	5 yr to life	—	—
Labyrinthine Prone	Blindfolded to rule out optical righting reflexes)	Posture in space	Extension of neck, bringing face horizontal to floor	1-2 mo	Present through life	Delayed maturation	—
	Suspended prone in space by support to abdomen		Flexion of head-neck, bringing face horizontal to floor	6 mo	Present through life	Delayed maturation	—
Supine	Same as prone but *supine*	Posture in space	Head will automatically right to vertical position with the mouth horizontal	6-8 mo	Present through life	Delayed maturation	—
Upright	Blindfolded, held at pelvis and suspended vertically in space	Tilt to either side	Same as above	6-8 mo	Present through life	Delayed maturation	—
Optical (Fig. 1-46)	Same as labyrinthine but eye *open*	Same as labyrinthine

Figures cited are in the above reference.

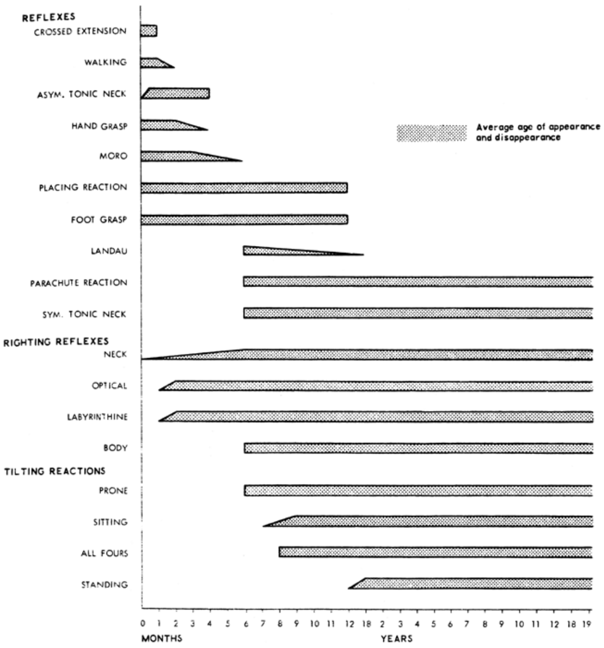

FIGURE 15. Reflex maturation chart. (From Tachdjian MO (1990): *Pediatric orthopaedics*, 2nd ed. Philadelphia: WB Saunders , with permission.)

TABLE 7. Locomotion Development

Age	Skill
3 mo	Lifts head up when prone
6 mo	Head held steady when sitting
	Turns head side to side
	No head lag when pulled to sitting
	Rolls over
9 mo	Sits without support, legs extended
	Sits “tallor fashion”-external rotation
	Sits with legs in internal rotation
	Pulls self to stand
	Stand with two-hand support
12 mo	Leans and recovers balance when sitting
	Walks with one-hand support
14 mo	Stands without support
	Walks forward without support
	Stoops and recovers balance
18 mo	Ascends stairs with two-hand support
2 yr	Ascends stairs with no support, one foot at a time
	Runs forward
	Kicks ball forward
3 yr	Ascends stairs without support, foot over foot
	Descends stairs with support, one foot at a time
	Jumps in place
	Pedals tricycle
4 yr	Descends stairs without support, foot over foot
	Beginning to balance on one foot
5 yr	Hops on one foot without support
	Heel-toe walk
6 yr	Skips one foot at a time
	Backward heel-toe walk
	Throws ball up and catches it with one hand
	Hits small target from 12-in. distance

TABLE 8. Manipulation, Upper Extremity Function, and Language Development

3 mo	Hand skills	Symmetric head and arm posture (supine)
		Active arm motion on sight of toys
	Feeding	Lip pressure
		Coordination of sucking and swallowing
	Language	Vocalizes without crying
6 mo	Hand skills	Purposefully reaches out and touches object
		Palmar grasp of rattle
		Involuntary release of rattle
	Feeding	Hand to mouth
	Language	Laughs and smiles
9 mo	Hand skills	Transfers object both ways
		Extended reach and grasp
		Uses finger and thumb to grasp object
		Releases object with flexed wrist
	Feeding	Can protrude tongue
		Feeds self cookies
	Language	Da-da, ma-ma (nonspecific)

1 yr	Hand skills	Attempts to stack one block on another (brings over and drops)
		Hits two objects together
		Voluntary release of object
		Rolls ball imitatively
		Puts round ball into round hole
		Puts cube into container
		Can hold crayon and imitate scribbling
	Feeding	Picks spoon up from table
		Chews cookies or toast
		Drooling controlled at all times
		Drinks milk from cup, if held
	Dressing	Cooperates (extends arm for sleeve)
	Language	Two or more words (other than ma-ma or da-da)
18 mo	Hand skills	Builds three-block tower (1-in cube)
		Turns pages (two or three at a time)
		Puts pegs into hole (1-in diameter)
		Pounds
		Hurls ball
		Points to nose, eyes, ears
	Feeding	Drinks from cup (one- or two-handed)
		Feeds self with spoon, but messy
	Dressing	Removes socks, shoes
	Language	Vocabulary of 10 words, including names
2 yr	Hand skills	Six-block tower
		Turns pages one at a time
		Throws bean bags
		Strings beads (1-in)
		Throws 3-in ball, but inaccurately
	Feeding	Feeds self semisolid food with spoon
		Drinks from cup or glass (one-handed)
		Drinks from straw
	Language	Three-word sentences
	Writing	Imitates vertical, horizontal, and circular strokes; cannot initiate himself
		Matches colors
21/2 yr	Dressing	Unlaces and removes shoes
		Takes off pants
	Writing	Holds crayon with fingers
3 yr	Hand skills	Creases paper neatly
		Nine-block tower
		Rides tricycle
	Feeding	Feeds self with fork
	Dressing	Dresses self with supervision
		Learning to lace shoes
		Puts on shoes, not necessarily on correct foot
		Tries to wash and dry hands
	Language	Knows whether boy or girl
	Writing	Copies circles, cannot copy cross
		Tries to use scissors, but cannot follow line
4 yr	Hand skills	Overhand throw of ball
	Feeding	Drinks through straw without mashing it
4 yr	Dressing	Puts on shoes on correct feet
		Laces shoes, but does not tie bow
		Dresses, knows back and front of clothes
		Washes and dries face
		Brushes or combs hair
		Brushes teeth
		Manages buttons on self
	Language	Counts three objects correctly
	Writing	Copies cross
5 yr	Hand skills	Bounces ball and catches it
		Performs three simple directions in sequence
	Dressing	Dresses self completely except for back fasteners
	Language	Names four colors
		Names penny, nickel, dime
		Counts 10 objects correctly
	Writing	Draws a recognizable man
		Colors within 1-in area
		Uses scissors, follows line
6 yr	Feeding	Cuts with knife and fork
	Dressing	Buttons small buttons on shirt
		Ties bows on shoes
		Combs and brushes hair
	Writing	Copies printing (A, B, C)

From Tachdjian MO (1999): *Pediatric orthopaedics*, 2nd ed. Philadelphia: WB Saunders, with permission.

Development is rated according to the Zausmer scale: O, no attempt made; T, attempt made but fails; P, poor or partial completion; F, fair performance, fluctuates; G, good, attaining speed; N, normal skill and speed; NT, not tested.

D. Growth Charts

1. **Recumbent Length Percentiles From Birth to 36 Months** (Figs. 16, 17)
2. **Weight Percentiles From Birth to 36 Months** (Figs. 18, 19)
3. **Head Circumference Percentiles From Birth to 36 Months/Weight by Length Percentiles From Birth to 36 Months** (Figs. 20, 21)
4. **Stature Percentiles From 2 to 18 Years** (Figs. 22, 23)
5. **Weight Percentiles From 2 to 18 Years** (Figs. 24, 25)
6. **Weight by Stature Percentiles for Prepubescent Children** (Figs. 26, 27)
7. **Sitting Height** (Fig. 28, Table 11)
8. **Upper-Lower Segment Ratio**

TABLE 9. Basic Motor Maturity Tests Performed at 3 to 10 Months

Age (mo)	Supine	Prone	Pull to Sit
3	Limb posture is flexion Limb and trunk poxsstures becoming symmetric	Holds chin and shoulders off table, weight on forearms Pelvis is flat when plane of face is 45 to 90 degrees to table	Head lag in beginning of movement, then keeps head in line with trunk Head will bob forward when sit is completed Lower limbs are flexed
4	Bilateral activities at midline (Resting) legs are in flexion, abduction, and outward rotation (Active) able to flex hips and extend legs, lifting them an inch	Head in midline Prone swimming, jerky movements	Slight head lag in beginning of movement, then keeps head in line with trunk (lower limbs flexed)
5	Back arches and child raises hips (bridges, no progression)	Arms forward, fully extended for support Arms retracted and flexed (hands off support) Support on one forearm and reaches for toys Free kicking of legs	Assists and brings head forward, no head lag (lower limbs flexed)
6	Rolls supine to prone Reaches forward with extended arms to be picked up Lifts legs and plays with feet	Rolls prone to supine (purposeful)	Spontaneous lifting of head Pulls him/herself to sitting Raises extended leg (hips are flexed, knees are extended)
7	Lifts head off table	Commando-crawls Assumes quadruped position	
8	Does not like supine position	Pivots	
9		Goes from prone to sitting	
10		Creeps on hands and knees	

From Bleck EE (1979): *Orthopaedic management of cerebral palsy*. Philadelphia: WB Saunders, with permission.

TABLE 10. Basic Motor Maturity Tests Performed at 3 to 15 Months

Age (mo)	Sitting	Standing
3	Back somewhat rounded Head mostly held up	Does not accept weight
4	Holds head steady, but set forward Head wobbles when child is swayed Back shows only a lumbar curvature (slight rounding)	Accepts some weight
5	No arm support, arms retracted at shoulders with elbows flexed Child tends to fall backwards (does not push back) Head stable when body is mildly rocked by examiner	Takes almost full weight
6	May sit alone unsupported briefly when placed Arm support forward Sits well when propped	Bounces
8	Sits unsupported, without hand support for 1 min Sits erect Has arm support sideways	Readily bears whole weight when supported (not rigid)
9	Adjusts posture to reach Good sitting balance, sits 10 min	Pulls self to standing
10	Pivots to pick up objects Arm support backward Leans forward and recovers Can lean over sideways and recover Goes forward from sitting to prone	Stands holding on and lifts one foot Lowers self to floor by holding on Collapses if not holding on
11		Walks holding on to furniture
12		Walks with one hand held; attempts to stand alone
13		Stands alone well; walks alone
14		Gets to standing unsupported
15		Stoops and recovers

9. **Height Velocity Standards** (Figs. 29, 30)
10. **Weight Velocity Standards** (Figs. 31, 32)
11. **Standard Growth Curves for Achondroplasia** (Figs. 33, 34)
12. **Mean Heights and Growth Curves for Height in Children With Skeletal Dysplasias**

Mean heights and growth curves for diastrophic dysplasia, spondyloepiphyseal dysplasia, and pseudoachondroplasia are given by Horton and colleagues. Only the mean heights at different ages are presented here (Table 12).

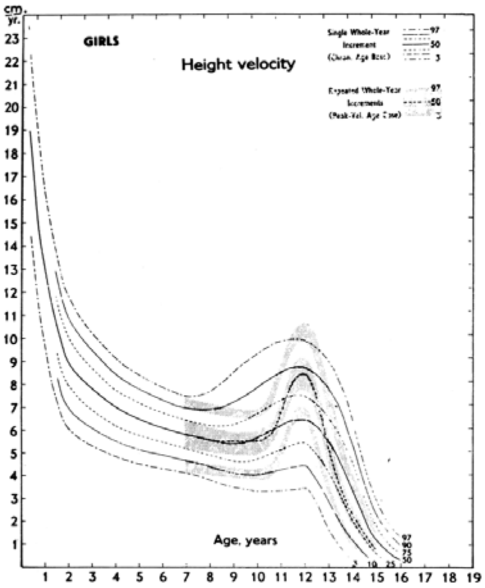

FIGURE 29. Peak height velocity for girls, the graph is composed of single whole-year increments with a chronologic age base displayed in a conventional manner by means of a continuous line indicating the 50th percentile, and broken lines indicating the 3rd and 97th percentiles. These are the standards used before and during adolescence if no data on developmental ages are available. Repeated whole-year increments (peak velocity age base) are plotted as shaded bands with a dashed line for 50th percentile. This individual curve represents the velocity taken at each successive year by an individual who has her peak at the average age and an average velocity through adolescence. The shaded curves represent the shape of the individual child's growth spurt at adolescence better than the increment line. (From Tanner JM, Whitehouse RH, Takaishi M (1966): Standards from birth to maturity for height, weight, height velocity and weight velocity: British children Parts I and II. *Arch Dis Child* 41:454–471, 613–635 , with permission.)

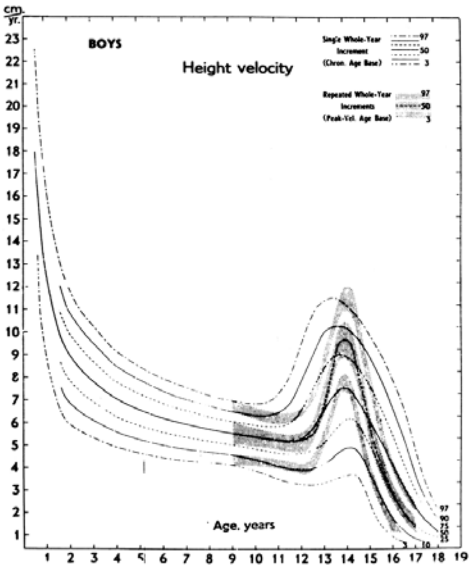

FIGURE 30. Peak height velocity for boys. (From Tanner JM, Whitehouse RH, Takaishi M (1966): Standards from birth to maturity for height, weight, height velocity and weight velocity: British children Parts I and II. *Arch Dis Child* 41:454–471, 613–635, with permission.)

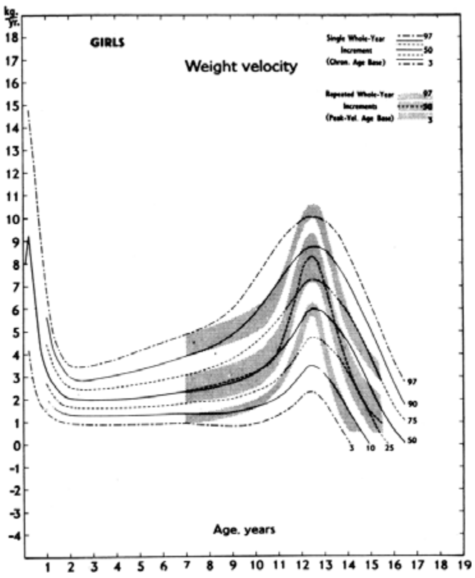

FIGURE 31. Weight velocity in girls. This graph is derived from the same data as the height velocity standards, with the single whole year increments noted at the 50th percentile as a smooth line and the 97th percentile and 3rd percentiles as dotted lines; from birth to adolescence, the peak velocity–centered curves and whole-year peak increments are presented by the dotted 50th percentile and shaded areas. (From Tanner JM, Whitehouse RH, Takaishi M (1966): Standards from birth to maturity for height, weight, height velocity and weight velocity: British children Parts I and II. *Arch Dis Child* 41:454–471, 613–635, with permission.)

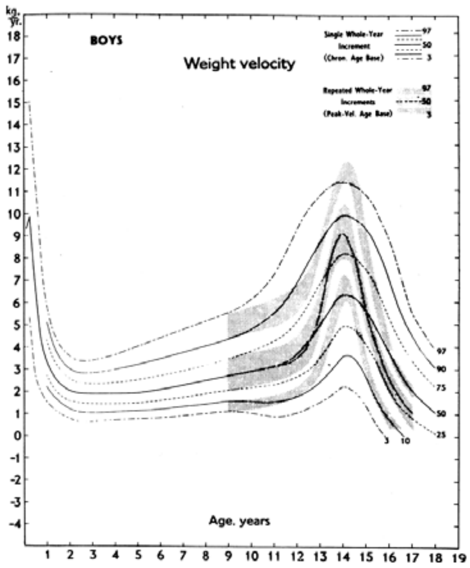

FIGURE 32. Peak weight velocity in boys. This graph is derived from the same data as the height velocity standards, with the single whole-year increments noted at the 50th percentile as a smooth line and the 97th and 3rd percentiles as dotted lines; from birth to adolescence, the peak velocity–centered curves whole-year peak increments are represented by the dotted 50th percentile and shaded areas. (From Tanner JM, Whitehouse RH, Takaishi M (1966): Standards from birth to maturity for height, weight, height velocity and weight velocity: British children Parts I and II. *Arch Dis Child* 41:454–471, 613–635, with permission.)

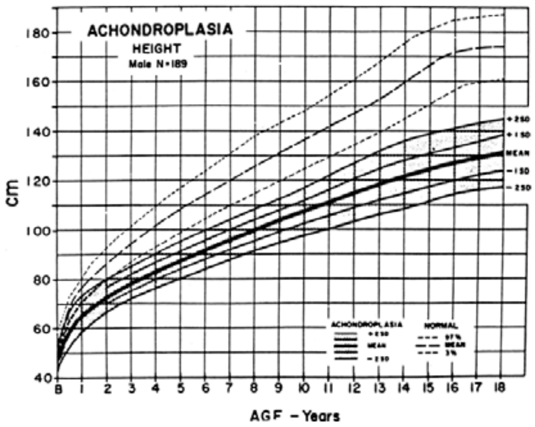

FIGURE 33. Height of men with achondroplasia (*stippled area*) compared with normal male standard height curve (3rd, 50th, and 97th percentiles). (From Horton WA, Rotter JI, Rimoin DL, Scott CI (1978): Standard growth curves for achondroplasia. *J Pediatr* 93:435–438, with permission.)

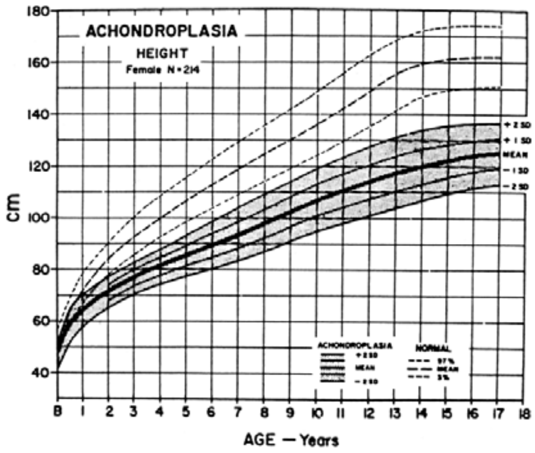

FIGURE 34. Height for women with achondroplasia (*stippled area*) compared to normal female standard height curve. (From Horton WA, Rotter JI, Rimoin DL, Scott CI (1978): Standard growth curves for achondroplasia. *J Pediatr* 93:435–438, with permission.)

Marshall WA, Tanner JM (1970): Variations in the pattern of pubertal changes in boys. *Arch Dis Child* 45:13–23.

TABLE 13. Pubertal Stages in Girls and Boys

Pubertal Stages in Girls	Pubertal Stages in Boys
Breast Staging	Genitalia Ratings
Stage 1. Preadolescent; elevation of papilla only	Stage 1. Preadolescent; testes, scrotum, and penis are of about the same size and proportion as in early childhood
Stage 2. Breast bud stage; elevation of breast and papilla as a small mound, enlargement of areola diameter	Stage 2. Scrotum and testes are enlarged with change in texture of the scrotal skin with slight reddening of the skin
Stage 3. Further enlargement of breast and areola, with no separation of their contours	Stage 3. Increase in size of the penis, in length mainly, but also in breadth, with continued growth of the testes and scrotum
Stage 4. Projection of areola and papilla to form a secondary mound above the level of the breast	Stage 4. Further enlargement of the testes, scrotum, and penis with development of the glans and darkening of the scrotal skin
Stage 5. Mature stage; projection of papilla only, due to recession of the areola to the general contour of the breast	Stage 5. Genitalia adult in size and shape
Pubic Hair Stages	Pubic Hair Stages
Stage 1. Preadolescent; no pubic hair	Stage 1. Preadolescent; no pubic hair
Stage 2. Slight growth of long, slightly pigmented, downy hair appearing chiefly along the labia	Stage 2. Slight growth of long, slightly pigmented, downy hair, appearing chiefly at the base of the penis
Stage 3. Darker, coarser hair that is more curled and spread sparsely over the junction of the pubes	Stage 3. Darker, coarser hair that is more curled and spread over the junction of the pubes
Stage 4. Hair is adult in type with no spread to medial surface of the thigh	Stage 4. Hair is adult in type with no spread to medial surface of the thigh
Stage 5. Adult in quantity and quality with no inverse triangle distribution and spread to the medial thighs	Stage 5. Adult in quantity and quality with no inverse triangle distribution and spread to the medial thighs

From Tanner JM (1975): Growth and endocrinology of the adolescent. In: Gardner L, ed. *Endocrine and genetic diseases of childhood*. Philadelphia: WB Saunders, with permission.

F. Assessment of Skeletal Maturation

1. Bone Age (Greulich-Pyle)

Pyle, Waterhouse, and Greulich have published a new radiographic reference standard for the assessment of skeletal age from hand-wrist film of children and youths. Studies of skeletal age assessments by research workers using left hand-wrist film and the bone-specific Greulich and Pyle method have shown intraobserver differences.

Gruelich WW, Pyle SI (1959): *Radiographic atlas of skeletal development of the hand and wrist*, 2nd ed. Palo Alto, CA: Stanford University Press.

Keats TE (1990): Skeletal maturation. In: *Atlas of roentgenographic measurement.* St. Louis: Mosby–Year Book.

Pyle SE, Waterhouse AM, Greulich WW (1971): *A radiographic standard of reference for the growing hand and wrist.* Cleveland: The Press of Case Western Reserve University.

Roche AF, Rohmann CG, French Y (1970): Effect of training on replicability of assessment of skeletal maturity. *Am J Roentgenol* 108:511–515.

2. **Method of Graham** (Table 14)
3. **The Oxford Method of Assessing Skeletal Maturity**

Standards are presented for the assessment of skeletal maturity based on radiographs of the pelvis and hip. A point is assigned for each maturity indicator, and a total maturity score is developed. The original text should be consulted for more detailed discussion. (Figs. 35, 36)

4. **Skeletal Ossification Centers**

From Graham BC (1976): Assessment of bone maturation: methods and pitfalls. *Clin North Am* 10:186–202, with permission.

[a] Based on a study of 143 healthy, middle-class Ohio-born children of northwestern European ancestry.

P, proximal; M, middle; D, distal.

Figures 37 and 38 indicate the range from 10th to the 90th percentiles in appearance time of centers of ossification. Numbers followed by m indicate months, otherwise all numbers indicate years. Where two sets of numbers are given for one center of ossification, the upper boldface numbers refer to men and the lower numbers refer to women. A single set of numbers applies to both sexes. AB indicates that the ossification center is visible at birth. Numbers in parentheses give approximate time of fusion.

G. **Neurologic Examination**

1. **Cranial Nerves** (Table 15)
2. **Dermatome Patterns** (Fig. 41)
3. **Motor Scale: Manual Testing**

The definitions recommended by the American Spinal Injury Association (ASIA) in the booklet Standards for Neurological Classifications of Spinal Injury Patients adapted from Austin, provide an accurate method of communicating information on the extent of neurologic injury. Manual muscle testing is performed using the standard six-grade scale:

Absent = 0

Trace = 1 Visible of palpable contraction

Poor = 2 Active movement through range of motion with gravity eliminated

Fair = 3 Active movement through range of motion against gravity

Good = 4 Active movement through range of motion against resistance

Normal = 5

TABLE 16. Innervation of Muscles Responsible For Movements of the Shoulder Girdle and Upper Extremity

Muscle	Segmental Innervation	Peripheral Nerve
Trapezius	Cranial XI: C(2)3–C4	Spinal accessory nerve
Levator anguli scapulae	C3–C4	Nerves to levator anguli scapulae
	C4–C5	Dorsal scapular nerve
Rhomboideus major	C4–C5	Dorsal scapular nerve
Rhomboideus minor	C4–C5	Dorsal scapular nerve
Serratus anterior	C5–C7	Long thoracic nerve
Deltoid	C5–C6	Axillary nerve
Teres minor	C5–C6	Axillary nerve
Supraspinatus	C(4)5–C6	Suprascapular nerve
Infraspinatus	C(4)5–C6	Suprascapular nerve
Latissimus dorsi	C6–C8	Thoracodorsal nerve (long subscapular)
Pectoralis major	C5–T1	Lateral and medial anterior thoracic
Pectoralis minor	C7–T1	Medial anterior thoracic
Subscapularis	C5–C7	Subscapular nerves
Teres major	C5–C7	Lower subscapular nerve
Subclavius	C5–C6	Nerve to subclavius
Coracobrachialis	C6–C7	Musculocutaneous nerve
Biceps brachia	C5–C6	Musculocutaneous nerve
Brachialis	C5–C6	Musculocutaneous nerve
Brachioradialis	C5–C6	Radial nerve
Triceps brachii	C6–C8 (T1)	Radial nerve
Anoconeus	C7–C8	Radial nerve
Supinator brevis	C5–C7	Radial nerve
Extensor carpi radialis longus	C(5)6–C7(8)	Radial nerve

Extensor carpi radialis brevis	C(5)6–C7(8)	Radial nerve
Extensor carpi ulnaris	C6–C8	Radial nerve
Extensor digitorum communis	C6–C8	Radial nerve
Extensor indicis proplus	C6–C8	Radial nerve
Extensor digiti minimi proprius	C6–C8	Radial nerve
Extensor pollicis longus	C6–C8	Radial nerve
Extensor pollicis brevis	C6–C8	Radial nerve
Abductor pollicis longus	C6–C8	Radial nerve
Pronator teres	C6–C7	Median nerve
Flexor carpi radialis	C6–C7(8)	Median nerve
Pronator quadratus	C7–T1	Median nerve
Palmaris longus	C7–T1	Median nerve
Flexor digitorum sublimis	C7–T1	Median nerve
Flexor digitorum profundus (radial half)	C7–T1	Median nerve
Lumbricales 1 and 2	C7–T1	Median nerve
Flexor pollicis longus	C8–T1	Median nerve
Flexor policis brevis (lateral head)	C8–T1	Median nerve
Abductor pollicis brevis	C8–T1	Median nerve
Opponens pollicis	C8–T1	Median nerve
Flexor carpi ulnaris	C7–T1	Ulnar nerve
Flexor digitorum profundus (ulnar half)	C7–T1	Ulnar nerve
Interossei	C8–T1	Ulnar nerve
Lumbricales 3 and 4	C8–T1	Ulnar nerve
Flexor pollicis brevis (medial head)	C8–T1	Ulnar nerve
Flexor digiti minimi brevis	C8–T1	Ulnar nerve
Abductor digiti minimi	C8–T1	Ulnar nerve
Opponenens digiti minimi	C8–T1	Ulnar nerve
Palmaris brevis	C8–T1	Ulnar nerve
Abductor pollicis	C8–T1	Ulnar nerve

C

Radiographic Measurements

Aurelio G. Martinez-Lozano

A. B. Martinez-Lozano: Universidad Autónoma De Nuevo León, Monterey, Mexico.

A. RADIOGRAPHIC MAGNIFICATION

The relative positions of the radiographic source, the spine, and the film are the factors that affect the magnification (Fig. 1).

The most commonly used value for the distance D1 (source-to-film distance) is 1.83 m (72 in); the magnification factors for different D2 (object-to-film distance) can be calculated (Table 1).

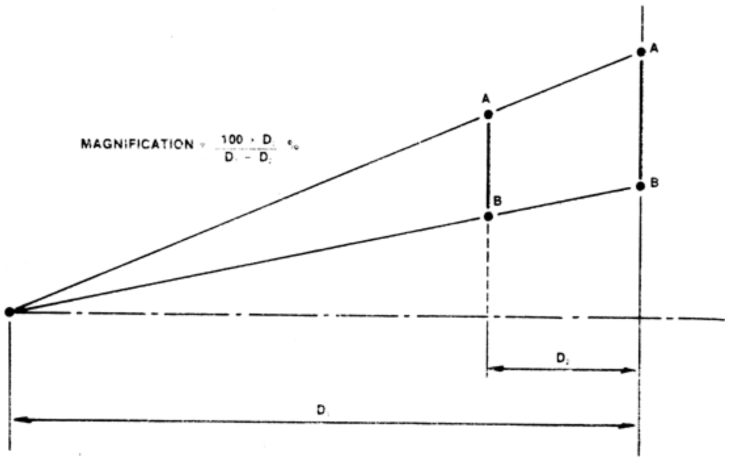

FIGURE 1. On a radiograph, the image is always bigger than the object: A'B' is greater than AB. The magnification depends on the source-to-film and object-to-film distances, D1 and D2, respectively. D2 is the distance that is the more sensitive in regard to magnification. (From

White AA, Panjabi MM (1990): The problem of clinical instability in the human spine. A systematic approach. In: *Clinical biomechanics of the spine.* Philadelphia: WB Saunders

, with permission.)

To avoid variations in the magnification, standardized distances have been suggested to facilitate comparisons of radiographs of the same patient, taken at different times. This approach also avoids the need for repeated computations to determine magnification for different patients. White and Panjabi have suggested the following standard distances:

ML > Radiographic source-to-film distance D1 = 1.83 m (72 in)

Spine to film distance D2 = 0.36 m (14 in)

These two distances give a linear magnification of 24%: M = 24%.

TABLE 1. Percentage Magnification of Image Associated with Different Spine-to-Film Distances

Spine-to-film Distance m (in.)	Magnification %
0.15 (6.0)	9
0.20 (8.0)	12.5
0.25 (10.0)	16
0.30 (12.0)	20
0.36 (14.0)	24

Source-to-film distance = 1.83 m (72 in.).

From White AA, Panjabi MM (1990): The problem of clinical instability in the human spine: a systematic approach.

In: *Clinical biomechanics of the spine*. Philadelphia: WB Saunders, with permission.

B. MAGNIFICATION: GEOMETRIC DISTORTION OF THE ROENTGEN IMAGE AND ITS CORRECTION

A number of devices have been constructed that give a fully compensated value of a given object dimension. These devices have usually been made for use in pelvicephalometry. A nomogram (Fig. 2) may be used for finding corrected dimensions.

C. RADIATION EXPOSURE

Compared with other conventional radiographic procedures, the radiographic examination of the lumbosacral spine delivers one of the highest doses of radiation to the skin, bone marrow, and gonads. The mean value of radiation to the gonads from a lumbosacral examination is exceeded only by urography and colon examinations. For women, the radiation dose to the gonads is higher than that for men during the lumbosacral examination. The current dose can be 1.5 to 4 times lower if newer film-screen combinations are used. Gonadal doses are higher when there is poor centering, poor coning, or poor calibration of radiographic equipment, or when repeated films are taken. Unfortunately, radiographs frequently ordered to evaluate acute low back pain (“strain”) in young adults deliver a high direct gonadal dose of radiation in this self-limiting disorder. Because of the high radiation dose of the lumbosacral examination, various authors have stressed the need for eliminating unnecessary radiographic examinations and limiting the number of views per radiographic study. Among those suggestions are the following: a single, well-centered lateral spine radiograph to replace the combination of lateral and cone lateral views; obtaining only anteroposterior and lateral views; and eliminating oblique views.

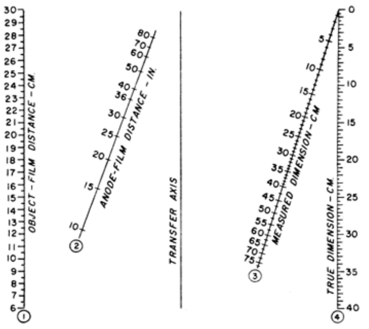

FIGURE 2. Nomogram (designed by Holmquist) for securing corrected dimension. 1. Draw a straight line from the object-film distance (a) through the anode-film distance (b) to the transfer axis. 2. Draw a second line from this point on the transfer axis through the measured dimension (c) to the true dimension (d). (From Holmquest HJ (1938): Nomogram for roentgenographic mensuration. *Radiology* 31:198–205, with permission.)

In patients with scoliosis who receive repeated follow-up examinations, there is also increased radiation to the gonads, thyroid gland, and breast (in girls). However, proper selection of screen-film-grid combinations, collimation of x-ray beam, proper technical factors, and proper shielding reduce the radiation burden. Using posteroanterior exposure reduces the radiation to the breast but increases the absorbed dose to bone marrow.

Kricun ME (1988): Conventional radiography. In: Kricun ME. *Imaging modalities in spinal disorders.* Philadelphia: WB Saunders.

Waggener RG, Kereiakes JG, Shalek, RJ (1984): *CRC handbook of medical physics*, Vol. 2. Boca Raton, Fla: CRC Press, Inc.

Webster EW, Merrill OE (1957): Radiation hazards. II. Measurements of gonadal dose in radiographic examinations. *N Engl J Med* 257:811–819.

D. RELATIVE COMPLICATIONS OF RADIOTHERAPY

Radiation, either from external or internal sources, may lead to alterations in the axial skeleton. The effects of radiation depend on the dose absorbed by bone, duration of radiation, quality of radiation, area of the spine irradiated, age of the patient when irradiated, and whether irradiation occurred to abnormal bone. As a general rule the greater the treatment dose and the younger the child at the time of radiotherapy, the greater the radiographic alterations. Children who receive less than 1000 cGy by orthovoltage therapy do not develop gross, permanent spinal abnormalities (although growth retardation can occur with 800 cGy); however, those who receive 1000 to 2000 cGy may develop minor changes of growth arrest. Those who receive over 2000 cGy will probably experience growth disturbance. Patients who receive less than 2600 cGy from megavoltage therapy do not develop spinal deformities, whereas those who receive more than 3070 cGy develop spinal deformities. The skeletal changes observed with megavoltage therapy occur as frequently but are not as pronounced as those following orthovoltage therapy (Table 2).

Riseborough EJ, Grabias SL, Burton RJ, et al. (1976): Skeletal alterations following irradiation for Wilms' tumor: with particular reference to scoliosis and kyphosis. *J Bone Joint Surg [Am]* 58:526–536.

TABLE 2. Relative Complications of Radiotherapy

	Orthovoltage	Megavoltage
Growth recovery lines	28%	45%
Endplate irregularity	83%	70%
Anterior beak	20%	25%
Decreased vertebral height	83%	Data not available

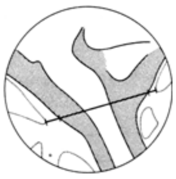

FIGURE 3. On a midsagittal pneumotomogram, the landmarks used for the measurement of the bony canal and the subarachnoidal canal at the level of the foramen magnum are indicated. (From Schmeltzer A, Babin E, Wenger JJ (1971): Foramen magnum in children: measurement of the anteroposterior diameter on midsagittal pneumotomograms. *Neuroradiology* 2:162–163, with permission.)

E. CRANIOVERTEBRAL JUNCTION

1. Measurement of the Foramen Magnum in Children and Adults

Measurements made on a line drawn between the lower margin of the occipital bone and the basion (anterior margin of foramen magnum) are shown in Figure 3 . During growth, the average anteroposterior diameter of the foramen increases from 30 to 35 mm and the average anteroposterior diameter of the subarachnoidal canal increases from 24 to 28 mm (Fig. 4).

2. Basilar Impression

a. *Lateral Craniometry*

Deformity of the bones of the base of the skull at the margin of the foramen magnum, where the base of the skull appears to be indented by the upper cervical spine. There are two types of basilar impression. Primary basilar impression is a congenital anomaly that is often associated with other vertebral defects. Secondary basilar impression is a developmental condition usually attributed to softening of the osseous structures of the base of the skull. It is difficult to assess radiographically, and many measurement schemes have been proposed. The most commonly used are the Chamberlain, McGregor, and McRae lines.

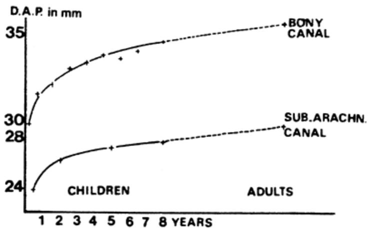

FIGURE 4. Diagram showing the anteroposterior diameter of the bony canal and subarachnoidal canal at the foramen magnum according to age: Normal measurements have been corrected for magnification. Based on measurement of 200 children and 100 adults. (From Schmeltzer A, Babin E, Wenger JJ (1971): Foramen magnum in children: measurement of the anteroposterior diameter on midsagittal pneumotomograms. *Neuroradiology* 2:162–163, with permission.)

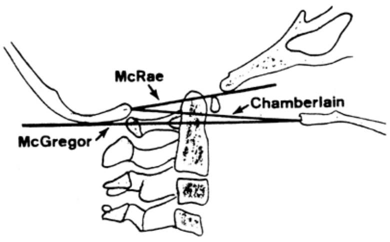

FIGURE 5. Lateral craniometry showing the three most commonly used lines to determine basilar impression. Chamberlain, McGregor, and McRae lines. McGregor's line is the best method for routine screening because the bony landmarks can be defined clearly at all ages on a routine lateral radiographic view. (From Hensinger RH (1986): Osseous anomalies of the craniovertebral junction. *Spine* 11:323–333, with permission.)

1. *Chamberlain's Line*. Chamberlain's line is drawn from the posterior margin of the hard palate to the posterior margin of the foramen magnum (opisthion). According to Poppel, the odontoid process should not project above this line in the normal case (SD 3.3 mm). In any individual case, an odontoid process 6.6 mm (2 SD) or more above the line should be considered strongly indicative of basilar impression, based on his study of 102 normal skull radiographs (Fig. 5)

Line	No. of cases	Mean position of tip of odontoid in relation to Chamberlain's line (mm)	Standard deviation (mm)
Saunders	100	-1	3.6
McGregor (Bantu)	203	-1.32	2.62
Poppel	102	+0.06	3.3

2. *McGregor's Line*. McGregor's line is drawn from the posterosuperior margin of the hard palate to the lower-most point on the midline occipital curve. It is the best method for routine screening because the bony landmarks can be defined clearly at all ages on a routine lateral radiographic view. The position of the tip of the odontoid is measured in relation to this baseline; a distance of 4.5 mm above McGregor's line is considered to be on the extreme edge of normality. However, Hinck and associates demonstrated a wide range of normal as well as differences between men and women (Table 3, Fig. 5)
3. *McRae's Line (Foramen Magnum Line)*. McRae's line is drawn from the anterior margin of the foramen magnum (basion) to the posterior border (opisthion). The tip of the odontoid should lie below this line (Fig. 5).
4. *Bull's Method*. Bull's method is a line drawn along the plane of hard palate that intersects a line drawn along the plane of the atlas. If the angle formed by the intersection of these two lines is greater than 13, the position of the odontoid process is abnormal. This angle has been shown to vary significantly with flexion and extension (Fig. 6).
5. *Ranawat's Method*. Ranawat's method is useful when the hard palate is not visualized in the film. The distance between the center of the pedicle of C2 and the line drawn in the coronal axis of C1 is measured. In men, this distance averages 17 mm, with a SD of 2 mm. In women, it measured 15 mm, with a SD of 2 mm. Superior migration of the odontoid has occurred in the cases in which this distance is decreased based on radiographs of 26 normal individuals and 33 patients with rheumatoid arthritis (Fig. 7).

TABLE 3. Meassurement of the Base of the Skull for Basilar Invagination[a]

	Children: Both Sexes (mm)	
Age	Mean Baseline	90% Tolerance Range
3	1.94	-0.8 to 4.7
4	2.07	-0.7 to 4.8
5	2.17	-0.6 to 4.9
6	2.24	-0.5 to 5.0
7	2.29	-0.4 to 5.1
8	2.31	-0.4 to 5.1
9	2.30	-0.4 to 5.1
10	2.27	-0.5 to 5.0
11	2.21	-0.5 to 5.0

12	2.13	-0.6 to 4.9
13	2.01	-0.7 to 4.8
14	1.88	-0.9 to 4.6
15	1.71	-1.0 to 4.5
16	1.52	-1.2 to 4.3
17	1.31	-1.4 to 4.1
18	1.07	-1.7 to 3.8

	Adults mm		
Sex	Mean	SD	90% Tolerance Range for Normal
Male subjects	0.33	3.81	-7.4 to +8.0 mm
Female subjects	3.67	1.69	-2.4 to +9.7 mm
M-F average difference	-3.06	—	—

From Hinck VC, Hopkins CE, Savara BS (1961): Diagnostic criteria of basilar impression. *Radiology* 76:572–85, with permission.

[a] McGregor's line: *Children*: mean baseline and 90% tolarance range for both sexes at different ages. *Adults*: mean, SD, and 90% tolerance range for both sexes. Based on radiographs of 66 normal adults and a series of 258 films taken at yearly intervals in 43 normal children aged 3–18 years.

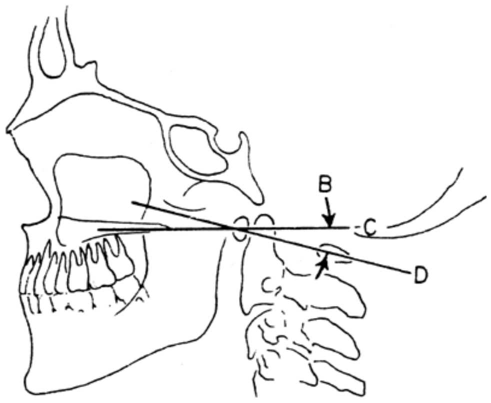

FIGURE 6. Bull's method. The angle formed by the intersection of a line drawn along the plane of the hard palate and a line drawn along the plane of the atlas should be normally less than 13 degrees. Based on roentgenograms of 120 normal skulls. (From Hinck VC, Hopkins CE, Savara BS (1961): Diagnostic criteria of basilar impression. *Radiology* 76:572–585, with permission.)

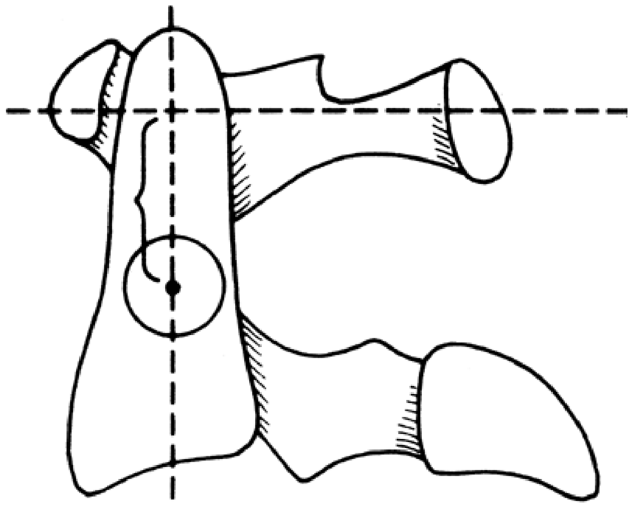

FIGURE 7. A line is drawn connecting the center of the anterior arch of the first cervical vertebra with its posterior ring. The center of the sclerotic ring of the second cervical vertebra, presenting the pedicle is marked. The distance between the center of the pedicle of C2 and the line drawn in the coronal axis of C1 is measured. (From Ranawat CS, O'Leary P, Pellicci P (1979): Cervical spine fusion in rheumatoid arthritis. *J Bone Joint Surgery [Am]* 61:1003–1010, with permission.)

6. *Redlund-Johnell Method*. Redlund-Johnell and Petterson described a method of measurement that uses McGregor's line, the apex of the dens, and the lower plate of C2. They measured the distance between the apex of the dens and McGregor's line, and the distance between the lower plate of C2 and McGregor's line in 200 normal adults (100 men and 100 women), and compared them with measurements in 61 patients with rheumatoid arthritis (10 men and 51 women). The distance between McGregor's line and the lower plate end of the body of C2 in normal men was 41.6 4.0 mm, in normal women it was 37.1 4.3 mm; in patients with rheumatoid arthritis: for men, 32.3 4.9 mm and women 28.7 4.3 mm. Values under 34 mm in men and 29 mm in women indicate cranial settling. The distance from McGregor's line to the apex of the dens was for normal subjects: men, 2.4 3.2 mm; women 2.5 3.3 mm; for patients with rheumatoid arthritis: men 10.2 3.3 mm; women 9.3 3.7 mm. All the differences between normal (control) patients and patients with rheumatoid arthritis were statistically significant. (Fig. 8).
7. *Station of the Atlas*. The station of the atlas is the simplest way to quickly screen for the possibility of cranial settline (Fig. 9)

b. *Anterior Craniometry*

1. *Bimastoid Line*. Line drawn between the tips of the mastoid processes is the bimastoid line. Normally it should cross the atlanto-occipital joints. This

line has been supplanted by the digastric line. Because the mastoid process varies considerably in length from one individual to another, the normal position of a reference line based on these structures is therefore quite variable. According to Fischgold, the odontoid apex should lie an average of 2 mm above this line, with a range between 3 mm below and 10 mm above (Fig. 10)

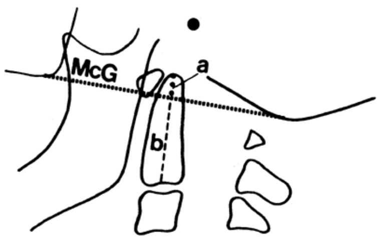

FIGURE 8. Redlund-Johnell measurement method. *McG*, the palato-occipital line, or McGregor's line. *a*, The distance between the apex of the dens and McG. If the apex is situated below this line, the value will be negative. *b*, The distance between the lower end plate of the C2 and McG. (From Redlund-Johnell I, Petterson H (1984): Radiographic measurements of the craniovertebral region. *Acta Radiol Diagn* 25:23–28, with permission.)

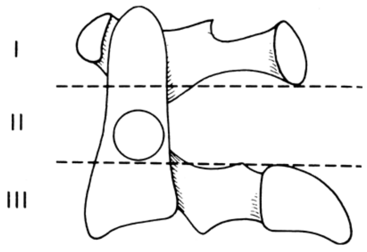

FIGURE 9. The station of the atlas is determined by dividing the odontoid process into thirds in the sagittal plane. Normally, the anterior ring of the atlas should be adjacent to the cephalad third of the axis *(station I).* If the ring of the atlas is adjacent to the middle third of the axis, mild cranial settling is indicated *(station II).* If the anterior ring of the atlas is adjacent to the base of the axis, it is considered evidence of severe cranial settline *(station III).* (From Clark CC, Goetz DD, Menezes AH (1989): Arthrodesis of the cervical spine in rheumatoid arthritis. *J Bone Joint Surg [Am]* 71:381–392, with permission.)

2. *Digastric Line*. The digastric line is between the two digastric grooves that lie just medial to the bases of the mastoid processes. According to Fischgold, the distance measured from this line to the middle of the atlanto-occipital joints is normally about 10 mm. The distance in millimeters between this line and the apex of the dens and the atlanto-occipital joint is shown in Table 4 .
3. *Temporomandibular Line*. The distance of the temporomandibular line is measured between two parallel lines, one (TM) at the level of the temporomandibular joints and one (AA) at the superior margin of the anterior arch of the atlas. Either an anteroposterior or lateral projection may be used. These lines are usually about 30 mm apart, with a range from 22 to 39 mm. The distance is diminished in basilar impression (Fig. 11).

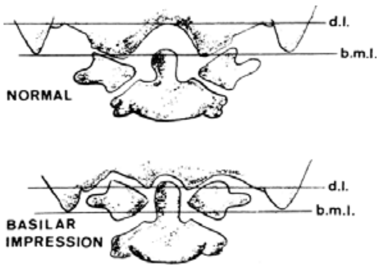

FIGURE 10. Anterior craniometry. Fischgold and Metzger noted that in the normal skull, a line joining the lower poles of the mastoid processes *(bml)* passes through the tip of the odontoid. Owing to the variability in the size of mastoid processes, this was further refined to a line drawn between the digastric grooves *(dl).* These lines are best visualized on an anteroposterior transoral tomogram. Although this is the most accurate method for assessing basilar impression, routine use of this method is impractical. (From Hensinger RN (1986): Osseous anomalies of the craniovertebral junction. *Spine* 11:323–333, with permission.)

TABLE 4. Measurement of the Base of the Skull for Basilar Invagination[a]

Sex	Mean	SD	90% Tolerance Range for Normals
Measured on laminagrams to atlanto-occipital joint (mm)			
M or F	11.66	4.04	3.8–19.5
Measured on laminagrams to apex of dens (mm)			
M or F	10.70	5.06	1.0–20.4

TABLE 5. Craniometric Lines in Lateral Views

Synonyms	Definition	Normal Measurements	Implications
Wackenheim's line (clivus canal line)	Line drawn along clivus into cervical canal	Odontoid tip is ventral and tangential to this line	Odontoid process transects the line in basilar invagination or forward position of skull
Chamberiain's line (palato-occipital line)	Joins posterior pole of hard palate to opisthion	Tip of dens 1 mm + 3.6 mm below this line	Odontoid process bisects the line in basilar invagination
McRae's line (foramen magnum line)	Joins anterior and posterior edges of foramen magnum (basion to opisthion)	Tip of dens does not exceed this line	When effective sagittal canal diameter is less than 20 mm, neurological symptoms occur
McGregor's line (basal line)	Hard palate to lowest point of occipital bone	Tip of dens should not exceed 5 mm above the line	Line position varies with flexion-extension—hence not important
Height-index of Klaus	Distance between tip of dens and tuberculum-cruciate line	40–41 mm	<30 mm seen in basilar invagination
Spinolamellar line (spinous interlaminar line)	Line drawn from interoccipital ridge above and down along the fused spinous process of C2 and C3	Should intersect posterior arch of atlas	If atlas is fused, posterior arch is anterior to the line; posterior compression of spinal cord may occur

From Menezes AM, VanGilder JC (1990): Anomalies of the craniovertebral junction. In: *Youman's neurological surgery*, 3rd ed. Philadelphia: WB Saunders, with permission.

TABLE 6. Craniometric Lines and Angles in Anteroposterior View

Synonyms	Definition	Normal Measurements	Implications
Fishgold's diagastric line (biventer line)	Joins the fossae for diagastric muscles on undersurface of skull just medial to mastoid process	Dens tip should not project above this line; central axis of dens should be perpendicular to the line	Corresponds to McRae's line on lateral view; may be oblique in unilateral condylar hypoplasia; oblique odontoid suggests paramedian abnormality
Fishgold's bimastoid line	Line connecting tips of mastoid process	Runs across atlanto-occipital joints; line is 10 mm below diagastric line	Odontoid tip may be 10 mm above the line
Schmidt–Fischer angle (angle of axes of atlanto-occipital joints)	Angle of axes of atlanto-occipital joints	124–127 degrees; should be measured in plane of dens on tomograms	Angle is wider in condylar hypoplasia

Platybasia

Platybasia denotes flattening of the angle formed by the intersection of the plane of the anterior fossa with the plane of the clivus. It does not have clinical significance and it is merely an anthropologic term. The basal angle is the angle formed by a line drawn from the nasion to the center of the seila turcica, and a line drawn from the center of the sella turcica to the anterior margin of the foramen magnum (Fig. 14).

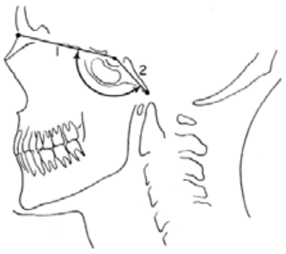

FIGURE 14. The basal angle. Line 1 drawn from the nasion to the center of the sella turcica. Line 2 drawn from the center of the sella turcica to the anterior margin of the foramen magnum. (From Poppel MH, Jacobson HG, Duff BK, Gottlieb C (1953): Basilar impression and platybasia in Paget's disease. *Am J Roentgenol* 61:639–644, with permission.)

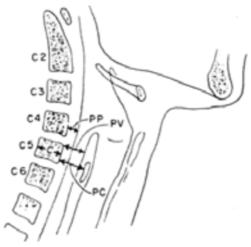

FIGURE 15. Measures of the soft tissues of the neck. *PV*, Postventricular soft tissues for use in children in which the cricoid cartilage is not visible. The distance is measured between the posterior commisure of the larynx and the nearest portion of the cervical spine. *PP*, Postpharyngeal soft tissue, measured at a point where the soft tissues run parallel to the vertebra. *PC*, Postcricoid soft tissue, measured between the posterior surface of the cricoid cartilage and the anterior surface of the adjacent cervical vertebra. *C*, Anteroposterior dimension of C5 vertebral body at its middle. (From Templeton PA, et al. The value of retropharyngeal soft tissue measurements in trauma of the adult cervical spine. *Skeletal Radiol* 16:98–104, with permission.)

B. CERVICAL SPINE

1. Measurement of the Soft Tissues of the Neck in Children

In children, the thickness of the soft tissue between the pharyngeal lumen and the vertebrae should be about three fourths the diameter of the adjacent vertebra. According to Templeton, in films made in the lateral projection using 40-in focus film distance, values between 7 and 10 mm at C2, C3, or C4 should suggest possible abnormality. Values of 10 mm or more definitely indicate the need for additional investigation. He found considerable overlap in the retropharyngeal soft tissue space of normal and abnormal patients. (Fig. 15).

Keats TE (1990): The neck. In: *Atlas of roentgenographic measurements*, 6th ed.

2. **Normal Cervical Spine Prevertebral Space in Adults**

Measurements made a line describing the shortest distance between (a) the anterior arch of the atlas and the anterosuperior and anteroinferior edges of the vertebral bodies of C2 and C7 and (b) the air shadows of the pharynx and trachea. (Fig. 16, Table 7).

Wholey MH, Brewer AJ, Baker HL Jr (1958): Lateral roentgenograms of the neck with comments on atlanto-odontoid-basion relationship. *Radiology* 71:350–356.

3. **Atlantodens Interval in Children**

Measurement of the atlantodens interval is made between the posteroinferior margin of the anterior arch of the atlas and the anterior surface of the odontoid process (Fig. 17).

Average normal distance is 2.0 mm; 99% of patients will be between 1 and 4 mm. Maximum distance found in a patient was 5 mm (Fig. 18). Less than 4 mm is considered normal in children.

4. **Atlantodens Interval in Adults**

The average normal atlantodens interval in adults is as follows:

Female (age 20 to 80): .238 - (0.0074 × age in years) 0.90 mm

Male (age 30 to 80): 2.052 - (0.0192 × age in years) 1.00 mm

About 95% of normal adults will have an atlas-odontoid distance in flexion between 0.3 and 1.8 mm, in neutral position between 0.4 mm and 2.0 mm, and in extension between 0.3 and 2.2 mm, based on studies of 25 men and 25 women. Less than 3 mm is considered normal. Values of 5 mm or more usually indicate rupture of the transverse ligament.

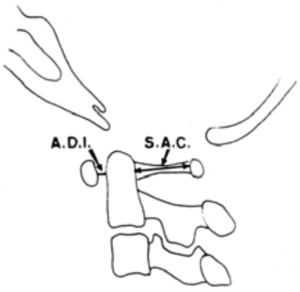

FIGURE 17. Atlantoaxial joint demonstrating the normal atlas-dens interval *(ADI)* and the normal space available for the spinal cord *(SAC)*, the distance between the posterior aspect of the odontoid and the nearest posterior structure. (From Hensinger RN (1986): Osseous anomalies of the craniovertebral junction. *Spine* 11:323–333, with permission.)

Fielding JW, Cochran GV, Lawsing JF, Hohl M (1974): Tears of the transverse ligament of the atlas. *J Bone Joint Surgery [Am]* 56:1683–1691.

5. **Space Available for the Spinal Cord**

The atlantodens interval is of limited value in evaluating chronic atlantoaxial instability. In this condition, the odontoid is frequently found to be hypermobile with a widened atlantodens interval, particularly in flexion (Fig. 19). In this situation, attention should be directed to the amount of space available for the spinal cord. This is accomplished by measuring the distance from the posterior aspect of the odontoid or axis to the nearest posterior structure (foramen magnum or posterior margin of the atlas). This measurement is particularly helpful when evaluating a patient with nonunion of the odontoid or os odontoideum because in both conditions the atlantodens interval may be normal, yet in flexion or extension there may be considerable reduction in the space available for the spinal cord (Fig. 20). Steel defined the "rule of thirds," in that the area of the vertebral canal at the first cervical vertebra can be divided into one-third cord, one-third cervical vertebra, and one-third "space." The one-third "space" represents a safe zone in which displacement can occur without neurologic impingement. It is generally agreed that a reduction of the lumen of the spinal canal to 13 mm or less may be associated with neurologic problems (Fig. 21).

6. Normal and Abnormal Relationships Between the Occiput and Atlas: Detection of Anterior Atlanto-occipital Dislocation.

The ratio BC/OA is used to determine anterior atlanto-occipital dislocation (Fig. 22). BC/OA is equal to or greater than 1 in all cases of atlanto-occipital dislocation. Ratios less than 1 are normal. This relationship is valid only in the absence of associated fractures of the atlas. Data are from 100 normal adults and 50 normal children, and four cases of dislocation.

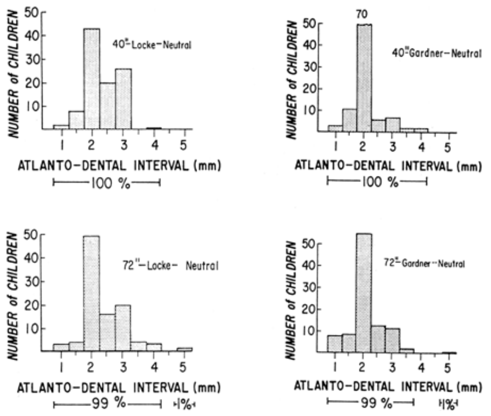

FIGURE 18. Atlantodens interval determined from lateral radiographs in 200 normal children 3 to 15 years of age. The lower limit of 3 years was selected because of the summit of the epiphysis of the odontoid process is not present earlier, and adequate radiographs are more dificult to obtain in the younger children. In the upright position, 100 studies were done using a 72-in tube-to-film distance and were interpreted by one examiner **(A, B)**. Another 100 studies were shot at 40-in tube-to-film distance with the patient supine and the film exposed with the horizontal beam and again read by one examiner **(C, D)**. These positions were selected because supine studies are usually used in trauma investigations, whereas children with inflammatory disease are examined upright. (From Locke GR, Gardner JL, Van Epps EF (1966): Atlas-dens interval (ADI) in children: survey based on 200 normal cervical spines. *Am J Roentgenol* 97:135–140, with permission.)

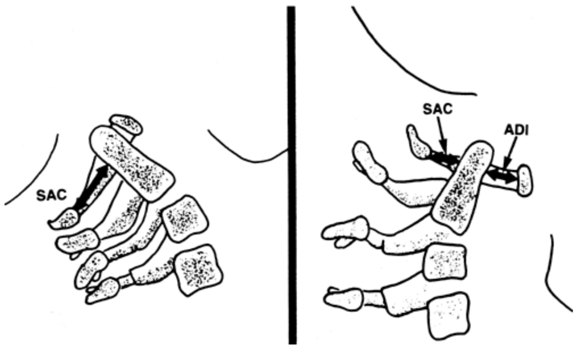

FIGURE 19. Atlantoaxial instability with intact odontoid. **A:** Extension: The atlas-dens interval (ADI) and space available for the spinal cord (SAC) are normal because the intact odontoid provides a bony block to subluxation in hyperextension. **B:** Flexion: Forward sliding of the atlas with an increased ADI and decreased SAC. (From Hensinger RN (1986): Osseous anomalies of the craniovertebral junction. *Spine* 11:323–333, with permission.)

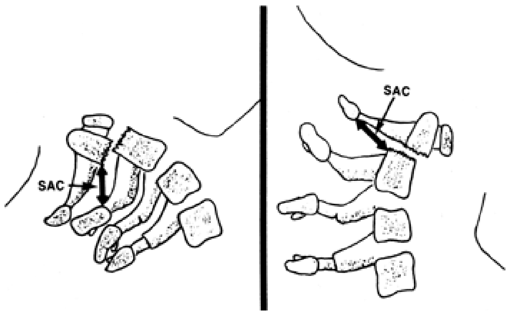

FIGURE 20. Atlantoaxial instability with os odontoideum, absent odontoid, or traumatic nonunion. **A:** Extension: Posterior subluxation with reduction in SAC and no change in the ADI. **B:** Flexion: Forward sliding of the atlas with reduction of the SAC. (From Hensinger RN (1986): Osseous anomalies of the craniovertebral junction. *Spine* 11:323–333, with permission.)

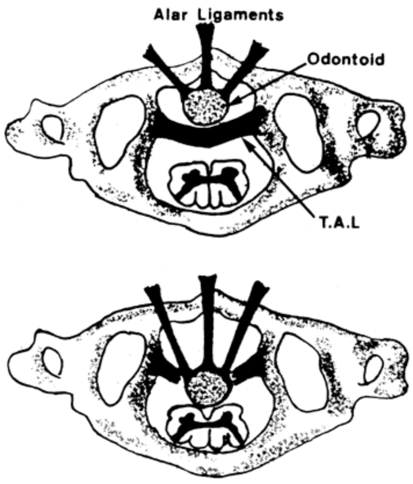

FIGURE 21. Atlantoaxial joint as viewed from above. **A:** Normal. **B:** Disruption of the transverse atlantal ligament (TAL); odontoid occupies the “safe zone of Steel.” The intact alar ligaments (second line of defense) prevent spinal cord compression. (From Hensinger RN (1986): Osseous anomalies of the craniovertebral junction. *Spine* 11:323–333, with permission.)

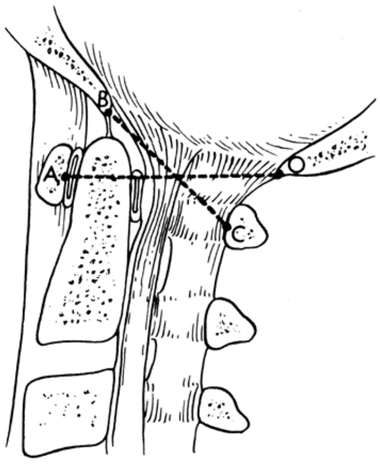

FIGURE 22. Normal relationship between the occipital and atlas. *A*, Anterior arch of the atlas; *B*, basion; *C*, Posterior arch of the atlas; *O*, Opisthion of the occipital bone. (From Powers B, Miller MD, Kramer RS, et al. (1979): Traumatic anterior atlanto-occipital dislocation. *Neurosurgery* 4:12–17, with permission.)

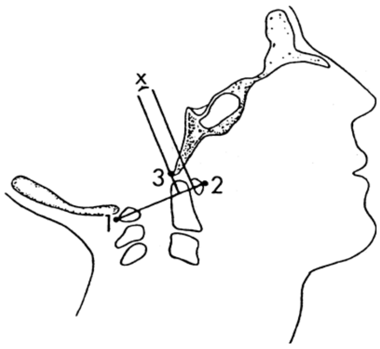

FIGURE 23. Method of measuring atlanto-occipital instability according to Wiesel and Rothman. These lines are drawn on flexion and extension lateral roentgenograms, and the translation should be no more than 1 mm. (From Gabriel KR, Mason DE, Carango P (1990): Occipitoatlantal translation in Down's syndrome. *Spine* 15:997).

The method of Weisel and Rothman of measuring atlanto-occipital instability. Lines are drawn on a lateral cervical spine x-ray as shown in Figure 23, on flexion and extension, and the translation should be no more than 1 mm.

7. **Anterior Displacement of C2 in Children. C2–3 Pseudo subluxation** (Fig. 24).
8. **Measurement of the Interspinous Distance for the Detection of Anterior Cervical Dislocation in the Supine Frontal Projection**

A widened interspinous distance (ISD), which measures more than 1.5 times the ISD above and more than 1.5 times the ISD below, indicates the presence of an anterior cervical dislocation at the level of the abnormal widening based on a study of 500 patients with normal cervical spine and 14 patients with documented anterior cervical dislocations.

Naidich JB, et al. (1977): The widened interspinous distance: a useful sign of anterior cervical dislocation in the supine frontal projection. *Radiology* 123:113–116.

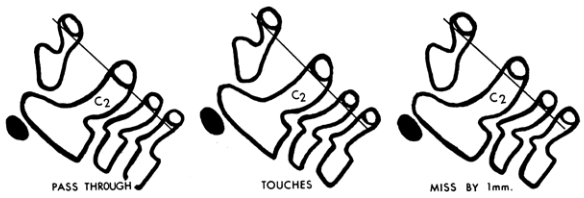

FIGURE 24. A line is drawn through the anterior cortex of the posterior arches of C1, C2, and C3. In the normal situation or in pseudosubluxation, the line is normal if it *(A)* passes through or just behind the anterior cortex of the posterior arch of C2, *(B)* touches the anterior aspect of the cortex of C2, or *(C)* comes within 1 mm of the cortex of C2. In pathologic dislocation of C2 or C3, the posterior cervical line misses the posterior arch of C2 by 2 mm or more. If the line misses the arch by 1.5 mm, one should be suspicious, but if the distance is 2 mm or more, true dislocation should be assumed unless further tests show that there is no dislocation. Based on a study of 500 children up to the age of 14 years. (From Swischuk LE (1977): Anterior displacement of C2 in children: physiologic or pathologic? *Radiology* 122:759–763, with permission.)

Vertebral level	Mean diameter in mm
C2	12.5
C3	11.5
C4	11.5
C5	12.2
C6	12.6
C7	12.1

9. **Measurement of the Sagittal Diameter of the Cervical Spinal Canal in Infants**

Standard deviation is 0.7 mm (Fig. 25).

10. **Sagittal Diameter of the Cervical Spine Canal in Children** (Figs. 26, 27, 28 ; Tables 8, 9)

[a] Based on lateral radiographic views of the cervical spine in 120 normal children between 3 and 14 years of age.
[b] Number in parentheses indicate number of subjects.

TABLE 9. Sagittal Diameter of the Bony Cervical Spinal Canal in 120 Normal Children: Relation to Height[a]

Height (cm)	Age (years)	No. of boys and girls	C1 Mean mm	C2 Mean mm	C3 Mean mm	C4 Mean mm	C5 Mean mm	C6 Mean mm	C7 Mean mm
91-100	2.84–4.41	12	19.0	17.2	15.3	15.0	14.9	14.8	14.6
101-110	3.13–5.78	13	19.9	17.7	15.9	15.6	15.5	15.4	15.3
111-120	4.04–7.48	16	20.6	18.5	16.8	16.5	16.4	16.1	15.7
121-130	5.44–10.50	20	20.5	18.8	17.2	16.9	16.6	16.4	16.0
131-140	7.79–11.51	18	20.7	18.9	17.3	17.0	16.7	16.4	16.1
141-150	8.83–13.50	19	21.2	19.2	17.6	17.2	16.9	16.6	16.0
151-160	11.22–14.39	14	21.3	19.5	17.8	17.2	17.1	16.8	16.5
161-170	13.09–14.48	8	21.4	19.6	17.9	17.5	17.2	16.9	16.4

From Markuske H (1977): Sagittal diameter measurements of the bony cervical spinal canal in children. *Pediatr Radiol* 6:129–131, with permission.

[a] Based on lateral radiographic views of the cervical spine in 120 normal children between 3 and 14 years of age.

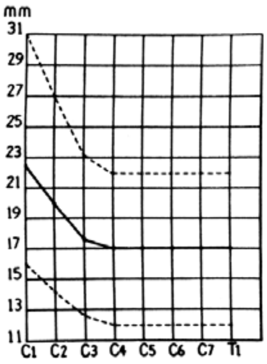

FIGURE 29. Curves for average, maximal, and minimal sagittal measurements of cervical spinal canal in adults. Plotted values are uncorrected measurements from lateral neck films taken at 72-in target-table top distance. Truce measurements are 1.5 mm less than those shown. Based on measurements made on 200 adults with no known neurologic disturbances and showing no obvious bone or joint changes on the films. (From Wolf BS, Khilnani M, Malis L (1956): The sagittal diameter of the bony cervical spinal canal and its significance in cervical spondylosis. *J Mount Sinai Hosp* 23:283–292, with permission.)

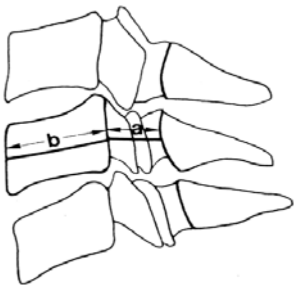

FIGURE 30. The ratio of the vertebral canal to the vertebral body is the distance from the midpoint of the posterior aspect of the vertebral body to the nearest point on the corresponding spinolaminar line *(a)* divided by the anteroposterior width of the vertebral body *(b).* Based on measurements made at the level of the third to the sixth vertebral body on a routine lateral view of the cervical spine on 24 patients and 49 normal adults. (From Torg JS, Pavlov H, Genuario SE, et al. (1986): Neuropraxia of the cervical spinal cord with transient quadriplegia. *J Bone Joint Surg [Am]* 68:1354–1370, with permission.)

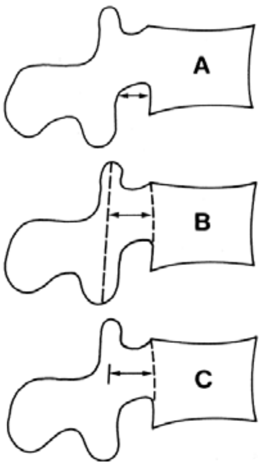

FIGURE 31. Three different methods recommended for measuring the sagittal diameter of the spinal canal. *A*, In Epstein's method, measurements are made from the uppermost level of the intervertebral foramen to the nearest point on the dorsal surface of the centrum. *B*, In Einstein's method, the sagittal diameter is measured from a line drawn from the midheight of posterior vertebral border to the nearest point of the interfacet line. The latter joints the apex of the superior articular facet to the inverted apex of the inferior facet. *C*, In Hinck's method, the sagittal diameter is the shortest perpendicular distance between the vertebral body and the inner surface of the neural arch. (From Omojola MF, Vas W, Banna M (1981): Plain film assessment of spinal canal stenosis. *J Can Assoc Radiol* 32:95–96, with permission.)

13. **Other Methods of Assessing Spinal Canal Stenosis on Plain Films**

    Methods of assessing spinal canal stenosis based on plain films have been criticized because significant discrepancy exists between them. Three-dimensional assessment by computed tomography has been recommended (Fig. 31).

    Einstein S (1977): The morphometry and pathological anatomy of the lumbar spine in South African negroes and caucasoids with specific reference to spinal stenosis. *J Bone Joint Surg [Br]* 59:173–180.

    Epstein BS, Epstein JA, Lavine L (1964): The effect of anatomic variations in the lumbar vertebrae and spinal canal on cauda equina and nerve root syndromes. *Am J Roentgenol* 91:1055–1063.

    Hinc VC Hopkins CE, Clark WM (1965): Sagittal diameter of the lumbar spinal canal in children and adults. *Radiology* 85:929–937.

14. **Developmental Segmental Sagittal Diameter, Spondylotic Segmental Sagittal Diameter, and Spondylosis Index**

    Normally, the spinal canal is oval shaped in the midcervical region, and there is a sagittal diameter of 17 mm. The cervical cord diameter varies little from C1 to C7 and averages 10 mm. The diameter of the spinal canal increases with flexion and decreases with extension. The spinal cord moves as much as 3 mm at C7 during flexion and extension, and results in angulation of the nerve roots at their foramina (Fig. 32).

    Burrows EH (1963): The sagittal diameter of the spinal canal in cervical spondylosis. *Clin Radiol* 14:77–86.

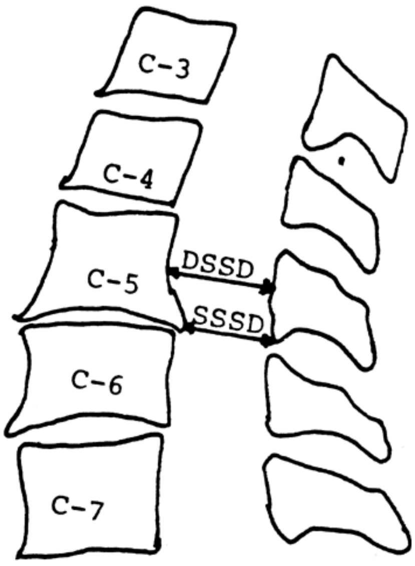

FIGURE 32. The developmental segmental sagittal diameter (DSSD) is determined at the level of the pedicle. A perpendicular line is drawn to the posterior margin of the spinal canal as determined by the most anterior bony landmark for the segment. A second perpendicular line is drawn at the level of the disc indicating the spondylotic segmental sagittal diameter (SSSD). The difference between these two measurements is the spondylosis index (SI) and represents the amount of narrowing of the spinal canal due to the disease process. (From

Edwards WC, LaRocca H (1983): The developmental segmental sagittal diameter of the cervical spinal canal in patients with cervical spondylosis. *Spine* 20–27

, with permission.)

15. **Cervical Spine Lordosis** (Table 10)
16. **Radiographic Measurements of the Normal Cervical and Thoracic Spinal Cord in Childhood** (Figs. 33, 34)
17. **Normal Cord (Cervical, Thoracic, and Conus) in Infants and Children Examined with Computed Tomographic Metrizamide Myelography** (Fig. 35 and Table 11).
18. **Measurement of the Width of the Cervical Spinal Cord in Adults**

    Measurements were made at the level of the fourth and sixth cervical vertebrae when possible. Average width = 1.4 cm; minimum width = 1.0 cm; maximum width = 1.7 cm. The distance between the “inner” shadow of the true cord was measured rather than the entire central shadow, which includes the nerve roots. Measurements were taken from 20 patients undergoing lumbar myelography because of suspected herniated disc. There was no clinical suspicion of cervical pathology.

TABLE 10. Cervical Spine Lordosis[a]

Age in Years	Angle in Degrees Men	 Women
20–25	16 ± 16	15 ± 10
30–35	21 ± 14	16 ± 16
40–45	27 ± 14	23 ± 17
50–55	22 ± 15	25 ± 11
60–65	22 ± 13	25 ± 16

From Gore DR, Sepic SB, Gardner GM (1986): Roentgenographic findings of the cervical spine in asymptomatic people. *Spine* 11:521–524, with permission.

[a] Mean (±1 standard deviation). Based on radiographs of 200 asymptomatic adults.

TABLE 11. Range of Cord Measurements by Age Group[a]

	Cervical		Midthoracic		Conus	
Age	Sagittal Diameter	Transverse Diameter	Sagittal Diameter	Transverse Diameter	Sagittal Diameter	Transverse Diameter
0–3 mo	4.5–5	4.5–7	2.5–5	3–4	4	5
3–18 mo	5–7	7–12	4.5–6	5–7.5	5.5–7	6.5–7
1 1/2–6 y	7–7.5	10.5–12	5–6.5	6–7	6.5–7	6.5–9
Older than 6 y	7.5–9	10–14	5–6.5	7–8.5	6.5–9	8–11

Nicholson AA, Roberts GM, Williams LA (1988): The measured height of the lumbosacral disc in patients with and without transitional vertebrae. *Br J Radiol* 61:454–455.

3. **Measurement of the Normal Wedging of the Dorsolumbar Vertebrae**

The degree of anterior wedging was measured as the ratio between the heights of the anterior (A) and the posterior (P) aspects of the vertebral bodies at a distance of 2 mm from the vertebral margins to avoid the edges, which are difficult to define. The mean A/P ratios were calculated and are shown in Table 18 .

4. **Scoliosis (See also under classifications)**
   a. *Radiographic Measurements*

Posteroanterior and lateral views of the entire spine are the basic films used for evaluation of any type of scoliosis. They should show the entire spine from the occiput to the coccyx on a single film. Appropriate filters can help render all parts of the spine almost equally visible, despite different tissue densities. The basic films can be taken in the supine position (gravity eliminated) or in the upright position, either sitting or standing. Standing films are the standard technique. Sitting films show the spine under the influence of gravity but eliminate the effect of leg length discrepancies and hip contractures on the spine. Supine films are recommended in patients who had just begun to walk (younger than the age of 2 or 3 years). For valid comparisons to be made on sequential radiographic examinations, it is important to use the same technique.

1. *Methods of Determining Magnitude*. The most commonly used method is that described by Cobb (Fig. 41). The Ferguson method is employed when the end plates of the vertebral bodies are difficult to determine (as in congenital scoliosis with multiple anomalies) (Fig. 42).

From Lauridsen KN, DeCarvalho A, Andersen AH (1991): Degree of vertebral wedging of the dorsolumbar spine. *Acta Radiol Diagn* 25:29–32, with permission.

[a] Data based on a study of 164 persons: 96 women aged 25 to 59 years and 68 men aged 17 to 59 years. Subjects selected at random, and those with fractures were excluded.

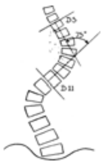

FIGURE 41. Cobb method. First, determine the end vertebrae. The top vertebra of the curve is the highest one whose superior surface tilts to the side of the concavity of the curve. The bottom vertebra is the lowest one whose inferior surface tilts to the side of the concavity of the curve. Draw intersecting perpendicular lines from the superior surface of the top and the inferior surface of the bottom vertebrae of the curve. The angle formed by these lines is “the angle of the curve.”

2. *Method of Determining Rotation*. In the Cobb method, the relationship of the spinous process to the center of the vertebral body is noted in the anteroposterior radiograph (Fig. 43). The Nash and Moe method is probably the most commonly used method of measuring vertebral rotation. It is based on the rotation of the pedicles (Figs. 44,45,46, Table 19).

Mehta MH (1973): Radiographic estimation of vertebral rotation in scoliosis. *J Bone Joint Surg (Br)* 55:513–520.

3. *Metha's Rib Vertebral Angle*. The value of Metha's rib vertebral angle is in the prediction of whether infantile scoliosis is of the resolving or progressive type. According to Metha, if the angle difference is greater than 20, there is an 80% chance that the scoliosis is progressive (Figs. 48, 49)
4. *Torso Balance*. Measured on a posteroanterior film of the entire spine, a plumb line dropped from C7 should fall on the midline of the sacrum.

Stage I:	1.5 cm off center	One-half vertebral body
Stage II:	3 cm	One vertebral body
Stage III:	5 cm	One and one-half vertebral bodies
Stage IV:	Over 5 cm	

5. Goldstein LA, Waugh TR (1973): Classification and terminology of scoliosis. *Clin Orthop* 93:10–22.
6. *Moire Screen Method* (*Fig. 50*). The Moire technique is adapted from the field of engineering and allows three-dimensional measurements of the spine. Moire fringe topography has been accepted optical engineering practice since it was first described by Rayleigh in 1974. Its reintroduction into the medical field has come through the work of Takasaki (1970,1973). Takasaki's work showed

the feasibility of using the shadow Moire fringe method to get accurate and reproducible contour lines on the suface of the back. Using the shadow Moire technique, three-dimensional evaluations have been carried out for a variety of disorders of the spine.

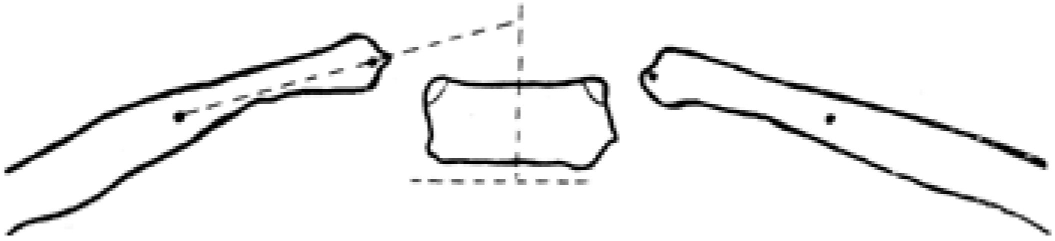

FIGURE 48. Method of measurement of Metha's rib vertebral angle (RVA). A perpendicular is drawn to the middle of either the upper or lower border of a selected thoracic vertebra (in a scoliotic curve, the apical vertebra). Another line is drawn from the midpoint of the head of the rib to the midpoint of the neck of the rib, just medial to the region where the neck widens into the shaft of the rib. The rib line is extended medially to intersect the vertebral line to make the RVA. (From Metha MH (1972): The rib-vertebral angle in the early diagnosis between resolving and progressive infantile scoliosis. *J Bone Joint Surg [Br]* 54:230–243, with permission.)

Moreland and colleagues (1981) defined fringe patterns for normal spines, kyphosis, and different types of scoliosis (Fig. 46). They based the pattern classification on the form of the contour lines formed by the Moire fringe. They described the following patterns: (a) Upper M (M1), (b) 0 (01), (c) W, (d) V, (e) Lower M (M2), and (f) Gluteal (02).

The M1 pattern is formed in the upper thoracic region, as the height descends cephalad from the elevated scapular regions toward the base of the neck, the contour lines become discontinuous laterally at the shoulder region to form an upper M pattern (M1). Because the contour lines formed by the Moire fringe represent lines of uniform height, they tend to be continuous around the elevated, and usually steeper areas of each scapula and the gluteal region form 0 patterns, designed 01 for the scapula and 02 for the gluteal region. Beginning at the scapula region, there is usually a descending pattern of contour lines proceeding caudally, becoming discontinuous laterally in the axillary region and forming a W pattern. The lower base points of the W descend along the paravertebral thoracolumbar ridges into the upper lumbar region, where they are replaced by vertically oriented contour levels descending on either side of the waist, designed lateral V left and right. The pattern of the upper back begins to repeat itself, proceeding caudally in the lumbar region, with the lower O (02) invariably representing the gluteal region and which evidences this rising slope through the lumbar region, creating the lower M (M2) pattern. The upper tips of the M represent extensions of the lumbar paravertebral ridges broadening into the gluteal mass.

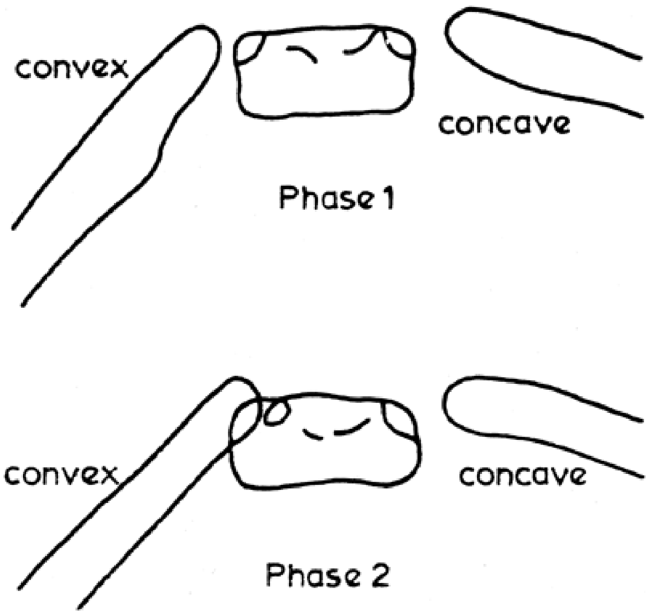

FIGURE 49. The two phases in progression of infantile scoliosis as described by Metha. Phase I (early stage): The rib head on the convex side of the curve does not overlap (is separated from) the vertebral body. Phase II: With progression of the curve, the rib head overlaps the vertebral body. According to Metha, the transition from Phase I to Phase II indicates a progressive curve. (From Metha MH (1972): The rib-vertebral angle in the early diagnosis between resolving and progressive infantile scoliosis. *J Bone Joint Surg Br* 54:230–243, with permission.)

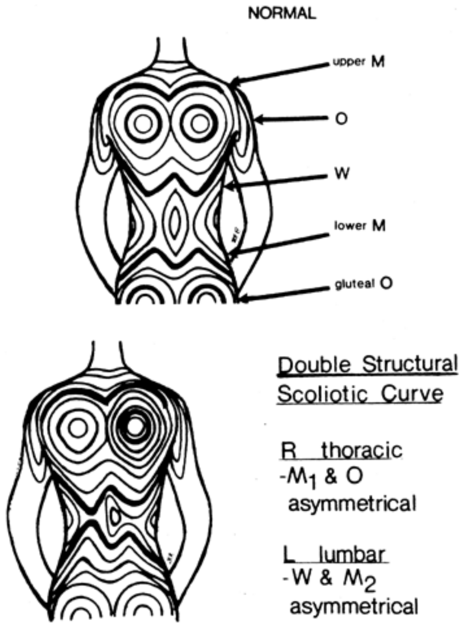

FIGURE 50. Moire fringe patterns. **A:** Normal patterns with symmetric right and left sides of the back. **B:** Deformed back surface patterns in a patient with right thoracic, left lumbar scoliosis. (From Moreland MD, Bigalow LC, Stokes IAF (1986): Concordance of back surface rotation and scoliosis. In: Harriw JD, Turner-Smith AR, eds. *Surface topography and spinal deformity.* Proceedings of the 3rd international symposium. Stuttgart: Gustav Fischer, with permission.)

Willner has devised a method of assessing the amount of asymmetry of the Moire fringe patterns. He described the use of an opalescent ruler consisting of horizontal and vertical lines. The thick mean vertical line is positioned between the vertebral prominence of C7 and the crena ani. One of the horizontal lines is placed over the lower point of the most asymmetric contour line at the convex side. A symmetric point on the same horizontal line (at the same distance of the vertical line, but on the opposite side) is found. These two points should, in a symmetric spine, be found on the same contour line. In structural scoliosis, these two points will be on different shadow lines. By recording the number of lines that differentiate these points, the difference in distance to the grid between these points can be calculated. He found a statistical significant correlation between the deviation of the Moire fringe shadows and the radiographic magnitude of the lateral deviation.

   b. *Prediction of Curve Progression in Idiopathic Scoliosis* (Fig. 54)

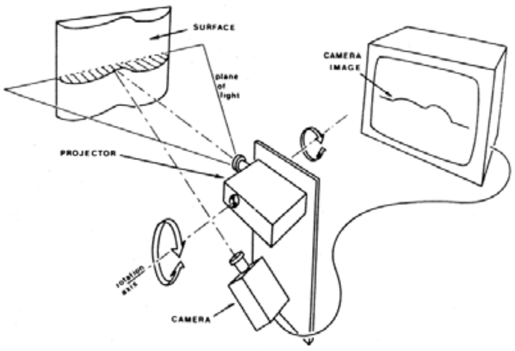

FIGURE 51. Principle of the integrated shape investigation system (ISIS). ISIS is a structured light technique in which a plane of light is cast across the patient by an ordinary 35-mm projector. This line is viewed from below the projector by a television camera mounted on a unit with the projector. The camera does not see a straight line but a curved line, the curvature being the result of the prospective view of the line as it falls on a curved three-dimensional surface. The shape of the line is recorded by a television computer system, while the projector and camera unit is scanned over the patient's back by a speed-controlled motor. The sequence of 50 to 100 television pictures is processed to convert the two dimensional television information and a record of the angle of the projector camera unit to three-dimensional real world coordinates. FIGURE 53. Median yearly rate of deterioration without treatment for each type of single congenital scoliosis in each region of spine. Numbers on the left in each column refer to patients seen while they were younger than 10 years of age; numbers on right refer to patients seen at age 10 years or older. (From McMaster MJ, Ohtsuka K (1982): The natural history of congenital scoliosis. *J Bone Joint Surg* 64-A:1128.)

Nomogram devised using the formula:

$$\text{progression factor} = \frac{\text{Cobb angle} - 3 \times \text{Risser sign}}{\text{chronological age}}$$

FIGURE 54. Knowing the Cobb angle of the major curve, the Risser grade (0 to 5) of the iliac crest apophysis, and the patient's age permits the likelihood of progression to be estimated for curves between 20 and 29 degrees. To use the nomogram, start with the Cobb angle and follow the corresponding line vertically until the oblique line corresponding to the appropriate Risser value is encountered. Turn horizontally until the chronologic age line is met, then turn directly vertically downward until the curved line is encountered, then horizontally to the right to read the approximate percentage incidence of progression. (Reproduced from Lonstein JE, Carlson JM (1984): The prediction of curve progression in untreated idiopathic scoliosis during growth. *J Bone Joint Surg* 66A:1061–1071).

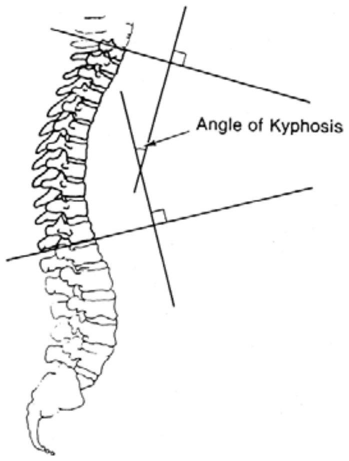

FIGURE 55. Method of measuring kyphosis. Modification of the Cobb method of measuring scoliosis. First, determine the end vertebrae, which are the last ones tilted to the convexity of the curve. Second, draw perpendicular lines to the inferior and superior vertebral end plates. The angle formed between these two lines is the degree of kyphosis (positive value) or lordosis (negative value). (From Fon GT, Pitt MJ, Thies AC Jr (1980): Thoracic kyphosis: range in normal subjects. *Am J Roentgenol* 134:979–983, with permission.)

e. Knowing the Cobb angle of the major curve, the Risser grade (0 to 5) of the iliac crest apophysis and the patient's age permits the likelihood of progression to be estimated for curves between 20 and 29 degrees. To use the nomogram, start with the Cobb angle and follow the corresponding line vertically until the oblique line corresponding to the appropriate Risser value is encountered. TABLE 20. Degree of Kyphosis in Males by Age

		Kyphosis (°)			
Age (Years)	**No. Cases**	**Mean**	**SD**	**Minimum**	**Maximum**
2–9	26	20.88	7.85	5	40
10–19	28	25.11	8.16	8	39
20–29	37	26.27	8.12	13	48
30–39	26	29.04	7.93	13	49
40–49	20	29.75	6.93	17	44
50–59	10	33.00	6.46	25	45
60–69	9	34.67	5.12	25	62
70–79	3	40.67	7.57	32	66

From Fon GT, Pitt MJ, Thies AC Jr (1980): Thoracic kyphosis: range in normal subjects. *Am J Roentgenol* 134:979–983, with permission.

6. **Thoracic Kyphosis: Range in Normal Subjects** (Fig. 55, 56 ; Tables 20, 21)
7. **Radiographic Determination of Lordosis and Kyphosis and Lumbosacral Angle in Normal and Scoliotic Children**

Lordosis was defined in this study as the angle formed by perpendicular lines drawn from the superior end plate of L1 and the inferior endplate of L5 on the lateral radiograph. Kyphosis was measured similarly from T5 to T12. The lumbosacral angle was measured as the angle formed by lines drawn on the lower endplate of L5 and the top of the sacrum (Table 22).

8. **Sagittal Profiles of the Spine: Kyphosis, Lordosis, Sacral Inclination**

The study was based on 670 normal subjects; lateral standing radiographs of the spine, with the arms supported and flexed about 50 to 60 degrees. Thoracic kyphosis between 20 and 50 degrees and lumbar lordosis between 20 and 70 degrees are considered normal (Table 23).

Stagnara P, et al. Reciprocal angulation of vertebral bodies in a sagittal plane: approach to references in the evaluation of kyphosis and lordosis. *Spine* 7:335–342.

9. **Sagittal Contour** (Figs. 57, 58)
10. **Measurement of the Lumbosacral Angle**

According to Hellems, the mean lumbosacral angle is 41.1 degrees and the standard deviation is 7.7 degrees. Ninety-five percent of all values will lie between 25.7 and 56.5 degrees. The angle was formed by the intersection of two lines. Line 1 is the plane of the top of the sacrum, and line 2 is a horizontal line drawn parallel to the bottom margin of the film. This was measured on a standing spot lateral radiographic view of L5-S1.

TABLE 21. Degree of Kyphosis in Females by Age

Age (Years)	No. Cases	Kyphosis (°) Mean	SD	Minimum	Maximum
2-9	23	23.87	6.67	8	36
10-19	22	26.00	7.43	11	41
20-29	24	26.83	7.98	7	40

Hellems HK, Keats TE (1971): Measurement of the normal lumbosacral angle. *Am J Roentgenol* 113:642–645.

11. **4–5 Seating: Intercrestal Line**

Based on the study of various skeletal configurations on the lumbar spine, MacGibbon and Farfan concluded (Fig. 59):

a. *Criteria for probable L4–5 degeneration*
    1. A high intercrestal line passing through the upper half of L4
    2. Long transverse processes on L5
    3. Rudimentary rib
    4. Transitional vertebra

b. *Criteria for probable L5–S1 degeneration*
    1. An intercrestal line passing through the body of L5
    2. Short transverse processes on L5
    3. No rudimentary ribs
    4. No transitional vertebra

12. **Spondylolisthesis (Also see under classifications)**

Measurements: Many different methods for measurement of spondylolisthesis have been used. The most comonly used are presented:

a. *Anterior Displacement: Meyerding* (Fig. 60)
b. *Anterior Displacement: Taillard* (Fig. 61)

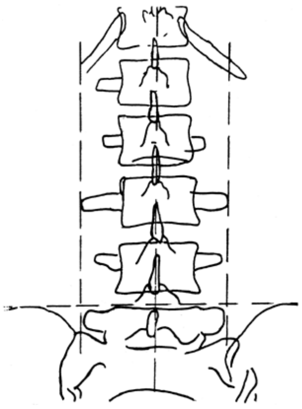

FIGURE 59. Tracing anteroposterior radiographic view showing construction lines for comparing transverse process length and height of the intercrestal line. (From MacGibbon B, Farfan HF (1979): A radiologic survey of various configurations of the lumbar spine. *Spine* 4:258–266, with permission.)

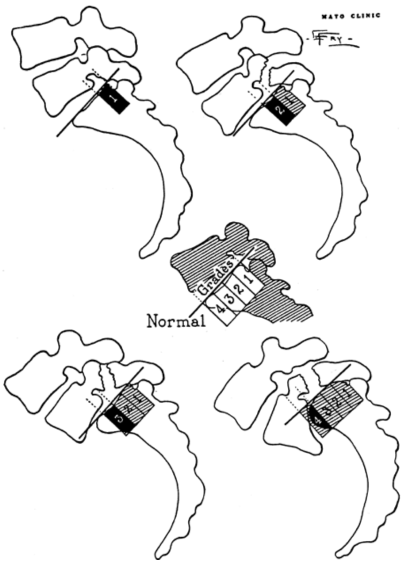

FIGURE 60. A: *Grade I*, The anterior displacement is 25% or less, that is, the posteroinferior angle of the displaced vertebra lies within the first segment. **B:** *Grade II*, The displacement is between 25% and 50%. **C:** *Grade III*, The displacement is between

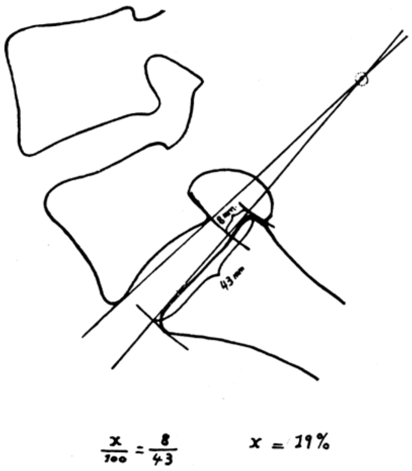
50% and 75%. **D:** *Grade IV*, The displacement is greater than 75%. **E:** *Normal*, The superior border of the anteroposterior diameter of the anteroposterior diameter of the subjacent vertebra is divided into four equal parts. Displacement greater than 100% (spondyloptosis) may be classified as type V. (From Meyerdin HW (1932): Spondylolisthesis. *Surg Gynecol Obstet* 54:371–377, with permission.)



8mm
43mm
$\frac{x}{100} = \frac{8}{43}$
$x = 19\%$

FIGURE 61. The anterior displacement is expressed as a percentage obtained by dividing the amount of displacement (determined by the relationship of the posterior part of the cortex of the fifth lumbar vertebral to the posterior part of the cortex of the first sacral vertebra) by the maximum anteroposterior diameter of the first sacral vertebra, and multiplying by 100. (From Taillard W (1964): Le spondylolisthesis chez l'enfant et l'adolescent: etude de 50 cas. *Acta Orthop Scand* 24:115–144, with permission.)

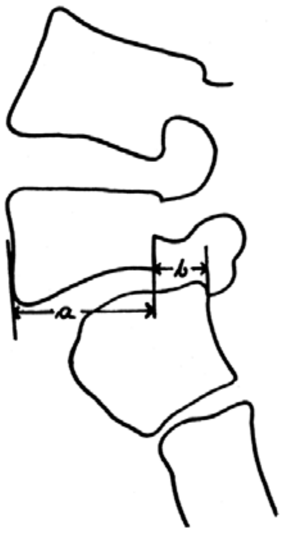


FIGURE 62. The amount of slipping is calculated by measuring the distance from a line parallel to the posterior portion of the first sacral vertebral body to a line drawn parallel to the posterior portion of the body of the fifth lumbar vertebra. The anteroposterior dimension of the fifth lumbar vertebra inferiorly is used to calculate the percentage of slipping. Taillard used the anteroposterior dimension of the first sacral vertebra. Because of the erosion of the first sacral vertebra, Boxall and coworkers proposed using the fifth lumbar vertebra (as described by Laurent and Einola) as a more accurate method. (From Laurent LE, Einola S (1961): Spondylolisthesis in children and adolescents. *Acta Orthop Scand* 31:45–64, with permission.)

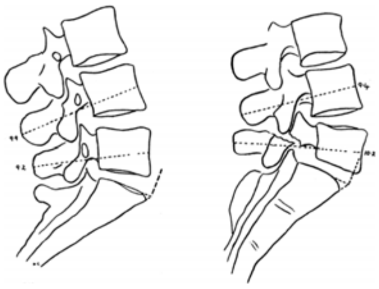

FIGURE 63. Displacement is measured by comparison of anteroposterior diameters of the spondylolytic vertebra and the normal vertebra above it. Ullmann's sign is demonstrated by drawing a line at right angles to the upper border of the sacrum at its anterior edge. Note that in the normal spine **(A)**, the fifth lumbar vertebra lies entirely behind this line, whereas in spondylolisthesis **(B)**, the perpendicular line is intersected by the slipped vertebral body. Garland and Thomas also reported on the value of Ullmann's line. (From Capener N (1931): Spondylolisthesis. *Br J Surg* 19:374–386, with permission.)

FIGURE 64. Two lines are drawn. The first line (A–B) extends between the posterior lower lip of the vertebra above and the posterior upper lip of the vertebra below. The second line (C–D) is drawn between the posterior upper and lower lips of the slipped vertebra. The lines are extended: If they are not parallel, they will meet and form an angle. When the angle is as much as 10 degrees, the spondylolisthesis can be called slight; 11 to 20 degrees, moderate; and greater than 20 degrees, severe. If the lines are parallel, a distance of more than 3 mm is abnormal. (From Mescham I (1945): Spondylolisthesis. *Am J Roentgenol* 53:230–243, with permission.)

h. *Anterior Displacement: Laurent-Einola and Boxall-Bradford Modification of Taillard Method* (Fig. 62)

Boxall D, Bradford DS, Winter RB, Moe JH (1979): Management of severe spondylolisthesis in children and adolescents. *J Bone Joint Surg [Am]* 61:479–495.

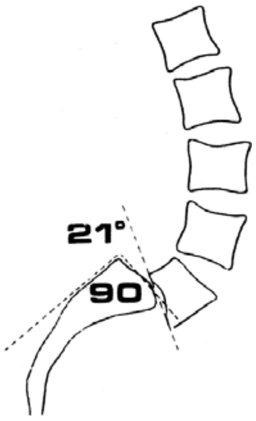

FIGURE 65. The angle of slipping measures the degree of forward tilting of the fifth lumbar vertebral body over the first sacral vertebral body, or the gibbus at the level of the slipping. The slip angle is formed by a line drawn parallel to the inferior aspect of the fifth lumbar vertebral body and a line drawn perpendicular to the posterior aspect of the body of the first sacral vertebra. (From Boxall D, Bradford DS, Winter RB, Moe JH (1979): Management of severe spondylolisthesis in children and adolescents. *J Bone Joint Surg [Am]* 61:479–495, with permission.)

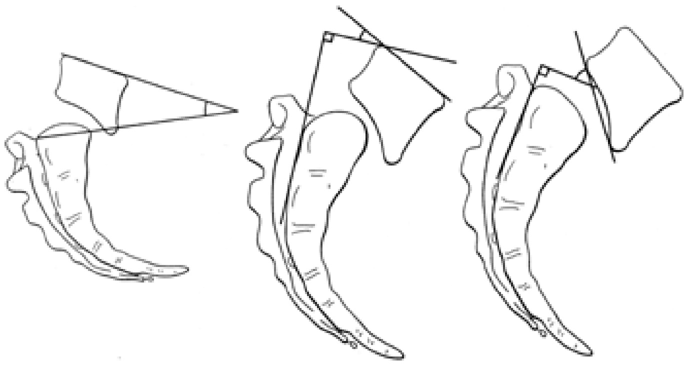

FIGURE 66. *Left*, Lumbosacral kyphosis is represented by the angle between the superior end plate of L5 and the superior end plate of S1. *Center*, it is difficult to establish a reference line for the superior end plate of a dome-shaped sacrum. The end plate can be approximated by a line drawn orthogonal to the posterior cortex of the sacrum. *Right*, The inferior end plate of L5 undergoes remodeling changes during slip progression and is not a reliable reference point. The superior end plate of L5 does not undergo these changes and should be used to measure the lumbosacral kyphosis. (Reproduced from Burkus JK, Lonstein JE, Winter RB, et al. (1992): Long term evaluation of adolescents treated operatively for spondylolisthesis. *J Bone Joint Surg* 74A:693–704.)

4. **KLIPPEL-FEIL SYNDROME**

   Type I: Extensive cervical and upper thoracic spine fusion

   Type II: One or two interspace fusions, often associated with hemivertebrae and occipitoatlantal fusion

   Type III: Combination of cervical and lower thoracic or lumbar fusion

   Pizzutillo and colleagues proposed the following classification based on clinical and radiographic findings on 111 patients flexion-extension lateral radiographs of the cervical spine.

   Class I: Normal range of motion in flexion and extension with no instability

   Class II: Excessive range of motion or instability of the upper cervical segment, or the presence of basilar impression or iniencephaly

   Class III: Hypermobility, instability, or degenerative changes of the lower cervical segment

   Class IV: Combination of the findings as defined by Class II and Class III

   Based on this study, they suggested that neurologic compromise is to be suspected in patients with hypermobility of the upper cervical segment or in the presence of iniencephaly (iniencephaly is an unusual disorder of the cervical spine consisting of congenital cervical synostoses, fixed retroflexion of the head, severe cervical lordosis, and varying degrees of incomplete posterior closure.) Degenerative changes of the cervical spine may be expected to develop when hypermobility of the lower cervical segment exists.

   Nagib and colleagues suggested a classification for patients at neurologic risk.

   Group I: Patients with an unstable fusion pattern

   Group II: Patients with craniocervical abnormalities

   Group III: Patients with fusions associated with spinal stenosis

   Hensinger and colleagues have pointed out the high incidence of associated conditions in patients with Klippel-Feil syndrome:

5. **BONY ABNORMALITIES OF THE CRANIOCERVICAL JUNCTION** (Table 2; Fig. 3)
6. **ARNOLD-CHIARI MALFORMATION** (Fig. 4)

Type I: The cerebellar tonsils are elongated, flattened, and atrophic. They are stretched downward through the foramen magnum to the level of the first cervical vertebra.

Type II: Not only is there downward displacement of the inferior portion of the cerebellar vermis and hemispheres but the medulla and fourth ventricle are also herniated into the upper reaches of the cervical canal.

Type III: Similar to type I, but associated with a meningocele at the craniocervical junction into which the prolapsed cerebellar tissue has descended.

Type IV: Hypoplasia of the cerebellar hemisphere with an enlarged fourth ventricle. This is not considered a type of dysraphism.

TABLE 2. Classification of Craniovertebral Junction Abnormalities

- I. Congenital anomalies and malformations
  - A. Malformations of the occipital bone
    - 1. Manifestations of occipital vertebrae
      - a. Clivus segmentation
      - b. Remnants around foramen magnum
      - c. Variants at atlas
      - d. Dens segmentation anomalies
    - 2. Basilar invagination
    - 3. Condylar hypoplasia
    - 4. Assimilation of atlas
  - B. Malformations of atlas
    - 1. Assimilation of atlas
    - 2. Atlantoaxial fusion
    - 3. Aplasia of atlas arches
  - C. Malformations of axis
    - 1. Irregular atlantoaxial segmentation
    - 2. Dens dysplasias
      - a. Ossiculum terminale persistens
      - b. Os odontoideum
      - c. Hypoplasia-aplasia
    - 3. Segmentation failure of C2–C3
- II. Development and acquired abnormalities
  - A. Abnormalities at the foramen magnum
    - 1. Secondary basilar invagination, e.g., Paget's disease, osteomalacia, rheumatoid cranial settling
    - 2. Foraminal stenosis, e.g., achondroplasia
  - B. Atlantoaxial instability
    - 1. Errors of metabolism, e.g., Morquio syndrome
    - 2. Down syndrome
    - 3. Infections, e.g., Grisel syndrome
    - 4. Inflammatory, e.g., rheumatoid arthritis
    - 5. Traumatic occipitoatlantal and atlantoaxial dislocations, os odontoideum
    - 6. Tumors, e.g., neurofibromatosis, syringomyella
    - 7. Miscellaneous, e.g., fetal warfarin syndrome, Conradi syndrome

From Menezes AH, Van Gilder JC (1990): Anomalies of the craniovertebral junction. In: *Youman's neurological surgery*, 3rd ed. Phildelphia: WB Saunders, with permission.

Type I is not necessarily associated with hydrocephalus, and symptoms, if they occur at all, are due to impaction and embarrassment of the brainstem at the foramen magnum. It is one of the conditions associated with a communicating syringomyelia. *Type II* is the most common of these abnormalities. It is usually associated with spina bifida. Obstruction to the outflow of cerebrospinal fluid (CSF) from the fourth ventricle leads to hydrocephalus, while compression of the brainstem can result in abnormalities affecting all the functions contained within it. One further syndrome may occur. With the obliteration of the outlets of the fourth ventricle, CSF is now pumped downward from the fourth ventricle into the central canal of the spinal cord, which may in turn become dilated causing the clinical complex known as syringomyelia.

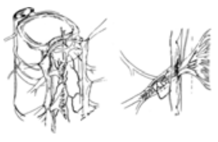

FIGURE 5. Normal vasculature of the spinal cord. **A:** The spinal ramus of each intercostal artery divides after entering the intervertebral foramen and penetrating the surface of the dura, into dural arteries, which supply the root sleeve and spinal dura, and radicular arteries, which supply the anterior and posterior nerve roots. In addition, the spinal ramus of the intercostal artery also is the origin of a medullary artery in a sporadic fashion. **B:** This vessel enters the dura adjacent to the nerve root ganglion, after which it ascends and joins an anterior or posterolateral spinal artery to supply the spinal parenchyma. The spinal cord is drained by radial veins, which carry blood to the coronal venous plexus, which is, in turn, drained by medullary veins, which pierce the dura adjacent to the nerve roots.

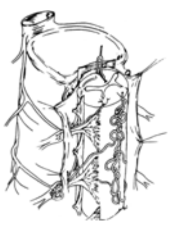

FIGURE 6. Dural arteriovenous (AV) fistula. The dural AV fistula is supplied by a dural artery and is drained by a medullary vein, which carries blood retrograde to the normal direction of venous drainage to the coronal venous plexus. The coronal plexus becomes elongated, tortuous, thickened, and dilated by the increased venous pressure, which is, in turn, transmitted to the cord tissue and causes myelopathy.

A. **Dural Arteriovenous Fistulas (Type I)**

B. **Intradural Arteriovenous Malformations (AVMs)**

- Glomus AVMs (Type II)
- Juvenile AVMs (Type III)
- Direct arteriovenous fistulas (Type IV)

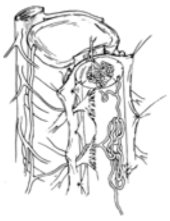

FIGURE 7. Glomus arteriovenous malformations (AVMs). The nidus of the glomus type of intramedullary AVM is a tightly packed congeries of blood vessels confined to a short segment of the spinal cord. It receives its blood supply from spinal medullary arteries.

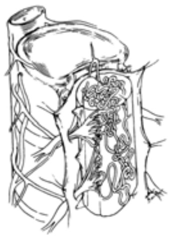

FIGURE 8. Juvenile arteriovenous malformations (AVMs). The juvenile type of intramedullary AVM is fed by medullary arteries through the anterior and posterolateral spinal arteries. The nidus of the AVM is large, often fills the spinal canal, and contains cord tissue within the interstices of the vessels of the AVM.

C. **Extradural Venous Varices (Type V)**

D. **Associated Conditions With Intradural Spinal AVMs**

- Other arteriovenous malformations
- Cerebral aneurysms
- Vascular agenesis/hypoplasia
- Rendu-Osler-Weber syndrome
- Klippel-Trenaunay-Weber syndrome

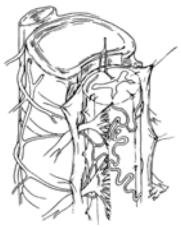

FIGURE 9. Direct intradural arteriovenous fistula in the pia. Medullary arteries provide the arterial supply.

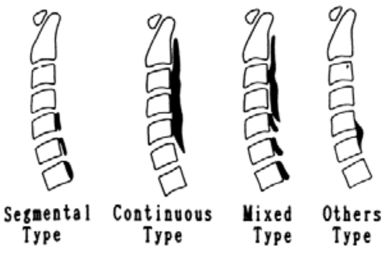

FIGURE 10. Classification of ossification of the posterior longitudinal ligament as seen on lateral radiographic views: *segmental type*, in which ossification is observed behind individual vertebral bodies; *continuous type*, in which ossification is observed through several vertebrae; *mixed type*, which is a combination of segmental and mixed; and other types, in which ossification is observed over the intervertebral disc space. (From Hirabayashi K, Miyakawa J, Satomi K, et al. (1981): Operative results and postoperative progression of ossifications among patients with ossification of cervical posterior longitudinal ligament. *Spine* 6:354–364, with permission.)

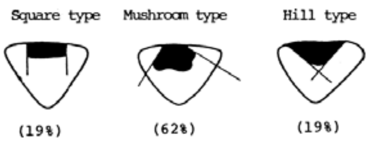

FIGURE 11. Classification of ossification of the posterior longitudinal ligament (OPLL) as seen on computed tomography (CT) scan. CT is particularly helpful in determining the existence of OPLL as well as its thickness, lateral extension, shape, and the extent of narrowing of the spinal canal. (From Hirabayashi K, Satomi K, Sasaki T (1989): Ossification of the posterior longitudinal ligament in the ervical spine. In The Cervical Spine Research Society, ed. *The cervical spine.* Phildelphia: JB Lippincott, 1989, with permission.)

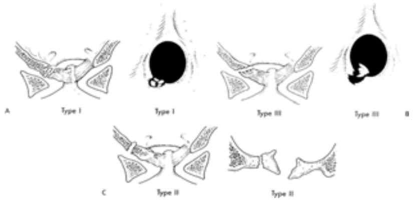

FIGURE 12. Three types of occipital condylar fractures, as described by Anderson and Montesano. **A:** *Type I:* Impacted fracture. **B:** *Type II:* Basilar skull fracture. **C:** *Type III:* Avulsion fracture (Redrawn from Anderson PA, Montesano PX (1988): Morphology and treatment of occipital condyle fractures. *Spine* 13:731.)

3. **CRANIOCERVICAL TRAUMA WITH INJURIES AROUND THE C1–C2 COMPLEX** (Figs. 13, 14)
    A. **Jefferson's Fracture**

Jefferson's fracture is a bursting of the ring of C1 as a result of axial loading. An anteroposterior view generally shows widening of the distance between the odontoid and lateral masses of C1. Spence's rule is that the overhang from the lateral masses of C1 on each side should not be more than 6.9 mm. Fractures are classified as stable if the transverse ligament is intact and unstable when it is ruptured. (Fig. 13)

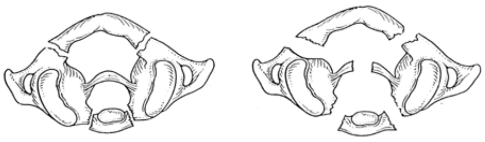

FIGURE 13. A: Drawing indicating axial view of stable Jefferson's fracture (transverse ligament intact). **B:** Drawing indicating axial view of unstable Jefferson's fracture (transverse ligament ruptured). (Redrawn from Schlicke LH, Callahan R (1981): A rational approach to burst fractures of the atlas. *Clin Orthop* 154:18).

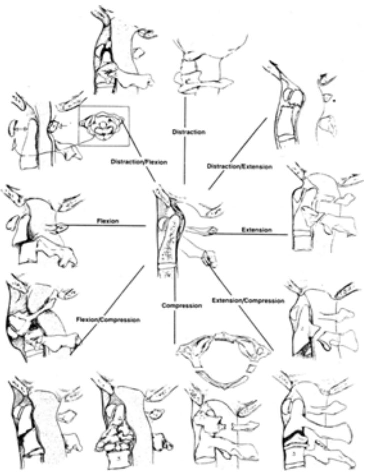

FIGURE 14. Craniocervical trauma with injuries around the C1–C2 complex. In injuries high in the cervical spine, there is a series of fractures that occur depending on the major vector of the traumatic force. As represented in this clock of injuries, the vector of force at 12 o'clock is distraction, at 3 o'clock is forced extension, at 6 o'clock is compression, and at 9 o'clock is forced flexion. When these vectors cause trauma at the C1–C2 complex, including the cranial junction, there are known injury patterns. If the resultant injury is severe with marked malalignment, the majority of the patients are killed instantaneously or die soon afterward for lack of respiration and cardiovascular support. Such injuries, which cause complete cord damage, give not only paralysis but also give a complete sympathectomy and destroy all drive for respiration, including the phrenic nerve function. However, many injuries through this area give an incomplete cord injury or do hardly any damage to the nervous system at all. Each of these injuries is discussed separately in this chapter.

At *12 o'clock*, there is primarily a distraction injury wherein the condyles of the occiput are pulled from the C1–C2 complex. This particular injury is more likely to be seen on the lateral skull radiograph as opposed to a lateral cervical spine radiograph. Also, it can occur in young children, in whom the head is much bigger in proportion to the body. It is also commonly reported in those patients sustaining an injury who are killed in the accident wherein there is no other obvious reason for death.

At *2 o'clock*, the extension injury may cause a high fracture of the odontoid process itself. There is usually retrolisthesis of the C1 complex on the C2 vertebral body and its surrounding lamina and spinous process.

At *3 o'clock*, the extension injury often causes fractures through the lamina of C1 and C2. If the fracture through C2 comes more anteriorly, then it will cause traumatic spondylolosis. Even on rare occasions, the odontoid may be fractured as well.

At *4 o'clock*, one sees a typical hangman's fracture with a traumatic spondylolosis between the facet area of C2 and the major body of C2. The line of trauma will separate the body of C2 with all of C1, leaving behind the C2 lamina and spinous process, which are in turn attached to the C3 vertebra. The hangman's fracture can truly occur with hangings, but one will rarely see that clinically. More commonly, it is associated with a vehicular acident in which there is forced extension of the head and upper part of the spine on the mid and lower part of the cervical spine.

At *5 o'clock*, one is more likely to see a compression fracture into the body of C2. This may be a form of the type III odontoid fracture, where there is a burst in the body.

At *6 o'clock*, there tends to be two types of fractures. When the C1 vertebra alone is involved, some form of a Jefferson ring fracture is apparent. Or, in some lesions, the ring of C1 will be maintained and there will be a burst fracture of C2. Admittedly, the latter is rare but has been documented. This would be marked as a very severe type III odontoid fracture in select cases, but there is bursting of the body below.

At *7 o'clock*, there are various types of type II and type II odontoid fractures. If the force is considerably anterior as well as compressed, there will be a form of the type III fracture. However, as the force becomes more pure flexion, more likely the patient will suffer a type I fracture. On rare occasions, one can see the trauma as depicted at *8 o'clock*, usually with a devastating outcome to the patient. There is marked displacement on a type II fracture with disruption of the anterior ligaments.

At *9 o'clock*, one typically sees the type II dens fracture with displacement of the C1 vertebra along with the dens of C2 anteriorly.

At 10 o'clock, there can be disruption of the ligaments from the C1 vertebral body, which holds the peg of the C2 dens in alignment. This rupture of the cruciate ligament can lead to anterior displacement of C1 with all the bony elements of C2 being maintained.

At *11 o'clock*, there is the rare type I dens fracture. This is an avulsion fracture. It is rarely documented.

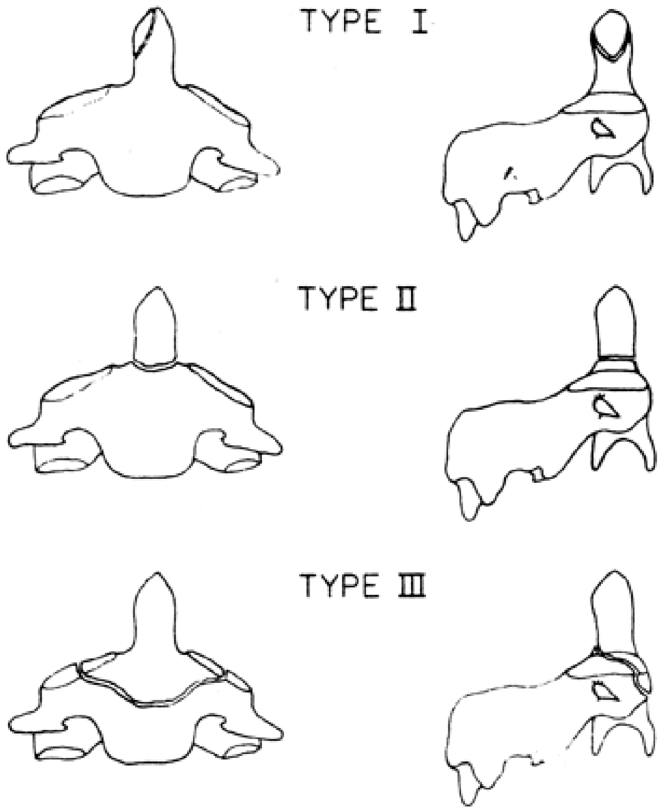

FIGURE 15. Three types of odontoid fractures as seen in the anteroposterior and lateral planes: *Type I* is an oblique fracture through the upper part of the odontoid process itself. *Type II* is a fracture at the junction of the odontoid process with the vertebral body of the second cervical vertebra. *Type III* is really a fracture through the body of the axis. (From Anderson LD, D'Alonzo RT (1974): Fractures of the odontoid process of the axis. *J Bone Joint Surg [Am]* 56:1663–1674, with permission.)

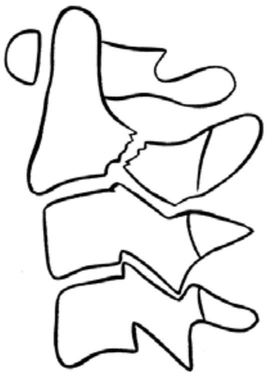

FIGURE 16. *Type I:* Fracture through the neural arch with no angulation and as much as 3 mm of displacement. (From Levine AM, Edwards CC (1985): The management of traumatic spondylolisthesis of the axis. *J Bone Joint Surg [Am]* 67:217–226, with permission.)

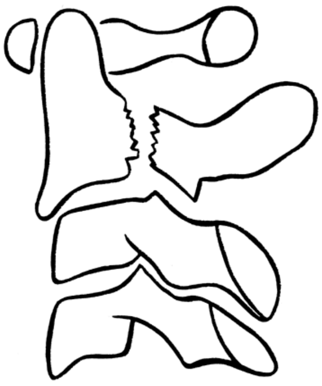

FIGURE 17. *Type II:* Fractures with both significant angulation and significant displacement. (From Levine AM, Edwards CC (1985): The management of traumatic spondylolisthesis of the axis. *J Bone Joint Surg [Am]* 67:217–226, with permission.)

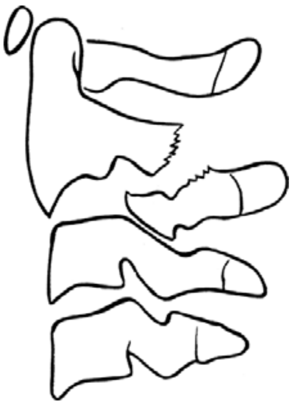

FIGURE 18. *Type IIA:* Fractures with minimal displacement but with severe angulation, apparently hinging from the anterior longitudinal ligament. (From Levine AM, Edwards CC (1985): The management of traumatic spondylolisthesis of the axis. *J Bone Joint Surg [Am]* 67:217–226, with permission.)

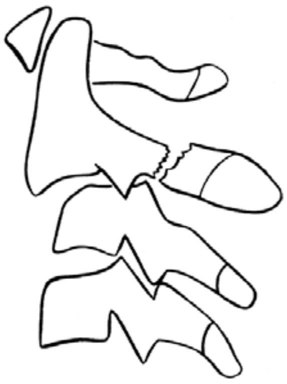

FIGURE 19. *Type III:* Fractures that combine bilateral facet dislocation between the second and third cervical vertebrae with a fracture of the neural arch. McAfee PC (1991): Cervical spine trauma. In: Frymoyer JW, ed. *The adult spine: principles and practice.* New York: Raven Press.

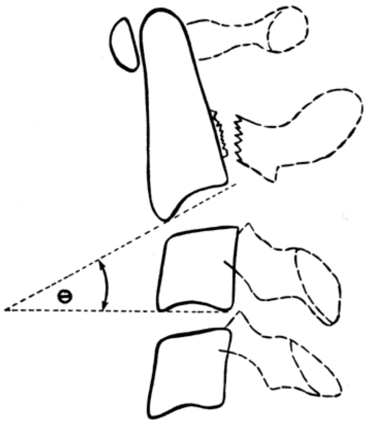

FIGURE 20. Angulation is calculated as the angle between the inferior end plate of the second cervical vertebra and the inferior end plate of the third cervical vertebra. (From Levine AM, Edwards CC (1985): The management of traumatic spondylolisthesis of the axis. *J Bone Joint Surg [Am]* 67:217–226, with permission.)

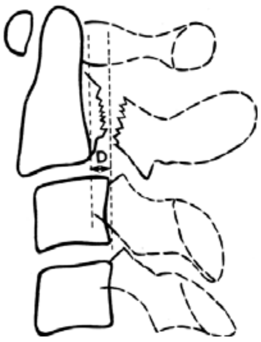

FIGURE 21. Anterior translation is measured as the distance between a line drawn parallel to the posterior margin of the body of the third cervical vertebra and the posterior margin of the second cervical vertebra at the level of the disc space between the second and the third cervical vertebrae. (From Levine AM, Edwards CC (1985): The management of traumatic spondylolisthesis of the axis. *J Bone Joint Surg [Am]* 67:217–226, with permission.)

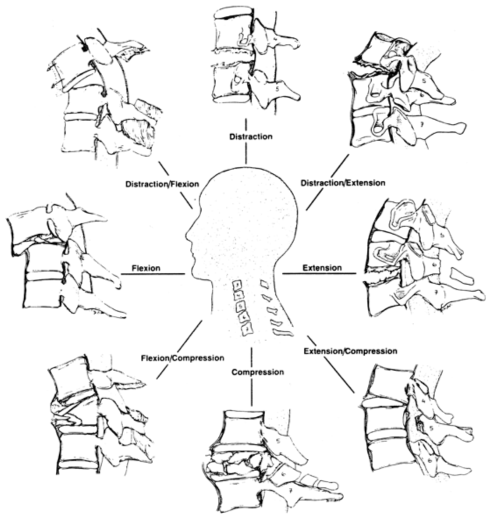

FIGURE 22. Mid and lower cervical spinal fractures involve the vertebrae 3 through 7 and do follow a common pattern. This clock of injuries (see also Figure 12) again shows 12 o'clock with distraction, 3 o'clock with extension, 6 o'clock with compression, and 9 o'clock with flexion injuries.

At *1* or *2 o'clock*, extension injuries in the midcervical spine can cause disruption of the anterior longitudinal ligament with some posterior displacement of the superior or cephalad vertebrae on the more caudal vertebrae. When there is some forced extension, as in the *3 o'clock* injury, there may be fracture of the spinous process, and even the lamina. This is to be differentiated from a stress fracture, referred to as clay shoveler's fracture, which occurs on the C7 spinous process.

A *4 o'clock* injury represents a forced extension injury, wherein there is some form of fracture through the facet area, like an incomplete spondylolosis, which is seen in the lumbar spine or seen at C2. All of the injuries at 2 o'clock, at 3 o'clock, and at 4 o'clock can occur in the elderly population in whom there is preexisting cervical spondylytic stenosis. When the injuries occur in the elderly patient, there is buckling of the disc and joint space anteriorly into the canal, and buckling of the inner spinous ligament and the ligamentum flavum posteriorly to squeeze the spinal canal and squeeze the spinal cord to give the central cord syndrome.

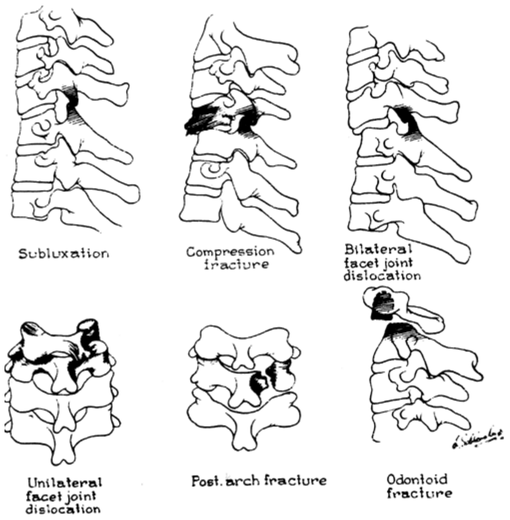
With further compression injuries, as seen at *6 o'clock*, the patient typically suffers a burst fracture. If there is a strong vector posteriorly, the bones may be displaced posteriorly. If there is a strong vector more anteriorly, the bones can be displaced and malaligned anteriorly. With the bursting of the fracture, the bone segments are in many pieces. Typically, bone is fractured back into the spinal canal to compress the spinal cord.

At *7* and *8 o'clock*, there is a combination of flexion and compression. The vertebral body anteriorly will fracture. There is permanent compression anteriorly. There may be posterior disruption of the inner spinous ligaments. If these injuries are mild, the neurologic deficit is not great, and the disc material may not be ruptured back into the canal, although that can occur.

At *9 o'clock*, the flexion injury causes either a unilateral or bilateral facet dislocation. There may be various fractures of the facet. In these injuries, the disc material is often disrupted. There is always a fear that the disc may be dislodged back in the canal with alignment.

At *10* and *11 o'clock*, there may be forced distraction injuries in which the posterior elements are torn and the vertebral bodies themselves are intact, along with the disc space. In some of these patients, the muscle spasm will cause the spine to realign, yet the neurologic injury may be quite devastating. In other cases, the muscle spasms will cause the spine to malalign with either a unilateral or bilateral facet dislocation. In these patients, the neurologic deficit is often severe and often will ascend above the level of the trauma.

Finally, the *12 o'clock* injuries, which are seen when there are separations of C4–5, are usually only documented after a forced flexion injury with traction maintained at a joint where there was complete ligamentous disruption. Obviously these lesions are very unstable. More likely, the distraction injuries will occur higher in the cervical spine.



Subluxation
Compression fracture
Bilateral facet joint dislocation
Unilateral facet joint dislocation
Post. arch fracture
Odontoid fracture

FIGURE 23. Robinson and Southwick's classification of cervical spine injuries.

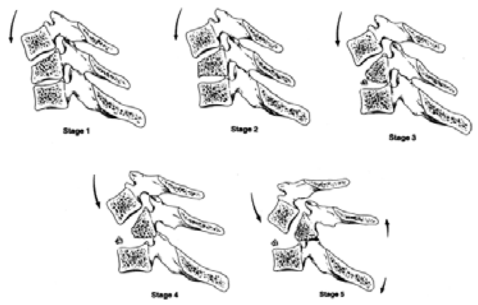


FIGURE 24. Allen and Ferguson classification of traumatic cervical spine injuries. Compression flexion injury. *Stage 1:* Blunting and rounding off of anterosuperior vertebral margin. *Stage 2:* Loss of anterior height and beaklike appearance anteroinferiorly. *Stage 3:* Fracture line from anterior surface of vertebral body extending obliquely through the subcondral plate (a fractured beak). *Stage 4:* Some displacement (< 3 mm) of the posteroinferior vertebral margin into the neural canal. *Stage 5:* Displacement (< 3 mm) of the posterior part of vertebral body. Although vertebral arch is intact, entire posterior ligamentous complex is ruptured (From Rizzolo SJ, Cotler JM (1993): Unstable cervical spine injuries: specific treatment approaches. *J Am Acad Orthop Surg* 1:57–66.)

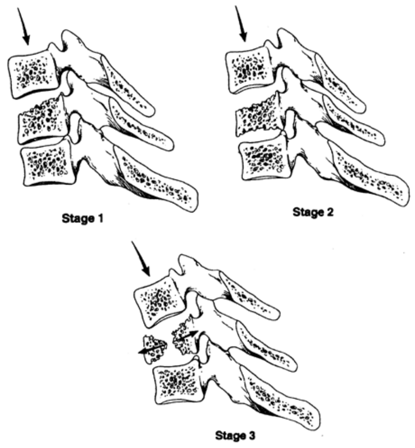

FIGURE 25. Allen and Ferguson classification of traumatic cervical spine injuries. Vertical compression injuries. *Stage 1:* Central cupping fracture of superior or inferior end plate. *Stage 2:* Similar to stage 1, but fracture of both end plates; any fracture of the centrum is minimal. *Stage 3:* Fragmentation and displacement of vertebral body. (From Rizzolo SJ, Cotler JM (1993): Unstable cervical spine injuries: specific treatment approaches. *J Am Acad Orthop Surg* 1:57–66.)

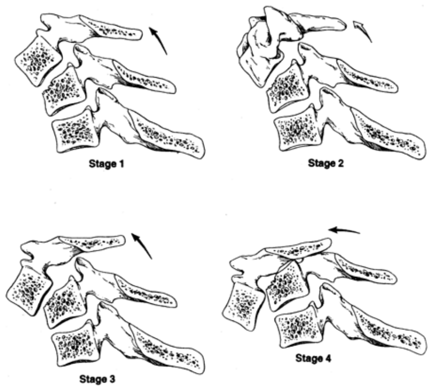

FIGURE 26. Allen and Ferguson classification of traumatic cervical spine injuries. Distraction flexion injury. *Stage 1:* Facet subluxation in flexion and divergence of spinous processes (flexion sprain); some blunting of anterosuperior vertebral margin as in a stage 1 compression flexion injury. *Stage 2:* Unilateral facet dislocation; there may be some rotary spondylolisthesis. *Stage 3:* Bilateral facet dislocation with about 50% anterior vertebral body displacement. Facets may have completely leap frogged over those below or may be "perched." *Stage 4:* Full width vertebral body displacement or completely unstable motion segment. (From Rizzolo SJ, Cotler JM (1993): Unstable cervical spine injuries: specific treatment approaches. *J Am Acad Orthop Surg* 1:57–66.)

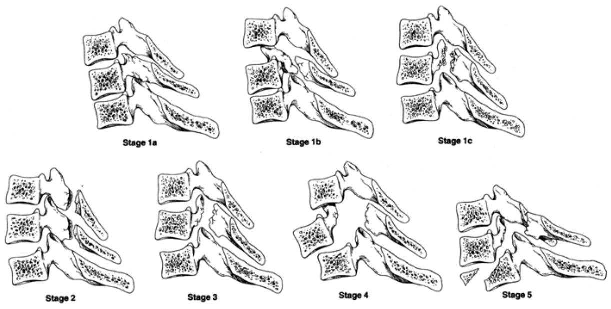

FIGURE 27. Allen and Ferguson classification of traumatic cervical spine injuries. Compression extension injury. *Stage 1:* Unilateral vertebral arch fracture; may be through articular process (stage 1a), pedicle (stage 1b), or lamina (stage 1c); there may be rotary spondylolisthesis of centrum. *Stage 2:* Bilaminar fracture, which may be at multiple contiguous levels. *Stage 3:* Hypothetical modes not seen clinically by authors of classification, characterized by bilateral fractures of vertebral arch (articular processes, pedicles, or laminae) and partial-width anterior vertebral body displacement. *Stage 4:* Partial-width anterior vertebral body displacement. *Stage 5:* Full-width anterior vertebral body displacement. (From Rizzolo SJ, Cotler JM (1993): Unstable cervical spine injuries: specific treatment approaches. *J Am Acad Orthop Surg* 1:57–66.)

Robinson RA, Southwick WO (1960): Surgical approaches to the cervical spine. *AAOS Instr Course Lect* 17:299–330.

B. **Mechanistic Classification of Fractures and Dislocations of the Lower Cervical Spine** (Figs. 24, 25, 26, 27, 28, 29)

Compression flexion: five stages

Vertical compression: three stages

Distractive flexion: four stages

Compressive extension: five stages

Distractive extension: two stages

Lateral flexion: two stages

The hypotheses on which this classification is based are as follows:

- The forces producing either fracture or dislocation of the cervical spine can be considered as major and minor injury vectors.
- The injury vectors can be deduced from the radiographic examination of the cervical spine.
- The magnitude of the vectors determines the severity of an injury.
- Similar injuries result from similar injury vectors.
- Within a given injury mechanism, there is a spectrum of injury, a phylogeny, which ranges from trivial to severe.

Allen BL Jr, Ferguson RL, Lehmann TR, O'Brien RP (1982): A mechanistic classification of closed, indirect fractures and dislocations of the lower cervical spine. *Spine* 7:1–27.

Rizzolo SJ, Cotler JM (1993): Unstable cervical spine injuries: specific treatment approaches. *J Am Acad Orthop Surg* 1:57–66.

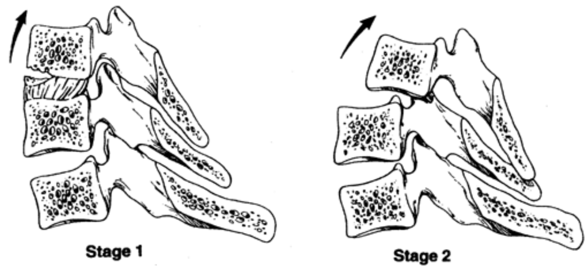

FIGURE 28. Allen and Ferguson classification of traumatic cervical spine injuries. Distractive extension injury. *Stage 1:* Failure of anterior ligamentous complex. Injury may be a nondeforming transverse fracture through the centrum or widening of disk space. *Stage 2:* Injury may be anterior marginal avulsion fracture of centrum. Some posterior ligamentous complex failure may be revealed by posterior displacement of upper vertebra. Fracture reduces in flexion. (From Rizzolo SJ, Cotler JM (1993): Unstable cervical spine injuries: specific treatment approaches. *J Am Acad Orthop Surg* 1:57–66.)

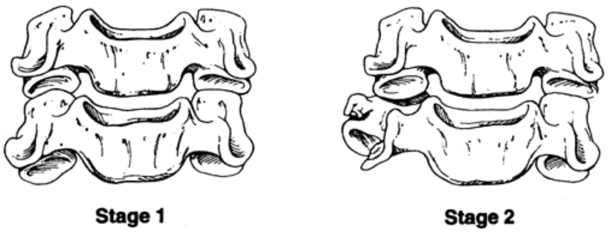

FIGURE 29. Allen and Ferguson classification of traumatic cervical spine injuries. Lateral flexion injury. *Stage 1:* Asymmetric compression fracture of centrum with associated vertebral arch fracture ipsilaterally; anteroposterior film shows no displacement. *Stage 2:* Displacement of ipsilateral arch fracture seen on anteroposterior view. There also may be ligamentous tension failure on contralateral side with facet separation. (From Rizzolo SJ, Cotler JM (1993): Unstable cervical spine injuries: specific treatment approaches. *J Am Acad Orthop Surg* 1:57–66.)

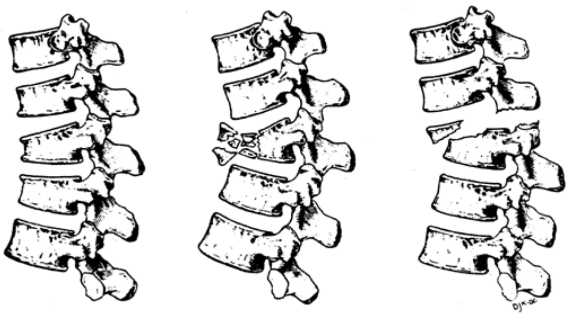

FIGURE 30. **A:** Simple wedge fracture. **B:** Comminuted fracture. **C:** Fracture-dislocation.

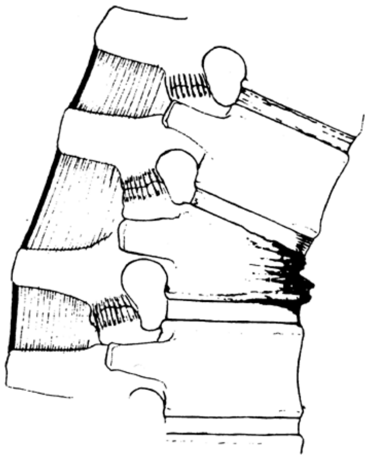

FIGURE 31. Diagram of a wedge compression fracture of the vertebral body. The posterior ligament complex is intact. (From Holdsworth FW (1963): Fractures, dislocations and fracture-dislocations of the spine. *J Bone Joint Surg [Br]* 45:6–20, with permission.)

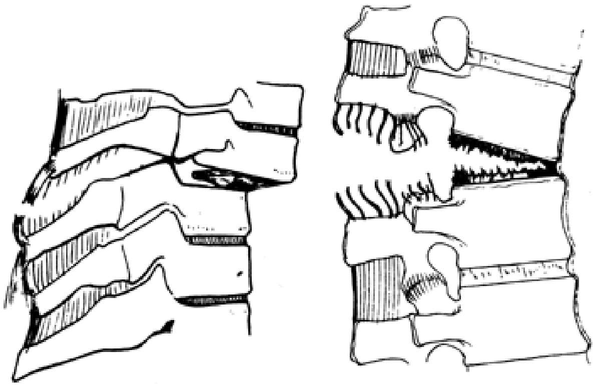

FIGURE 32. Diagrams of dislocations of the cervical and of the lumbar spine. The posterior ligament complex is ruptured in each case. More flexion is necessary to dislocate the lumbar spine than to dislocate the cervical spine. (From Holdsworth FW (1963): Fractures, dislocations and fracture-dislocations of the spine. *J Bone Joint Surg [Br]* 45:6–20, with permission.)

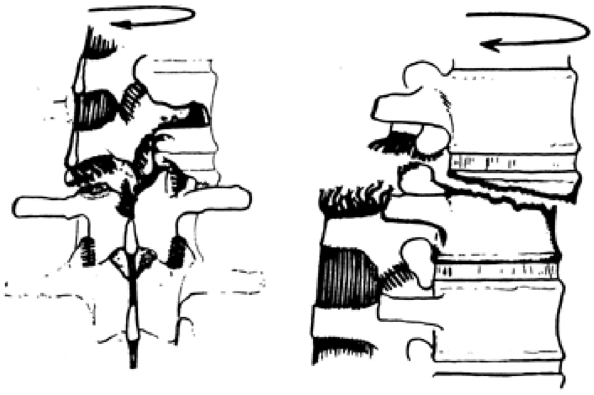

FIGURE 33. Diagram of rotational fracture-dislocation of the lumbar spine. The posterior ligament complex is ruptured, and the vertebral body is fractured. This is a very unstable injury. (From Holdsworth FW (1963): Fractures, dislocations and fracture-dislocations of the spine. *J Bone Joint Surg [Br]* 45:6–20, with permission.)

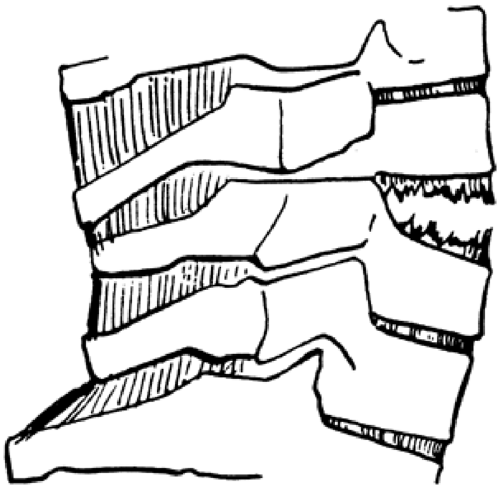

FIGURE 34. Diagram of extension injury. The anterior common ligament is ruptured. The posterior complex is intact. (From Holdsworth FW (1963): Fractures, dislocations and fracture-dislocations of the spine. *J Bone Joint Surg [Br]* 45:6–20, with permission.)

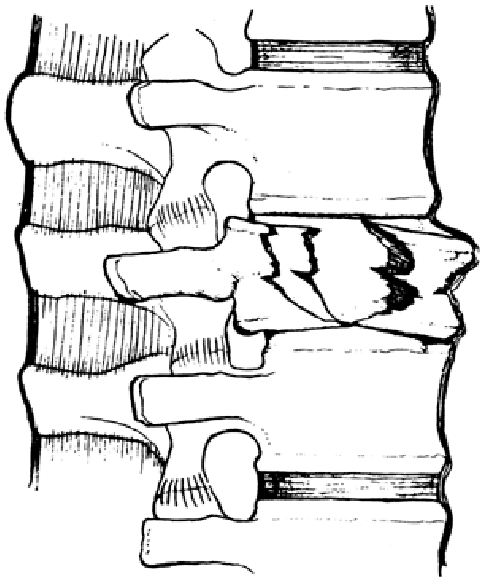

FIGURE 35. Diagram of a “burst” fracture. All the ligaments are intact. (From Holdsworth FW (1963): Fractures, dislocations and fracture-dislocations of the spine. *J Bone Joint Surg [Br]* 45:6–20, with permission.)

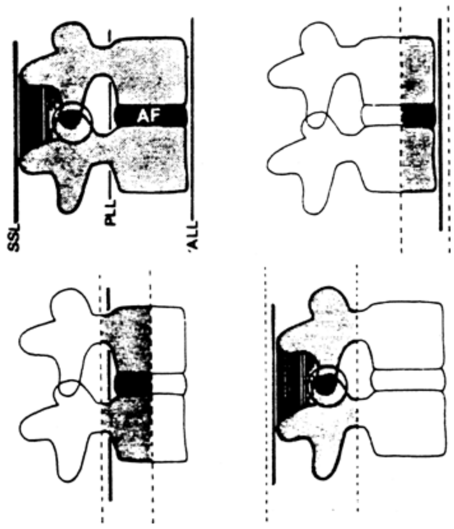

FIGURE 36. The three-column spine. The anterior column is formed by the anterior longitudinal ligament, the anterior annulus fibrosus, and the anterior part of the vertebral body. The middle column is formed by the posterior longitudinal ligament, the posterior annulus fibrosus, and the posterior wall of the vertebral body. The posterior column is formed by the posterior bony complex (posterior arch), alternating with the posterior ligamentous complex (supraspinous ligament, interspinous ligament, capsule, and ligamentum flavum). (From Denis F (1983): The three-column spine and its significance in the classification of acute thoracolumbar spinal injuries. *Spine* 8:817–831, with permission.)

5. THORACOLUMBAR SPINE FRACTURES

A. Watson-Jones Classification

According to Watson-Jones, three types of vertebral body fractures are to be distinguished (Fig. 30).

Watson-Jones R (1938): The results of postural reduction of fractures of the spine. *J Bone Joint Surg [Am]* 20:567–586.

B. **Nicoll Classification** (1949)

Nicoll classified thoracolumbar fractures into four main types:

1. Anterior wedge fracture
2. Lateral wedge fracture
3. Fracture-dislocation
4. Isolated fractures of the neural arch

Nicoll considered stable fractures to be all anterior and lateral wedge fractures and all laminar fractures above the fourth lumbar level. Unstable fractures included fracture-dislocations and all laminar fractures at the level of the fourth and fifth lumbar level.

Nicoll EA (1949): Fractures of the dorso-lumbar spine. *J Bone Joint Surg [Br]* 31:376–394.

C. **Holdsworth Classification** (1963)

According to Holdsworth, the spine may be subjected to four types of violence: flexion, flexion and rotation, extension, and compression. The type of fracture, dislocation, or fracture-dislocation that results from each of these types of violence will depend on whether or not the posterior ligament complex is ruptured and on the part of the spine involved. This classification is based on a two-column subdivision of the spine.

Compression fractures result from pure *flexion.* Most common in the thoracic and lumbar spine, these are stable injuries (Fig. 31).

With *flexion-rotation* violence the posterior ligament ruptures and a pure dislocation results. Pure dislocations are unstable (Fig. 32). Rotation or flexion-rotation may result in fracture-dislocation in the lumbar spine. These are generally very unstable injuries (Fig. 33).

In pure *extension*, either the posterior elements (lamina and pedicles) fracture or an extension dislocation occurs. This is common in the cervical spine as a result of “whiplash” injuries (Fig. 34) *Compression* leads to the comminuted “burst fracture” (Fig. 35).

TABLE 3. Basic Modes of Failure of the Three Columns in the Four Major Types of Spinal Injuries

	Column		
Type	**Anterior**	**Middle**	**Posterior**
Compression	Compression	None	None or distraction (severe)
Burst	Compression	Compression	None or splaying of pedicles
Flexion-distraction	None or distraction	Distraction	Distraction
Fracture/dislocation	Compression Rotation Shear	Distraction Rotation Shear	Distraction Rotation Shear

From Denis F (1985): The three-column spine and its significance in the classification of acute thoracolumbar spinal injuries. *Spine* 8:817–831, with permission.

In seat belt-type injuries, the component of compression failure on the anterior column is either absent or minimal and takes place in the anterior part of the vertebral body (collapse of about 10% to 20% of the anterior height).

Holdsworth FW (1970): Fractures, dislocations and fracture-dislocations of the spine. *J Bone Joint Surg [Br]* 52:1534–1551.

D. **Denis Classification**

Denis popularized the concept of the *three-column theory* (Fig. 36; Table 3). Denis classified spinal fractures into major and minor injuries. He identified four major types of spinal injuries: compression fractures, burst fractures, seat-belt injuries, and fracture-dislocations. The key in distinguishing among these injuries is the middle column's mode of failure.

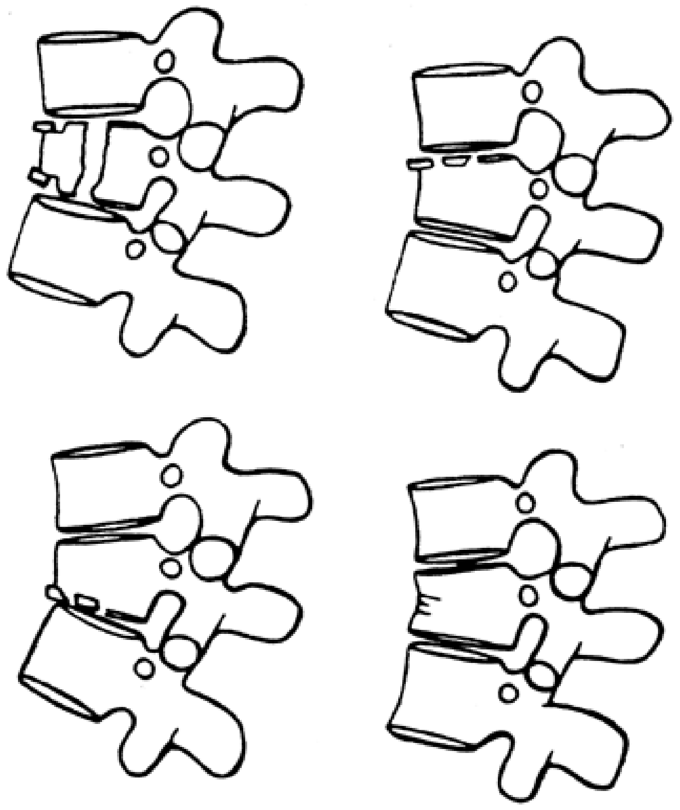

FIGURE 37. Compression fractures. **A:** Fracture of both lower and upper end plates. **B:** Isolated fracture of the upper end plate. **C:** Lower end plate fracture. **D:** Lateral compression (this is best identified in the frontal plane, anteroposterior radiographic view). (From Denis F (1983): The three-column spine and its significance in the classification of acute thoracolumbar spinal injuries. *Spine* 8:817–831, with permission.)

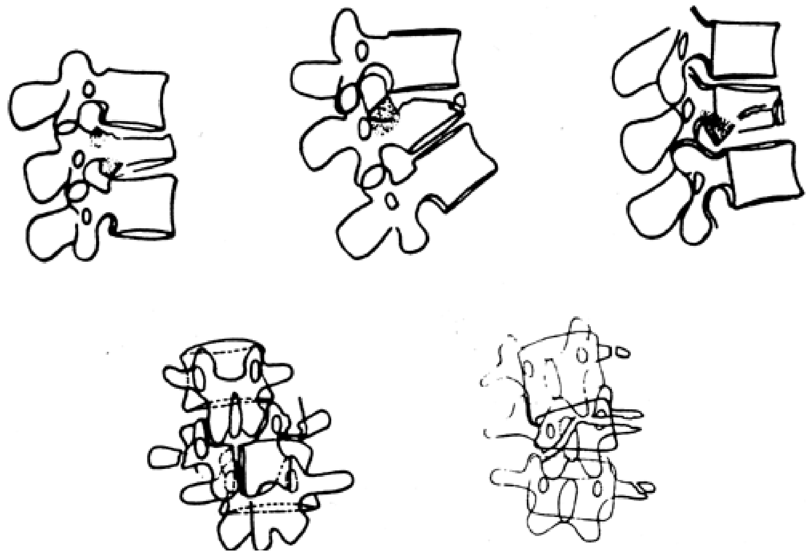

FIGURE 38. Burst fractures. Types A, B, and C are mainly diagnosed on lateral radiographic views: *Type A:* Fracture of both endplates, seen in the low lumbar region. Its mechanism is pure axial load. *Type B:* Fracture of the superior end plate. This is the most frequent burst fracture. It is seen at the thoracolumbar junction. The mechanism of injury is axial load and flexion. *Type C:* Fracture of the inferior end plate. This fracture is rare. The mechanism of injury also appears to be axial load and flexion. *Type D:* Burst rotation. This is typically a midlumbar fracture, which could be misdiagnosed as a fracture-dislocation. The mechanism of injury is axial load and rotation. *Type E:* Burst lateral flexion. This fracture results from axial load and lateral flexion. It differs from the lateral compression fracture in that the posterior wall of the vertebral body fractures, allowing retropulsion of bone back into the canal. (From Denis F (1983): The three-column spine and its significance in the classification of acute thoracolumbar spinal injuries. *Spine* 8:817–831, with permission.)

In compression fractures, the middle column is not injured and the fracture is stable. In burst fractures, the middle column fails in compression and the injury is most likely unstable. In shearing injuries, such as the seat-belt–related fractures, the middle column fails in distraction, whereas in fracture-dislocations, the middle column fails in rotation or shear. In addition to the injury to individual motion segments of the spine, stability relates to the presence or absence of neurologic injury.

1. *Compression Fractures*

   Compression fractures result from an axial load combined with flexion or lateral bend (Fig. 37). They are the most common injury, comprising 89% of Denis' series. If the loss of vertebral body height is less than 50% (40% according to some authors) or the angled deformity is less than 20°, the fractures have been considered stable. In instances in which compression injuries are contiguous, the angulatory and compression deformities are summated. The two subtypes of compression fractures are anterior and lateral. The most frequent type of compression fracture involves fracture of the upper end plate of the vertebra in its anterior portion; however, other types occur.

2. *Burst Fractures*

   The burst fracture results from failure of the vertebral body under axial load (Fig. 38). The essential feature of the burst injury is disruption of the middle column with varying degrees of retropulsion into the neural canal, best identified on CT scans. Involvement of the posterior elements is common. When the posterior elements are involved, neurologic injury is present in 50% of the cases. The neural injury may be the result of neural element entrapment in laminal fractures. Dural laceration is to be anticipated. Five subtypes have been identified by Denis, based on which end plate is involved and on the rotational or lateral flexion component.

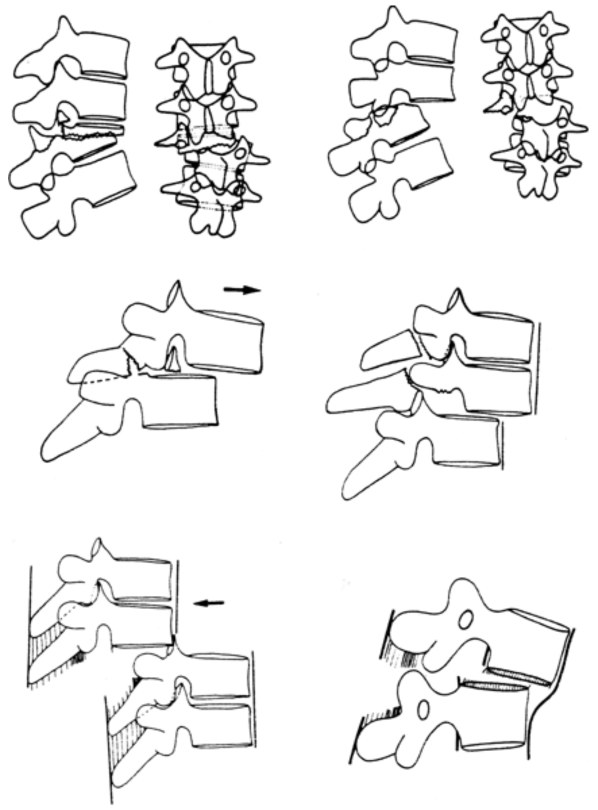

FIGURE 39. Fracture-dislocations. **A:** Flexion rotation through the vertebral body “slice fracture.” **B:** Flexion rotation through the disc. It is accompanied by unilateral fracture of the superior articular process. **C:** Posteroanterior shear injury. Intact anterior vertebral bodies and fracture of the superior articular facet, which has been sheared off by the anterior. The spinous process or entire posterior arch may be fractured by the same mechanism. **D:** Posteroanterior shear injury in which a large part of the posterior arch may be left behind (floating lamina). **E:** Anteroposterior shear injury. The posterior arches and anterior vertebral bodies may be entirely intact, but the three ligamentous columns are disrupted. **F:** Flexion distraction. The posterior, middle, and anterior ligamentous columns are disrupted but for the anterior longitudinal ligament, which strips off the vertebral body below. (From Denis F (1983): The three-column spine and its significance in the classification of acute thoracolumbar spinal injuries. *Spine* 8:817–831, with permission.)

3. *Fracture-Dislocations*

Fracture-dislocation injuries are unstable because all three columns have failed (Fig. 39). Multiple forces are involved, including rotation, distraction, compression, and shear. In general, these injuries are divided into

I: Flexion rotation

II: Shear

III: Flexion-distraction

Gertzbein and Eismont have added a fourth category: the combined dislocation-burst injury.

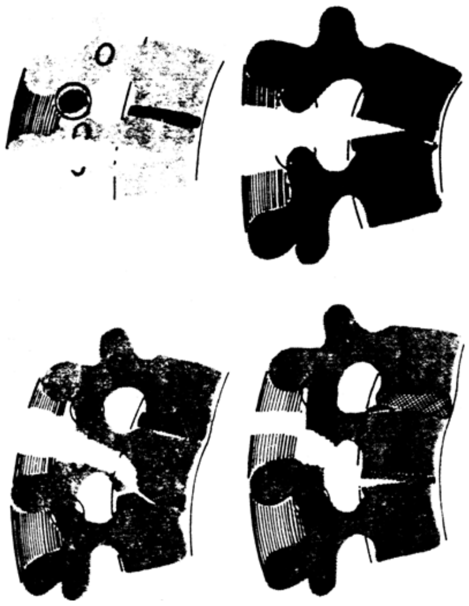

FIGURE 40. Seat-belt-type injuries: flexion distraction injuries. **A:** One-level, through bone (Chance fracture). **B:** One-level, through the ligaments. **C:** Two-level, through bone at the level of the middle column. **D:** Two-level, through ligaments at the level of the middle column. (From Denis F (1983): The three-column spine and its significance in the classification of acute thoracolumbar spinal injuries. *Spine* 8:817–831, with permission.)

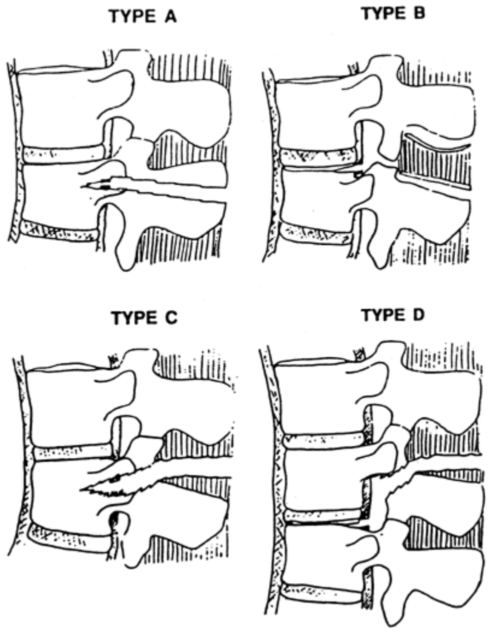

FIGURE 41. Seat-belt fracture patterns in skeletally immature children. *Type A* is a bony disruption of the posterior column extending just into the middle column. *Type B* is an avulsion of the posterior elements with facet joint disruption or fracture and extension into the apophysis of the vertebral body. *Type C* is a posterior ligamentous disruption with a fracture line entering the vertebra close to the pars interarticularis and extending into the middle column. *Type D* is a posterior ligamentous disruption with a fracture line traversing the lamina and extending into the apophysis of the adjacent vertebral body. (From Rumball K, Jarvis J (1992): Seat-belt injuries of the spine in young children. *J Bone Joint Surg* 74B:571–574, with permission.)

4. *Seat-Belt Injuries*
    1. *Seat-Belt–Type Spinal Injuries (Flexion Distraction Injuries) in Adults*

        The seat-belt-type of injury represents failure of both the posterior and middle columns under tension forces generated by flexion and sometimes by superadded distraction (Fig. 40)

    2. *Seat-Belt Fractures in Children* (Fig. 41)
5. *Fractures (Slipping of the Vertebral apophysis)* (Fig. 42)

    Slipping of the apophysis can be classified into three types according to radiographic appearance:

    Type I: Separation of the posterior rim of the involved vertebra. A calcified arc is seen on CT scan with no evidence of associated large bony fracture. This type is most common in children aged 11 to 13.

    Type II: Avulsion fracture of part of the vertebral body, annular rim, and cartilage. This type is most common in adolescents and young adults aged 13 to 18 years.

    Type III: More localized injury that includes smaller posterior irregularities of the cartilaginous end plate. This is most common in young adults older than age 18 years.

    Type IV: Spans the entire length and breadth of the posterior vertebral margin between end plates.

    Epstein NE, Epstein JA (1991): Limbus lumbar vertebral fractures in 27 adolescents and adults. *Spine* 16:962–966.

    Epstein NE, Epstein JA, Mauri T (1989): Treatment of fractures of the vertebral limbus and spinal stenosis in five adolescents and five adults. *Neurosurgery* 24:595–604.

6. *Isolated Injuries of the Posterior Elements (Minor Injuries)*

    Transverse process fractures are the result of blunt trauma or violent contracture of the spinal musculature. When multiple fractures are present, or particularly when the L5 transverse process is fractured, there is a significant association with intraabdominal (renal) injuries and pelvic disruption. Occasionally, neuropraxias results, most typically involving the L3 and L4 nerve roots.

    Spinous process avulsions are fairly rare in the lumbar spine and are usually the result of direct trauma.

    Isolated facet fractures (articular process fractures) are uncommon but may occur in patients with prior laminectomies, most commonly by a fatigure, rather than an acute injury mechanism.

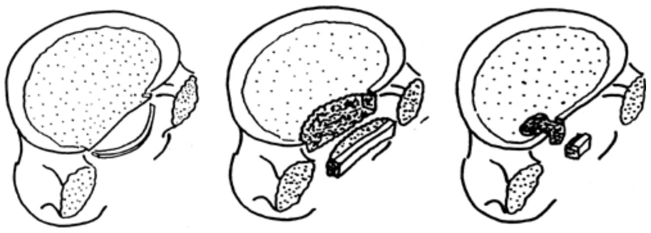

FIGURE 42. Schematic representation of the three types of avulsion fractures. In type I *(left)*, an arcuate fragment is found, but no osseous defect is seen at the posterior rim of the vertebral body. Type II *(middle)* is an avulsion fracture of the posterior rim of the vertebral body that includes a rim of bone. The fragment is not arcuate, and it is thicker than in type I. The sharply avulsed osseous edge is recognized on computed tomograms. Type III *(right)* is a localized fracture posterior to an irregularity of the cartilage end plate. The osseous defect anterior to the fragment, as depicted on computed tomograms, is larger than the fragment. (From Tarr RW, et al. (1987): Imaging of recent spinal trauma. *J Comput Assist Tomogr* 11:412–417.)

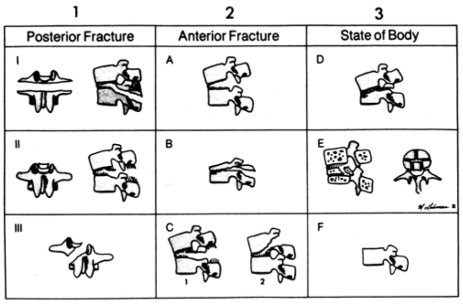

FIGURE 43. Flexion-distraction injuries. *Posterior fractures:* In type I, the fracture line enters the spinous process and passes symmetrically through the laminae, transverse processes, and pedicles to enter the vertebral body. Type II is similarly symmetric, but the fracture line enters at the base of the spinous process. Type III enters obliquely, involving more of the posterior elements on one side than the other. *Anterior fractures:* There are three constant locations of the exiting anterior fracture in the vertebral body. Group A: The injury exits through the disc; Group B: the fracture passes through the vertebral body; Group C: extension occurs through the superior end plate (Subgroup 1) or the inferior end plate (Subgroup 2). State of the vertebral body: Group D: the injury may affect the vertebral body by a wedge compression fracture, or Group E: a burst injury, or Group F: the vertebral body may be intact. (From Gertzbein SD, Court-Brown CM (1988): Flexion-distraction injuries of the lumbar spine. *Clin Orthop* 227:52–60, with permission.)

Traumatic spondylolisthesis (pars interarticularis fracture) is rare compared with the far more common isthmic defect.

E. Flexion-Distraction Injuries (Gertzbein and Court-Brown)

Court-Brown and Gertzbein have further subdivided flexion-distraction injuries into three categories related to the posterior element fracture, the anterior column fracture, and the state of the vertebral body (Fig. 43).

F. Magerl Classification (1989)

Magerl and associates have proposed a classification based on morphologic injury patterns. Three basic forces (compression, distraction, rotation) produce main injury types. These types have been applied to all levels of the spine and are divided into A, B, and C with subcategories (A1, A2, A3, and so on), with the further subdivisions of 1, 2, and 3 indicating severity.

Type A: Compression lesions (loss of vertebral body height)

Type A1: Body impaction

Type A2: Splitting

Type A3: Burst

Type B: Distraction injuries

Types B1 and B2: Increased distance between posterior elements

Type B3: Increased distance between the anterior structures

Type C: Torsional injuries, which are the most unstable injuries and are a combination of types A and B with rotation; there is anteroposterior element destruction with torsion

Magerl F, Harms H, Gertzbein S, Aebi M (1989): Classification of spinal fractures. Presented at a meeting of the American Academy of Orthopaedic Surgeons, Vail, Colorado, 1989.

1. SACRAL FRACTURES

Denis and Comfort have classified sacral fractures based on direction, location, and level of fracture (Fig. 44).

Zone I, the region of the ala, was occasionally associated with partial damage to the fifth lumbar root.

Zone II, the region of the sacral foramina, is frequently associated with sciatica but rarely with bladder dysfunction.

Zone III, the region of the central sacral canal, is frequently associated with saddle anesthesia and loss of sphincter function.

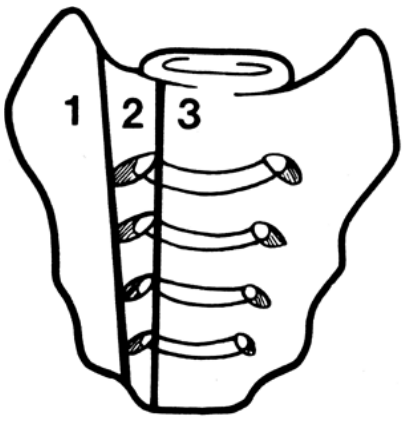

FIGURE 44. Denis classification of sacral fractures: *Zone I*—the region of the ala; *Zone II*—the region of the foramina; and *Zone III*—the region of the central canal. (From Denis F, Davis S, Comfort T (1988): Sacral fractures: an important problem. *Clin Orthop* 227:67–81, with permission.)

Routine pelvic radiographs were almost useless in identifying the pathologic process in sacral injuries with neurologic symptoms. Computed tomography is recommended.

2. POSTTRAUMATIC NEUROLOGIC DEFICIT

A. Definitions

The definitions recommended by the American Spinal Injury Association (ASIA) in the booklet Standards for Neurological Classifications of Spinal Injury Patients, adapted from Austin, provide an accurate method of communicating information on the extent of neurologic injury.

1. *Manual Muscle Testing*

Manual muscle testing is performed using the standard six-grade scale:

Absent = 0

Trace = 1, visible or palpable contraction

Poor = 2, active movement through range of motion with gravity eliminated

Fair = 3, active movement through range of motion against gravity

Good = 4, active movement through range of motion against resistence

Normal = 5

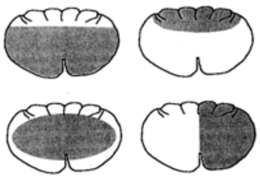

FIGURE 45. Incomplete spinal cord injury syndromes. Anterior cord syndrome: Only deep pressure sensitivity is retained, no evidence of sharp or dull discrimination or voluntary muscle control. These patients have only a 10% to 20% chance of any functional recovery. There is virtually no chance of full recovery. Posterior cord syndrome is rare. There is preservation of motor function with loss of sensory function below the level of injury. Central cord syndrome: The patient has severe quadriparesis but has "sacral sparing." This means sharp or dull discrimination is present around the perineum. The prognosis is good for functional recovery in 50% to 70% of the patients. Approximately 5% may have full recovery. Brown-Séquard syndrome: The patient has voluntary function and sensibility below the zone of injury, and the muscle weakness is greater on one side and the loss of sensibility is greater on the opposite side. The prognosis for progressive recovery is excellent. (From Kasser JR, ed (1996): *Orthopaedic knowledge update 5.* Rosemont, IL, American Academy of Orthopaedic Surgeons, p 576, with permission.)

TABLE 4. SUNNYBROOK CORD INJURY SCALE

Grade	Description	Corresponding Frankel Scale
1	Complete motor and sensory loss	A
2	Complete motor loss; incomplete sensory loss	B
3	Incomplete motor but unclear	C
4	Incomplete motor loss; incomplete sensory loss	C
5	Incomplete motor but useless; normal sensory	C
6	Incomplete motor; complete sensory	D
7	Incomplete motor; incomplete sensory	D
8	Incomplete motor; normal sensory	D
9	Normal motor; incomplete sensory	D
10	Normal motor; normal sensory	E

TABLE 5. Criteria Used for Sensory Severity Scale

		Pain (pinprick)				
Sensory Severity Scale	Description	Higher Level			Lower Level	
		Normal	Decreased	Absent	Decreased	Normal
7	Quadraplegic	Yes	Yes	C1 to T1	No	No
6	Paraplegic	Yes	Yes	T2 to S5	No	No
5	Quadraparetic	Yes	C1 to T1	No	Yes	No
4	Paraparetic	Yes	T2 to S5	No	Yes	No
3	Some segments absent	Yes	Yes	Any level	Yes	Yes
2	Some segments decreased	Yes	Any level	No	No	Yes
1	Normal	Yes	No	No	No	Yes

From Bracken MB, Wabb SB, Wagner FC (1978): Classification of the severity of acute spinal cord injury: Implications for management. *Paraplegia* 15:319–26, with permission.

2. *Neurologic Level of Injury*

   The most caudal segment that tests as intact for both sensory and motor functions on both sides of the body is the neurological level of injury. If a muscle has at least a grade of "Fair," it is considered intact.

3. *Motor Level*

   The motor level is the level of the lowest key muscle having a grade of at least "Fair." All levels above the neurologic level of injury or motor level must be intact.

4. *Incomplete Spinal Cord Injury*

   When the preservation of sensory or motor function exists more than three neural segments below the neurologic level of injury, the spinal cord injury is incomplete. These patients have a good potential for progressive recovery of neurologic function. There are three basic syndromes that can be identified, each with its own specific physical findings and prognostic implications (Fig. 45).

5. *Complete Spinal Cord Injury*

   Complete spinal cord injury (SCI) means no preservation of motor and sensory function exists more than three segments below the neurologic level of injury. If the patient has no active muscle control or sensibility below the zone of injury, specifically with no retained perianal sensation or sphincter, one may diagnose a "presumed" complete lesion. The patient may be in spinal shock, however, which is a short period of paralysis, insensitivity, and absence of reflex activity following any severe traumatic injury to the spinal cord. This period rarely lasts more than several hours. The end of spinal shock is heralded by the presence of the bulbocavernosus reflex. Therefore, if the patient has no active muscle power and has no sensibility below the level of the injury, and the bulbocavernosis reflex is present, the patient has a "confirmed" complete spinal cord lesion. The relevance of this finding is that the patient will make no significant functional recovery.

   a. *Zone of Injury*

      In patients with complete SCI, the zone of injury is defined as up to three neural segments below the level of injury having partial motor and sensory function. Because the most caudal normal sensory segment may not be the same as the most caudal normal motor segment, and the motor and sensory levels may not be the same on the right and left sides, it is possible to express the differences individually in a given patient.

   b. *Vertebral Level of Injury*

      The vertebral level of injury is the highest spinal level with radiographic evidence of vertebral injury.

   c. *Respirator-Dependent Quadriplegia*

      If the patient has a functional level above C4, he will be respirator dependent. These patients usually die at the scene of the accident owing to respiratory paralysis. These patients have control only of their face, head, and mouth muscles.

   d. *Pentaplegia*

      If the patient has an injury of C1 or C2, which produces a complete spinal cord injury, the patient is not only respirator-dependent but has lost the use of the head and neck muscles, and only has sensation over the face with no voluntary control of the head other than facial muscles.

American Spinal Injury Association (1989): *Standards for neurological classification of spinal injury patients.* pp 1–21.

3. NEUROLOGIC GRADING SCALES

The classifications are designed to monitor the extent of the initial neurologic injury and its progression, as well as to provide a method for assessing treatment efficacy by different methods.

The Frankel scale is well known and widely used. Its disadvantage is that it does not include complete assessment of rectal or bladder function, nor is it sensitive to significant neurologic improvement in those patients classified as grade D. An additional problem is that the lesion level is not indicated, so that a paraplegic falls into the same category as a quadriplegic.

The Sunnybrook cord injury scale consists of 10 neurologic grades. It differs from the Frankel system in that sensory loss can be classified as complete or incomplete. There is also a coding system to assess change in neurologic status. Unfortunately, motor grades 6 to 8 comprise a large and heterogeneous group. Bladder and bowel function are not assessed. It is not easy to commit to memory and thus has diminished bedside utility, particularly in acute management.

The motor index of Lucas and Ducker has been modified by the American Spinal Injury Association into a motor index score in which 100 represents the perfect score. Its deficiency is that bowel and bladder function are not evaluated.

The classification of Lucas and Duckworth has two subdivisions:

1. The level of vertebral trauma documented by radiographic examination
2. The resulting motor examination

The level of vertebral trauma was subdivided into single sites, multiple sites, and no evidence of vertebral trauma. The motor function was assessed by testing different muscle groups and grading them on a scale of 0 to 5. Certain patterns of motor dysfunction below the level of injury were found and used to classify patients into five different motor patterns—two complete and three partial lesions.

Complete at bony level (CBL): complete loss of motor function within two cord segments below the site of vertebral trauma

Graded complete (GC): complete motor loss that occurs two to four cord segments below the site of vertebral trauma

Partial with secondary caudal loss (PCL): partial loss may be secondary or complete; by definition, approaches zero function at least four segments below the level of bony trauma

Partial with caudal gain or caudal sparing (PCS)

Uniform partial lesions (PLU)

The classification of Bracken and colleagues has many of the features of the Sunnybrook cord injury system and, like it, is difficult to memorize and apply at the bedside. It also makes no specific mention of bowel or bladder function.

Recently, Esses and Botsford described a neurologic grading system, attempting to overcome some of these deficits. The scale includes assessment of motor and sensory function, rectal tone, and bladder control. Motor index is assessed by function.

C. **Frankel Classification**

Each patient should be classified at the time of injury and again at 1-year follow-up to document improvement.

A. *Complete:* The lesion is found to be complete both motor and sensory below the segmental level marked.
B. *Incomplete:* Sensory only: There is some sensation present below the level of the lesion, but the motor paralysis is complete below that level.

TABLE 6. Criteria Used for Motor Severity Scale

	Higher Level			Lower Level	
Motor Severity Scale	**Active Antigravity Against Resistance**	**Flicker, Trace Active Antigravity**	**No Contraction**	**Flicker, Trace Active Antigravity**	**Active Antigravity Against Resistance**
5	Yes	Yes	C5 → T1	No	No
4	Yes	Yes	L1 → S2	No	No
3	Yes	C5 → T1	No	Yes	No
2	Yes	L1 → S2	No	Yes	No
1	C5 → T1	No	No	No	Yes

From Bracken MB, Webb SB, Wagner FC (1978): Classification of the severity of acute spinal cord injury: implications for management. *Paraplegia* 15:319–326, with permission.

C. *Incomplete:* Motor useless: There is some motor power present below the lesion, but it is of no practical use to the patient.
D. *Incomplete:* Motor useful: There is useful motor power below the level of the lesion. Patients in this group can move the lower limbs and many can walk with or without aids.
E. *Normal:* Full recovery. The patient is free of neurologic symptoms (i.e., no weakness, no sensory loss, no sphincter disturbance). Abnormal reflexes may be present.

D. **Sunnybrook Cord Injury Scale** (Table 4)
E. **Bracken Classification** (Tables 5, 6)

In the Bracken classification, assessment of sensory level was based on the patient's response to five stimuli:

Superficial pain

Light touch

Position sense

Vibratory sense

Deep pain

The patients were then grouped in a Sensory Severity Scale:

1. Normal
2. Some segments decreased
3. Some segments absent
4. Paraparetic
5. Quadriparetic
6. Paraplegic
7. Quadriplegic

The motor level of function was assessed by a 0 to 5 scale, and the patients were then grouped in a five-category Motor Severity Scale.

TABLE 7. American Spinal Injury Association (Asia) Motor Score[a]

Grade On Right		Muscle		Grade On Left
0 to 5	C5	Deltoid and/or biceps	C5	0 to 5
0 to 5	C6	Wrist extensors	C6	0 to 5
0 to 5	C7	Triceps	C7	0 to 5
0 to 5	C8	Flexor profundus	C8	0 to 5
0 to 5	T1	Hand intrinsics	T1	0 to 5
0 to 5	L2	Iliopsoas	L2	0 to 5
0 to 5	L3	Quadriceps	L3	0 to 5
0 to 5	L4	Ankle dorsiflexors	L4	0 to 5
0 to 5	L5	Extensor hallucis longus	L5	0 to 5
0 to 5	S1	Gastrocnemius/soleus		0 to 5
0 to 50			S1	0 to 50

[a] Total possible score: 100.

F. **ASIA Motor Score**

The extent of motor function below the level of injury can be determined numerically by the ASIA motor score (Lucas). The strength of a key muscle at each level from C5 through T1 and from L2 through S1 is determined using the numerical scale for motor strength described above. A total score of 100 is possible (Table 7).

In gunshot injuries, the neurologic level is at least one level higher than the vertebral level in approximately 70% of injuries; in 20%, the neurologic and vertebral level are the same, and in 10%, the vertebral level is two levels lower than the neurologic level. More than half of all gunshot injuries, resulting in spinal cord injury, cause a complete neurologic lesion.

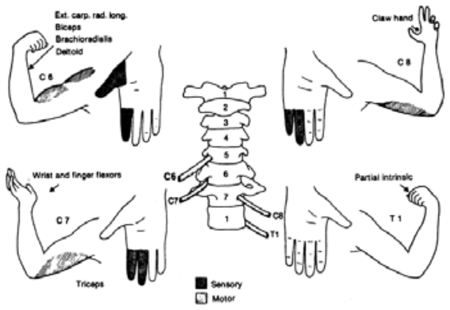

FIGURE 46. Segmental motor and sensory changes, C6 to T1. (From McQueen JD, Khan MI (1989): Neurologic evaluation. In: The Cervical Spine Research Society, ed. *The cervical spine.* Philadelphia: JB Lippincott, with permission.)

1. **DETERMINATION OF LEVEL OF NEUROLOGIC INJURY**
   A. **Localization of Cervical and Lumbar Root Lesions** (Table 8)
   B. **Segmental Motor and Sensory Changes, C6 to T1** (Fig. 46)
   C. **Method to Determine Level of Neurologic Injury** (Table 9)
2. **ASSOCIATION OF NEUROLOGIC PATTERNS AND INJURY MECHANISM IN THE CERVICAL SPINE** (Table 10)
3. **NEUROLOGIC LOSS IN CERVICAL SPONDYLOTIC MYELOPATHY**

Nurick classified cervical spondylotic myelopathy largely on the basis of gait (Table 11).

The Japanese Orthopaedic Association has devised an objective assessment scale to quantitate the degree of involvement secondary to spondylotic myelopathy. The scale involves four categories (Table 12).

4. **CLINICAL FEATURES OF INTERMEDULLARY AND EXTRAMEDULLARY LESIONS OF THE CERVICAL SPINE** (Table 13)
5. **CLINICAL MANIFESTATIONS OF SPINAL CORD, PERIPHERAL NERVE, AND SKELETAL MUSCLE DISEASES** (Table 14)

TABLE 9. Method to Determine Level of Neurologic Injury

Level	Muscle Power	Sensory	Reflexes
T2–T5	Upper extremity intact; intercostals paralyzed; breathing diaphragmatic	T2 axialla lost T5 nipple line	None
T6–T9	Intact Intercostals above level of involvement	T6 xiphoid	Abdominals absent
	Supraumbilical segments of rectus abdominus intact; umbilicus moves cephalad with forced respiration	T7 costal margins	
T10	Infraumbilical segments of rectus abdominus intact; umbilicus shifts caudad with forced respiration	Umbilicus	
T12	Abdominal muscles intact	Groin	Abdominals present
L1	No lower extremity	Buttocks	Intact ankle jerk, knee jerk = upper motor neuron paralysis
			Cremasteric present
L2	Possible iliopsoas	Anterior upper third of the thighs	Cremasteric absent
L3	Hip flexion sartorius and iliopsoas intact	Anterior two-thirds of the thighs	Knee jerk absent
L4	Hip flexion; hip adduction; intact sartorius permits some knee flexion	Anterior thigh, medial leg	Knee jerk present
L5	Ankle dorsiflexion	Medial ankle	
	Anterior tibial intact	Dorsum of the foot, great toe absent	
S1	As above	Plantar, lateral border of foot absent	
S2	Plantar flexion, intact	Peripheral sensation intact	Ankle jerk present
S3–S4	Cauda equina-type syndrome, including potential loss of bladder and bowel control with sensory losses confined to the genitalia, perineum, anus, and posterior upper thigh; no peripheral motor loss		

TABLE 10. Association of Neurologic Patterns and Injury Mechanism in the Cervical Spine

	Neurologic Damage	Injury
Group 1	Total motor and sensory loss to all four limbs; total transection of cord; no recovery occurred	Burst fracture or bilateral facet dislocation, flexion injury
Group II	Motor loss of varying degrees, either in all four extremities or in the upper limbs only: sometimes segmental or patchy transient sensory loss was associated (*central spinal cord damage*)	Hyperextension injuries
Group III	Complete motor loss in the extremities, with hypoesthesia and hypalgesia up to the level of the lesion; no loss of position and vibratory sense (*anterior spinal cord damage*)	Vertical compression, bursting injury, “teardrop” fracture-dislocation: possibly some associated flexion or extension
Group IV	Motor power in all four limbs or the upper extremities along with no sensory loss	Unilateral facet dislocation, fractured arch of altas, and a variety of injuries
Group V	Brown-Séquard syndrome	Unilateral facet dislocation or a burst fracture

From Marar BC (1974): The patterns of neurological damage as an aid to the diagnosis of the mechanism in cervical-spine injuries. *J Bone Joint Surg (Am)* 56:1648–1654, with permission.

TABLE 11. Nurick's Classification of Disability in Spondylotic Myelopathy

Grade 0	Root signs and symptoms No evidence of cord involvement
Grade I	Signs of cord involvement Normal gait
Grade II	Mildgait improvement Able to be employed
Grade III	Gait abnormality prevents employment
Grade IV	Able to ambulate only with assistance
Grade V	Chairbound or bedridden

From Nurick S. (1972): The pathogenesis of the spinal cord disorder associated with cervical spondylosis. *Brain* 95:687–100, with permission.

TABLE 12. The Assessment Scale Proposed by the Japanese Orthopaedic Association

I. Motor dysfunction of the upper extremity *Score*
    0 = Unable to feed oneself
    1 = Unable to handle chopsticks, able to eat with a spoon
    2 = Handle chopsticks with much difficulty
    3 = Handle chopsticks with slight difficulty
    4 = None
II. Motor dysfunction of the lower extremity *Score*
    0 = Unable to work
    1 = Walk on flat floor with walking aid
    2 = Up and/or down stairs with handrail
    3 = Lack of stability and smooth reciprocation
    4 = None
III. Sensory deficit
    A. The upper extremity *Score*
        0 = Severe sensory loss or pain
        1 = Mild sensory loss
        2 = None
    B. The lower extremity, same as A
    C. The trunk, same as A
IV. Sphincter dysfunction *Score*
    0 = Unable to void
    1 = Marked difficulty in micturition (retention, strangury)
    2 = Difficulty in micturition (pollakiuria, hesitation)
    3 = None

From Hirabayashi K, Miyakawa J, Satomi K, et al. (1981): Operative results and postoperative progression of ossification among patients with ossification of cervical posterior longitudinal ligament. *Spine* 6:354–364, with permission.

TABLE 13. Clinical Features of Intramedullary and Extramedullary Lesions of the Cervical Spine

Clinical Features	Intramedullary Lesions	Extramedullary Lesions
Motor disturbances		
Spastic paresis	Late onset, lower limbs	Early onset, more marked distally
Flaccid paresis	Early onset, upper limbs	Often absent, except at segmental level
Atrophy of muscles	Often prominent, upper limbs	Uncommon but may be segmental
Fasciculations	Present	Present
Reflex changes		
Muscle stretch reflex	Depressed early in upper limbs, late hyperactivity in lower limbs	Early hyperactivity with possible segmental depression
Babinski's sign	Late appearance	Early sign
Sensory disturbances		
Root pains	Often absent	Often presenting symptom
Local vertebral pain	Usually absent	Often present
Sensory loss	Dissociated sensory loss, maximal at level of lesion	Usually begins below level of lesion
Others		
Tropic skin changes	Often present	Rare
Bladder function	Early incontinence	Late incontinence

From McQueen JD, Khan MI (1989): Neurologic evaluation. In: The Cervical Spine Research Society, ed. *The cervical spine*. Philadelphia: JB Lippincott, with permission.

TABLE 14. Clinical Manifestations of Spinal Cord, Peripheral Nerve, and Skeletal Muscle Diseases

Clinical Manifestations	Spinal Cord Lesions (Myelopathies)	Peripharal Nerve Lesions (Neuropathies)	Muscle Disease (Myopathies)
Motor	Upper or lower motor neuron-type weakness, depending on acuity and “age” of the lesion and its location in relation to cord segments Trunk and limb(s) below the lesion affected Atrophy from disuse only	Lower motor neuron (flaccid) weakness only Predominantly in extremities; tends to involve distal limb segments more than proximal Atrophy early	Flaccid weakness only Tends to involve trunk and proximal limb segments earliest
Sensory	Cutaneous “sensory level” or “suspended level” on trunk Sensory dissociation, if present, usually in terms of cord tracts	Rarely involves trunk; tends to begin distally in limbs and ascend limbs or follows distribution of a peripheral nerve supply Dissociation, if present, may be of any combination of modalities	None
Reflexes	Hyperactive tendon reflexes below lesion except during “spinal shock” with acute lesions At level of lesion, if limb segments are involved, hyporeflexia or areflexia persists or both hyper- and hyporeflexia occur in same limb(s) Pathologic reflexes (Babinski's sign, spontaneous flexor or extensor spasms) below lesion likely Cutaneous reflexes lost below lesion	Hyporeflexia or areflexia found early and persists No pathologic relaxes Cutaneous reflexes spared unless their effecter muscles are completely paralyzed	Tendon reflexes normal early, become progressively hypoactive as disease advances Cutaneous reflexes spared No pathologic reflexes
Sphincters	External urethral and anal sphincters often impaired	Sphincters very rarely involved	No sphincter disturbances

From Talbert OR (1990): General methods of clinical examination. In: *Youman's neurological surgery*, 3rd ed. Philadelphia: WB Saunders, with permission.

TABLE 15. Differential Diagnosis of Myeloradiculopathy

Degenerative
- Cervical spondylosis
- Intervertebral disc disease

Neoplastic
- Metastatic carcinoma (prostate, lung, breast, colon, myeloma, renal, thyroid)
- Spinal cord tumor (glioma, ependymoma, hemangioblastoma, neurofibroma, maningioma)
- Paraneoplastic (acute necrotic myelopathy secondary to systemic carcinoma)

Infectious
- Epidural abscess
- Transverse myelitis (mumps, rabies, vaccinia, variola, varicella, HTLV)
- Infectious arteritis (chronic meningovascular syphilis)
- Tuberculous osteomyelitis of the spine (Pott's disease)
- Acute disseminated encephalomyelitis

Traumatic
- Blunt
- Penetrating

Neurodegenerative (autoimmune, nutritional)
- Demyelinating disease (Devic's neuromyelitis optica)
- Amyotrophic lateral sclerosis (motor neuron disease)
- Subacute combined degeneration (vitamin B_{12} deficiency)

Developmental
- Syringomyelia
- Arachnoid cyst
- Meningomyelocele
- Spinal arteriovenous malformation
- Intracranial dural arteriovenous fistula

1. **DIFFERENTIAL DIAGNOSIS OF MYELORADICULOPATHY** (Table 15)
2. **SPINE INSTABILITY**

Segmental instability is a loss of spinal motion segment stiffness, such that force application to that motion segment produces greater displacement or displacements than would be seen in a normal structure, resulting in a painful condition, the potential for progressive deformity, and neurologic structures at risk.

A. **C0-1-2 Instability** (Table 16; Fig. 47)

White AA, Panjabi MM, Posner I, et al. (1981): Spinal stability: evaluation and treatment. *AAOS Inst Course Lect* 30:457–483.

TABLE 16. Criteria for C0-1-2 Instability

>8°	Axial rotation C0–1 to one side
>1 mm	C0–1 translation*
>7 mm	Overhang C1–2 (total right and left)
>45°	Axial rotation C1–C2 to one side
>4 mm	C1–2 translation[a]
<13 mm	Posterior body C2-posterior ring C1
Avulsed transverse ligament	

[a] See Figures 37, 38, and 39 for measurement techniques.

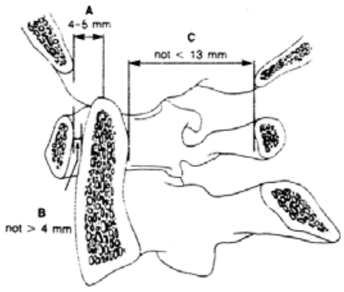

FIGURE 47. C0-1-2 lateral view. **A:** The distance between the basion of the occiput and the top of the dens is 4 to 5 mm. An increase of more than 1 mm in this distance with flexion or extension views is believed to indicate instability of C0-1, if one assumes that the transverse ligament of the atlas is intact. **B:** The distance between the anterior border of the dens and the posterior border of the ring of C1 should not be greater than 4 mm. **C:** There is another important measurement that we must consider. We refer to the distance between the posterior margin of the dens and the anterior cortex of the posterior ring of C1. This distance is of concern should it be less than 13 mm. (From White AA, Panjabi MM (1990): The problem of clinical instability in the human spine: a systematic approach. In *Clinical biomechanics of the spine*, 2nd ed. Philadelphia: JB Lippincott, with permission.)

TABLE 17. Clinical Checklist for the Diagnosis of Clinical Instability in the Lower Cervical Spine

Element	Point Value
Anterior elements destroyed or unable to function	2
Posterior elements destroyed or unable to function	2
Positive stretch test	2
Radiographic criteria	4
A. Flexion/extension radiographs 1. Sagittal plane translation >3.5 mm or 20% (2 points) 2. Sagittal plane rotation >20° (2 points) *or* B. Resting radiographs 1. Sagittal plane displacement >3.5 mm or 20% (2 points) 2. Relative sagittal plane angulation >11° (2 points)	
Abnormal disc narrowing	1
Developmentally narrow spinal canal	1
3. Sagittal diameter <13 mm *or* 4. Pavlov's ratio <0.8	
Spinal cord damage	2
Nerve root damage	1
Dangerous loading anticipated	1
Total of 5 or more = unstable	

From White AA, Panjabi MM (1990): The problem of clinical instability in the human spine: a systematic approach. In: *Clinical biomechanics of the spine* 2nd ed. Philadelphia: JB Lippincott, with permission.
See Figures 38 and 39 for Information on making radiographic measurements.

B. **Lower Cervical Spine**

See Table 17 and Figures 48 and 49.

C. **Thoracic and Thoracolumbar Spine** (Table 18)

See Figures 48 and 49 for information on making radiographic measurements. Measurement techniques are the same as for the cervical spine, except for Pavlov's ratio.

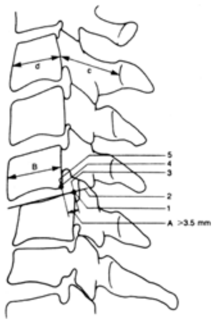

FIGURE 48. The method for measuring translatory displacement is as follows: *1*, A point is marked at the posterosuperior angle of the projected image of the vertebral body below the interspace of the functional spinal unit (FSU) being evaluated. *2*, A line is drawn along the upper vertebral end plate of the vertebra, below the interspace of the FSU under analysis. *3*, At the point where this intersects the mark, at the posterior portion of the end plate, a short perpendicular line is drawn. *4*, Next, a mark is made at the posteroinferior angle of image of the vertebral body above the interspace of the FSU being evaluated. *5*, A short line that goes through the second mark and is perpendicular to the line on the subjacent vertebral end plate is drawn. The linear distance between the two perpendicular lines is measured. This can be called distance *A.* The anteroposterior sagittal plane diameter at the midlevel of the supraadjacent vertebra is measured. This distance is called *B.* If distance A is less than 20% of distance B, then this is considered evidence of instability and should be so entered on the checklist. An alternative method is simply to measure the linear distance A, and if this is greater than 3.5 mm, it is considered to be suggestive of instability, and two points are entered onto the checklist. Pavlov's ratio is a reliable, accurate method for recognizing a developmentally narrow canal without the variables involved in linear measurements. The measurement *c* is the distance between the midlevel of the posterior aspect of the vertebral body and the nearest point on the corresponding spinolaminar line. The measurement *d* is seen on lateral view as the anteroposterior distance from the front to the back of the vertebral body measured at the midlevel. The ratio c/d is considered normal if ≤1 and abnormal is <0.80. These measurements are used in conjunction with the checklist. (From White AA, Panjabi MM (1990): The problem of clinical instability in the human spine: a systematic approach. In *Clinical biomechanics of the spine*, 2nd ed. Philadelphia: JB Lippincott, with permission.)

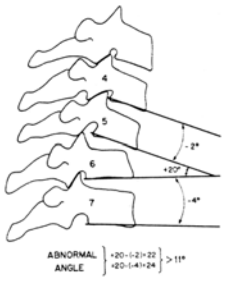

FIGURE 49. Measurement of rotation. The angulation between C5 and C6 is 20°, which is more than 11° greater than at either adjacent interspace. The angle at C4 and C5 measures -20°, and the one at C6 and C7 measures -4. (From White AA, Johnson RM, Panjabi MM, Southwick WO (1975): Biomechanical analysis of clinical stability in the cervical spine. *Clin Orthop* 109:85–96, with permission.)

1. **PEDICLE ABNORMALITIES** (Tables 23, 24)

TABLE 18. Checklist for the Diagnosis of Clinical Instability in the Thoracic and Thoracolumbar Spine

Element	Point Value
Anterior elements destroyed or unable to function	2
Posterior elements destroyed or unable to function	2
Disruptions of costovertebral articulations	1
Radiographic criteria[a] 1. Sagittal plane displacement >2.5 mm (2 points) 2. Relative sagittal plane angulation >5° (2 points)	4
Spinal cord or cauda equina damage	2
Dangerous loading anticipated	1
Total of 5 or more = unstable	

From White AA, Panjabi MM (1990): The problem of clinical instability in the human spine: a systematic approach. In: *Clinical biomechanics of the spine*, 2nd ed. Philadelphia: JB Lippincott, with permission.

[a] See Figures 42, 43, and 44 for measurement techniques.

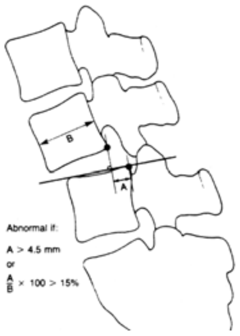

FIGURE 50. Measurement to determine vertebral translation or displacement in the lumbar spine. If the translation or displacement is as much as 4.5 mm or 15% of the sagittal diameter of the adjacent vertebra, it is considered to be abnormal. These measurements are to be used in conjunction with the checklist in Table 19. (From White AA, Panjabi MM (1990): The problem of clinical instability in the human spine: a systematic approach. In *Clinical biomechanics of the spine*, 2nd ed. Philadelphia: JB Lippincott, with permission.)

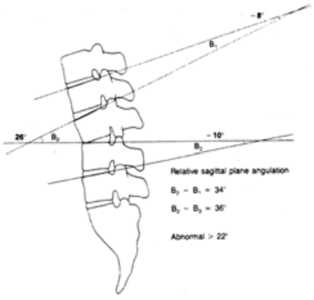

FIGURE 51. Measurement of relative sagittal plane angulation in the lumbar spine. A method of measuring relative sagittal plane angulation on the L4–5 functional spine unit (FSU) on a static (resting) lateral view radiograph. Relative sagittal plane angulation greater than 22 degrees is abnormal and potentially unstable in the lumbar spine. Note that this means 22 degrees greater than the amount of angulation at the FSU above or below the FSU in question. By convention, negative values denote lordosis, and positive values denote kyphosis. These measurements are to be used in conjunction with the checklist in Table 19.

TABLE 19. Checklist for the Diagnosis of Clinical Instability in the Lumbar Spine

Element	Point Value
Anterior elements destroyed or unable to function	2
Posterior elements destroyed or unable to function	2
Radiographic criteria[a]	4
A. Flexion-extension radiographs 1. Sagittal plane translation >4.5 mm or 15% (2 points) 2. Sagittal plane rotation >15° at L1–L2, L2–L3, and L3–L4 (2 points) >20° at L4–L5 (2 points) >25° at L5–S1 (2 points) *or*	
B. Resting radiographs 1. Sagittal plane displacement >4.5 mm or 15% (2 points) 2. Relative sagittal plane angulation >22° (2 points)	
Cauda equina damage	3
Dangerous loading anticipated	1
Total of 5 or more = unstable	

From White AA, Panjabi MM (1990): The problem of clinical instability in the human spine: a systematic approach. In: *Clinical biomechanics of the spine*, 2nd ed. Philadelphia: JB Lippincott, with permission.
See Figures 41 and 42 for measurement techniques.

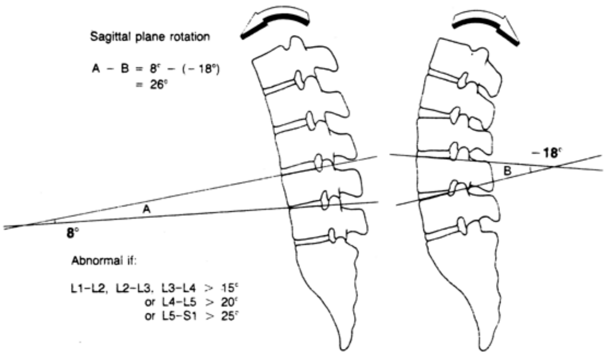

FIGURE 52. Measurement of sagittal plane rotation in the lumbar spine. A method of measuring sagittal plane rotation of the L4–5 functional spinal unit on dynamic (flexion and extension) lateral radiographs. The sagittal plane rotation is the difference between the Cobb measurements taken in flexion (*A*) and extension (*B*). Sagittal plane rotation greater than 15 degrees at L1–2, L2–3, and L3–4, greater than 20 degrees at L4–5, or greater than 258 at L5–S1 is abnormal and potentially unstable. Note that negative values denote lordosis and positive values denote kyphosis. These measurements are to be used in conjunction with the checklist in Table 19.

TABLE 20. Checklist for the Diagnosis of Clinical Instability of the Sacroiliac Joint and Pubis

1. Element	Point Value
Pain relief with pelvic fixation	3
Abnormal displacement	
>1 cm sacroiliac	2
>2 cm pubic diastasis (horizontal)	1
>1 cm pubic displacement (vertical)	1
Audible click with associated pain	1
Pain with maneuvers to stress pelvic ring	1
Dangerous loads anticipated	1
Total of 5 or more = unstable	

From White AA, Panjabi MM (1990): The problem of clinical instability in the human spine: a systematic approach. In: *Clinical biomechanics of the spine*, 2nd ed. Philadelphia; JB Lippincott, with permission.

TABLE 21. Lumbar Segmental Instabilities

- I. Fractures and fracture-dislocations
- II. Infections involving anterior columns
  - A. With progressive loss of vertebral body height and deformity despite treatment with antibiotics
  - B. With progressing neurologic symptoms despite treatment with antibiotics (if accompanied by progressive loss of vertebral body height and deformity)
- III. Primary and metastatic neoplasms
  - A. With progressive loss of vertebral body height and deformity
  - B. With progressing neurologic symptoms not resulting from direct tumor involvement of the spinal cord, cauda equina, or nerve roots (e.g., caused by progressive loss of vertebral body height and deformity)
  - C. Postsurgical (after resection of neoplasm)
- IV. Spondylolisthesis
  - A. Isthmic spondylolisthesis
    - 1. L5–S1 progressive deformity in a child, particularly when accompanied by radiographic risk signs (this lesion is rarely unstable in adults)
    - 2. L4–L5 deformity (probably unstable in adults)
- V. Degenerative instabilities
- VI. Scoliosis (any progressive deformity in a child, subclassified by the criteria of the Scoliosis Research Society)

From Hazlett JW, Kinnard P (1982): Lumbar apophyseal process excisions and spinal instability. *Spine* 7:171–178, with permission.

TABLE 22. Degenerative Segmental Instabilities

- *Primary instabilities*
  - Axial rotational instability
  - Translational instability
  - Retrolisthetic instability
  - Progressing degenerative scoliosis
  - Disc disruption syndrome
- *Secondary instabilities*
  - Post-disc excision: subclassified according to the pattern of instability as subscribed under primary instabilities
  - Postdecompressive laminectomy
    - Accentuation of preexistent deformity
    - New deformity, i.e., no deformity existed at the time of original decompression: further subclassified as for primary instabilities
  - Postspinal fusion
    - Above or below a spinal fusion, subclassified as for primary instabilities
    - Pseudarthrosis
  - Postchemonucleolysis

1. **SPINAL DEFORMITIES: SCOLIOSIS, KYPHOSIS, LORDOSIS** (Table 25)

Goldstein LA, Waugh TR (1973): Classification and terminology of scoliosis. *Clin Orthop* 93:10–22.

McAlister WH, Schackelford GD (1975): Classification of spinal curvatures. *Radiol Clin North Am* 13:93–112.

White AA, Panjabi MM (1990): Biomechanical classification of scoliosis. In: *Clinical biomechanics of the spine*, 2nd ed. Philadelphia: JP Lippincott.

A. **Congenital Scoliosis** (Fig. 53)

There are three basic categories, as classified by Winter (based on MacEwen classification): defects of formation, defects of segmentation, and mixed defects.

I. Unclassifiable; usually a collection of defects
II. Fusion of ribs
    A. At a distance from the vertebrae, with little or no significance
    B. Adjacent or continuous with the vertebrae (usually associated with an unsegmented bar) where curve progression is very likely
III. Unilateral, partial failure of formation of a vertebra (wedge or trapezoid vertebra)
IV. Unilateral, complete failure of formation of a vertebra (hemivertebra)
V. Bilateral failure of segmentation (block vertebra)
VI. Unilateral failure of segmentation (unsegmented bar)

B. **Congenital Kyphosis** (Fig. 54)

In 1973, Winter and associates proposed a three-type classification. This classification was modified in 1977, and it is widely accepted in this form.

Type I: Failure of formation: aplasia or hypoplasia

Absence of the body

Absence of the body associated with microspondylia of neighboring body

Microspondylia of one body

Microspondylia of two neighboring bodies

Type II: Failure of segmentation

Type III: Mixed

Kostuik JP (1991): Adult kyphosis. In: Frymoyer JW, ed. *The adult spine: principles and practice.* New York: Raven Press.

Winter RB, Moe JH, Wang JF (1973): Congenital kyphosis. Its natural history as observed in a study of one hundred and thirty patients. *J Bone Joint Surg [Am]* 55:223–256.

Winter RB (1977): Congenital kyphosis. *Clin Orthop* 128:26–32.

C. **Congenital Spine Deformities (Winter)**

In 1983, Winter presented a comprehensive classification of congenital deformities of the spine.

1. *Defects of Segmentation*
    - Anterior failure of segmentation results in kyphosis. Commonly called *anterior unsegmented bar* (Fig. 55).
    - Posterior failure of segmentation results in lordosis; the condition Commonly called *laminar synostosis.* Usually involves the lamina and the facet joints (Fig. 56).
    - Lateral failure of segmentation. Commonly called *unilateral unsegmented bar.* Produces a purely lateral curvature without kyphosis or lordosis (Fig. 57).
    - Posterolateral failure of segmentation. Because of the continued growth anteriorly and on the opposite side, a *lordoscoliosis* is produced.
    - Anterolateral failure of segmentation (very rare). Produces *kyphoscoliosis.*
    - Total failure of segmentation. Commonly known as *block vertebra* (Fig. 58).

TABLE 25. Classification Endorsed by the Scoliosis Research Society

- *SCOLIOSIS*
- Idiopathic
    - Infantile (0–3 years)
        - Resolving
        - Progressive
    - Juvenile (4 years to puberty onset)
    - Adolescent (puberty onset to epiphyseal closure)
    - Adult (epiphyses closed)
- Neuromuscular
    - Spinal muscular atrophy
    - Myelomeningocele (paralytic)
    - Dysautonomia (Riley-Day syndrome)
    - Other
- Myopathic
    - Arthrogryposis
    - Muscular dystrophy
        - Duchenne syndrome (pseudohypertrophic)
        - Limb-girdle
        - Facioscapulohumeral
    - Congenital hypotonia
    - Myotonia dystrophica
    - Other
- Congenital
    - Failure of formation
        - Partial unilateral (wedge vertebra)
        - Complete unilateral (hemivertebra)
            - Fully segmented
            - Semisegmented
            - Nonsegmented
    - Failure of segmentation
        - Unilateral (unilateral unsegmented bar)
        - Bilateral (bloc vertebrae)
- Mixed
    - Associated with neural tissue defect
        - Myelomeningocele
        - Meningocele
        - Spinal dysraphism
            - Diastematomyelia
            - Other
- Neurofibromatosis
- Mesenchymal
    - Marfan syndrome
    - Homocystinuria
    - Ehlers-Danlos syndrome
    - Other
- Traumatic
    - Fracture or dislocation (nonparalytic)
    - Postradlation
    - Other
- Soft tissue contractures
    - Postempyema
    - Burns
    - Other
- Osteochondrodystrophies
    - Achondroplasia

  - Spondyloepiphyseal dysplasia
  - Diastrophic dwarfism
  - Mucopolysaccharidoses
  - Other
- Tumor
  - Benign
  - Malignant
- Rheumatoid disease
- Metabolic
  - Rickets
  - Juvenile osteoporosis
  - Osteogenesis imperfecta
- Related to lumbosacral area
  - Spondylolysis
- Neuropathic
  - Upper motor neuron lesion
    - Cerebral palsy
    - Spinocerebeliar degeneration
      - Friedreich's disease
      - Charcot-Marie-Tooth disease
      - Roussy-Levy syndrome
    - Syringomyelia
    - Spinal cord tumor
    - Spinal cord trauma
    - Other
  - Lower motor neuron lesion
    - Poliomyelitis
    - Traumatic
  - Spondylolisthesis
  - Other
- Thoracogenic
  - Postthoracoplasty
  - Postthoracotomy
  - Other
- Hysterical
- Functional
  - Postural
  - Secondary to short leg
  - Due to muscle spasm
  - Other

KYPHOSIS

- Postural
- Scheuermann disease
- Congenital
  - Defect of segmentation
  - Defect of formation
  - Mixed
- Paralytic
  - Poliomyelitis
  - Anterior horn cell
  - Upper motor neuron
- Myelomeningocele
- Posttraumatic
  - Acute
  - Chronic
- Inflammatory
  - Tuberculosis
  - Other infections
  - Ankylosing spondylitis
- Postsurgical
  - Postlaminectomy
  - Postexcision (e.g., tumor)
- Postradiation
- Metabolic
  - Osteoporosis
    - Senile
    - Juvenile
  - Osteogenesis imperfecta
  - Other
- Developmental
  - Achondroplasia
  - Mucopolysaccharidoses
  - Other
- Tumor
  - Benign
  - Malignant
    - Primary
    - Metastatic

LORDOSIS

- Postural
- Congenital
- Paralytic
  - Neuropathic
  - Myopathic
- Contracture of hip flexors
- Secondary to shunts

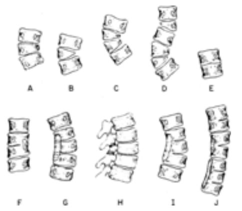

FIGURE 53. Congenital scoliosis. **A:** Unilateral failure of vertebral formation, partial (wedged vertebra). **B:** Unilateral failure of vertebral formation, complete (hemivertebra). **C:** Double hemivertebra, unbalanced. **D:** Double hemivertebra, balanced. **E:** Symmetric failure of segmentation (congenital fusion). **F:** Asymmetric failure of segmentation (unsegmented bar). **G:** Asymmetric failure of segmentation (unsegmented bar involving posterior elements only, anteroposterior view) **H:** Asymmetric failure of segmentation, oblique view showing intact disc space and lack of segmentation confined to the posterior elements (surgically easy to divide). **I:** Unsegmented bar involving both the disc area and posterior elements (a very difficult surgical problem to divide). **J:** Multiple unsegmented bar, unbalanced. (From Winter RB, Moe JH, Eilers VE (1968): Congenital scoliosis: a study of 234 patients treated and untreated. *J Bone Joint Surg [Am]* 50:1–47, with permission.)

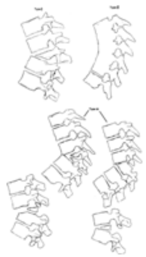

FIGURE 54. Congenital kyphosis *type I:* failure of segmentation; *type II:* failure of formation; *type III:* mixed. (From Winter RB (1983): Classification and terminology. In: *Congenital deformities of the spine.* New York: Thieme-Stratton, with permission.)

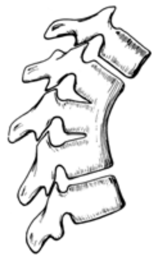

FIGURE 55. Anterior unsegmented bar (congenital kyphosis type I). (From Winter RB (1983): Classification and terminology. In: *Congenital deformities of the spine.* New York: Thieme-Stratton, with permission.)

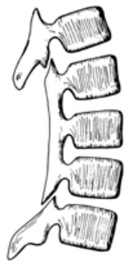

FIGURE 56. Laminar synostosis. (From Winter RB (1983): Classification and terminology. In *Congenital deformities of the spine.* New York: Thieme-Stratton, with permission.)

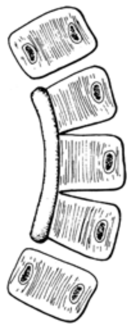

FIGURE 57. Unilateral unsegmented bar. (From Winter RB (1983): Classification and terminology. In *Congenital deformities of the spine.* New York: Thieme-Stratton, with permission.)

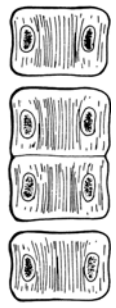

FIGURE 58. Block vertebra. (From Winter RB (1983): Classification and terminology. In *Congenital deformities of the spine.* New York: Thieme-Stratton, with permission.)

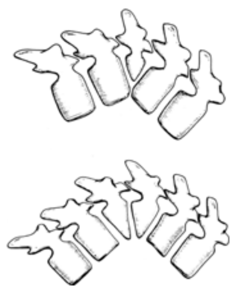

FIGURE 59. Anterior failure of formation (congenital kyphosis type II). (From Winter RB (1983): Classification and terminology. In *Congenital deformities of the spine.* New York: Thieme-Stratton, with permission.)

2. *Defects of Formation*
    - Anterior failure of formation. Results in kyphosis. These defects may range from only a minimal failure to total absence of the bodies of several adjacent vertebrae (Fig. 59).
    - Posterior failure of formation (extremely rare). Results in lordosis.
    - Lateral failure of formation. This is a very common defect. May vary from a mild wedging for a vertebra to nearly total absence of all, except a pedicle and facet joint on one side. This is commonly called a hemivertebra (Fig. 60).
    - Anterolateral defect of formation. This is frequently called a "corner" hemivertebra but is in reality more of a "quarter" vertebra. This defect results in an angular true kyphoscoliosis.
    - Anterior central defect of formation. Involves a defect in midline fusion of the lateral halves of the vertebral body. This is commonly called a "butterfly" vertebra. Frequently associated with kyphosis (Fig. 61).
3. *Mixed Failures*
    - Mixed failure of formation and segmentation in the sagittal plane (mixed congenital kyphosis) (Fig. 62). Mixed failure of segmentation and formation in the frontal plane leads to scoliosis.
    - Unilateral unsegmented bar with hemivertebra (Fig. 63).
    - Hemivertebra with defects of segmentation (Fig. 64).

D. Hemivertebra

1. *Incarcerated Versus Nonincarcerated Hemivertebrae*

An incarcerated hemivertebra is one that is "tucked into" the spine without producing any distortion of the vertebral column. The pedicle line is intact (Fig. 65*A*).

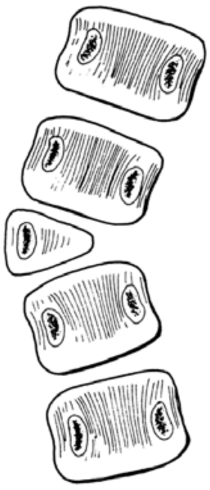

FIGURE 60. Lateral failure of formation. Hemivertebra. (From Winter RB (1983): Classification and terminology. In *Congenital deformities of the spine.* New York: Thieme-Stratton, with permission.)

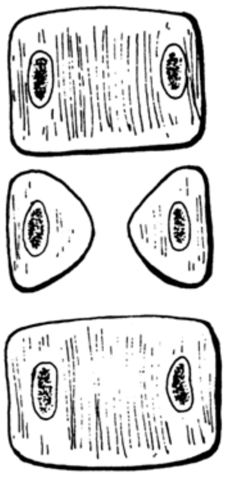

FIGURE 61. Butterfly vertebra. (From Winter RB (1983): Classification and terminology. In *Congenital deformities of the spine.* New York: Thieme-Stratton, with permission.)

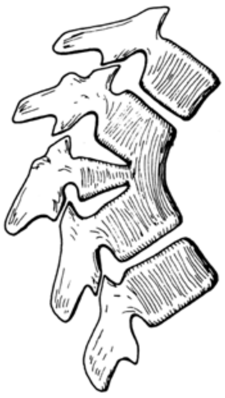

FIGURE 62. Mixed congenital kyphosis (type III congenital kyphosis). (From Winter RB (1983): Classification and terminology. In *Congenital deformities of the spine.* New York: Thieme-Stratton, with permission.)

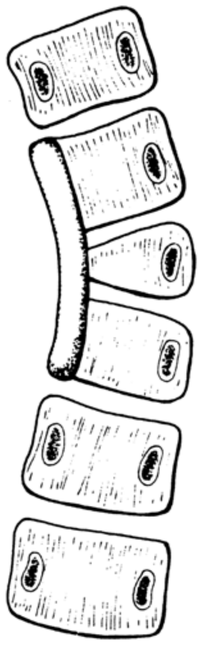

FIGURE 63. Unilateral unsegmented bar with hemivertebra. (From Winter RB (1983): Classification and terminology. In *Congenital deformities of the spine.* New York: Thieme-Stratton, with permission.)

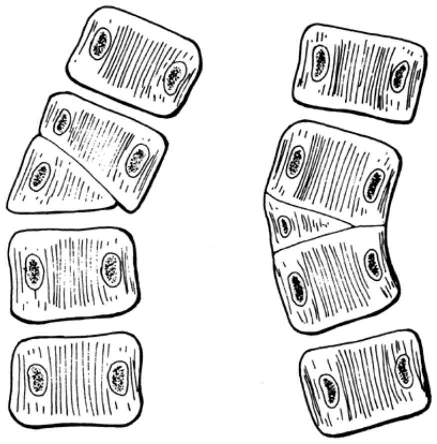

FIGURE 64. Hemivertebra with defects of segmentation. (From Winter RB (1983): Classification and terminology. In *Congenital deformities of the spine.* New York: Thieme-Stratton, with permission.)

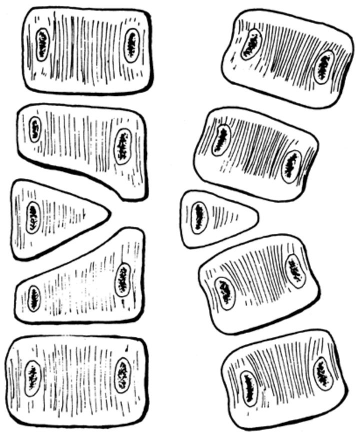

FIGURE 65. A: Incarcerated hemivertebra. **B:** Nonincarcerated hemivertebra. (From Winter RB (1983): Classification and terminology. In *Congenital deformities of the spine.* New York: Thieme-Stratton, with permission.)

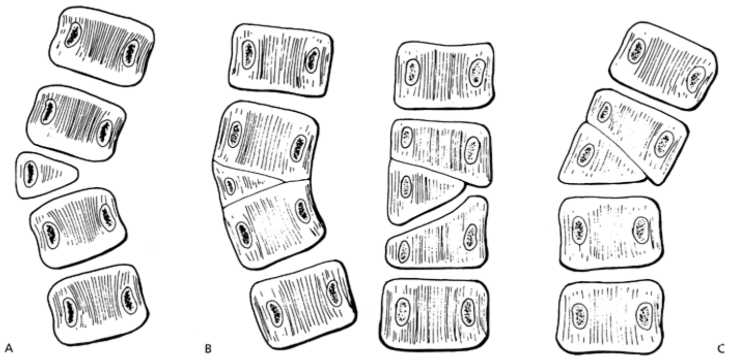

FIGURE 66. A: Fully segmented, “free” hemivertebra. **B:** Nonsegmented hemivertebra. **C:** Semisegmented hemivertebra. (From Winter RB (1983): Classification and terminology. In *Congenital deformities of the spine.* New York: Thieme-Stratton, with permission.)

A nonincarcerated hemivertebra is one that is lying at the apex of the definite scoliosis. The pedicle line is disturbed, that is, the vertebral column is distorted (Fig. 65B).

2. *Segmented Versus Nonsegmented Hemivertebrae*

A fully segmented hemivertebra is one in which there is a normal disc space above and below. It is frequently called a “free” hemivertebra (Fig. 66A).

A nonsegmented hemivertebra is one in which there is a defect of segmentation both above and below (Fig. 66B).

A semisegmented hemivertebra is one in which there is a normal disc space on one side of the hemivertebra, but the other side is nonsegmented from the adjacent vertebra (Fig. 66C).

3. *Hemimetameric Segmental Displacement*

Hemimetameric segmental displacement results from a failure of the normal union of hemimetameres across the midline. One or more malunions occur, resulting in two “hemivertebrae,” one on each side at the top and bottom of the area of malunion. It is usually called hemimetameric “shift” (Fig. 67).

E. **Idiopathic Scoliosis**

Approximately 80% of the patients with structural scoliosis have idiopathic scoliosis.

1. Chronologic Classification

Infantile: From birth to 3 years of age

Juvenile: From 4 years until the onset of puberty

Adolescent: At or about the onset of puberty and before closure of the physes

Adult: After skeletal maturity

2. *Clinical Measurements*

Decompensation: Balance of the thorax over the pelvis. A plumb line from C7 should fall in the intergluteal cleft; otherwise describe if it is to the left or right, and measure in centimeters the distance between the plumb line and the cleft.

Shoulder level: Measured from the acromioclavicular joints. The height of the high shoulder is compared with that of the low shoulder measured and recorded.

Trapezius neckline: Record asymmetries.

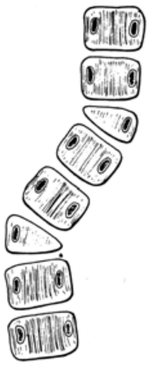

FIGURE 67. Hemimetameric segmental displacement. emimetameric shift. (Figures 45, 46, 47, 48, 49, 50, 51, 52, 53, 54, 55, 56, 57) (From Winter RB (1983): Classification and terminology. In *Congenital deformities of the spine.* New York: Thieme-Stratton, with permission.)

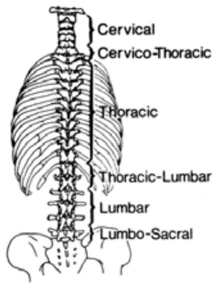

FIGURE 68. Description of the curve based on the apical vertebra (Scoliosis Research Society). (From Morrissy RT (1985): Clinical and radiologic evaluation of spinal disease. In: Bradford DS, Hensinger RM, eds. *The pediatric spine.* Stuttgart: Georg Thieme, with permission.)

Pelvis level: Differences in the levels of the anterosuperior iliac spine are measured in centimeters.

With the patient viewed from the side, the sagittal contours are noted on the forward-bending test (Adams' test):

- Trunk rotation angle (scoliometer)
    - Thoracic rib hump; measurement of the prominence in centimeters
    - Also can be measured in the Tangential Rib View (See Fig. 47, Appendix C)
- Sagittal alignment (kyphosis, lordosis)
- Determine flexibility by side bending and by head-neck traction
- Moire screen

3. *Curve Patterns*

Curves are designated according to the level of the apex of the curvature. Right and left refer to the side of the convexity of the curve (Fig. 68). Ponseti and Friedman in 1950 defined five curve patterns in idiopathic scoliosis:

Curve Type	Apex	End Vertebrae
Cervicothoracic	T3	C7 or T1 to T4 or T5
Thoracic	T8 or T9	T6 to T11
Thoracolumbar	T11 or T12	T6 or T7 to L1 or L2
Lumbar	L1 or L2	T6 or T7 to L1 or L2
Double curve	L1 or L2	T11 to L3

According to the Terminology Committee of the Scoliosis Research Society.

Cervical: When the apex is between C1 and C6

Cervicothoracic: Apex between C7 and T1

Thoracic: Apex between T2 and T11

Thoracolumbar: Apex at T12 and L1

Lumbar: Apex between L2 and L4

Lumbosacral: Apex between L5 and S1

Double structural curves:

A. Double thoracic
B. Combined thoracic and lumbar
C. Combined thoracic and thoracolumbar

Girdany

Vertebral ring apophysis

6. *Selection of Fusion Levels*

A traditional teaching principle has been fusion from T4 to L4 for combined thoracic and lumbar curves. However, fusion in the lumbar spine should be avoided when possible.

TABLE 26. Curve Patterns

	Criteria	No. of Patients in the Present Series (%)
Type I	S-shaped curve in which both thoracic curve and lumbar curve cross midline Lumbar curve larger than thoracic curve on standing radiograph Flexibility index a negative value (thoracic curve = lumbar curve on standing radiograph, but more flexible on side-bending)	52 (12.9)
Type II	S-shaped curve in which thoracic curve and lumbar curve cross midline Thoracic curve = lumbar curve Flexibility index = 0	132 (32.6)
Type III	Thoracic curve in which lumbar curve does not cross midline (so-called overhang)	133 (32.8)
Type IV	Long thoracic curve in which L5 is centered over sacrum, but L4 tilts into long thoracic curve	37 (9.2)
Type V	Double thoracic curve with T1 tilted into convexity of upper curve Upper curve structural on side-bending	47 (11.6)

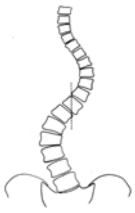

FIGURE 70. Type 2 curve. (From King HA, Moe JH, Bradford DS, Winter RB (1983): The selection of fusion levels in thoracic idiopathic scoliosis. *J Bone Joint Surg [Am]* 65:1302–1313, with permission.)

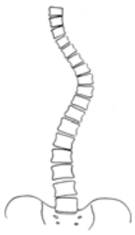

FIGURE 71. Type 3 curve. (From King HA, Moe JH, Bradford DS, Winter RB (1983): The selection of fusion levels in thoracic idiopathic scoliosis. *J Bone Joint Surg [Am]* 65:1302–1313, with permission.)

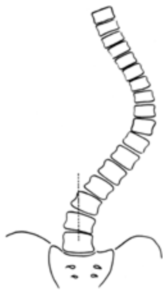

FIGURE 72. Type 4 curve. (From King HA, Moe JH, Bradford DS, Winter RB (1983): The selection of fusion levels in thoracic idiopathic scoliosis. *J Bone Joint Surg [Am]* 65:1302–1313, with permission.)

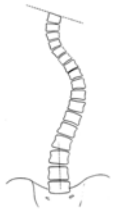

FIGURE 73. Type 5 curve. (From King HA, Moe JH, Bradford DS, Winter RB (1983): The selection of fusion levels in thoracic idiopathic scoliosis. *J Bone Joint Surg [Am]* 65:1302–1313, with permission.)

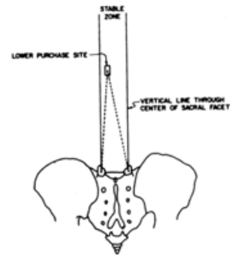

FIGURE 74. The “stable zone” of Harrington, defined by parallel lines drawn through the lumbosacral facets. The vertebral bodies within these lines are in the stable zone. (From Harrington PR (1972): Technical details in relation to the successful use of instrumentation in scoliosis. *Orthop Clin North Am* 3:49–67, with permission.)

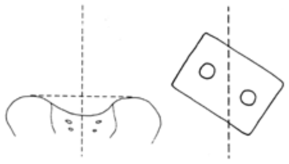

FIGURE 75. A: Center sacral line. The line is drawn through the center of the sacrum perpendicular to the iliac crest. When a limb length discrepancy is present, the pelvis should be leveled with an appropriate lift under the short limb. The central vertical line must always be based on a horizontal pelvis. **B:** The vertebra that is bisected or most closely bisected by this line is determined and is recorded as being the stable vertebra. (From King HA, Moe JH, Bradford DS, Winter RB (1983): The selection of fusion levels in thoracic idiopathic scoliosis. *J Bone Joint Surg [Am]* 65:1302–1313, with permission.)

Ferguson suggested that the ideal fusion should extend to the vertebrae that have their distant surfaces parallel to each other.

Moe and Goldstein suggested that the levels of fusion should extend from the neutrally rotated vertebra above to the neutrally rotated vertebra below. The neutral vertebra is determined by the criteria established by Nash and Moe. It can be established when both pedicles are symmetric on a posteroanterior radiograph. Moe has also recommended side-bending radiographic views to define curve flexibility. He has advocated selective thoracic fusion in patients with double curves but a flexible lumbar curve.

a. *Harrington's "Stable Zone"*

Harrington proposed that the lower level of the fusion should lie between two vertical lines drawn through the lumbosacral facets. He recommended that the fusion should be extended one level above and two levels below the measured curve (by the Cobb method) if the end vertebra was in the "stable zone" (Fig. 74).

b. *King's Center Sacral Line and Stable Vertebra*

King and colleagues have proposed the central sacral line and the concept of the stable vertebra. The fusion should extend to the stable vertebra (Fig. 75).

Nash CL, Moe JH (1969): Study of vertebral rotation. *J Bone Joint Surg [Am]* 51:223–229.

7. *Special Views*

a. *Supine Films for Detail: Spot Films*

Supine cone-down views or spot films give good detail of specific areas of the spine.

b. *Bending Films*

Bending films are used to evaluate the rigidity or flexibility of a curve. These films should be taken with the patient supine and should use the maximal voluntary cooperation of the patient. For uncooperative or nonunderstanding patients, passive bending films can be obtained.

c. *Traction Films*

For patients with neuromuscular scoliosis, a good evaluation of the rigidity or flexibility of a curve can be obtained by using traction in the supine position, or vertically by using suspension devices.

d. *Hyperextension Films*

In hyperextension films, to assess flexibility or rigidity in patients with kyphosis, a lateral view is taken with a firm radiolucent object placed under the apex of the kyphosis and the patient supine.

e. *Oblique Views*

Oblique views are useful to evaluate the fusion mass. They are also used to evaluate the pars interarticularis in cases where spondylolysis is suspected.

f. *Ferguson View*

The Ferguson view is taken with the film tilted 30 degrees cephalad in men and 35 degrees in women, or with the patient's hips flexed 90 degrees to eliminate lordosis. This view shows the anatomy of the lumbosacral junction.

g. *Derotated View (Stagnara)*

The derotated view is useful in large curves (usually around 100 degrees or larger). This view eliminates the kyphosis associated with rotation in large curves. This view should be a true coronal view of the apical vertebra, revealing the true scoliosis.

h. *Tangential rib view*

Method of assesment of the rib prominence. This view is taken with the patient standing in the Adams maneuver position. (See Fig. 47 in Appendix C.)

1. **PELVIC OBLIQUITY** (Fig. 76)
2. **SCHEUERMANN DISEASE (JUVENILE KYPHOSIS)**

Thoracic Scheuermann disease usually affects the T7–9 area, less often the T11–12. There are also cases of "lumbar Scheuermann disease" in which the affection predominantly affects the L1–2 area.

The radiographic diagnosis of Scheuermann kyphosis is made by the presence of irregularities of the vertebral endplates, anterior vertebral wedging, Schmorl's nodes, and decreased intervertebral disc space height. There is some discrepancy in the literature as to the number of consecutive vertebrae that need to be wedged to make the diagnosis of Scheuermann kyphosis. By one criterion

(Sorensen's criterion) there should be wedging in three or more adjacent vertebrae of more than 5 degrees. In other studies the diagnosis is made by the presence of only wedged vertebrae of more than 5 degrees. Total kyphosis in excess of 50 degrees is considered abnormal.

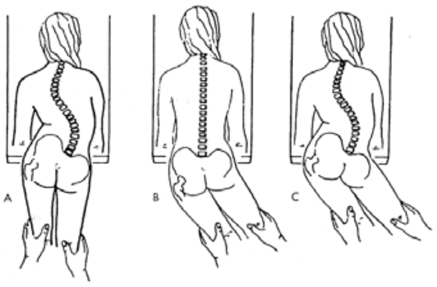

FIGURE 76. A: Pelvic Obliquity. **B:** If pelvic obliquity is eliminated by abduction or adduction of hips, pelvic-femoral muscle contracture is caused. **C:** If obliquity persists despite abducion or adduction of hips, fixed spinal-pelvic deformity exists. (From Shook JE, Lubicky JP (1996): Paralytic scoliosis. In: Bridwell KH, DeWald RI, eds. *The textbook of spinal surgery*, 2nd ed. Philadelphia: JB Lippincott.)

3. **SPONDYLOLISTHESIS**

A. **Classification** (Figs. 77, 78; Table 27)

Newmann PH (1963): Spondylolisthesis, its course and effect. *Ann R Coll Surg Engl* 16:305–323.

This classification was later modified and it is now the most widely accepted classification (Wiltse et al., 1976).

I. *Dysplastic.* In this type, congenital abnormalities of the upper sacrum or the arch of L5 permit the listhesis to occur.
II. *Isthmic.* The lesion is in the pars interarticularis. Three types can be recognized.
    A. Lytic-fatigue fracture of the parts.
    B. Elongated but intact pars.
    C. Acute fracture.
III. *Degenerative.* Owing to long-standing intersegmental instability.
IV. *Traumatic.* Owing to fractures in other areas of the bony hook than the pars.
V. *Pathologic.* There is generalized or localized bone disease (Fig. 67).

Wiltse LL, Newmann PH, Macnab I (1976): Classification of spondylolisis and spondylolisthesis. *Clin Orthop* 117:23–29.

(From McCulloch JA, Inoue S, Moriya H, et al. (1990): The intervertebral disc: surgical indications and techniques. In: The International Society for the Study of the Lumbar Spine, ed. *The lumbar spine.* Philadelphia: WB Saunders, with permission.)

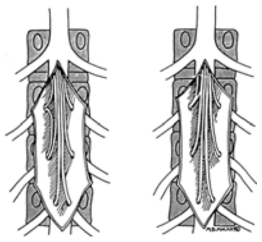

FIGURE 81. Nerve root anomalies. Type I nerve root anomaly: intradural anastomosis. (From Kadish LJ, Simmons EH (1984): Anomalies of the lumbosacral nerve roots: an anatomical investigation and myelographic study. *J Bone Joint Surg [Br]* 66:411.)

1. *Radiologic*

   Type of spondylolisthesis

   Dysplastic lesions have greater tendency than isthemic defects

2. *Degree of Slips*

   Mild displacement, minimal chances; 50% and over, greater probability; high slip angle—40 to 50 degrees and over.

3. *Mobility at L5–S1*

   Mobility at L5–S1 indicates instability and greater probability of progression.

4. *Anatomic Stability*

   A trapezoid or wedge-shaped fifth lumbar vertebra and a dome-shaped top of the first sacral vertebra means instability and greater likelihood of progression. An anterior slip of the sacrum and narrowed L5–S1 disc interspace indicates stability and minimal chance of further slip.

1. **SPINAL STENOSIS**

Definition: Any type of narrowing of the spinal canal, nerve root canals (or tunnels), or intervertebral foramina. It may be local, segmental, or generalized. It may be caused by bone or by soft tissue, and the narrowing may involve the bony canal alone, the dural sac, or both. It can be classified according to the Anatomical area of the spine affected and the specific pathologic entity involved (Table 28).

TABLE 28. Classification of Spinal Stenosis

Anatomical Area	Anatomical Region (Local Segment)
ANATOMIC	
Cervical	Central Foraminal
Thoracic	Central
Lumbar	Central Lateral recess Foraminal Extraforaminal (far-out)
PATHOLOGIC Congenital	
Achondroplastic (dwarfism) Congenital forms of spondylolisthesis Scoliosis Kyphosis Idiopathis	
Degenerative and inflammatory Osteoarthritis Inflammatory arthritis Diffuse idiopathic skeletal hyperostosis (DISH) Scoliosis Kyphosis Degenerative forms of spondylolisthesis	
Metabolic Paget disease Fluorosis

        - 3. Forestier disease
        - 4. DISH

Modifiers

- III. Segmental disease
- IV. Generalized disease

Adapted from Arnoldi CC, Brodsky AE, Cauchoix J. et al. (1976): *Clin Orthop* 115:4.

1. **LUMBAR SPINAL STENOSIS: Arnoldi proposed a classification scheme for the lumbar spine based on pathologic processes** (Fig. 79; Table 29).

    Postacchini F (1990): Lumbar spinal stenosis: classification and treatment. In: The International Society for the Study of the Lumbar Spine, ed. *The Lumbar Spine.* pp 594–611.

2. **DISC HERNIATION** (Fig. 80)

    The distortion of the annular contour that occurs because of a disc herniation may be as follows:

    Contained: This is a simple disc protrusion in which the annular fibers are intact and contain the protruded nuclear material.

    Noncontained: Disc material has ruptured through the annulus and is no longer contained.

    The following two varieties occur:

    1. Extruded disc material: subligamentous (subannular) or transligamentous
    2. Sequestered: free fragment of disc material in the spinal canal

    C. **Criteria for the Diagnosis of Acute Radicular Syndrome (Sciatica due to a Herniated Nucleus Pulposus)** (Table 30)
3. **CLASSIFICATION OF NERVE ROOT ANOMALIES** (Figs. 81, 82, 83, 84)
4. **DIFFERENTIAL DIAGNOSIS OF BACK AND LEG PAIN** (Table 31)

TABLE 30. Criteria for the Diagnosis of Acute Radicular Syndrome (Sciatica Due to a Herniated Nucleus Pulposus[a]

1. Leg pain (including buttock) is the dominant complaint, rather than back pain
2. Neurologic symptoms are specific (e.g., paresthesia in a typical dermatomal distribution)
3. Significant straight-leg raising (SLR) changes occur
    - SLR less than 50% of normal
    - Bowstring discomfort
    - Crossover pain (any one or a combination of these)
4. Neurologic signs: 2 out of 4 of weakness, wasting, sensory loss, or reflext alteration

From McCuiloch JA, et al. (1990): The intervertebral disc: surgical indications and techniques. In: The International Society for the Study of the Lumbar Spine, ed. *The lumbar spine*. Philadelphia: WB Saunders, with permission.

[a] Three or four of these criteria must be present, the only exception being the young patients who are very resistant to the effects of nerve root compression and thus may not have neurologic symptoms (criterion 2) or signs (criterion 4).

TABLE 31. Differential Diagnosis of Back and Leg Pain

5. Peripheral nerve problems
    a. Piriformis syndrome
    b. Meralgia paresthetica
    c. Iliohypogastric ilioinguinal, and genitofemoral neuritis
    d. Femoral neuropathy
    e. Obturator neuropathy
    f. Sacral notch or sciatic neuropathy
6. Metabolic and inflammatory diseases
    a. Bony infection of the spine (pyogenic, fungal, parasitic, tuberculosis)
    b. Spinal epidural abscess
    c. Rheumatoid variants: ankylosing spondylitis, psoriatic arthritis, Reiter syndrome, intestinal arthropathies
    d. Paget disease
    e. Gout
    f. Pseudogout
    g. Fibrositis
    h. Ochronosis
    i. Hemochromatosis
    j. Osteogenesis imperfecta
    k. Diabetic amyotrophy
    l. Hyperparathyroidism
    m. Bursitis
    n. Osteoporosis
    o. Osteoarthritis
    p. Diffuse idiopathic skeletal hyperostosis
    q. Adhesive arachnoiditis
7. Psychogenic pain
8. Tumors
    a. Intramedullary
    b. Extradural
    c. Intradural-extramedullary
    d. Metastatic tumors of the spine
    e. Primary benign and malignant tumors to bone
    f. Sacral cysts
    g. Retroperitoneal tumors and fibrosis
9. Referred pain syndrome
    a. Gastrointestinal: peptic ulcer, pancreatic disorders, gallbladder disorders
    b. Vascular: abdominal aortic aneurysm, arterial occlusion or insufficiency, other aneurysms
    c. Renal: nephrolithiasis, infection, prostatitis
    d. Gynecological/obstetrical: pregnancy, pelvic tumors, pelvic inflammatory disorders
    e. Hip disorders
    f. Knee disorders
    g. Sacroiliac disorders
    h. Coccygodynia
10. Mechanical
    a. Segmental instability
    b. Trauma
    c. Spinal deformity
    d. Spinal stenosis
    e. Leg length inequality
    f. Iliac crest syndrome
    g. Facet syndrome
    h. Herniated intervertebral disc
11. Congenital
    a. Ilium—transverse process pseudarthrosis
12. Miscellaneous
    a. Charcot's spine (vertebral osteoarthropathy)
    b. Compartment syndromes (posterior thigh and paraspinal muscles)
    c. Scheuermann disease
    d. Radiation-induced disorders
    e. Spondylosis and spondylolithesis

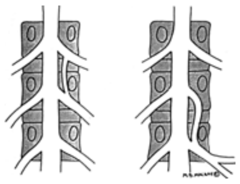

FIGURE 83. Nerve root anomalies. Type III. Extradural anastomosis. (From Kadish LJ, Simmons EH (1984): Anomalies of the lumbosacral nerve roots an anatomical investigation and myelographic study. *J Bone Joint Surg Br* 66:411.)

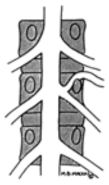

FIGURE 84. Nerve root anomalies. Type IV. Extradural division. (From Kadish LJ, Simmons EH (1984): Anomalies of the lumbosacral nerve roots an anatomical investigation and myelographic study. *J Bone Joint Surg [Br]* 66:411.)

1. **DIFFERENTIAL DIAGNOSIS OF SCIATICA** (Table 32)
2. **NONORGANIC PHYSICAL SIGNS OF LOW BACK PAIN**

Waddell's tests (nonorganic physical signs of low back pain):

Tenderness: This category should be scored positive if light touch or rolling of the skin on the back causes pain, or if deep tenderness is spread over large areas of the body.

Simulation test: This is scored positive if gentle axial rotation of the pelvis and shoulders causes back pain, or if light pressure of 1 to 2 pounds of force applied to the head by the examiner's hand causes back pain.

Distraction test: This is scored positive if the patient's pain, which is presented in some activities, is not present when those same activities occur in a different context, for example, if the straight leg-raising test is present in the supine position but totally absent when sitting. This is considered a positive distraction test.

Regional disturbances: This is positive when the patient demonstrates "cogwheel" weakness ("give-away weakness" followed by increased resistance) or nonneuroanatomic numbness, such as stocking-and-glove numbness in the absence of peripheral neuropathy.

TABLE 32. Differential Diagnosis of Sciatica

- *Intraspinal causes*
  - Proximal to disc
    - Conus and cauda equina lesions (e.g., neurofibroma, ependymoma)
  - Disc level
    - HNP
    - Stenosis (canal or recess)
    - Infection—osteomyelitis or discitis (with nerve root pressure)
    - Inflammation—arachnoiditis
    - Neoplasm—benign or malignant with nerve root pressure
- *Extraspinal causes*
  - Pelvis
    - Cardiovascular conditions (e.g., peripheral vascular disease)
    - Gynecologic conditions
    - Orthopaedic conditions (e.g., osteoarthritis of hip)
    - Sacroiliac joint disease
    - Neoplasms (invading or compressing lumbosacral plexus)
  - Peripheral nerve lesions
    - Neuropathy (diabetic. tumor, alcohol)
    - Local sciatic nerve conditions (trauma, tumor),
    - Inflammation (herpes zoster)

From McCulloch JA, et al. (1990): *The intervertebral disc*. Philadelphia: WB Saunders, with permission.

Overreaction: A positive score is awarded here when there is excessive body language, grimacing, verbalization, groans, tremors, collapsing, excessive sweating, or stumbling.

Scoring: If three out of the five tests listed are positive, then nonorganic psychological pain behavior is likely.

Wadell G, McCulloch JA, Kummel E, Venner RM (1980): Nonorganic physical signs in low-back pain. *Spine* 5:117–125.

3. **MIDLINE DYSRAPHISM** (Table 33)
4. **CONGENITAL ABSENCE OF THE SACRUM AND LUMBOSACRAL VERTEBRAE (LUMBOSACRAL AGENESIS)** (Figs. 85, 86, 87, 88)
5. **LUMBOSACRAL TRANSITIONAL VERTEBRA**

Classification of the different types of lumbosacral transitional vertebra

Type 1: Dysplastic transverse process:

Unilateral
Bilateral

This type presents a large transverse process that is triangular in shape and measures at least 19 mm in width.

Type 2: Incomplete lumbarization and sacralization (i.e., the total number of vertebrae were not determined.)

TABLE 33. Classification of Cranial and Spinal Dysraphism

- Spina bifida aperta
  - Myeloschisis
  - Myelomeningocele
  - Hemimyelomeningocele
  - Syringomyelomeningocele
  - Spinal meningocele
- Arnold-Chiari malformation
- Dandy-Walker malformation
- Cranium bifidum
  - Cranial meningocele
  - Encephalomeningocele
- Occult cranial dysraphism
  - Cranial dermal sinus
- Occult spinal dysraphism
  - Spinal dermal sinus
  - Tethered cord syndrome
  - Lumbosacral lipoma
  - Diastematomyelia
  - Neurenteric cyst
  - Combined anterior and posterior spina bifida
  - Anterior sacral meningocele
  - Occult intrasacral meningocele
- Nondysraphic malformations
  - Perineurial (Tarlov's) cyst
  - Spinal extradural cyst
  - Nondysraphic spinal meningocele
  - Caudal regression syndrome
  - Sacrococcygeal teratoma

- Thoracic or upper lumbar aneurysm
- Tortuous iliac arteries
- Paravertebral tumor (metastasis, lymphoma, neurofibroma, and sarcoma)
- Abscess
- Bony dysplasia of neurofibromatosis
- A pseudoscalloping appearance may occur on the lateral radiograph in patients with osteopenia and anterolateral osteophyte formation, or in those with overlying densities

TABLE 38. Lateral Scalloping

- Tumor (metastasis, lymphoma, neurofibroma, sarcoma)
- Abscess
- Bony dysplasia of neurofibromatosis
- Tortuosity of vertebral arteries in the cervical region and dilated lumbar venous collaterals with or without vena cava obstruction may also cause lateral vertebral scalloping

From Kricun ME (1988): Conventional radiography. In: *Imaging modalities in spinal disorders*. Philadelphia: WB Saunders, pp. 75–78, with permission.

Unilateral
Bilateral

This type has a large transverse process, which appears to follow the contour of the sacral ala. They are considered incomplete because there appears to be a diarthrodial joint between the transverse process and the sacrum.

Type 3: Complete lumbarization and sacralization (i.e., the total number of vertebrae were not determined)

Unilateral
Bilateral

This is similar to type 2 except that instead of a diarthrodial joint between the transverse process and the sacrum, there is a true bony union.

Type 4: Mixed.

The patients who fall in this category exhibit type 2 on one side and type III on the other.

Type 2 presents a high incidence of herniated lumbar disc at the level of transition. It also presents a greater incidence of disc herniations at the level just above the lumbosacral transitional vertebra (Fig. 89).

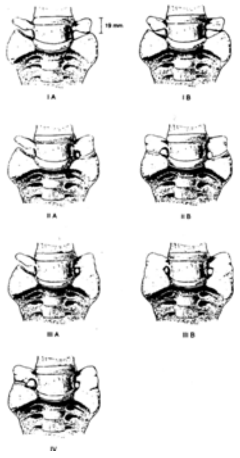

FIGURE 89. Classification of lumbosacral transitional vertebrae according to radiomorphological and clinical relevance with respect to lumbar disc herniation. (From Castelvi AE, Goldstein LA, Chan DPK (1984): Lumbosacral transitional vertebrae and their relationship with lumbar extradural defects. *Spine* 9:493–495, with permission.)

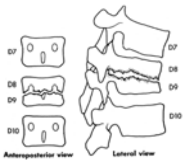

FIGURE 93. Line diagram showing method of assessment of loss of vertebral body (From Rajasekaran S, Shanmugasundaram TK (1987): Prediction of the angle of gibbus deformity in tuberculosis of the spine. *J Bone Joint Surg [Am]* 69:503.)

B. **Prediction of final gibbus deformity in Spinal Tuberculosis** (Figs. 92, 93)

Rajasekaran and Shanmugasundaram compared the development of kyphosis with the degree of collapse at the time of presentation of tubercular disease and the institution for antibiotic treatment. A formula was developed to predict the degree of final gibbus deformity: x is the initial loss of vertebral body, and a and b are constants 5.5 and 30.5, retropectively. Initial vertebral loss was determined by dividing the vertebra into tenths for each involved vertebra (Figs. 92, 93). This formula may be used to identify patients who are most likely to develop significant kyphosis.

  - Epidermoids

Extradural
- Primary malignant tumors
  - Chordomas
  - Myeloma
  - Lymphoma
  - Chondrosarcoma
  - Osteosarcoma
  - Ewing sarcoma
  - Fibrosarcoma
  - Anglosarcoma
  - Giant cell tumor
- Primary benign tumors
  - Osteochondroma
  - Osteoblastoma-osteoid osteoma
  - Aneurysmal bone cyst
  - Hemangioma
  - Eosinophilic granuloma
  - Giant cell tumors

Metastatic (most common)

TABLE 49. Anatomic Extent by Zone

Zones I to IV	Site A—intraosseous; site B—extraosseous; site C—regional or distant metastasis
Zones IA to IVA	Intraosseous lesions confined within the cortical boundaries
Zones IA	Includes spinous processes to the pars interarticularis and inferior articular processes
Zones IIA	Includes the transverse processes, superior articular processes, and the pedicles to their junction with the vertebral body
Zones IIIA	Anterior three fourths of the vertebral body
Zones IVA	Posterior and medial one fourth of the vertebral body
Zones IB to IVB	Extraosseous extension beyond the cortical boundaries. Lesions having extraosseous extension extend beyond the bony margins of their respective zones.
Zones IC to IVC	Intraosseous or extraosseous lesions associated with regional or distant metastases

Weinstein JN, 1991.

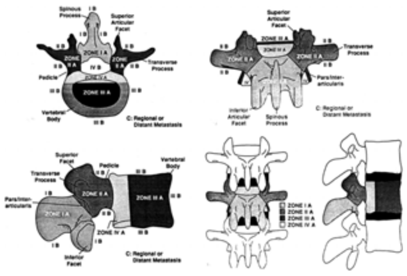

FIGURE 94. A: Anatomic extent of spinal tumors by zone *A:* axial cut through L1; *zones I–IVA:* intraosseous lesions are confined within the boundaries of the cortical spine. **B:** Posterior view of L1, *zones I–IVB:* extraosseous extension beyond the boundaries of the cortical spine. **C:** Lateral view of L1. **D:** Posterior view of L1–3.

TABLE 50. Differential Diagnosis of Pediatric Spinal Tumors

Lesion	History	Physical Examination	Neurodiagnostic Findings	Cerebrospinal Fluid
Syringomyelia/hydromyelia	Slow onset	Dissociated sensory loss, atrophy	Widened cord, syrinx on magnetic resonance imaging, associated Chiari malformation	Normal
Lipomeningocele	Slow onset, autonomic dysfunction	Lumbosacral soft tissue mass, pes cavus, atrophy	Spina bifida, large subarachnoid space lipoma on magnetic resonance imaging	Normal
Tethered cord	Slow onset, autonomic dysfunction	Pes cavus	Spina bifida; conus below L2–3 thickened or fatty filum on magnetic resonance imaging	Normal
Dermoid/epidermoid	Slow onset, autonomic dysfunction	Dermal sinus, wiry hairs, hemangioma	Spina bifida, intradural extramedullary mass	Normal, unless previous meningitis
Multiple sclerosis	Rapid onset, multiple metachronous lesions	Determined by location of current plaque	Normal, magnetic resonance imaging may show multiple intracranial foci of demyelination	Increased oligoclonal bands; increased IgG index
Vitamin B_{12} deficiency	Insidious onset, motor and sensory deficits start distally	Weakness, loss of proprioception (most marked distally)	Normal	Normal
Landry-Guillain-Barré syndrome	Weakness over days, starts distally	Weakness without sensory loss, loss of tendon reflexes, autonomic function usually preserved	Normal	Increased protein, increased cells
Congenital myopathy	Decreased motor activity from birth, delayed development	Decreased muscle tone, rigidity, diagnosis by muscle biopsy	Normal	Normal
Perinatal ischemic brain injury	Decreased motor activity in one extremity or on one side of the body	Increased tone, weakness, athetosis	Normal spine, infarcts on computed tomography or magnetic resonance imaging scans of brain	Normal
Transverse myelitis	Rapidly progressive painful paraplegia	Motor and sensory level, spinal shock, may have associated blindness (neuromyelitis optica)	Normal	Increased protein

E. **Classification of Spinal Metastases** (Fig. 95)

Harrington has described five classes of tumors. Class I is present without significant bony destruction or canal compromise. Class II bone destruction is present in less than half the vertebral body, without any evidence of fracture or instability, and with no compromise of the spinal canal or neurologic deficit. Class III, spinal compromise due to epidural disease without significant bone involvement. Class IV pathologic fracture with or without spinal deformity but without significant neurologic compromise. Class V pathologic fracture with collapse, instability, and significant neurologic compromise due to either epidural tumor, retropulsed bony debris, or kyphosis.

TABLE 51. Classification of Movement Disorders

Type	Major Clinical Findings	Common Etiology
Physiological (according to the movement disorder)		
Spasticity (pyramidal)	Increased stretch reflex in muscles, i.e., hypertonicity of “clasp knife type” Hyperreflexia (deep tendon reflexes) Clonus Presence of Babinski sign Esotropia or exotropic	Prematurity Perinatal hypoxia Cerebral trauma Rubella (maternal) Familial
Athetosis		
Tension type	Tension can be “shaken out” of limb by examiner Extensor pattern (usually) Normal or depressed reflexes Paralysis of upward gaze Deafness (often)	Kernicterus due to Rh incompatibility
Dystonia	Intermittent distorted posturing of limbs, neck, trunk No contractures Full range of joint motion when relaxed	
Chorea	Spontaneous jerking of distal joints (fingers and toes)	Neonatal jaundice Hyperbilirubinemia Cerebral anoxia Encephalitis, meningitis, or both
Ballismus (rotary, flailing)	Uncontrolled involuntary motions of proximal joints (shoulders, elbows, hips, and knees)	
Rigidity	Rigid limbs Lead pipe type—continuous resistance to passive motion Cog-wheel type—discontinuous resistance to passive motion	
Ataxia	Lack of balance Uncoordinated movement Dysmetria Dysarthria Wide-based gait (patient sways when walking) Pes valgus (flexible) common	Head injury Cerebral maldevelopment
Tremor	Rare Intentional or nonintentional Rhythmic or nonrhythmic	
Atonia	Rare Hypotonia of limbs and trunk Often evolves into athetosis as child matures	Cerebral anoxia
Mixed types	Spasticity and athetosis usual Total body involvement used	Encephalitis Cerebral anoxia Birth trauma
Topographical		
Monopregia	One limb involved Spasticity (usually) Patient should run to excluda hemiplegic pattern	
Hemiplegia	Spastic upper and lower limb on same side	
Paraplegia	Lower limb involvement only Rare in spastic type of cerebral palsy Common in familial type Spasticity	
Diplegia	Minor involvement of upper limbs (slight incoordination of finger movement) Major involvement of lower limbs Spasticity	
Triplegia	Three limbs involved Spasticity	
Quadriplegia or total body involved	Total body involvement (all four limbs, head, neck, and trunk) Spastic, athetoid, and mixed types

Harrington KD (1993): Metastatic tumors of the spine: Diagnosis and treatment. *J Am Acad Orthop Surg* 1:76–86.

5. NEUROFIBROMATOSIS

Young and associates (1970) classified neurofibromatosis into three hereditary forms:

1. The peripheral form, with café au lait spots and neurofibromas
2. The central form, with multiple tumors in the central nervous system, which are typical of neurofibromatosis
3. A mixed form, with both peripheral signs of neurofibromatosis and tumors in the central nervous system

Most investigators now accept two clinical forms of neurofibromatosis: central and peripheral.

NF-1: Von Recklinhausen's neurofibromatosis; peripheral neurofibromatosis (most common type, autosomal dominant affects about 1 in 4,000 persons)

NF-2: Central neurofibromatosis; bilateral acoustic neurofibromatosis (autosomal dominant, affects about 1 in 50,000 persons)

Central neurofibromatosis may be subdivided in two groups:

D. Isolated bilateral acoustic neuroma
E. Patients with multiple nervous system involvement, such as neuroaxial neoplasia, meningoneuroplasia, and cranial schwannoma

Diagnostic criteria for von Recklinhausen's neurofibromatosis (NF-1 neurofibromatosis or peripheral neurofibromatosis). Two or more of the following criteria must be met:

F. Six or more café au lait macules larger than 5 mm in greatest diameter in prepubertal children and more than 15 mm in greatest diameter in postpubertal persons
G. Two or more neurofibromas of any type or one plexiform neurofibroma
H. Freckling in the axillary or inguinal regions
I. Optical glioma
J. Two or more Lisch nodules (iris hamartomas)
K. A distinctive osseous lesion, such as sphenoid dysplasia or thinning of long bone cortex with or without pseudarthrosis
L. A first-degree relative (parent, sibling, or offspring) with NF-1 by the above-mentioned critera

Diagnostic criteria for central neurofibromatosis (NF-2):

M. Evidence from computed tomography scans or magnetic resonance imaging of bilateral internal auditory canal masses consistent with acoustic neuroma

or

N. A first-degree relative with NF-2 and either
    1. Unilateral acoustic neuroma or
    2. Two of the following:

Neurofibroma

Meningioma

Glioma

Schwannoma

Juvenile posterior subcapsular lentricular opacity

Scoliosis is the most common osseous defect associated with neurofibromatosis. Up to 60% of the patients with neurofibromatosis may have some spinal disorder.

There are two patterns of scoliosis found in neurofibromatosis:

Dysplastic: The dysplastic curves are characteristically short-segmented, sharply angled, with severe wedging of the vertebral bodies, strong rotation of the apical vertebra, scalloping of the vertebral bodies, spindling of the transverse processes, foraminal enlargement, and penciling of the apical ribs.

Nondysplastic: These curves resemble idiopathic scoliosis and show no dysplastic changes in the vertebral bodies.

The dysplastic curves usually present in the thoracic area produce a short-segmented, sharply angled curvature involving four to six vertebrae and are usually progressive. Scoliosis is frequently accompanied by severe kyphosis. This has very important implications. Kyphosis produces elongation and deformation of the spinal cord that may lead to paraplegia. Also a high incidence of pseudarthrosis has been reported when dystrophic scoliosis associated with kyphosis in excess of 50 degrees is treated by posterior fusion with or without instrumentation. Combined anterior and posterior fusion is recommended in these cases.

Another common problem is the abnormalities found in the cervical spine in patients with neurofibromatosis. These are more common and more severe in patients with dystrophic scoliosis.

1. NEUROMUSCULAR DISORDERS

A. Cerebral Palsy

Most of the classifications used today are modifications of the one presented by Phelps in 1932 (not published). Bleck has proposed the following classifications according to the type of movement disorder and topography (Table 51).

Bleck EE (1987): Classification. In: *Orthopaedic management in cerebral palsy.* London: Mac Keith Press.

Phelps WM (1932): *Cerebral birth injuries: their orthopedic classification and subsequent treatment.* New York: Academy of Medicine.

B. Hereditary Sensory Motor Neuropathies

Hereditary sensory motor neuropathies (HSMNs) are a heterogeneous group of familial distal muscular atrophy and weakness with relatively minor sensory deficit. Dick and Lambert developed a classification of peripheral neuropathies in which intrinsic atrophy and weakness are prominent features early in the course of the disease. These neuropathies are slowly progressive, but life expectancy is normal. Women are more severely affected than men.

Type I: Hypertrophic type of Charcot-Marie-Tooth disease, includes hereditary areflexic dystaxia (Roussy-Levy syndrome), and is inherited as an autosomal dominant disease. Compared with patients affected with type II, these patients have a greater tendency to show weakness of the hands, upper limb tremor and ataxia, generalized tendon areflexia, more distal sensory loss, and more frequent foot and spinal deformities. Clinical presentation is most common during the second decade.

Type II: Represents the neuronal form of Charcot-Marie-Tooth disease and is inherited as an autosomal dominant trait. Onset is delayed until the second decade, with more profound distal lower extremity involvement than in type I. A characteristic “stork leg” appearance is frequently seen caused by atrophy of the distal third of the quadriceps and hamstrings.

Type III: This includes the hypertrophic neuropathy of infancy (Déjérine-Sottas disease) and is an autosomal recessive trait. The disease is first noted in infants or in young children with delayed lower extremity motor milestones. Sensory modalities are lost in a stocking-and-glove type of distribution. Significant spinal deformity develops in most patients, and confinement to a wheelchair occurs during the third or fourth decade of life. The motor nerve conduction velocity is markedly slow. Nerve biopsy shows “onion bulb” formation with frequent segmental demyelinization.

TABLE 52. Muscular Dystrophies

- **The Pure Muscular Dystrophies**
  - X-linked recessive
    - Duchenne muscular dystrophy—severe
    - Backer muscular dystrophy—benign
    - Emery-Dreifus dystrophy—benign with early contracture
  - Autosomal recessive
    - Scapulohumeral—“limb girdle,” “quadriceps myopathy”
    - Early onset in childhood—“Duchenne-like”
    - Congenital muscular dystrophies
  - Autosomal dominant
    - Facioscapulohumeral
    - Scapuloperoneal
    - Late-onset proximal
    - Distal (adult onset)
    - Distal (infantile onset)
    - Ocular
    - Oculopharyngeal
- **Dystrophies with Myotonia**
  - Myotonia congenita
  - Dystrophia myotonica
  - Paramyotonia congenita

TABLE 53. Differential Diagnosis of the Principal Types of Muscular Dystrophy

Clinical Features	Duchenne-Type	Limb Girdle	Facioscapulohumeral	Distal	Progressive Dystrophia Ophthalmoplegia	Congenital or Infantile
Incidence	Commonest	Less common, but not infrequent	Not common	Rare	Rare	Rare
Age at onset	Usually prior to 3 y, some between 3 and 8 y	Variable (usually by second decade, occasionally latar)	Variable (usually in second decade)	20–77 y (mean: 47 y)	At any age (infancy to >50 y)	At or soon after birth
Sex preponderance	Male	Either sex	Male and female equally affected	Either sex	Either sex	Not yet determined
Inheritance	Sex-linked recessive, autosomal less than 10%	Autosomal recessive, on rare occasions autosomal dominant	Autosomal dominant usually, autosomal recessive very rarely	Autosomal dominant	Simple dominant or simple recessive	Unknown
Pattern of muscle involvement	Proximal (pelvic and shoulder girdle muscles affected early, spreads to periphery limbs late in course)	Proximal (shoulder and pelvic girdle, spreads to periphery late)	Face and shoulder girdle, later spreads to pelvic girdle)	Distal (hand first, anterior tibial, and calf in leg)	Usuality limited to extend ocular muscles	Generalized
Muscle spared until late	Gastrocnemius, toe flexors posterior tibial, hamstrings, hand muscles, upper trapezius, biceps, triceps, face, jaw, pharyngeal, laryngeal, and ocular	In upper extremity brachioradialis and hand, calf muscles	Back extensors, iliopsoas, hip abductors, quadriceps	Proximal until late	See above	—
Pseudohypertrophy	80% of cases (calf muscles)	Less than 33% of cases	Rare	Not seen	Not seen	Not seen
Myotonia	Absent	Absent	Absent	Absent	Absent	Absent
Contractural deformities	Common	Develop late in course, less severe than Duchenne syndrome	Mild, occur late	Mild, late	—	Severe
Scoliosis and kyphoscoliosis	Common in late stage	Mild, in late stage	Mild, occur late	—	—	?
Heart involvement	Hypertrophy and tachycardia common: in late stages widespread degeneration, fibrosis, and fatty infiltration	Very rare	Very rare	Very rare	Not seen	Not observed
Endocrine changes	Not seen	Not seen	Not seen	Not seen	Not seen	?
Intellectual level	Commonly decreased	Normal	Normal	Normal	Normal	?
Course	Steady rapid progression	Slow progression, considerable variation in pace of disease	Progresses insidiously	Comparatively benign	Slow progression	Steady progression

From Tachdjian MO (1990): Progressive muscular dystrophy. In: *Pediatric orthopaedics*. Philadelphia: WB Saunders, with permission.

Type IV: Type IV is Refsum disease. The condition is inherited as a autosomal recessive trait, with onset in childhood or puberty. Initial findings are anosmia, progressive deafness, and night blindness. Hypertrophic neuropathy and areflexia are common. Orthopaedic manifestations include scoliosis, pes cavus, and pes equinus. Motor nerve conduction are slow. Onion bulb formation is noted on nerve biopsy. Serum elevation of phytanic acid levels is pathognomonic.

TABLE 54. Dynamic Classification of Bone Dysplasias

I. Epiphys
II. eal dysplasias
  A. Epiphyseal hypoplasias
    1. Failure of articular cartilage: spondyloepiphyseal dysplasia, congenita, and tarda
    2. Failure of ossification of center: multiple epiphyseal dysplasia, congenita, and tarda
  B. Epiphyseal hyperplasia
    1. Excess of articular cartilage; dysplasia epiphysealis hemimelica
III. Physeal dysplasias
  A. Cartilage hypoplasias
    1. Failure of proliferating cartilage: achondroplasia, congenita, and tarda
    2. Failure of hypertrophic cartilage: metaphyseal dysostosis, congenita, and tarda
  B. Cartilage hyperplasias
    1. Excess of proliferating cartilage: hyperchondroplasia
    2. Excess of hypertrophic cartilage: enchondromatosis
IV. Metaphyseal dysplasias
  A. Metaphyseal hypoplasias
    1. Failure to form primary spongiosa: hypophosphatasia, congenita, and tarda
    2. Failure to absorb primary spongiosa: osteopetrosis, congenita, and tarda
    3. Failure to absorb secondary spongiosa: craniometaphyseal dysplasia, congenita, and tarda
  B. Metaphyseal hyperplasias
    1. Excessive spongiosa: multiple exostoses
V. Diaphyseal dysplasias
  A. Diaphyseal hypoplasias
    1. Failure of periosteal bone formation: osteogenesis imperfecta, congenita, and tarda
    2. Failure of endosteal bone formation: idiopathic osteoporosis, congenita, and tarda
  B. Diaphyseal hyperplasias
    1. Excessive periosteal bone formation: progressive diaphyseal dysplasia
    2. Excessive endosteal bone formation: hyperphosphatasemia

From Rubin P (1964): *Dynamic classification of bone dysplasias*. Chicago: Year Book Medical Publishers, with permission.

TABLE 55. International Nomenclature of Constitutional Disease of Bone

Osteochondrodysplasias
  Abnormalities of cartilage and/or bone growth and development
Defects of Growth of Tubular Bone and/or Spine
A. Identifiable at birth
  1. Achondrogenesis type I, Parenti-Fraccaro
  2. Achondrogenesis type II, Langer-Saldino
  3. Thanatophoric dysplasia
  4. Thanatophoric dysplasia with clover-leaf skull
  5. Short rib-polydactyly syndrome type I, Saldino-Noonas (perhaps several forms)
  6. Short rib-polydactyly syndrome type II, Majewski
  7. Chondryodysplasia punctata
    a. Rhizomelic form
    b. Dominant form
    c. Other forms, excluding symptomatic stippling in other disorders (e.g., Zellweger syndrome, Warfarin embryopathy)
  8. Campomelic dysplasia
  9. Other dysplasias with congenital bowing of long bones (several forms)
  10. Achondroplasia
  11. Diastrophic dysplasia
  12. Metatropic dysplasia (several forms)
  13. Chondroectodermal dysplasia, Ellis Van Creveld
  14. Asphyxiating thoracic dysplasia, Jeune
  15. Spondyloepiphyseal dysplasia congenita
    a. Type Spranger-Wiedemann
    b. Other forms (see B, 11–12)
  16. Kniest dysplasia
  17. Mesomelic dysplasia
    a. Type Nievergelt
    b. Type Langer (probable homozygous dyschondrosteosis)
    c. Type Robinow
    d. Type Rheinhardt
    e. Other forms
  18. Acromesomelic dysplasia
  19. Cleidocranial dysplasia
  20. Larsen syndrome
  21. Otopalatodigital syndrome
B. Identifiable in later life
  1. Hypochondroplasia
  2. Dyschondrosteosis
  3. Metaphyseal chondrodysplasia type Jansen
  4. Metaphyseal chondrodysplasia type Schmid
  5. Metaphyseal chondrodysplasia type McKusick
  6. Metaphyseal chondrodysplasia with exocrine pancreatic insufficiency and cyclic neutropenia
  7. Spondylometaphyseal dysplasia
    a. Type Kozlowski
    b. Other forms
  8. Multiple epiphyseal dysplasia
    a. Type Fairbank
    b. Other forms
  9. Arthro-ophthalmopathy, Stickler
  10. Pseudoachondroplasia
    a. Dominant
    b. Recessive
  11. Spondyloepiphyseal dysplasia tarda
  12. Spondyloepiphyseal dysplasia, other forms (see A, 15–16)
  13. Dyggve-Melchior-Clausen dysplasia
  14. Spondyloepiphyseal dysplasia (several forms)
  15. Myotonic chondrodysplasia, Catel-Schwartz-Jampel
  16. Parastremmatic dysplasia
  17. Trichorhinophalangeal dysplasia
  18. Acrodysplasia with retinitis pigmentosa and nephropathy Saldino-Mainzer
Disorganized Development of Cartilage and Fibrous Components of Skeleton
  1. Dysplasia epiphysealis hemimelica
  2. Multiple cartilaginous exotoses
  3. Acrodysplasia with exotoses Giedion-Langer
  4. Enchondromatosis, Olliar
  5. Enchondromatosis with hemangioma, Maffucci
  6. Metachondromatosis
  7. Fibrous dysplasia, Jaffe-Lichtenstein
  8. Fibrous dysplasia with skin pigmentation and precocious puberty, McCune-Albright
  9. Cherubism (familial fibrous dysplasia of the jaws)
  10. Neurofibromatosis

Abnormalities of Density of Cortical Diaphyseal Structure and/or Metaphyseal Modelling

1. Osteogenesis imperfecta congenita (several forms)
2. Osteogenesis imperfecta tarda (several forms)
3. Juvenile idiopathic osteoporosis
4. Osteoporosis with pseudoglioma
5. Osteoporosis with precocious manifestations
6. Osteopetrosis with delayed manifestations (several forms)
7. Pycnodysostosis
8. Osteopoikliosis
9. Osteopathia striata
10. Melorheostosis
11. Diaphyseal dysplasia, Camurati-Engelmann
12. Craniodiaphyseal dysplasia
13. Endosteal hyperostosis
    a. Autosomal dominant, Worth
    b. Autosomal recessive, Van Buchem
14. Tubular stenosis, Kenny-Caffey
15. Pachydermoperiostosis
16. Osteodysplasty, Melnick-Needles
17. Frontometaphyseal dysplasia
18. Craniometaphyseal dysplasia (several forms)
19. Metaphyseal dysplasia, Pyle
20. Sclerosteosis
21. Dysosteosclerosis
22. Osteoectasia with hyperphosphatasia

Dysostoses

Malformation of individual bones singly or in combination.

Dysostoses with Cranial and Facial Involvement

1. Craniosynostosis (several forms)
2. Craniofacial dysostosis, Crouzon
3. Acrocephalosyndactyly, Apert (and others)
4. Acrocephalopolysyndactyly, Carpenter (and others)
5. Mandibulofacial dysostosis
    a. Type Treacher Collins, Franceschetti
    b. Other forms
6. Oculomandibulofacial syndrome, Hallermann-Streiff-Francois
7. Nevoid basal cell carcinoma syndrome

Dysostoses with Predominant Axial Involvement

1. Vertebral segmentation defects, including Klippel-Feil
2. Cervico-oculoacoustic syndrome, Wildervanck
3. Sprengel anomaly
4. Spondylocostal dysostosis
    a. Dominant form
    b. Recessive forms
5. Oculovertebral syndrome, Weyers
6. Osteo-onychodysostosis
7. Cerebrocostomandibular syndrome

Dysostoses with Predominant Involvement of Extremities

1. Acheiria
2. Apodia
3. Ectodactyly syndrome
4. Aglossia-adactyly syndrome
5. Congenital bowing of long bones (several forms) (see also osteochondrodysplasias)
6. Familial radioulnar synostosis
7. Brachydactyly (several forms)
8. Symphalangism
9. Polydactyly (several forms)
10. Syndactyly (several forms)
11. Polysyndactyly (several forms)
12. Camptodactyly
13. Poland syndrome
14. Rubenstein-Taybi syndrome
15. Pancytopenia-dysmelia syndrome, Fanconi
16. Thrombocytopenia-radialaplasia syndrome
17. Orodigitofacial syndrome
    a. Type Papillon-Leage
    b. Type Mohr
18. Cardiomelic syndrome, Holt-Oram (and others)
19. Femoral facial syndrome
20. Multiple-synostoses (includes some forms of symphalangism)
21. Scapuloiliac dysostosis, Kosenow-Sinlos
22. Hand-foot-genital syndrome
23. Focal dermal hypoplasia, Goltz

Idiopathic Osteolyses

1. Phalangeal (several forms)
2. Tarsocarpal
    a. including Francois form (and others)
    b. With nephropathy
3. Multicentric
    a. Hajdu-Cheney form
    b. Winchester form
    c. Other forms

Chromosomal Aberrations

Specific entities not listed

Pulmonary Metabolic Abnormalities

Calcium and/or Phosphorus

1. Hypophosphatemic rickets
2. Pseudodeficiency rickets, Prader, Royer
3. Late rickets, McCance
4. Idiopathic hypercalcuria
5. Hypophosphatasia (several forms)
6. Pseudohypoparathyroidism (normo- and hypocalcaemic forms, include acrodysostosis)

Complex Carbohydrates

1. Mucopolysaccharidosis, type I (alpha-l-iduronidase deficiency)
    a. Hurler form
    b. Scheie form
    c. Other forms
2. Mucopolysaccharidosis, type II, Hunter (sulfolduronate sulfatase deficiency)
3. Mucopolysaccharidosis, type III San Filippo
    a. Type A (heparin sulfamidase deficiency)
    b. Type B (N-acetyl-alpha-glucosaminidase deficiency)
4. Mucopolysaccharidosis, type IV, Morquio (*N*-acetylgalactosamine-6-sulfate-sulfatase deficiency)
5. Mucopolysaccharidosis, type VI, Maroteaux-Lamy (aryl sulfate B deficiency)
6. Mucopolysaccharidosis, type VII (beta-glucuronidase deficiency)
7. Aspartylglucosaminuria (aspartylglucosaminidase deficiency)
8. Mannosidosis (alpha-mannosidase deficiency)
9. Fucosidosis (alpha-fucosidase deficiency)
10. GMI-gangilosidosis (beta-galatosidase deficiency)
11. Multiple sulfatase deficiency, Austin, Thieffry
12. Neuraminidase deficiency (formerly mucolipidosis I)
13. Mucolipidosis II
14. Mucolipidosis III

Lipids

1. Niemann-Pick disease
2. Gaucher disease

Nuclic Acids

1. Adneosine-deaminase deficiency and others

Amino Acids

1. Homocystinuria and others

Metals

1. Menkes' kinky hair syndrome and others

From Horan F, Beighton P (1982): *Orthopaedic problems in inherited skeletal disorders.* New York: Springer Verlag, with permission.

TABLE 56. Characteristic Spinal Problems in Skeletal Dysplasias

Condition	Deformity	Anomaly	Instability	Stenosis	Special Features
Achondroplasia	T1 kyphosis ages 0–2	0		Foramen magnum; entire spine	Adult weakness due to stenosis
Diastrophic dysplasia	Cervical kyphosis; T1 scoliosis	Cervical spina bifida occulta			Cervical kyphosis may resolve; scoliosis usually rigid
SED congenita	Scoliosis	Odontoid hypoplasia	C1–2		
Morquio syndrome	T1 scoliosis	Odontoid hypoplasia	C1–2		
Hurler syndrome	T1 kyphosis; scoliosis		C1–2		Most live 1–2 decades
Osteogenesis imperfecta	Kyphosis; scoliosis				Scoliosis related to overall severity
Larsen syndrome	Cervical kyphosis	Cervical spondylolisthesis; cervical spina bifida	Midcervical		Kyphosis should be fused posteriorly

Orthopaedic Knowledge Update #6, American Academy of Orthopaedic Surgeons 1999:28.

TABLE 57. Osteogenesis Imperfecta

Type		Transmission*	Biochemistry	Orthopaedic	Miscellaneous
I	A	AD	Half normal amount of type I collagen	Mild to moderate bone fragility, osteoporosis	Blue sclerae, hearing loss, easy bruising, dentinogenesis imperfecta absent
	B	AD		Short stature	More severe than IA with dentinogenesis imperfecta
II		AD, AR and mosaic	Unstable triple helix	Multiple intrauterine fractures, extreme bone fragility	Usually lethal in perinatal period, delayed ossification of skull, interuterine growth retardation
	A		Long bones broad, crumpled; ribs broad with continuous beading		
	B		Long bones broad, crumpled; ribs discontinuous or no beading		
	C		Long bones thin, fractured; ribs thin, beaded		
	D		Severely osteopenic with generally well-formed skeleton; normally shaped vertebrae and pelvis		
III		AD (new mutation) and AR (rare)	Abnormal type I collagen	Progressive deforming phenotype, severe bone fragility with fractures at birth, scoliosis, severe osteoporosis, extreme short stature	Hearing loss, short stature, blue sclerae becoming less blue with age, shortened life expectancy, dentinogenesis imperfecta, relative macrocephaly with triangular faces
IV	A	AD	Shortened pro alpha, (I) chains	Mild to moderate bone fragility, osteoporosis, bowing of long bones, scoliosis	Light sclerae, normal hearing, normal dentition, dentinogenesis imperfecta absent
	B	AD			Dentinogenesis imperfecta present

* AR, autosomal recessive; AD, autosomal dominant

* Cole WG. The molecular pathology of osteogenesis imperfecta. *Clin Orthop* 1997;343:235–248.

TABLE 58. Diagnostic Criteria for Marfan Syndrome

System	Major Criteria	Minor Criteria
Musculoskeletal[a]	Pectus carinatum; pectus excovatum requiring surgery; dolichostenomelia, wrist and thumb signs; scoliosis > 20° or spondylolisthesis; reduced elbow extension; pes planus; protrusio acetabulae	Moderately severe pes excovatum; joint hypermobility; highly arched palate with crowding of teeth; focies (dolichocephaly, malar hypoplasia, enophihalmos, retognathio, down-slanting palebral fissures)
Ocular[b]	Ectopia lentis	Abnormally flat comea; increased axial length of globe; hypoplastic iris or hypoplastic ciliary muscle causing decreased miosis
Cardiovascular[c]	Dilatation of ascending aorta ± aortic regurgitation, involving sinuses of Valsalva; or dissection of ascending aorta	Mitrol valve prolapse ± regurgitation; dilatation of main pulmonary artery without valvular or peripheral pulmonic stenosis or obvious cause below 40 years; calcification of mitrol anulus below 40 years; or dilatation or dissection of descending aorta below 50 years
Family/genetic history[d]	Parent, child, or sibling meets diagnostic criteria; mutation in *FBN1* known to cause Marfan syndrome; or inherited haplotype around *FBN1* associated with Marfan syndrome in family	None
Skin and integument**	None	Stretch marks not associated with pregnancy, weight gain, or repetitive stress; or recurrent or incisional hernias
Dural[d]	Lumbosacral dural ecstasia	None
Pulmonary**	None	Spontaneous pneumothorax or apical blebs

[a] Two or more major or one major + two minor criteria required for involvement

[b] At least two minor criteria required for involvement

[c] One major or minor criteria required for involvement

[d] One major criteria required for involvement

** One minor criteria required for involvement

Data taken from Paepe A, Deveraux RB, Dietz HC, et al. (1996): Revised diagnostic criteria for the Marfan Syndrome. *Am J Med Genet* 62:417–426.

TABLE 59. Ehlers-Danlos Syndrome (Cutis Hyperelastica)

Type	Acronym	Transmission[a]	Clinical Findings	Miscellaneous	Basic Defect
I	Gravis type	AD	Hyperextensible skin, poor wound healing, scoliosis, pes planus; hypermobility of small and large joints; osteoarthritis, clubfoot and hip dislocation in the newborn	Easy bruising, “cigarette paper” scars, varicose veins, miscarriages, prematurity, mitral valve prolapse	COL5A1 mutations
II	Mitis type	AD	Similar to EDS I; joint laxity less severe but remarkable in small joints	Less severe than EDS I, no prematurity	COL5A1 mutations, COL1A2 null alleles
III	Hypermobile type	AD	Early onset osteoarthritis, joint dislocations, marked large and small joint hypermobility	Soft skin, no scarring	Unknown
IV	Vascular type	AR (rare)	Hands and feet appear prematurely aged, thin skin without hyperextensibility, minimal joint hypermobility	Severe vascular fragility; uterine and bowel ruptures; stroke; abnormal facies with large eyes, thin nose, thin lips; short life expectancy	COL3A1 mutations; numerous point mutations and exon skips, rarely deletions
	IVA acrogeric	AD			
	IVB acrogeric	AR			
	IVC ecchymotic	AD			
V	x-linked type	XR	Joint laxity	Very rare; similar to EDS I, II, III	Unknown
VI	Ocular scoliotic VIA decreased lysyl hydroxylase levels, VIA normal levels	AR	Kyphoscoliosis (occasionally intractable), muscle hypotonia, moderate joint laxity, skin hyperextensibility	Easy bruising, arterial rupture, ocular fragility	Lysyl hydroxylase point mutations or exon skips (homozygosity and double heterozygosity)
VII	A and B arthrocholosis multiplex congenita	AD	Multiple joint dislocations, bilateral hip dislocation at birth, increased skin elasticity without fragility; diffuse hypotonia, increased bone fragility	Easy bruising, short stature	A: COL1A1 exon 6 skipping mutations; B: COL1A2 exon B skipping mutations
	C	AR	Soft fragile, bruisable skin; marked joint hypermobility	Blue sclera	C: procollagen peptidase deficiency
VIII	Periodontis type	AD	Joint laxity, increased skin elasticity with fragility	Periodontal disease with early tooth loss, easy bruising	Some are COL3A1, others not
IX[b]	Vacant				
X	Fibronectin abnormality	AR	Mild, similar to EDS II or EDS III without dislocations	Platelet aggregation dysfunction resulting in poor clotting	Defect in fiber section
XI[c]	Vacant				

[a] AD, autosomal dominant; AR, autosomal recessive; XR, x-linked recessive

[b] EDS type IX is no longer part of EDS; it has been reclassified as a disease of copper metabolism

[c] EDS type XI is now reclassified as a disorder of joint instability Pope FM, Burrow NP: Ehlers-Danlos syndrome has varied molecular mechanisms. *Am J Med Genet* 1997;34:400–410.

TABLE 60. Differential Diagnosis of Mucopolysaccharidosis

Type	Enzyme Defect	Increased Urinary Excretion of Acid Mucopolysaccharide	Inheritance	Age at Which Features Present	Facies	Corneal Clouding	Deafness	Hepatosplenomegaly	Cardiovascular Abnormalities	Stature	Skeletal Changes	Mental Retardation	Prognosis
Hurler syndrome MPS 1	Deficient α-L-iduronidase	Dermatan sulfate ++ Heparan sulfate +	Autosomal recessive	First few months; may appear normal at birth	Grotesque Gargoyle	Present	Present	Present	Present	Normal at birth; later may be moderately short	Moderate dorsolumbar kyphosis; anterior-inferior beaking of body of L2 or L1	Severe	Progressive disease, usually death by 10 years of age, due to heart disease or respiratory infection
Hunter syndrome MPS II	Low sulfoiduronate sulfatase	Heparan sulfate ++ Dermatan sulfate +	Sex-linked recessive; all patients male	6–12 m	Similar to Hurler syndrome; less severe	Absent	Frequent	Present	Present; pulmonary hypertension	Normal at birth; later may be moderately short	Moderate, absence of lumbar kyphosis	Late in onset, less severe than in Hurler	Survival usually into the third decade of life; eventual death from cardiopulmonary disease
San Filippo syndrome MPS III	Low N-heparan sulfatase or α-acetyl-glucosaminase	Heparan sulfate ++	Autosomal recessive	Early childhood	Not coarse	Absent	Present	Minimal or moderate	Absent	Normal	Minimal widening of clavicles at medial ends, no kyphosis	Severe	Survival to third or fourth decade
Morquio syndrome MPS IV	N-Ac-Gal-8 sulfate sulfatase	Keratin sulfate ++ (diminishes with age)	Autosomal recessive	2–4 y	Not coarse Wide mouth Prominent maxilla	Present; slowly progressive	Present	Usually absent	Minimal, if present aortic regurgitation	Markedly short (under 4 ft)	Severe and diffuse platyspondyly with central tongue; capital femoral epiphyses irregular, eventually disappear	Absent	Normal longevity; respiratory failure due to rib cage rigidity
Scheie syndrome MPS I-S	α-L-iduronidase	Heparan sulfate + Dermatan sulfate ++	Autosomal recessive	Late childhood	Somewhat coarse	Present	Present	Absent	Present, aortic valve disease	Normal	Small epiphysis on hands	Absent	Normal longevity
Maroteaux-Lamy syndrome MPS VI	N-Ac-Gal-4-sulfate	Dermatan sulfate ++	Autosomal recessive	Early to late childhood	Coarse	Present, poor vision	Present	Hepatomegaly rather than splenomegaly	Absent	Normal at birth; later markedly short	Severe (same as Hurler syndrome)	Absent	Guarded, death from cardiovascular complications

TABLE 61. Causes of Osteoporosis in Childhood

Endocrine disorders
   Hyperthyroidism
   Hyperparathyrodism
   Hypogonadism
   Glucocorticoid excess—Cushing syndrome, steroid therapy
Metabolic disorders
   Homocystinuria
   Gastrointestinal malabsorption
   Idiopathic hypoproteinemia
   Vitamin C deficiency
   Rickets-osteomalacia
   Liver disease
Renal disease
   Chronic tubular acidosis
   Idiopathic hypercalciuria
   Lowe syndrome
   Uremia and regular hemodialysis
Bone affections
   Osteogenesis imperfecta
   Idiopathic juvenile osteoporosis
   Idiopathic osteolysis
   Turner syndrome (XO chromosome anomaly)
Malignant diseases
   Leukemia
   Lymphoma
Miscellaneous causes
   Disuse osteoporosis of paralyzed limbs as in myelomeningocele
   Generalized osteoporosis of Still disease, especially after steroid therapy
   Heparin therapy
   Anticonvulsant drug therapy

From Tachdijian MO (1990): Idiopathic juvenile osteoporosis. In: *Pediatric orthopedics*. 2nd ed. Philadelphia: WB Saunders, with permission.

TABLE 62. The 1987 Revised Criteria for the Classification of Rheumatoid Arthritis (Traditional Format)[a]

Criterion	Definition
1. Morning stiffness	Morning stiffness in and around the joints, lasting at least 1 hour before maximal improvement
2. Arthritis of 3 or more joint areas	At least 3 joint areas simultaneously have had soft tissue swelling or fluid (not bony overgrowth alone) observed by a physician. The 14 possible areas are right or left PIP, MCP, wrist, elbow, knee, ankle, and MTP joints
3. Arthritis of hand joints	At least 1 area swollen (as defined above) In a wrist, MCP, or PIP joint
4. Symmetric arthritis	Simultaneous involvement of the same joint areas (as defined in criterion 2) on both sides of the body (bilateral involvement of PIPs, MCPs, or MTPs is acceptable without absolute symmetry)
5. Rheumatoid nodules	Subcutaneous nodules, over bony prominences, or extensor surfaces, or in juxtaarticular regions, observed by a physician
6. Serum rheumatoid factor	Demonstration of abnormal amounts of serum rheumatoid factor by any method for which the result has been positive in <5% of normal control subjects
7. Radiographic changes	Radiographic changes typical of rheumatoid arthritis on posteroanterior hand and wrist radiographs, which must include erosions or unequivocal bony decalcification localized in or most marked adjacent to the involved joints (osteoarthritis changes alone do not qualify)

From Arnett FC, Edworthy SM, Bloch DA, et al. (1988): The American Rheumatism Association 1987 revised criteria for the classification of rheumatoid arthritis. *Arthritis Rheum* 31:315–324, with permission.

[a] For classification purposes, a patient shall be said to have rheumatoid arthritis if he or she has satisfied at least four of these seven criteria. Criteria 1 through 4 must have been present for at least 6 weeks. Patients with two clinical diagnoses are not excluded. Designation as classic, definite, or probable rheumatoid arthritis is not to be made.
PIP, proximal interphalangeal joint; MCP, metacarpophalangeal joint; MTP, metatarsophalangeal joint.

TABLE 63. Rome Criteria for the Diagnosis of Ankylosing Spondylitis

1. Low back pain and stiffness for more than 3 months, which is not relieved by rest
2. Pain and stiffness in the thoracic region
3. Limited motion in the lumbar spine
4. Limited chest expansion
5. History or evidence of iritis or its sequelae

Ankylosing spondylitis diagnosed if bilateral sacroiliitis present and associated with any one of the above clinical criteria

TABLE 64. New York Criteria for the Diagnosis of Ankylosing Spondylitis

1. Limitation of motion of the lumbar spine in all three planes (anterior flexion, lateral flexion, and extension)
2. A history of pain or the presence of pain at the dorsolumbar junction or in the lumbar spine
3. Limitation of chest expansion to 1 inch (2.5 cm) or less, measured at the level of the fourth intercostal space

Radiographic sacroiliac changes	
0.	Normal
I.	Suspicious
II.	Minimal sacroillitis
III.	Moderate sacroillitis
IV.	Ankylosis

Definite ankylosing spondylitis if
   Grade 3–4 bilateral sacroillitis associated with at least one clinical criterion
   Grade 3–4 unilateral or grade bilateral sacroillitis associated with clinical criterion 1 or with both clinical criteria 2 and 3
   Probable ankylosing spondylitis if grade 3–4 bilateral sacroiliitis exists without any signs or symptoms satisfying the clinical criteria

Cervical traction, in basilar invagination 228–229
Cervicomedullary junction
  in os odontoideum 231
  stenosis of 206–207
Cervicooculoacoustic syndrome 244
Chamberlain's line 223*f*, 227, 308, 308*f*, 970*t*
  normal measurements in 970*t*
Chance fracture, orthotic treatment of 913, 914*f*
Charcot joints 525, 607
  in hereditary sensory and autonomic neuropathy 887, 888*f*
Charcot-Marie-Tooth disease 885–886, 886*f*
Charleston nighttime bending brace 906
  in adolescent idiopathic scoliosis 373, 374–375, 375*f*, 378
  biomechanics of 907*f*
  design of 910
  in juvenile idiopathic scoliosis 333
Chemonucleolysis, in disc herniation 465
Chest, deformity of, in homocystinuria 782
Chest circumference/head circumference ratio, in children 553, 554*f*
Chest vests 333
Chest wall
  deformities of 143*See also* Pectus carinatum; Pectus excavatum
    in idiopathic scoliosis 77
    in Marfan syndrome 514
  osteomyelitis of 495
Chiari malformations 517–524
  in assimilation of the atlas 225
  basilar impression in 226
  basilar invagination in 229
  central cord syndrome in 591
  clinical features of 520–521, 521*t*
  condylar hypoplasia in 228
  diagnostic evaluation in 521–522
  etiology of 517–520, 518*f*
    hydrodynamic theory of 519–520, 520*f*, 522
  in myelomeningocele 263, 266–268, 267*f*, 267*t*, 270, 271
  pseudojoint in 224
  surgical treatment of 522–524, 523*f*, 524*f*
  syringomyelia in 522, 524–525
  syrinx in 717, 717*f*
Child abuse
  as cervical spinal injury cause 553, 563*f*
  as fracture cause 567, 577*f*, 581
  as spinal cord injury cause 601
Childhood Depression Scale 131
Chondrification 16, 17*f*, 18*f*
Chondrodysplasia, metaphyseal 295
Chondrodysplasia punctata (Conradi-Hünermann syndrome) 234, 280*t*, 295
Chondroitin-4-sulfate, in Sly syndrome 779
Chondrosarcoma 697
  mesenchymal 704*f*
  of right pedicle 107*f*
Chordoma, embryonic development of 44
Chorea 1054*t*
Chronic granulomatous disease, fungal infections associated with 649, 650, 655, 656
Cisternography 522
Claudication, neurogenic, in achondroplasia 213
Claw-toe deformity 272
Cleft lip and palate 138
  in Klippel-Feil syndrome 244–245
Cleidocranial dysplasia 234, 280*t*, 295
Clivus, abnormal segmentation of 224
Clivus-canal line 223*f*, 970*t*
Clonus test 407
Clubfoot
  in congenital kyphosis 181
  in Goldenhar syndrome 241–242
  in sacral agenesis 196, 196*f*, 197, 199–200
Cobb angle, in scoliosis 76, 148, 150, 151*f*
  in adolescent idiopathic scoliosis 355, 356*t*, 398, 398*f*
  in Duchenne muscular dystrophy 820
  in Friedreich's ataxia 811–812
  in juvenile idiopathic scoliosis 330, 336
  spinal instrumentation correction of 66
Cobb ruler 150, 151*f*
Coccidioidomycosis 649, 650
  diagnosis of 654
  treatment of 655–656
Cohn-Bay-Nielson syndrome 194, 195
Collagen, disorders of
  in adolescent idiopathic scoliosis 348–349
  in idiopathic juvenile osteoporosis 746
  in junctional kyphosis 501
  in Kniest dysplasia 292
  in osteogenesis imperfecta 753
  in spondyloepiphyseal dysplasia 292
Compartment syndrome, congenital muscular torticollis as 303
Compression studies, of spinal cord injury 547
Computed tomography (CT) 99–100
  in atlantoaxial ossification centers 115*f*
  in atlantoaxial rotatory subluxation 557, 559*f*
  in back pain 127
  in bacterial meningitis 672
  in Chiari malformations 521, 522
  in craniovertebral junction abnormalities 221
  in disc herniation 131
  in fractures 560*f*, 568
  in fungal infections 650, 653*f*, 654
  in giant cell tumor 694
  in myelomeningocele 846–847
  in odontoid process fracture 560*f*
  in osteoblastoma 691, 692*f*
  in pyogenic infectious spondylitis 622
  in sacral agenesis 197
  in skeletal dysplasia 279
  in spinal cord injury 588
  in spinal cord tumors 711
  in spinal deformity 153, 154*f*
  in spinal stenosis 205, 206, 206*f*
  in spinal tumors 686
  in spondylolisthesis 438
  three-dimensional 99–100, 100*f*
  in tuberculosis 637, 638
Computed tomography/myelography, in spondylolisthesis 438
Condylar hypoplasia 227–228
Condyle, third 224
Condylicus tertius syndrome 207
Congenital anomalies, fetal radiation exposure-related 101
Congenital fiber-type disproportion myopathy 889
Congenital heart disease, in congenital scoliosis 169
Congenital insensitivity, to pain 886, 887*f*, 888*f*
Congenital malformations, lumbar, in disc herniation 457
Congenital muscular torticollis 303–304, 304*f*
Congenital myopathy 889–890
Connective tissue disorders, in adolescent idiopathic scoliosis 348–349
Conradi-Hünermann syndrome (chondrodysplasia punctata) 234, 280*t*, 295
Continuous positive airway pressure (CPAP) 149

Contractures
  of the Achilles tendon 819, 820
  flexion 143
  of the hip 493
    in cerebral palsy 806
    in Duchenne muscular dystrophy 819–820
    in myelomeningocele 845, 847
    in neuromuscular spinal deformities 795
    in poliomyelitis scoliosis 870
    surgical treatment of 794*f*
  of the iliotibial band, in Duchenne muscular dystrophy 819
  of the knee 493
    in Duchenne muscular dystrophy 819–820
    in poliomyelitis scoliosis 870
    in sacral agenesis 197, 198, 199
  in neuromuscular spinal deformities 789, 790, 793, 794*f*
  in Rett syndrome 881
  soft-tissue, in spinal cord injury 607
  of sternocleidomastoid muscle, in congenital muscular torticollis 303, 304*f*
Contrast agents, in magnetic resonance imaging 106
Conus geographus peptide, as calcium-ion channel inhibitor 543
Conus medullaris
  ascent of 254, 255*f*, 256, 926*f*
  dermoid tumors of 718, 720*f*
  injuries to 590, 593
  in lipomyelomeningocele 271, 272
  low-lying, in congenital scoliosis 168
  in tethered cord syndrome 529
Conversion reactions, as back pain cause 124, 129*t*, 131
Convex compression 80
Convex growth arrest procedure 171–172
Coordinate system, of spinal axes 57
Coronal plane, scoliosis-related curvature of 76
Corpectomy 686
Corpectomy model, of instrumentation 68
Cor pulmonale
  in congenital scoliosis 164
  in idiopathic scoliosis 357
Corset, lumbosacral, in idiopathic juvenile osteoporosis 749
Costotransversectomy
  in Scheuermann's kyphosis 424–425
  in tuberculosis 641
Costovertebral joints, in scoliosis 77
Cotrel-Dubousset spinal instrumentation
  biomechanics of 65, 65*f*
  broken 98*f*
  in burst fractures 578*f*, 579*f*
  in idiopathic scoliosis 76
    overcorrection with 77
  in Marfan syndrome-associated scoliosis 509, 511*f*
  in osteogenesis imperfecta 760*f*
  in poliomyelitis scoliosis 876*f*, 877
  in Riley-Day syndrome 889
  in Scheuermann's kyphosis 422, 422*f*, 425–426, 426*f*, 428–429
  in thoracic scoliosis 476
  in thoracolumbar injuries 913
Coupling, biomechanical 59, 63
Coxa valga, in homocystinuria 782
Cranial nerves
  in basilar impression 308
  functions of 958*t*
  in posterior decompression 523
Cranial vault, postnatal changes in 4–5
Craniocaudal gradient fields 9
Craniocervical abnormalities, in osteogenesis imperfecta 762–764, 763*f*
Craniometry 223, 223*f*, 308, 308*fSee also* Chamberlain's line; McGregor's line: McRae's line
  anterior 968–969, 969*f*, 970*f*, 970*t*
  lateral 967–968, 967*f*, 968*f*, 968*t*, 970*f*, 970*t*
Craniovertebral junction 219–237
  abnormalities of
    assimilation of the atlas 224–226, 225*f*, 226*f*
    basilar invagination and impression 226–229, 227*f*, 228*f*
    classification of 220, 220*t*, 1002*t*
    clinical presentation of 220–221
    in Down syndrome 231–234, 232*f*
    in Grisel syndrome 223
    in Klippel-Feil syndrome 242, 246
    neuroradiologic evaluation of 221–223, 222*f*, 223*t*
    in occipital vertebral malformations 224, 224*f*
    in odontoid process anomalies 229–231, 229*f*, 230*f*, 232*f*
    in skeletal dysplasias 234–235, 234*f*, 235*f*
  during anesthesia 220
  embryogenesis of 219
  hyperextension at 219–220
  hyperflexion at 220
  lymphatic drainage of 219
  radiographic measurement of 967–971
Cranium, growth of 4–5
Crankshaft phenomenon 74, 493
  in adolescent idiopathic scoliosis 403
  definition 65
  growth imbalance etiology of 492
  in juvenile idiopathic scoliosis 335, 337*f*, 338*f*, 340, 343
  in neuromuscular spinal deformities 795
  risk factors for 74
C-reactive protein
  in juvenile rheumatoid arthritis 660
  in pyogenic infectious spondylitis 625
  in spondyloarthropahy 663
Crossed extension (Phillippson's) reflex 936*t*
Crossed straight-leg raising test 124
Crouzon syndrome 234
Cryptococcosis 649, 654, 655
  diagnostic tests for 654
  treatment of 655–656
Cryptococcus neoformans infections 649
Cubitus valgus, in homocystinuria 782
Curare 334–335
Cushing syndrome, differentiated from idiopathic juvenile osteoporosis 748
Cutis hyperelastica *See* Ehlers-Danlos syndrome
Cyst
  aneurysmal bone 691, 694, 694*f*, 700, 738
  arachnoid 675, 729, 732, 732*f*, 733*f*
  dermoid 253
    in congenital scoliosis 168
    craniocervical 245
    posterior fossa 245
  epidermoid, in congenital scoliosis 168
  intrathoracic gastrogenic 245
  mediastinal, of foregut origin 245
  neurenteric 709, 717, 721–723, 721*f*
    in congenital scoliosis 168
  of spinal cord 608–608

D

Dactylitis 663
Dantrolene, as spinal cord injury-related spasticity treatment 606
Darth Vader skull, in osteogenesis imperfecta 763–764, 763*f*
Débridement
  of fungal lesions 655
  in tuberculosis 641, 643
Decompensation
  adolescent idiopathic scoliosis surgery-related 407
  orthosis-related 902, 903*f*, 904
  in selective thoracic fusion 400–401
Deep tendon reflexes 960*t*
Deformation
  developmental 4
  in intervertebral discs 60
  in motion segments 59
  plastic 57
Deformity, spinal *See also specific types of deformities, e.g.,* Scoliosis
  evaluation of 133–157
    bone scan in 155–156, 156*f*
    computed tomography in 153, 154*f*, 155

Swischuk line 588
Synchondroses
  dentocentral 25, 26*f*, 27*f*
  neurocentral 110, 111*f*, 114*f*, 931*f*, 932*f*
    development of 7
    fusion of 114
    postnatal development of 22–23, 23*f*, 24*f*
  of spinous process, development of 7
Syndesmophytes 665
Syndrome of inappropriate secretion of antidiuretic hormone 673
Synkinesia (mirror movements), in Klippel-Feil syndrome 245
Syringobulbia, basilar impression in 226
Syringohydromyelia, pseudojoint in 224
Syringomyelia 12, 40, 524–526
  arachnoiditis in 674
  in arteriovenous malformation 526
  basilar impression in 226
  central cord syndrome in 591
  cervicomedullary junction bony anomalies in 207
  in Chiari malformation 522, 523*f*
  clinical features of 525–526
  communicating 524
  in congenital scoliosis 155*f*, 168
  diagnostic evaluation in 526
  in Klippel-Feil syndrome 245
  noncommunicating 524–525
  in spinal cord injury 608–609
  in spinal cord tumors 526
  treatment of 526
Syrinx 717–718, 717*f*
  in idiopathic juvenile scoliosis 331*f*
Systemic lupus erythematosus 665–666
  acute transverse myelopathy associated with 678, 679*f*

T

Tam-o'-shanter skull, in osteogenesis imperfecta 763–764, 763*f*
Tanner stages, of pubertal development 136, 143
  in neuromuscular deformities 790
  relationship with spinal growth velocity 358, 358*f*
Tarsal disease 663
Temporomandibular line 969, 969*f*
Tendon transfers, in spinal cord injury 610–611
Teratoma
  in congenital scoliosis 168
  presacral, in Ashcraft syndrome 195
  sacrococcygeal 720–721, 721*f*
Tethered cord syndrome 43–44, 527–532
  clinical syndromes of 528–529
  in congenital scoliosis 168
  conus in 255
  diagnostic evaluation in 529–531, 529*f*, 530*f*
  embryogenesis of 527–528
  in lipoma 155*f*
  in myelomeningocele 268–270, 268*f*, 846
    treatment of 848-849, 853
  pathophysiology of 527–528
  in sacral agenesis 197
  in scoliosis 63
  treatment of 531–532
Tetraplegia
  bracing in 607
  functional electrical stimulation in 611
  hand function in 610–611
  pain in 607–608
  prevalence of 601
  in tuberculosis 637
  urinary incontinence management in 604
Texas Scottish Rite Hospital (TSRH) instrumentation, in Duchenne muscular dystrophy 827*f*
Thalassemia, osteoporosis in 744*t*
Thoracic outlet syndrome, cervical ribs in 244
Thoracic spine
  in congenital scoliosis 164, 167–168, 169
  embryogenesis of 19*f*
  flexion (compression) fractures of 570–571, 571*f*
  fungal infections of 650, 651*f*, 655
  growth curve of 933*f*
  in idiopathic scoliosis 79
  instability of 1027*t*
  length of 934*f*
  postnatal development of 22–23
  in tuberculosis 307
Thoracolumbar junction
  burst fractures of 75
  in tuberculosis 637
Thoracolumbar spine
  in congenital scoliosis 169, 171*f*, 174*f*
  fractures of, classification of 912, 1014–1019, 1014*f*, 1015–1018*f*
  injuries to, orthotic treatment of 912–915, 914*f*
  instability of 1027*t*
  length of 983, 984*f*
  radiographic measurements of 983, 984*f*, 984*t*, 985*f*, 985*t*
Thoracolumbosacral orthosis
  in congenital scoliosis 911
  design of 908–901, 909*f*
  in kyphosis 911–912, 912*f*
  results with 907–908
Thoracoplasty, in adolescent idiopathic scoliosis 405
Thoracoscopic techniques, in adolescent idiopathic scoliosis 403
Thoracotomy, as iatrogenic spinal deformity cause 495
Three-column model, of the spine 569, 569*f*, 912, 1015*f*
Three-dimensional analysis, of the scoliotic spine 75–78, 76*t*
Thrombosis
  arterial, in homocystinuria 781
  deep venous
    in homocystinuria 781–782
    postoperative 426
    in spinal cord injury 602
Tibia bone graft, in spinal-pelvic fusion 199
Tilting reflex 937*t*
Time-dependent behavior, of tissue 57–58, 58*f*
Tine skin test, for tuberculosis 638
Tissue, stress-strain relationships in 57–59, 58*f*
Tizanidine, as spinal cord injury-related spasticity treatment 606
TLSO *See* Thoracolumbosacral orthosis
Tomographic angle 97
Tomography, conventional 97–99, 97*f*, 98*f*
Tonic neck reflex 937*t*
Tonsillectomy, as atlantoaxial rotary displacement cause 311–312
Tonsillitis, as Grisel syndrome cause 223
Tonsils, caudal descent of 522
Torque 67
Torticollis 303–314
  atypical 305
  congenital muscular, differential diagnosis of 1002*t*
  in craniovertebral junction abnormalities 221
  differential diagnosis of 303, 304*t*
  in Grisel syndrome 223
  in hemiatlas 309
  in juvenile rheumatoid arthritis 660–661
  in Klippel-Feil syndrome 244
  nonosseous types of 303–307
    congenital muscular 303–304, 304*f*
    inflammatory etiology of 305–307, 306*f*, 307*f*
    neurogenic etiology of 305
    Sandifer syndrome 304–305

- orthotic treatment of 917
- osseous types of 307–314
  - in atlantoaxial rotary displacement 310–313, 311*f*, 312*f*, 313*f*
  - in atlantooccipital anomalies 308–309, 309*f*
  - in basilar impression 308, 308*f*
  - in familial cervical dysplasia 310, 311*f*
  - in hemiatlas 309–310
- paroxysmal of infancy 305
- in spinal muscular atrophy 835

Total-contact thoracolumbosacral orthoses, as rib cage deformity cause 334, 335

Trabeculae, microscopic damage to 60

Traction
- in-line, in cervical spinal injury 554
- in scoliotic curve assessment 77

Transcutaneous electrical nerve stimulation, as spinal cord injury-related pain treatment 607

Translation, in cranial osseuous growth 405

Transverse atlantal ligament, disruption of 974

Transverse ligament, rupture of, atlantodens interval in 557, 558*f*

Transverse process, fractures of 581, 1018–1019

Trauma, as disc herniation cause 453, 454*t*

Triceps reflex 960*t*

Triplegia 1054*t*

Truncal rotation symmetry, assessment of 142–143

Trunk
- biomechanical models of 61–62
- growth of 337*f*
- height of *See* Sitting height
- in Rett syndrome 882*f*
- in spinal muscular atrophy 833
- symmetry assessment of 134–136, 139, 139*f*

Trunk incurvation reflex 936*t*

Tuberculosis 635–648
- anterior lesions of 635, 636*f*
- bacteriology of 635, 638, 641
- central lesions of 635, 637
- of cervical spine 307
- clinical presentation of 637
- diagnosis of 638–641, 639*f*, 640*f*
- differentiated from pyogenic infectious spondylitis 625, 628, 628*f*
- epidemiology of 635
- as epidural abscess cause 676
- fungal infections as mimics of 649, 650
- of lumbar spine 307
- of lumbosacral junction 644
- paradiscal lesions of 635
- pathology of 635, 636*f*, 637
- Pott's paraplegia in 637, 638*t*
- of subaxial cervical spine 644
- of thoracic spine 307
- torticollis in 307
- treatment of
  - nonsurgical 635, 641
    - comparison with surgical treatment 641, 643, 643*t*
  - surgical 641
    - British Medical Research Council Trial of 641, 643, 643*t*
    - complications of 645*t*
    - for paraplegia of healed disease 645, 646*f*
    - preoperative 644
    - for severe kyphotic deformity 645, 647
- of upper cervical spine 644
- vertebra-within-a-vertebra phenomenon in 638

Tumors, spinal 685–707
- anatomic extent of 1051*f*, 1051*t*
- back pain in 131
- benign 696–697
  - aneurysmal bone cyst 691, 694, 694*f*
  - eosinophilic granuloma 695–697, 696*f*
  - giant cell tumor 694–695, 696*f*
  - osteoblastoma 691, 692–693*f*, 738
  - osteochondroma 697, 738
  - osteoid osteoma 313*f*, 314, 689–691, 690*f*
  - staging of 687*f*
- clinical presentation of 685
- diagnosis of 685
- differential diagnosis of 1052*t*
- imaging of 685–686
- malignant 698–703
  - Ewing sarcoma 698, 699*f*
  - leukemia 700–701, 701*f*
  - metastatic 701–703, 702*f*
  - osteogenic sarcoma (osteosarcoma) 698–700, 700*f*
  - staging of 687*f*, 688
- mesenchymal 738
- metastatic 686
- most common types of 1051*t*
- as pathologic fracture risk factor 569
- premalignant 697
- spinal cord 709–740
  - clinical symptoms and signs of 709–711, 710*t*
  - diagnostic studies of 711–713, 712*f*
  - differential diagnosis of 713
  - extramedullary, clinical features of 1025*t*
  - extramedullary-extradural 737–738, 737*f*, 710*t*
  - extramedullary-intradural 718–736, 719–736*f*, 710*t*
  - intramedullary 713–718, 714*f*, 715*f*, 716*f*, 717*f*, 718*f*, 710*t*
    - clinical features of 1025*t*
  - laser therapy of 738
  - somatosensory evoked potentials in 738
  - as spinal cord injury cause 601
  - spinal deformity in 738–739
  - ultrasonic aspiration in 738
- staging of 686–689
  - oncologic system 686–688, 687*f*
  - surgical system 688–689, 688*f*
- symptoms of 685
- terminology of 686
- treatment of 703–705
  - algorithm for 703, 703*t*
  - complications of 704–705

Turner syndrome, as osteoporosis cause 744*t*

Twins
- adolescent idiopathic scoliosis in 348
- monozygotic, congenital scoliosis in 161

Two-column theory, of spinal anatomy 569

U

Ultrasonography
- of conus medullaris 529
- Doppler, in spinal deformity assessment 155
- renal, in Klippel-Feil syndrome 245
- in sacral agenesis 197
- in spinal cord tumors 711
- in spinal stenosis 206

Unit Rod instrumentation, in spinal muscular atrophy 838, 839*f*

Upper extremities
- function development in 940*t*
- innervation of 959*t*

Ureteric obstruction, in congenital scoliosis 169

Urinary incontinence
- in lipomyelomeningocele 271–272
- medical history of 124
- in sacral agenesis 198

Urinary retention 678

Urinary tract infections, as reactive arthritis cause 664

Urologic disorders, in spinal cord injury 604

V

Valsalva maneuver
- in Chiari malformation 525
- in syringomyelia 525

Vanillymandelic acid, as neuroblastoma marker 737

Vascular lakes, within ossification centers 38, 38*f*, 39*f*

Vasculature
- development of 7, 7*f*
- of intervertebral discs 619, 620*f*
- pulmonary, development of 322
- of spinal cord 1003*f*
- vertebral
  - development of 29, 31, 32*f*, 35–39, 36*f*, 37*f*
    - of perichondral vessels 38–39

VATER association 241, 310*f*

Velopharyngeal insufficiency 245

Venous channels, plexiform, in neurofibromatosis 486, 488*f*

Ventricular septal defect, in Klippel-Feil syndrome 245

Ventriculomegaly, in Hunter syndrome 774

Vertebrae *See also* Hemivertebrae
- beaking of 1047*t*
- in congenital scoliosis 161, 163, 169
- coronal cleft 112, 112*f*
- growth of 28
- in homocystinuria 782
- lumbosacral transitional 1044, 1047, 1047*f*
- postnatal growth of 930, 933*f*
- segmentation failure of
  - bilateral 164
  - unilateral 162–164
- shape of
  - abnormalities in 1047–1048, 1047*t*, 1048*t*
  - normal variations in 1048*f*
- wedge, in congenital scoliosis 163, 167

Vertebra-within-a-vertebra phenomenon 35*f*, 1049*t*
- in tuberculosis 638

Vertebral arches
  ossification of 927*t*
  posterior, developmental failure of 162
Vertebral bodies
  agenesis of 181
  blood supply to 619, 620*f*
  child abuse-related fractures of 581
  in congenital kyphosis 179–181
  density of 1047–1048, 1049*t*
  in diastrophic dysplasia 290
  in eosinophilic granuloma 695
  flexibility of 60
  in fungal infections 655
  growth of 57
    biomechanics of 63–64

    latitudinal 29, 30*f*, 31*f*
    longitudinal 28–29, 30*f*
    ring apophyseal 31–34, 32*f*, 33*f*
  growth slowdown lines in 34–35, 35*f*
  in Morquio syndrome 777, 778*f*
  in neurofibromatosis 477, 478*f*
  ossification of 928*t*, 930*t*
  in osteosarcoma 700, 700*f*
  postnatal development of 110, 112*f*
  shape of 931*f*
  strength of 60
  in tuberculosis 638
Vertebral body:vertebral canal ratio 975, 977*f*
Vertebral canal
  development of 204
  lumbar, age-related changes in 204
  postnatal development of 23–24, 23*f*, 24
  sagittal diameter of 204, 205*t*, 206*f*, 208*f*, 211–212
  size of 204
Vertebral canal tumors 45
Vertebral columns
  anatomy of 569, 569*f*
  dislocation of, in neurofibromatosis 486, 488*f*
  embryogenesis of 109–110
    in congenital scoliosis 162
  osteosarcoma of 700
Vertebral limbus, fractures of 464*f*
Vertebra plana 45
  in eosinophilic granuloma 695–697
  in idiopathic juvenile osteoporosis 744–745*t*, 746
  in tuberculosis 637
Vertebrectomy 686
  in congenital scoliosis 175
  in spondylolisthesis 445–446
Viscoelasticity 58*f*
Vision impairment 138
  in cerebral palsy 797
Vital capacity
  in poliomyelitis scoliosis 870–871
  in spinal muscular atrophy 837–838
Vitamin D supplementation, in idiopathic juvenile osteoporosis 749
Vitamin E deficiency, in Werdnig-Hoffmann disease 833–834
Vocal impairment, in Klippel-Feil syndrome 241
Von Hippel-Lindau complex 734, 735
Von Recklinghausen disease 697, 1053

W

Wackenheim clivus-canal line 223*f*, 970*t*
Wake-up test 407
  in Friedreich's ataxia 815–816
Walking reflex, neonatal 936*t*
Water buffalo, neurocentral synchrondroses in 33*f*
Weight
  by age percentiles 943*f*, 946*f*
  by stature percentiles 947*f*
  velocity standards for 950*f*
Werdnig-Hoffmann disease (spinal muscular atrophy variant) 833
  acute 834
  chronic 834–835
Wheelchairs
  seating orthoses for 910
  spinal support systems for 822
Wheelchair use
  by muscular dystrophy patients 820, 822
  by sacral agenesis patients 198
Wildervanck syndrome 244
Wilmington orthosis 909*f*
  in adolescent idiopathic scoliosis 372, 374, 374*f*, 378, 379
  design of 910
  in spinal muscular atrophy 837
Wilms tumor 737
  radiation therapy for, as iatrogenic deformity cause 493, 494*f*
Withdrawal reflex, neonatal 936*t*
Wolff's law 641
Wrist, flexion and extension of, in spinal cord injury 610*f*

X

Xanthine oxidase, inhibition of 546
X-rays *See* Radiography

Z

Zebra, secondary ossification centers of 33–34, 34*f*
Zielke VDS instrumentation, in poliomyelitis scoliosis 877–878
Zone of Ranvier 31, 38
Z-plasty, in congenital muscular torticollis 304, 305*f*
