Care has been taken to confirm the accuracy of the information presented and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of this information in a particular situation remains the professional responsibility of the practitioner.

The authors, editors, and publisher have exerted every effort to ensure that drug selections and dosages set forth in this text are in accordance with current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.
Some drugs and medical devices presented in this publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the health care provider to ascertain the FDA status of each drug or device planned for use in their clinical practice.

Preface

The practice of medicine is in an exciting era of change because of explosive advances in molecular genetics and biophysics, and the development of new biomaterials. The concepts and principles developed in the laboratory must be rapidly applied to the clinical setting. Pediatric patients with a disease or disorder of the spine often requires a multidisciplinary team of health care professionals. The effective management of these patients requires collaboration between basic scientists and clinicians of various disciplines to deal with these complex problems.

The Pediatric Spine brings together international experts from several disciplines to provide a definitive reference text for the health care professional interested in problems related to the pediatric spine. This book is the only comprehensive text devoted exclusively to this subject. It provides the reader with an in-depth study of disorders of the pediatric spine and related conditions. Strong emphasis is given to the basic sciences in the introductory chapters and throughout the text. The authors of each chapter, with their considerable experience and expertise, provide complete and in-depth coverage of each subject. The chapters focusing on disease entities place strong emphasis on natural history, diagnosis, pathobiology of disease, and scope and breadth of operative and nonoperative management options.

The text also provides the reader with an in-depth look at related topics of imaging of the spine, and a detailed appendix of radiographic measurements, classifications, and definitions. Each chapter is accompanied by a comprehensive bibliography on the subject.

The Pediatric Spine is aimed at the senior resident and the practicing pediatric spine specialist. It should also be of interest to orthopaedic surgeons, pediatricians, neurosurgeons, bioengineers, therapists and orthotists, and anyone who has interest in patients with pediatric spinal disorders.

Stuart L. Weinstein MD

Acknowledgements

The completion of the first edition of The *Pediatric Spine: Principles and Practice* would not have been possible without the guidance, direction, encouragement, and hard work of Kathey Alexander of Lippincott Williams & Wilkins. Ms. Alexander's work ethic, dedication to purpose, and professional manner of dealing with the complex aspects of producing a high-quality textbook are greatly appreciated. Ms. Alexander was assisted by the equally capable and hardworking Beth Weiselberg. While their responsibilities and ongoing projects at Lippincott Williams & Wilkins are many, Ms. Alexander and Ms. Weiselberg always made me feel that *The Pediatric Spine: Principles and Practice* was their only concern. For this second edition, I would also like to thank Ms. Anne Snyder for her dedication to task and particularly for her perseverance.

I would also like to express my appreciation and gratitude to medical illustrators Tom Weinzeril of the University of Iowa and Paul Gross of Vanderbilt University, who worked very closely with each chapter author and the editor to bring the authors' words, principles, and techniques to life.

To Joyce Roller, my secretary and colleague over the last 22 years, I owe an extreme debt of gratitude for keeping me organized and on track. She never let being overworked interfere with her pleasant and professional manner in dealing with patients, families, and professional colleagues; she is an inspiration to all.

Finally, and most importantly, I am indebted to an outstanding group of experts who assembled their considerable knowledge and experience in the form of text chapters. Their spirit of cooperation and sense of common purpose was displayed time and time again during the production of this text in meeting editorial deadlines, revising and re-revising chapters, and sharing case photos and case materials. It is to these caring and talented health care providers that credit for this text is due.

Stuart L. Weinstein M.D.

Development and Maturation of the Axial Skeleton

Timothy M. Ganey

John A. Ogden

T. M. Ganey and J. A. Ogden: Atlantic Medical Center, Atlanta, Georgia 30312.

General Developmental Concepts

Developmental biology reflects the interactive dynamics of molecules and organisms guided by genetic and physical cues, including those external to the organism. These responses eventually bridge the distinction of genotype and phenotype, embryogenesis orchestrating a synthetic yet specific response to the workings of normal and modified mechanochemical controls (92,197).

The recognizable development of any specific axial skeletal structure begins with cellular proliferation (multiplication) to produce a critical cell mass, defined as the *anlage*, which may be affected by separate inductive biochemical and biophysical (mechanochemical) factors (245,249). Induction, coupled with permissive interactions, promotes further cell differentiation to form modified or additional anlagen (primordia) for the progressive development of intermediate and final overall vertebral structure.

Molecular, cellular, and tissue interactions; hierarchies; and increasing organ complexity are the fundamental features of embryonic development during axial embryogenesis (137,161). One of the most important aspects of the embryonic period is interactive induction, which is the evocative mechanochemical action of one cell or tissue type on another (252). Early cell or tissue forms may act on an adjacent type to elicit the origin of a third, usually different, cell or tissue. Specificity of such inductions not only resides in the inducing and responding cells but also is subject to the timing and duration of the interaction (126,137). Such interactions, which are molecularly based, are important to axial structuring of the vertebrate embryo, especially through progressive activation of homeoboxes (43).

Differentiation often is followed by a migration phase in which a committed cellular group moves to a more specific region within the embryo. During migration, animal cells release traces of material in the matrix as footprints of their locomotion and adhesion (116,378). Although the phenomenon is poorly understood, traces of integrin and other components of focal contacts in the tracks suggest that deposition and interactive recognition may extrude a patterned scaffold during elaboration of the anlage material (276). The group may either repeat the entire sequence (inductive cell change followed by further migration) or undergo revision in place to form the final structure through localized cell growth, matrix elaboration and modification, and, on occasion, programmed cell death (100,143,144,145). Changes to and virtual disappearance of the notochord typify such cellular alterations and disappearances (143,170,213,346).

Morphogenesis of the axial skeleton of vertebrates is characterized by mechanical and molecularly directed programmed movements of regions of embryonic cells to form and rearrange the three primary tissue groupings—ectoderm, endoderm, and mesoderm (51,53,70,102). These stages of reactive tissue pattern formation lead to progressive spatial biologic organization. Tabin (326) described such pattern formations as the “choreography of developmental processes in three dimensions.” These cellular amalgamations, rearrangements, and migrations during embryogenesis play a critical role in organizing the basic physical structure that defines axial structure and orientation and in mediating those interactions between the various cell populations that regulate progressive patterns of gene expression, specification of cell fates, and the final definition of axial skeletal structures at the end of embryogenesis (45,90,91,102,146,161,186,189,193,227).

Axial skeletogenesis is further characterized by the orderly, progressive appearance of mesenchymal, cartilaginous, and osseous cell types. These cellular “skeletal” changes are conferred as reactive modifications to the biosynthesis of extracellular matrix components. Matrix molecules such as hyaluronan may enhance a chondrogenic phase (endochondral bone formation), and fibronectin may inhibit cartilage differentiation (membranous bone formation) (375). Polarity of the cell may be instrumental in influencing differentiation of the cell. For instance, disrupting the actin cytoskeleton of mesenchymal cells causes them not only to round up but also to produce type II (versus type I) collagen (376). Wedging of one end of the neuroectodermal cells, due to the influence of the basement membrane, likewise facilitates progressive formation and deepening of the neural groove to form the neural tube (317,318).

Abnormal Development

Alterations in a molecular or a macromolecular process may lead to structural defects involving the spine and spinal cord. Such defects may occur prenatally, manifest postnatally, or be combined over the course of both periods. The alterations can be divided into three basic categories from the standpoint of developmental pathogenesis.

Malformation

Malformation follows a failure of embryologic differentiation, development, or both of a specific anatomic structure, resulting in either absence or improper formation of the structure before the fetal period. An example in the axial skeleton is formation of a hemivertebra. Malformations involve a defect intrinsic to the developing embryo and thus occur during organogenesis. Once anatomically established, the defect may continue to adversely affect spinal development throughout subsequent fetal and postnatal periods. Malformations such as hemivertebrae or bars affect three-dimensional development and growth, contributing to both the rate of progression and severity of congenital scoliosis.

Ultimately, malformation and its severity depend on the stage of the developmental or maturation cycle affected (173). Inhibition of cellular proliferation before differentiation can cause either embryonic death or structural agenesis (e.g., failure to differentiate disc material, which may lead to fusion of adjacent vertebral bodies, although the posterior elements, which have a relatively independent origin, may remain separate). Failure of induction through a qualitative lack of an inducer substance or unresponsiveness of target cells also can lead to agenesis of a structure (e.g., lumbosacral agenesis), depending on when during embryogenesis the failure occurs (173). Because cell migration follows induction and differentiation, alterations at this stage in the cycle do not usually produce complete agenesis (222). In extreme cases, ineffective migration can cause adhesion of adjacent primordia and yield fused structures, as in Klippel-Feil syndrome. Failure in cell growth and maturation after migration may result in structural hypoplasia. Alterations at this stage may involve modification of an antecedent structure that had differentiated normally at first. Programmed cell death also is an important factor in the final shaping of structures.

Disruption

Disruption is a structural defect caused by destruction of a part that formed normally during the embryonic period. This mechanism involves the limbs (e.g., amniotic band syndrome with intrauterine autoamputation) more frequently than the spine during the fetal stage. Among children disruption is likely to have an acquired cause that involves alteration of growth patterns and destruction or distortion of basic morphologic features by trauma, infection, tumors, or metabolic alterations. Among children with discitis, for example, alteration of a structure, such as calcification of a disc, may cause fusion of the contiguous vertebrae and loss of the end plate contributions to longitudinal growth. Fractures of end plate growth mechanisms may cause kyphosis or scoliosis through altered growth patterns.

Deformation

Deformation embodies alteration in the shape or structure of an individual vertebra or the entire spine during the fetal or postnatal period. The involved region would have initially differentiated normally, as in infantile or adolescent scoliosis. The nature and severity of deformations are contingent not only on the magnitude and direction of the extrinsic deforming forces but also on the intrinsic properties of the structure or tissue on which they act. Relative resistance of each skeletal spinal tissue component to mechanical stress is important. However, inherent growth potential also is a factor in any final morphologic deformation (34). In general, compressive forces applied along a major growth axis such as the spine produce varying distortion in multiple planes as the tissues grow despite the imposed biomechanical restrictions.

Deformations may be divided between those intrinsically derived and those that are extrinsically acquired (173). *Intrinsic deformation* is caused by a reduction in the ability of the fetus or child to move away from normal imposed forces. It depends on the integrity of the neuromuscular system to respond effectively. Underlying abnormalities of the brain, spinal cord, peripheral nerves, neuromuscular junction, muscle, tendon, or bone may be responsible (340). Some of these are genetically derived and thus carry a latent risk of recurrence. Many deformations persist in their deleterious effects. The results are progressive spinal deformation and a reduction in the likelihood of normal function and response to treatments, which must often be directed at the deformation rather than at the specific underlying cause.

Extrinsic prenatal deformations are caused by a reduction in the space in which a developing fetus can move. Such reduction may be either physiologic or pathologic. Physiologic structural deformations usually are limited and relatively reversible once the constraining influences are removed. In contrast, pathologic structural deformation is permanent. In both physiologic and pathologic extrinsic deformation, the specific fetal part usually is genetically programmed to be normal. Because they usually are caused by extrinsic (epigenetic) factors, deformational and disruptive defects may occur or recur at variable periods throughout fetal and postnatal development.

Late gestational deformations have an excellent prognosis. Approximately 90% of deformations found at birth correct spontaneously. Of those that do not, most can be corrected by early means of postural intervention. This emphasizes the importance of early detection of infantile scoliosis (88). The earlier a deformation is recognized, the greater is the likelihood of correcting it or at least preventing progression, as with early bracing of idiopathic scoliosis.

Basic Patterns of Bone Formation

At birth the bones of the cranial vault consist of plates of resilient compact bone. After birth, the outer surface becomes a dense structure through rapid subperiosteal formation of new bone, cortical thickening, and mechanically induced remodeling. The inner surface, which undergoes both resorption and deposition, forms a less prominent inner table. This variable postnatal hardness of the outer and inner tables affects the ability to use halo fixation devices. Halo pins can easily penetrate this relatively soft bone of children, especially those younger than 10 years. Careful monitoring of pin sites is essential whenever pins are used to treat patients with immature skeletons.

A major method of cranial osseous expansion that is responsive to concomitant brain growth is *translation.* This is the tectonic displacement of the individual cranial plates relative to each other and the underlying neural tissue expansion. The sutures allow such expansion. When the sutures closure prematurely, as in Apert syndrome and other craniofacial abnormality syndromes, the brain continues to grow against a nonexpansile cranial vault. Early postnatal neurosurgical intervention to make pseudosutures may allow relatively adequate skull expansion and avert brain and intellectual impairment. Conversely, exaggerated expansion of the intracranial contents, as in hydrocephalus, can increase separation of the cranial plates and cause cranial enlargement. Early placement of a shunt usually prevents this complication for a patient with a myelomeningocele or any other predisposing neurologic condition. The expanding brain and uterine compression can cause microstructural failures and incomplete healing to form the multiple wormian bones of osteogenesis imperfecta.

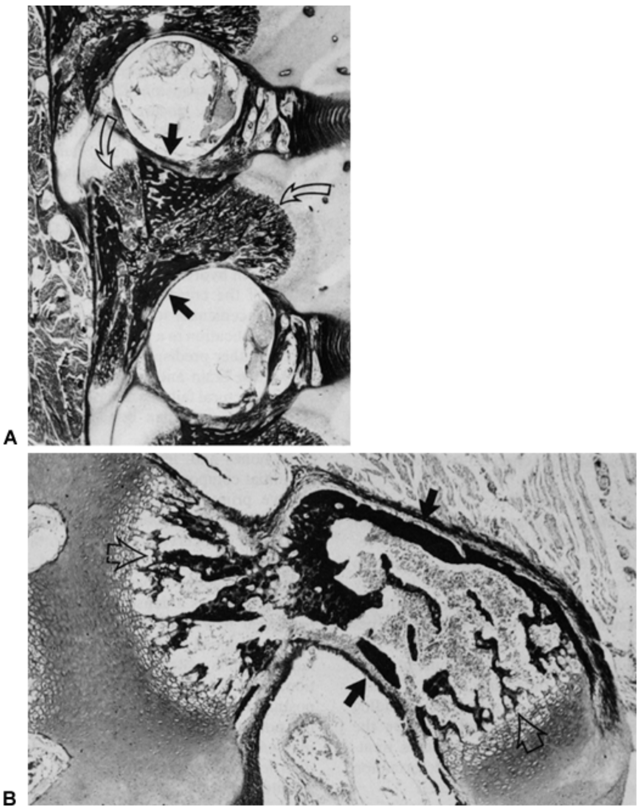

FIGURE 1. A: Combination of membranous cortical bone (*solid arrows*) and endochondral bone (*open arrows*) in the posterior segment (lamina and pedicle, as they extend from the vertebral centrum, *left*). A growth plate is present at each end of the expanding posterior primary ossification. Portions of the physis around the anterior primary ossification process are just visible at the *left.* **B:** More extensively remodeled posterior element membranous bone with thickened, mechanically defined trabecula (*solid arrows*) in contrast to the endochondral trabeculae associated with the physis adjacent to the facet joints (*open arrows*) and the junction with the vertebral centrum (*right*).

The components of the axial skeletal are involved in membranous ossification. The cortex of the developing bone of the posterior elements is derived from specialized mesenchymal tissue known as *periosteum,* which surrounds the chondroosseous model (267,277). This periosteum-derived membranous bone eventually forms much of the cortical bone of the posterior elements of the mature axial skeleton of skeletal maturity (Fig. 1). Periosteal membranous bone contributes to the cortical shells of the vertebral bodies, but usually not until the primary ossification

center has expanded to the edges of the vertebral centrum and modified the perichondrium into periosteum. This modification varies with both postnatal age and spinal region.

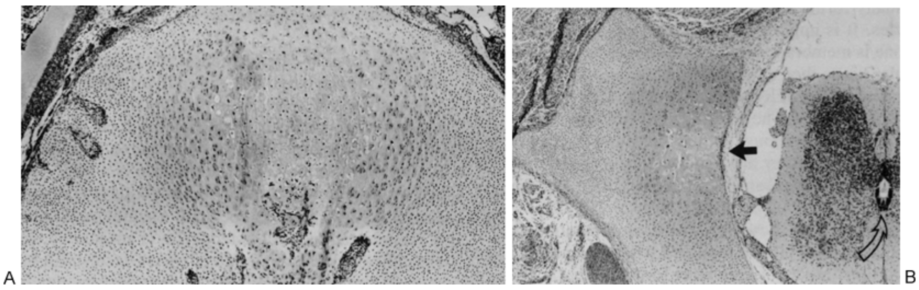

FIGURE 2. Early development of the primary ossification centers in the centrum **(A)** and posterior elements **(B)**. Definite osseous collars comparable with the long bones are not evident. Early vascular penetration is present anterolaterally and posteriorly. This eventually forms cartilage canals. Posteriorly **(B)** a condensation (*solid arrow*) indicates the first evidence of eccentric membranous bone formation. This condensation initially forms on the spinal canal surface. The closing neural canal is visible (*open arrow*).

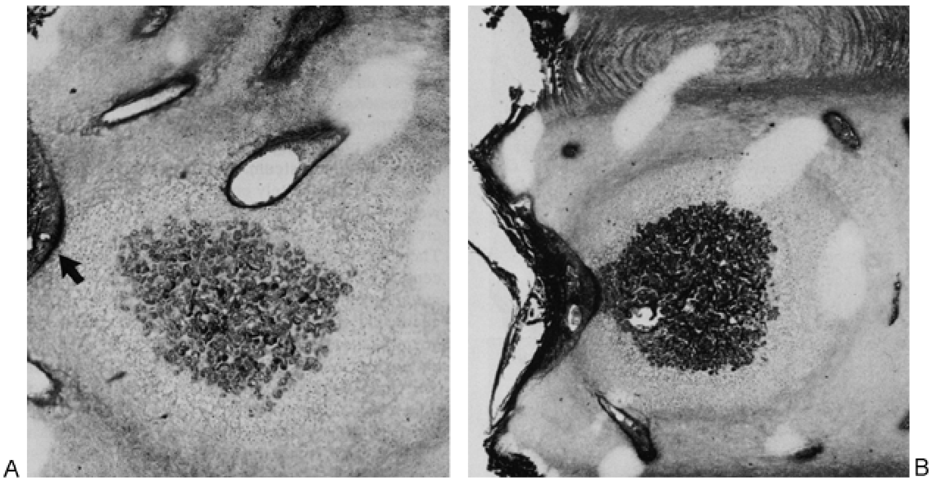

FIGURE 3. A: Early formation of the primary ossification center of a lumbar anterior segment (centrum). Large vessels are present within the cartilage. A very thin area of membranous bone is present anteriorly (*arrow*). This occurs in some vertebrae concomitant with ossification in the primary center. In other vertebrae it does not appear peripherally until after primary ossification begins. **B:** Ossification, more advanced than in **A**, within the primary center of a thoracic vertebra. This ossification has expanded eccentrically toward the anterior border. **A** and **B** are images of the same embryo, indicating the variable extent of ossification within the multiple spinal vertebrae. A forming intervertebral disc region is present in **B**.

Endochondral Bone Formation

Endochondral bone formation is the primary developmental process of the occipital bone and axial postcranial skeletal components in utero. Such bone formation is the result of synchronous replacement of the mesenchymal precursor first by a cartilaginous intermediate in the embryonic phase and then by osseous tissue, which prevails in the fetal phase. This overall process is a continuum that can be divided conceptually into a series of relatively discrete transformations (141).

Initial formation of a precartilaginous, cellular mesenchymal condensation—the basic anlage—elaborates extracellular matrix to form the hyaline cartilage model (41,138). Axial skeletal cartilage can be detected in the human embryo by the fifth week of gestation (140). Once they differentiate into chondroblasts, cells elaborate an appropriate extracellular matrix, the composition of which defines the basic cartilage types—hyaline cartilage, fibrocartilage, and elastic cartilage. The skeletal anlage of a given vertebra enlarges by means of cellular duplication, an increase in extracellular matrix, an appositional increase from the perichondrium, and subsequent selective hypertrophy of the chondrocytes in the central region of the anlage (211). The initial patterns of central and peripheral formation differ between the posterior and anterior elements (Fig. 2) The progressive chondroosseous transformation in each of the posterior elements is similar to, but not the same as, primary ossification of a typical longitudinal bone. In contrast, the anterior element (vertebral centrum) undergoes primary ossification in a manner analogous to secondary epiphyseal ossification in a long bone (Fig. 3).

In the long bones, concomitant with central cellular hypertrophy, peripheral primary membranous bone usually forms near the hypertrophic central chondrocytes. It is important to conceptualize that this initial bone is membrane-derived (woven) bone. Fibrovascular tissue then enters from the primary bone into the central region of hypertrophic cells, becoming the nutrient artery. The “directions” for the anlage to undergo hypertrophic changes, form membranous “outer” bone and then a primary ossification center are undoubtedly responses to biophysical (biomechanical) changes within the embryo (8,56,57,60,129,139,187,257,275,371).

In the spine, however, the aforementioned processes are selectively modified in relation to the “classic” model of limb bone formation (108). A completely encircling periosteal “cortex” and shell are not significant early components of formation of either anterior or posterior elements. Instead, the vertebral centrum ossification center expands toward the periphery eventually to define the cortex in the fetal period. Vascular penetration is through a perichondrial sleeve rather than a periosteum and thin outer osseous shell. Vascular penetration is multiple in the anterior elements (Fig. 4) and more restricted in the posterior elements. True periosteum around the centrum is minimal until later fetal and postnatal stages. The posterior elements also differ. Peripheral membranous ossification begins eccentrically from the dural (inner) surface rather than centrally and symmetrically (see later).

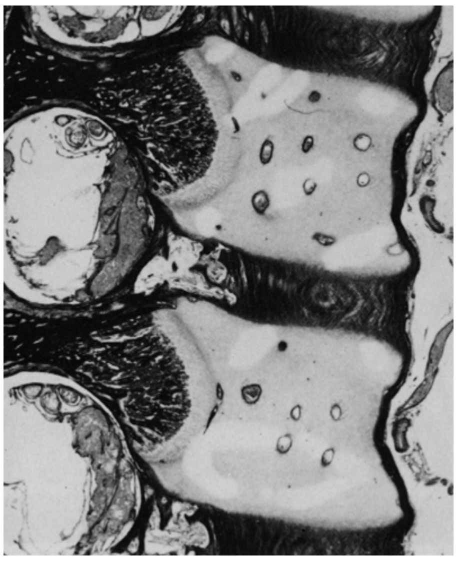

FIGURE 4. Numerous vascular channels in the thoracic vertebra, At this stage the channels have not begun primary ossification in the anterior elements. The posterior elements are well ossified. Physes extend toward the centrum, where they will contribute to the final vertebral body below, or anterior to the spinal canal.

The process of calcification in the hypertrophic regions of the developing vertebra involves ordered “remodeling” of the extracellular matrix (218). In the process calcified cartilage is modified and replaced with bone. This process extends toward each end of the centrum and posterior element anlagen. Reconstruction also entails integrated, concomitant development and extension of the periosteum and bone collar longitudinally toward the ends of the anlage. The periosteum and membranous bone collar, although incompletely encircling the pedicle, become well established in the posterior elements before there are any traces of such structures around the centrum. The combined processes form the primary ossification center, which enlarges to become the diaphyseal and metaphyseal equivalents of similar regions in the appendicular skeleton. As discussed later, these processes are variably modified in the chondroosseous transformation of the vertebral anlagen. Each of the three components of the final vertebra (one anterior, two posterior) form areas analogous to the diaphysis and metaphyses. The epiphyses become the neurocentral and spinous process synchondroses between anterior and posterior elements and the superior and inferior end plates of the centrum. An orderly arrangement of the cells is established adjacent to the expanding primary ossification centers and is equivalent in many respects to a long bone physis. This arrangement forms a site of active modeling and remodeling metaphyses more in the posterior elements than in the centrum (Fig. 5).

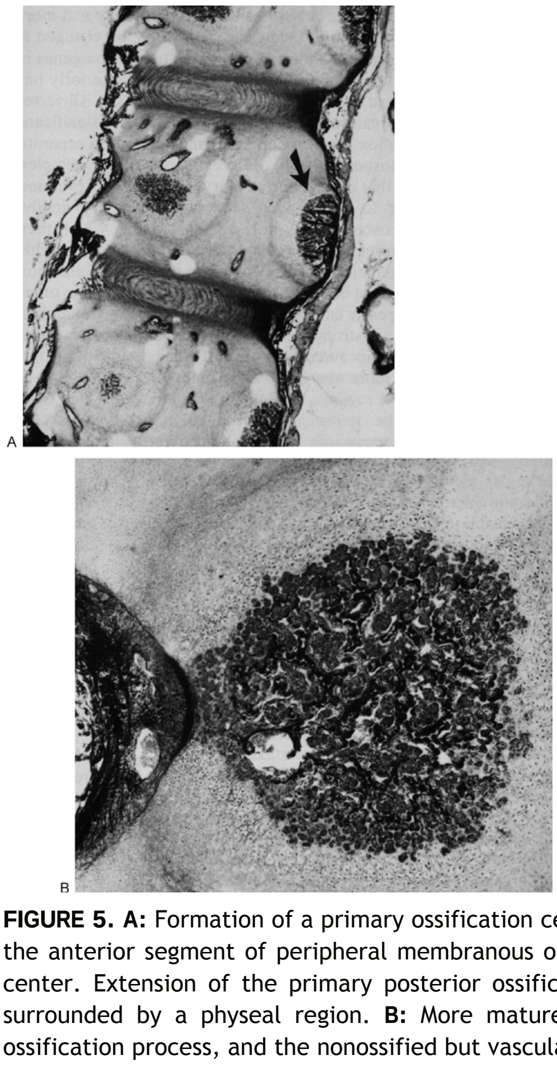

FIGURE 5. A: Formation of a primary ossification center in the anterior regions of the lumbar vertebrae (*left*). The presence of the anterior segment of peripheral membranous ossification is variable. A physis is evident around each anterior ossification center. Extension of the primary posterior ossification centers into the centrum is evident (*right, arrows*), a process also surrounded by a physeal region. **B:** More mature primary ossification in the centrum. The physeal region surrounds the ossification process, and the nonossified but vascularized ossification center extends to the membranous peripheral collar.

With the establishment of a primary ossification center within the centrum, endochondral bone formation progressively localizes to the ends and synchondroses of each vertebra. The central (diaphyseal) area models and remodels by means of peripheral membranous ossification that gradually replaces most, if not all, of the endochondral bone. The presence of growth regions like those of long bones helps explain the altered growth of vertebral height in the centrum in many types of skeletal dysplasia.

Embryogenesis

Molecular Embryology

Differentiation occurs through progressive, controlled division of cells. However, before most cells form specialized groupings, a master plan designating axial orientation and major body regions (e.g., head, trunk, tail) has been established at the molecular level. According to such a genetic blueprint, apparently identical combinations of cells and tissues (at least by current analytical methods) are arranged into distinctly different microanatomic regions and then recognizable macrostructures (76,77). Early establishment of the head-to-tail (craniocaudal) axis provides the orientation for subsequent structural development (236,294,295,296,297,372).

Cellular regions that develop the potential for expression into a discrete structure are defined as *morphogenetic fields* (29,77,370). Within each morphogenetic field, the potential for forming individual organs, such as specific bones, varies gradually. These areas of potential are called *gradient fields*, which correspond closely with the pattern of expression of certain more discrete sets of genes. *Craniocaudal, preaxial, postaxial*, and *proximodistal* are common terms that reflect such gradient-field expression.

The families of genes responsible for complex, early differentiation processes are called *homeobox genes* (77,119,157,233). They direct subdivision of the early embryo into progressively differentiated fields of cells with inherent potential for tissue and organ specificity. Homeobox genes specify the identities and fates of embryonic cells and gradually shape the body conformation into either a normal or an abnormal pattern (84,119,124,125,127,166,179,185,186,189,193,197,282,289,298,319,338,342,347,359,363,364,365,372,373).

According to homeobox gene expression patterns, embryo sequentially subdivides into fields of cells with different developmental capabilities. Such field subdivision precedes any histologic evidence of specific organs or structures (77). The identity and morphologic features of an individual vertebra can change if the domain of action of one of the homeobox genes is altered, as when it is normally expressed anteriorly but is instead expressed more posteriorly (179). All vertebrate organisms appear to have at least four important homeobox gene complexes, each located on separate chromosomes (86). These complex genes controlling early embryonic cellular expression are arranged sequentially (linearly) in the chromosomal DNA in the same order in which they are expressed along the craniocaudal body axis. This arrangement may have come about because homeobox genes must be sequentially activated in a specific order during early embryonic development (359). Homeobox genes are strongly expressed in sequential bands along the craniocaudal axis in early development. Later, when more specific tissues or organs are forming in discrete regions, the same homeobox genes may once again be intensely expressed (77).

An increased understanding of homeoboxes and diffuse growth factors has led to the embryologic concept of *morphoregulation*, in which the notion of biologic shape and intrinsic tissue patterns is linked to those of specific molecular regulatory loops, genetic controls, and cellular driving forces within both inductive and target tissues (92). The evocative forces that shepherd morphogenesis are cellular (biomechanical) in origin—division, movement, adhesion, cell death; they are extrinsic, often phenotypic, forces perceived by cells. Molecules, however, serve as the essential and regulating linkage between gene expression and mechanical driving forces (92,93).

The developmental patterns of disease expression often reflect a continuum of relatively discrete molecular processes. An abnormal developmental gene, initially active in embryogenesis, can be reactivated at various times throughout life in highly regular temporal and spatial patterns (87,123,174). Some of these genes and certain growth factors have the potential to become oncogenic when activated after birth (87,123).

Mesoderm Formation (Gastrulation)

In the spherical embryo of the clawed frog *Xenopus*, which is often used to understand the early phases of basic embryonic development, mesodermal formation is induced by growth factors released by cells within the ventral embryonic pole. The mesoderm forms at the “equator” between the ectodermal (animal) and endodermal (vegetal) hemispheres. Fibroblast growth factor may act as this ventrovegetalizing factor and induce mesoderm formation. Fibroblast growth factor may exert biologic effects on a wide variety of mesoderm- and neuroectoderm-derived cells. It also may act as a morphogen or mitogen in later phases of development (128).

The invagination process in the human embryo is analogous to gastrulation in spherical embryos (3,6,22,23,39,101,103,111,147,148,149,184,243,301,302,303,344,360,368). At the caudal end of the bilaminar, flat mammalian embryo, circumscribed areas of tissue invaginate through a basement membrane between the ectoderm and the endoderm during the second week of gestation. This modified process first involves formation of a specialized cellular aggregation in the ectoderm, the *primitive streak* (22), which is located at the caudal end of the embryo. The area of invagination, the *primitive pit*, is surrounded by a cellular aggregation known as the *primitive knot.* These invaginating tissues elongate in a caudal to cranial direction. The mesenchymal tissues on either side of the primitive streak become mesoderm, establishing the trilaminar—ectoderm, mesoderm, endoderm—embryo.

In the midline the primitive knot produces the first important “skeletal” structure, the *notochord*, which intercalates between the ectoderm and the endoderm. Continuing elongation of both the notochord and the mesoderm takes place in a caudal to cranial sequence.

Notochord Formation and Induction

The initial notochord forms as the rostral extension of cells from the primitive streak that then fuses to the endoderm. A pit appears in the primitive node and extends in the caudal to cranial direction along the notochord as the *notochordal canal.* The canal floor undergoes degradation. The true notochord then forms from the dorsal portion associated with the ectoderm. Persistence of the canal has been implicated as a cause of diastematomyelia and the various rachischisis deformities (228,229). Abnormal ectoendodermal adhesion may cause split notochord syndrome, which consists of vertebral anomalies, a mediastinal cyst, and intestinal abnormalities. Several investigators have implicated this stage in the coexistence of spinal and enteric deformities (17,18,26).

When formation of the notochord is suppressed, as with lithium, several consequences may occur (337,349). The somites may fuse across the midline. The notochord normally acts as a barrier to prevent fusion of contralateral somites and block fusion of spinal ganglia across the midline until the appropriate stage of development. The neural tube may lack a floor plate. The notochord induces and localizes the floor plate of the neural tube. In regions lacking a notochord, cartilage develops variably or may not develop. Absence of the notochord may not uniformly suppress cartilage formation but certainly can lead to altered morphogenesis of the vertebral column (160,162). Instead of separate vertebrae, a continuous cartilage tube may develop that has openings for the segmented nerves. Neural arches and vertebral processes may form but may be fused. In various experiments investigators have concluded that the notochord is indispensable for development of the intervertebral regions (intervertebral discs) and individualization of somites to form vertebrae (337).

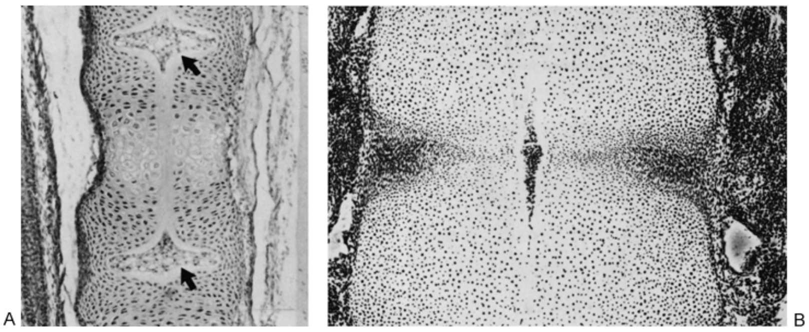

FIGURE 6. A: Early developmental changes in hamster vertebrae. The notochord (*arrows*) is expanding between vertebrae to induce (form) the disc material, especially the nucleus pulposus. As in human embryonic vertebrae, there is notochordal continuity between the intervertebral discs. Central hypertrophy of cells on either side of the notochord traversing the vertebral body indicates the future site of the paired primary ossification centers that will coalesce around the notochord. **B:** Similar notochord presence in the center of the presumptive disc region of a human embryo. Condensation of disc material is more evident laterally than centrally, where the notochord is still evident but regressing.

The notochord remains within the developing vertebral bodies but progressively constricts during the fetal period. It remains for a longer time between vertebrae in the presumptive disc region (Fig. 6). The retention of notochordal tissue is an inductive factor in further differentiation of the disc components.

Neurulation and Tube Closure

Critical developmental events usually are regulated by groups of genes that encode components of signal transduction pathways. One such group, the neurogenic loci, is required for normal segregation of epidermal from neural cell lineages (171). The neurogenic gene products are believed to function in cellular communication pathways that ultimately involve nuclear regulatory components (30,35,50,51). In neurulation, the final product is a group of cells (cell lineage) programmed to become the subsequent neural tube (306,320,345).

The basement membrane between the notochord and the ectoderm is necessary to induce the differentiation of the neuroectoderm (45,46,70). Cells must attach to this membrane to release the appropriate signal. Cells to be stimulated also must attach to the basement membrane. Attachment failures may be responsible for structural defects such as myelomeningocele (107,176,177,250).

Once the neural plate forms, the edges at the junction with the remaining surface ectoderm elevate and produce a neural groove that deepens until the apices of the folds approach and appose each other (Fig. 7A). Elevation of the neural fold is associated with a change in cell shape from columnar to apically wedged (305,308,315,316,317,318). Cytoskeletal proteins likely stabilize this wedging process (168) as disassembly of microfilaments by cytochalasins results in the collapse of convex cranial neural folds (307).

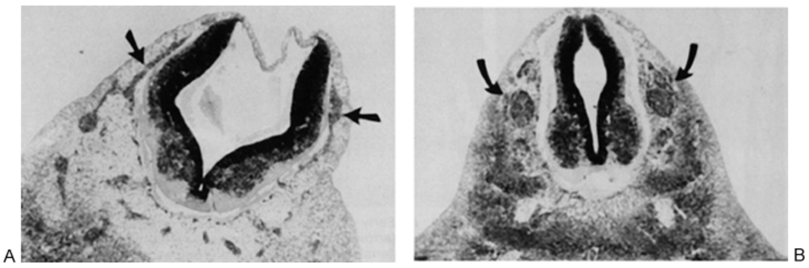

FIGURE 7. A: Closing neural tube. Although closure is incomplete, further cellular differentiation is evident within the lateral cord masses. The neural crest (*arrows*) is also starting to differentiate. **B:** Almost completed closure of the neural tube. The neuroectodermal cleft is still evident dorsally. Overlying nonneural ectoderm closure, however, is complete. Neural crest–derived spinal ganglia are forming (*arrows*). The differentiating vertebral anlagen (somites) and central notochord are evident below the neural tube. The presumptive somite has dorsal and ventral cellular regions separated by a relatively dense cellular zone.

The edges of the induced neural plate curve dorsally to progressively constitute the neural tube (248). This process begins centrally along the longitudinal axis and continues in both cranial and caudal directions, leaving the neural tube temporarily incomplete (open) at each end. Interruption of the tubularization process can lead to entities such as anencephaly or myelomeningocele. This bidirectional closure pattern also explains the frequent concomitant occurrence of abnormalities at each end of the neural system, such as hydrocephalus due to proximal ventricular abnormalities in association with distal myelomeningocele. If the notochord initially induces a defective neural plate or tube, either may induce defective differentiation of the paraxial mesoderm (spinal skeletal precursor) (96,133). The result may be abnormal vertebral development (congenital scoliosis) and abnormalities of the spinal cord (324).

The apposed folds fuse along the midline and lose continuity with the surface ectoderm, which then also fuses across the midline, internalizing the neural folds (Fig. 7B). As the neural folds contact each other, multiple cell surface projections interdigitate. The mechanics of neurulation appear to vary by level within the same embryo; this is particularly evident between cephalic and somitic levels in the chick (107). Convergence of the apposed folds is more important at cephalic and caudal regions than along the somites. Essential to convergence are isolation of the basal lamina from the nonneural ectoderm and formation of a new basal lamina associated with the nonneural ectoderm. At somitic levels this produces a cavity between the basal lamina through cellular adhesion. This process allows not only closure of the neural tube but also reestablishment of nonneural ectodermal continuity over the closed tube. This concomitance of cellular fusion processes helps explain why dorsal skin does not form over a myelomeningocele.

Different mechanisms may underlie neurulation at different levels of the body axis (55,175,225,318). There appears to be a qualitative difference between de novo initiation of closure, bidirectional continuation of closure, and final closure at either end (36,225). Initial closure involves the embryo in establishing a new set of conditions, whereas continuation and final closure are the replication of a previously existing set of conditions to an adjacent portion of the body axis. Muller and O'Rahilly (244), who studied anencephalic fetuses, proposed independent development of the skull and the brain and suggested that certain disorders are related primarily to skeletal disturbance and only secondarily to the contiguous neural component.

Closure of the posterior neuropore appears to be the most susceptible to disturbance. The critical events are the coordinated growth of the various axially arranged tissue types and their mutual attachment by means of the extracellular matrices. Neural tube defects result when growth imbalances occur or when the axial components become dissociated from each other, as when the notochord becomes detached from the neural plate (242). Under such circumstances, axial elongation does not occur normally, or abnormal curvature is induced and neural tube defects result. Lack of adherence to the basement membrane and failure to transform cell shape (apical wedging) lead to failure to form a neural tube, leaving a relatively flat sheet of neuroectoderm that may differentiate further. Irregular neurologic development and subsequent attachment to the neural crest–derived ganglia may occur. Because the peripheral nerves are derived from neural crest ganglia, they may still develop normally, but these cellular groupings lack the appropriate completion of the neural loop as well as higher cortical connectivity.

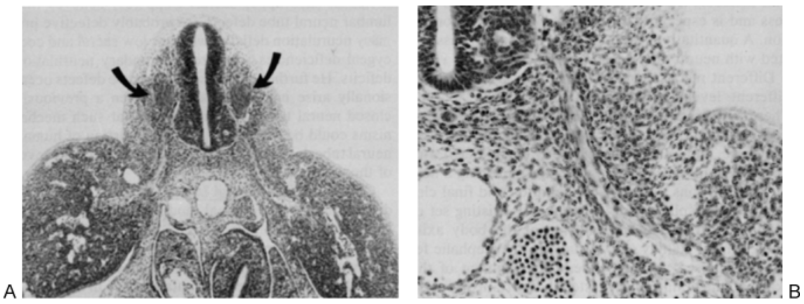

FIGURE 8. A: Section of embryo through upper limb bud level shows closed neural canal and neural crest condensations into ganglia (*arrows*). **B:** Higher-power view shows early formation of a peripheral nerve extending from the developing ganglion to the limb bud. Some communication with the developing spinal cord is evident. The regressing notochord is present just below the ventral cord cells.

Neural Crest Differentiation

As the neural tube is closing, another group of cells, the *neural crest* (Fig. 7), differentiates from the more lateralized neuroectoderm (1,232,350). The neural tube differentiates primarily into the various cellular components of the central nervous system. The neural crest cells give rise to the dorsal root ganglia and much of the peripheral nervous system, including the autonomic nervous system. They serve as the connecting link to the developing spinal cord and upper motor neurons (2,163,199,213).

Neural crest cell migration is the prime example of a system in which it was previously assumed that a population of precursor cells would migrate along different pathways and differentiate into specific cell types (13,353). It now appears that at a very early stage, the neural crest cells establish specific cell lineages. These “predetermined” cells then undergo differential migration (Fig. 8), particularly as they associate with limb morphogenetic fields for subsequent appendicular innervation (54,206,223,234,253,254,352,377).

Neural crest cell migration, especially into the limb buds (Fig. 8), does not usually begin until neurulation is complete (231,243,285,311,312,336,361,362). Migration involves a change in intercellular adhesion. The notochord initially produces a molecular substance that inhibits neural crest cell migration while sclerotomal cells are attracted (74,251,279). There is a morphologic increase in extracellular space in the dorsal neuroepithelium immediately before migration of the neural crest (37,98,99). This is associated with decreased expression of cell adhesion molecules and expression of chondroitin sulfate proteoglycan, which is thought to decrease cell adhesion to fibronectin and collagen substrates. Changes in the basal lamina also may be necessary for crest migration. Abnormalities of the extracellular matrix may delay or prevent neural crest cell migration, as in the neural tube defect mutant splotch (230,231).

Neural Tube Maturation

The neural tube thins at both the roof and floor plates and the lateral walls thicken, effectively narrowing the central canal (Fig. 9). Lateral thickening leads to formation of distinct, chemically active cell masses—the alar (dorsal) plate and the basal (ventral) plate. These become, respectively, the afferent and efferent areas of the developing spinal cord and serve as the basis for the reflex loop (48). The alar plate cells form the dorsal roots, and the basal plates form the anterior root contributions to the spinal nerves. This process normally causes complete obliteration of the central canal. However, the canal may be retained as hydromyelia or may enlarge as a syrinx (syringomyelia), a phenomenon that may not become clinically evident until late adolescence or even adulthood. While the loops are forming, longitudinal pathways for interactive brain cell function also develop and integrate with appropriate spinal nerve levels (158,180). Fibroblast growth factor appears to be necessary for the development of the central nervous system neurons during these early stages (356).

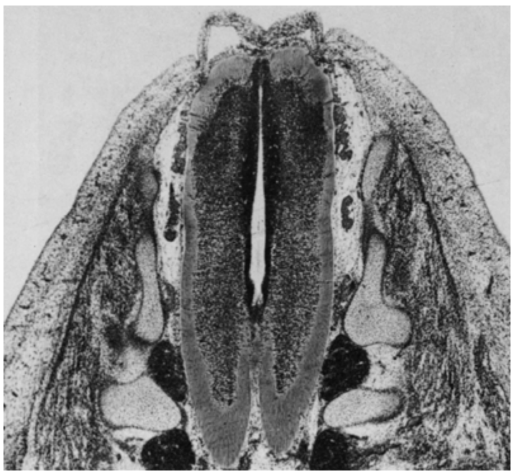

FIGURE 9. Further differentiation of the neural tube leads to formation of the intrinsic cellular structure necessary for progressive development of reflex loops and higher cortical communication.

Paraxial Mesoderm Formation

After differentiation of the notochord and neural tube, further mechanochemical induction produces the mesenchyma that forms the paraxial mesoderm (357,358). Additional proliferation of these two parallel cell masses results in elaboration of three distinct areas of the mesodermal plate—the medial paraxial columns, the intermediate columns, and the peripheral lateral plates. The lateral plates give rise to the layers of the thoracic and abdominal cavities; the intermediate columns differentiate into the urogenital system. Paraxial columns primarily form the axial musculoskeletal system. The early integration of neuromusculoskeletal anlagen and urogenital anlagen helps explain the frequent finding of urogenital abnormalities among patients with congenital scoliosis (88). The early morphologic developmental patterns of the neural, muscular, and axial skeletal elements are thus intimately coordinated and related to both the development of the notochord and the more generalized biologic process of metamerism (linear repetition of anatomically similar segments) (19,21,71,181,264).

Somite Formation

Cellular groupings along the notochord are evident in humans at 3 weeks of gestation. This serial segmentation depends on the presence of a normal notochord (182,194,220,221,270,271,327,354,366), which conditions (patterns) the presomitic mesoderm. These mesodermal cells condense into paired segments, the *somites.* Although much emphasis is placed on the inductive role of the notochord in initial formation of the somites, further differentiation into vertebrae may be greatly affected by permissive interactions and interactive induction (mechanochemical) from the developing neural tube (65,80,113,114,115,159). As cellular proliferation and differentiation continue, the somites develop as distinct cell masses (274). The outer cell mass, which contributes to the tissue layers of the skin and subcutaneous tissue, is called the *dermatome.* The inner cell mass further differentiates into two components. A dorsal cellular aggregation becomes striated muscle (the *myotome*), and a ventral cell mass becomes skeletogenic tissue (the *sclerotome*) (5,20,121,255). The myotomal tissue may differentiate to some degree and independently of the contiguous sclerotomal tissue. Such differentiation may occur in the absence of somites (176).

Segmentation is a prevalent developmental feature that is not limited to mammals (117,118). The pair-rule gene family, shown to be involved in this process, is characterized by the presence of a paired-homeobox sequence (81,224). Mistakes during this segmentation and cellular rearrangement process, such as erroneous cellular boundary formation, may result in variable vertebral fusion or hemivertebra (segmented or unsegmented).

The cellular aggregation of each sclerotome follows a pattern of loosely packed cells in the cranial half and densely packed cells in the caudal half (Fig. 10) (272,310,328). These cellular groupings appear to be biochemically different (255). Theiler (337) stated that there is no resegmentation of the vertebral blastema, as originally proposed by Baur, Sensenig, Verbout, and others (16,310,348,349). What had been described as the *sclerotomic fissure* (16,337,349) was, in essence, the loosely packed cell population giving rise to the intervertebral disc material (278). Each sclerotome thus yields a single, centrally differentiating intervertebral disc that separates the cells that will become portions of adjoining vertebrae, as well as all the contiguous processes (rib, transverse, articular, and neural). Cells juxtaposed to the sclerotome (lateral mesenchymal condensations) give rise to vertebral processes; axial condensations independently form the perichordal ring (the precursor of the intervertebral disc) (195). The neural arch, the pedicle, and the ribs originate from one somite. The cellular structure of each mammalian vertebra is thus exclusively derived from a single somite rather than portions of adjacent somites. The sclerotomes of one pair of bilateral somites yield one single intervertebral disc, the adjoining vertebrae, and all the processes (rib, transverse, articular, and neural).

The somites acquire a craniocaudal polarity through aggregation of mesodermal cells. The segmental distribution of spinal nerves and ganglia is governed by the somites and their polarity. The notochord induces mesenchyma-cartilage transformation, induces the floor plate of the neural tube, and prevents the bilateral somites from premature fusion across the midline. It also promotes differentiation of the discs and yields cells to the nucleus pulposus. Somites may develop in the absence of the notochord. Theiler (337) presented a detailed array of genetic strains of mice with developing vertebral malformations that could have been caused by disturbances of somites, notochord, and sclerotome differentiation (alone or in combination).

Sclerotome differentiation, which primarily forms the anterior portion of the eventual vertebral body, appears to be mediated by the neural tube in conjunction with notochordal induction, whereas the neural crest may markedly and relatively independently affect or induce the neural arch (posterior) elements. Serial segmentation of the neural arches is integrated with (dependent on) the presence of developing spinal ganglia (neural crest derivation). Embryonic and fetal movement is essential for proper progressive development (198).

The vertebral bodies and neural arches thus are guided by separate inductive influences and retain a degree of independence in their initial developmental patterns. Congenital deformation of the spine may involve only posterior elements, only anterior elements, or respond to a variable combination of either. Fused vertebral bodies (centra) may not necessarily be associated with fused posterior (neural arch) elements, and vice versa. The extent of involvement affects the type and eventual rate of progression of congenital scoliosis. Aspects of such variable fusion are discussed in the section on congenital scoliosis.

When somite segmentation and initial vertebral condensation are completed, the notochord is surrounded by a series of vertebral centra derived from cells respective to somite determination (Fig. 11). Failure to adequately segment may be one mechanism that leads to formation of congenital scoliosis (Fig. 12). If the intervertebral sclerotomic cells do not occur bilaterally, fused vertebral bodies might result. Unilateral separation failure may produce a unilateral bar or hemivertebra. Unilateral developmental failure also may produce an unbalanced hemivertebra that is either fused or unfused to an adjacent vertebra (25).

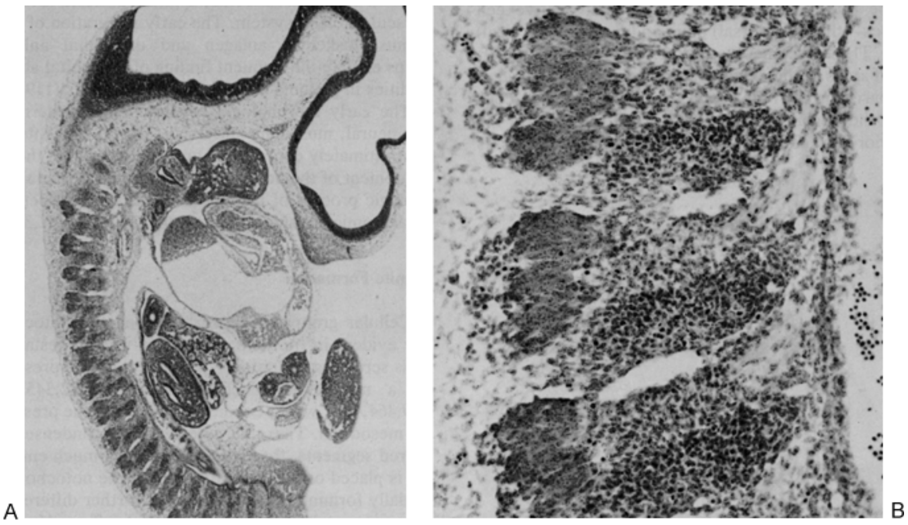

FIGURE 10. Early somite formation. Densely and loosely packed zones of cells are evident. Early muscle formation also is evident. **A:** Low-power midsagittal section of entire embryo. **B:** Higher-power image shows the division of each somite into a cell-loose cranial half and a cell-dense caudal half. A variably sized cell-free region separates each anlage (previously described as the sclerotomic fissure). Presumptive muscle paraxial muscle tissue (*left*) is associated principally with the loose cell zone. The muscle bridges the joint to associate with adjacent motion segments (vertebral bodies).

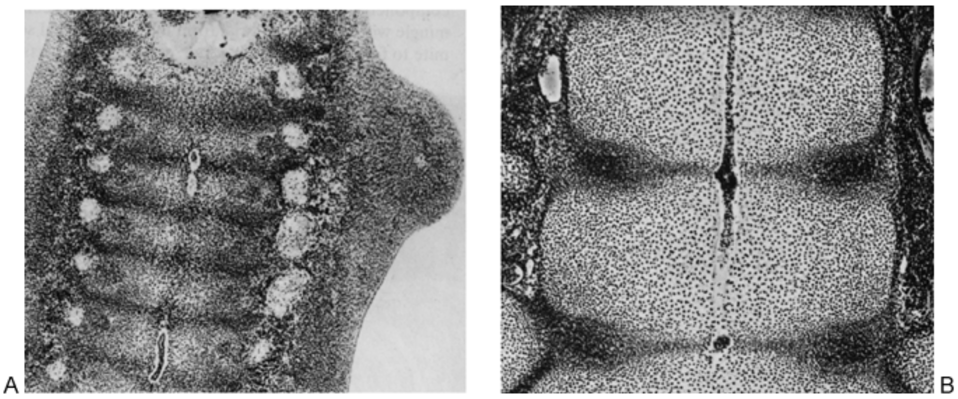

FIGURE 11. **A:** Early vertebral condensations around the central notochord. The intervertebral regions are beginning to demarcate from the vertebral bodies. **B:** Further development enlarges each vertebra and compresses the presumptive disc. Gradation typifies the disc region, even at this stage. The regressing notochord is slightly more retained in the disc regions.

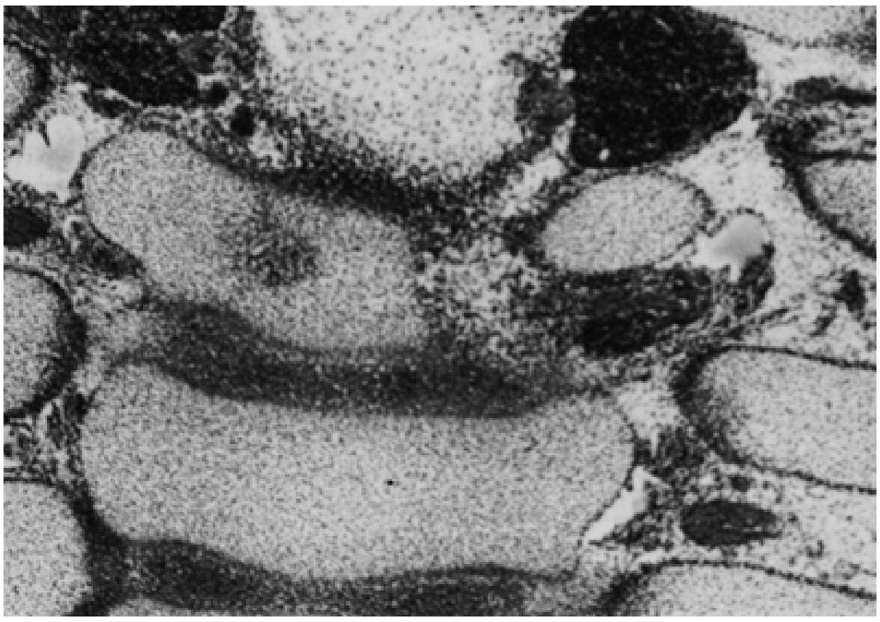

FIGURE 12. Partial condensation failure in an embryo. This probably would have resulted in a hemivertebra. The disc regions are well demarcated by a cellular vertebral boundary, the presumptive perichondrial tissue.

Atlas and Axis Formation

Formation of the atlas (C1) and axis (C2) differs from the typical vertebral formation patterns. Cellular components from the fourth occipital somite may commingle with cellular material from the first cervical somite to form the proatlas. Although it is classically taught that the cranial bones are of membranous origin, the occipital bone exhibits considerable endochondral bone formation (Fig. 13). This differentiation facilitates extension of the ligaments from the skull to the odontoid process (dens) and to the cranial end of the odontoid process, the portion that eventually ossifies to become the os terminale. Failure of occipital and cervical somites to divide may cause variable fusion of C1 to the skull (occipitalization of C1).

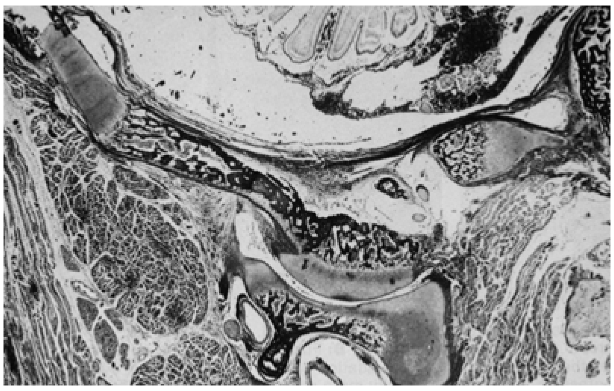

FIGURE 13. Occipital endochondral bone formation in a term woolly monkey fetus. Cartilage is evident where the occipital bone apposes other cranial bones in the anterior (*right*) and posterior (*left*) aspects. Inferiorly located occipital bone endochondral ossification is evident at the occiput-C1 joint.

The cell mass constituting the odontoid process (dens) appears to be derived from cellular components of the first and second cervical somites. This C1–2 somite amalgamation contributes to formation of the anterior arch (centrum) of C1 and some of the supporting ligaments connecting C1 to the odontoid process, at least in classic cellular embryology. Failure of the C1 centrum to separate into anterior arch and odontoid might be a cause of absence or hypoplasia of the odontoid process, especially in skeletal dysplasia. Trauma, however, is a more likely factor in the causation of os odontoideum among children with otherwise normal skeletons (109,152).

Neural Arch Formation

Cells of sclerotomal origin migrate dorsally (Fig. 14) juxtaposed to the neural tube to form the neural (vertebral) arch. The neural arch does not form until after anterior somite-centrum amalgamation is under way, another factor in the variable presentation of morphologic deformities of the spine. The neural arches alternate with the spinal ganglia and thus are situated intersegmentally with respect to the myotomes such that each neural arch is associated with two successive myotomal segments (59). An induced neural arch appears between successive ganglia. Absence of a ganglion may allow unilateral arch fusion (a congenital bar). The cellular components of each neural arch (in reality, paired arches per somite) progressively condense near the somite (basal region of the cord) toward the alar region, where the condensations must unite. Condensations continue farther dorsally to produce the anlagen of the spinous process or processes.

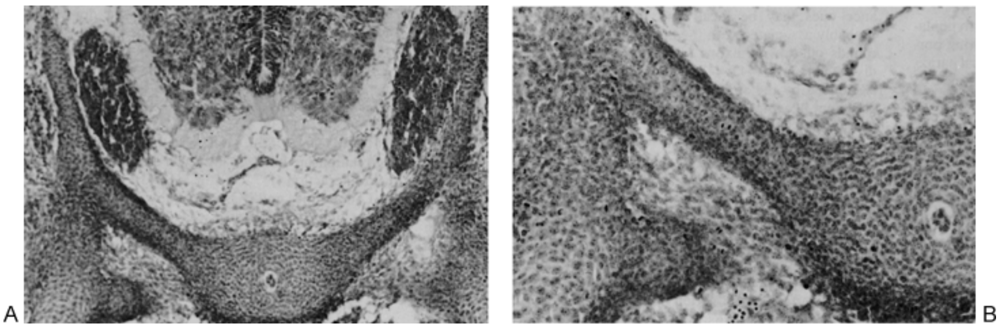

FIGURE 14. Mesenchymal vertebral anlage. Continuity of the differentiating posterior elements and ribs is evident. There is a centrally located notochord. **A:** Low power. **B:** High power.

Vertebral anomalies therefore can be caused by primary neurogenic defects that induce maldevelopment of the associated vertebral centrum, the neural arch, or both (330). The variable contributions of the neural arch to the centrum consequently progressively affect any specific pattern of congenital scoliosis.

Serious posterior chondroosseous defects may accompany major neural tissue defects (12,67,283). The various spinal cord membranes may be exposed (meningocele), or the neural tissue may be directly exposed (myelomeningocele). The flat structure of the exposed cord in myelomeningocele reflects early failure of neural tube closure, although the variable presence of spinal nerves indicates that failure of tubulation does not necessarily preclude further cellular differentiation within the spinal cord anlage. As such, scattered function below the level of a major osseous deformity is possible. Meningocele and myelomeningocele always coexist with posterior spina bifida. The suggestion is that a closed neural tube is a prerequisite for complete development of the neural arch anlagen.

Concomitant with developmental failure or hypoplasia of the neural arch is variable failure to bring portions of the myotome dorsally to form the dorsal paraxial musculature. As a result, this musculature may be shifted more anteriorly than is normal. Because of such positional changes, the developing (maturing) myotome may effectively function as a spinal flexor rather than an extensor, increasing the probability of progressive kyphosis.

Peripheral Innervation

The process of somite formation proceeds in conjunction with the formation of ganglia by the neural crest, such that a one nerve–one somite relation becomes established early, the dorsal root ganglion being situated opposite to the median surface of each myotome (24,40,63,73,79,122,132,204,212,214,215,313,322). Thus any muscle derived from a particular somite, no matter how far it may subsequently migrate, retains its initial nerve relation (14,75,82,83,105,164,167,169,183,202,203,205,207,208,209,237,238,256,314,322). However, there is a complex relation between muscular and neural induction and interaction (104,200,201,269,339).

Notochord Regression

As the vertebral column differentiates, the notochord gradually regresses within the vertebral centra. This process allows cellular and matrix fusion across the midline to form the mesenchymal centrum. In contrast, notochordal cells between the vertebral bodies markedly affect formation of the nucleus pulposus and the anulus fibrosus. Remnants of the notochord may persist (Fig. 15), usually in either the basisphenoid region or the coccygeal region, where they may play a role in formation of a chordoma.

Chondrification

During the sixth embryonic week, the mesenchymal vertebral anlagen develop primary centers of chondrification (Fig. 16). As in bilateral somite differentiation, chondrifying centers appear on either side of the notochord and fuse to make a unified chondrified centrum (131). A center of chondrification also forms in each neural arch, fuses dorsally to establish a solid chondral neural arch, and begins chondrification within the spinous process (341). The final chondrification centers appear at the junctions of the centrum and neural arches and by means of lateral extension form the transverse processes. While vertebral chondrification is occurring, the perichordal tissue condenses into a dense anulus fibrosus around the differentiating nucleus pulposus. By means of expansion of the chondrification centers, the composite cartilaginous model of the vertebra becomes a solid unit, presenting variable demarcation between the body, neural arches, and transverse processes.

Ossification

After the cartilaginous axial skeleton forms, the next developmental stage is primary ossification (Figs. 17, 18). This process is enhanced with the onset of motion within the embryo (139,198,280). Within the centrum, this process is also highly dependent on the presence of a developing vascular system. Three primary centers of ossification are present within each vertebra, except for C1, C2, and the sacrum (270,271,272,273,290). According to most investigators, one ossification center appears in each body (centrum) and one in each of the neural arches (139,198). Chandraraj and Briggs (61) showed that in the neural arch, a single ossification center expands to effectively form three growth regions that become progressively independent. These zones are for the pedicle, lamina, and transverse process. A few investigators have suggested that as many as six ossification centers may be present: two forming in the vertebral body; two forming the pedicles, lateral masses, and transverse processes; and two for the lamina and spinous processes (4,299).

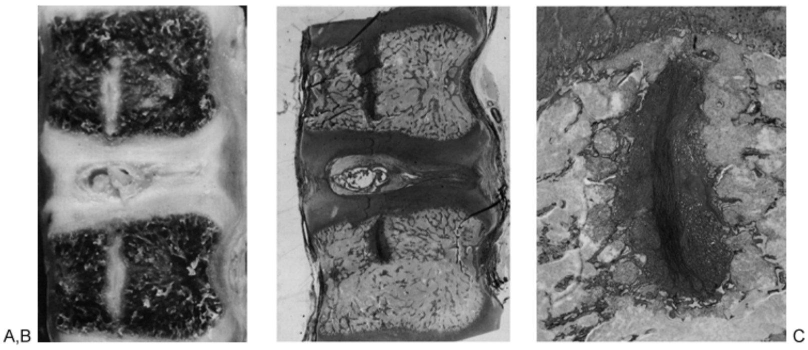

FIGURE 15. A: Segment of thoracic spine from a stillborn with congenital heart disease. Notochordal remnants are evident. **B:** Histologic features. **C:** Higher-power view shows cartilage around the notochordal remnants.

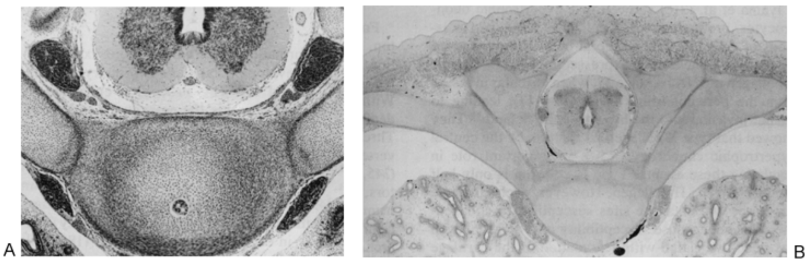

FIGURE 16. A: Thoracic vertebra during the early transition from mesenchymal to cartilaginous tissue. The change is initiated centrally, around the evident notochord. **B:** Further chondrification. The spinal cord is developing changes (gray and white matter). A demarcation is becoming evident between posterior and anterior elements and ribs. Chondrification is occurring throughout.

Primary ossification in the centrum is similar to epiphyseal ossification in long bones but with minimal or no primary bone collar (Figs. 17, 18). Cartilage canals exist within the cartilage of the centrum (Fig. 19); however, no antecedent encircling ossification ring in the vertebra is evident, as in a long bone. In contrast, formation of each primary ossification center in the posterior arches is similar to the diaphyseal ossification an eccentric bone collar forms and progressive vasoosseous transformation occurs (Figs. 20, 21).

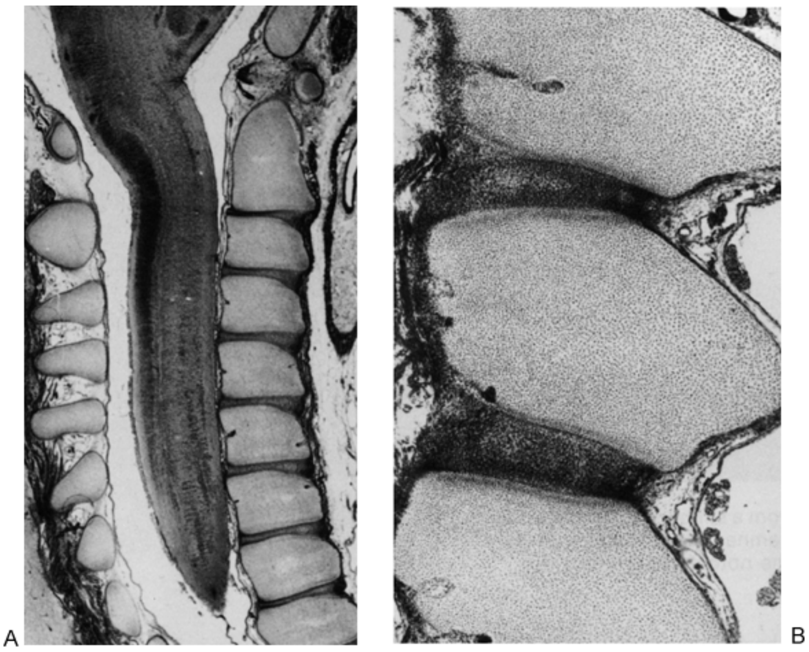

FIGURE 17. A: Low-power sagittal section of the chondrified cervical and upper thoracic spines. Early commencement of vascular ingrowth at multiple levels is evident. The dens of C2 appears to be below C1, but this finding is probably artifactual. An anterior slope on the dens is indicative of eventual flexion-extension between C1 and C2. **B:** Higher-power view of the vascular sprouts. Vascular establishment is essential for chondroosseous transformation.

Ossification of the vertebral body in humans begins in the lower thoracic and upper lumbar regions and diverges craniad and caudad. In the cervical region, however, the primary ossification centers of the vertebral bodies appear sequentially after the primary centers appear in the vertebral arches (59). Within the cervical spine, centrum ossification begins in the lower region (C6, C7) before it starts in the upper region, an occurrence that may be fairly common throughout animal species (263). Again, disruption of the endochondral ossification process may adversely affect development of the spin as another causal mechanism of congenital scoliosis.

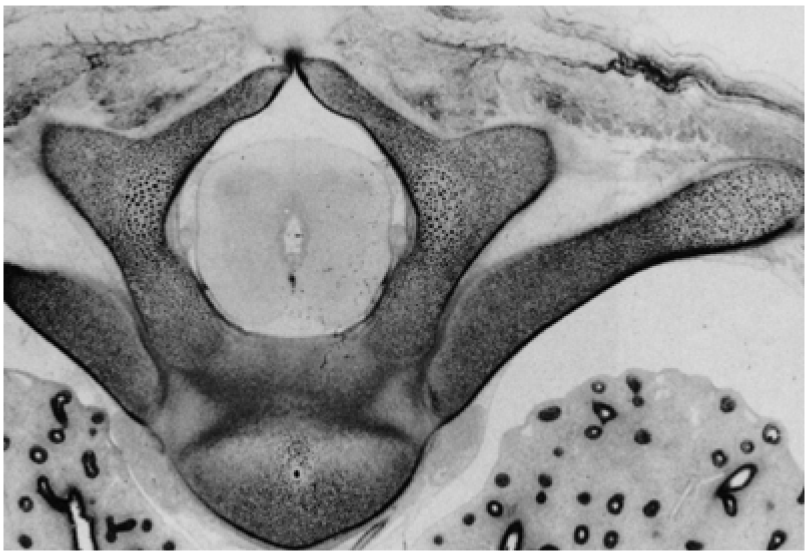

FIGURE 18. Localized hypertrophic cartilage changes preceding ossification within thoracic vertebral components. Relative demarcation of the anterior, posterior, and costal regions is evident. The posterior elements are incompletely fused (spina bifida occulta). Chondroosseous transformation apparently can occur even before the neural arch is fully fused into a spinal process anlage. Retention of this stage probably causes spina bifida occulta.

The ossification patterns of the atlas (C1) and axis (C2) differ from those of the other vertebrae (258,259). The atlas centrum has one primary center of ossification, and each of the two neural arches has a primary center. The two posterior centers are present prenatally, and the anterior center may not appear until several months postnatally—an important factor in assessing this region in neonates and infants. The axis develops five primary and two secondary centers of ossification. The centrum and neural arch centers form in the conventional manner, and the odontoid process forms two laterally situated centers. These two odontoid centers almost always fuse in the perinatal period, although a cleft may persist for several months after birth (259).

Posterior osseous defects in which the ossification centers of the neural arch fail to fuse are quite common, especially those involving the L5 and S1 vertebrae. In some studies the incidence of spina bifida occulta is estimated to be as high as 20% in the general population. This condition, however, is rarely accompanied

by serious primary neurologic defects. Larger areas of spina bifida may involve the sacrum and culminate in failure to form the spinous processes properly. The presence of large areas of spina bifida and may even predispose the child to a developmental form of spondylolisthesis in which there is progressive deformation of the normal angulation of the L5–S1 facet joints. Minor structural abnormalities in the neural arch, especially the facet joints, may be an overlooked cause of "idiopathic" scoliosis (172).

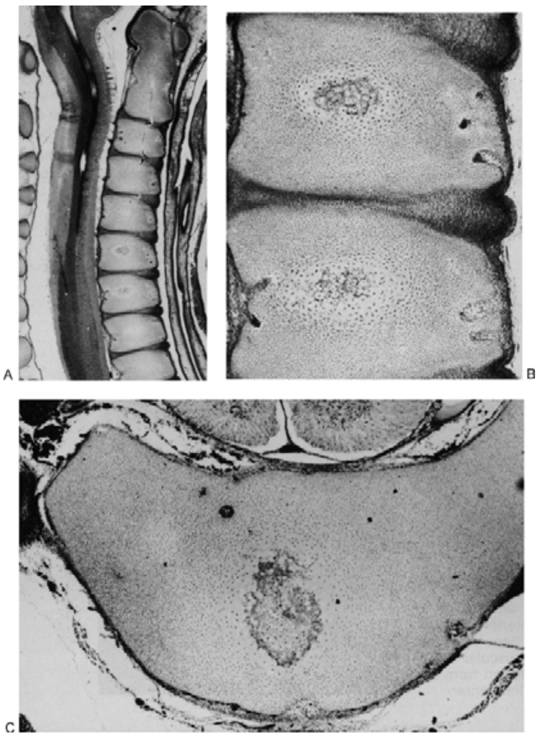

FIGURE 19. A: Early development of the cervical and thoracic spine. The continuity of the various component parts of C2 and the developing anterior portion of C1 is evident. The dens is now distinctly behind C1 (compare with Fig. 17A). Cartilage canals penetrate both anteriorly and posteriorly. The intervertebral discs, especially the nucleus pulposus, are minimally developed. The notochord is evident within C2 and C3. Ossification is beginning in C6 and C7. The incompletely closed neural canal extends from the brain to C4. **B**, **C:** Higher-power views demonstrate these hypertrophic preossification centers (**B**, sagittal; **C**, transverse). The ingrowing cartilage canals still do not reach these regions, and there is no peripheral bone collar, as in primary ossification of a long bone.

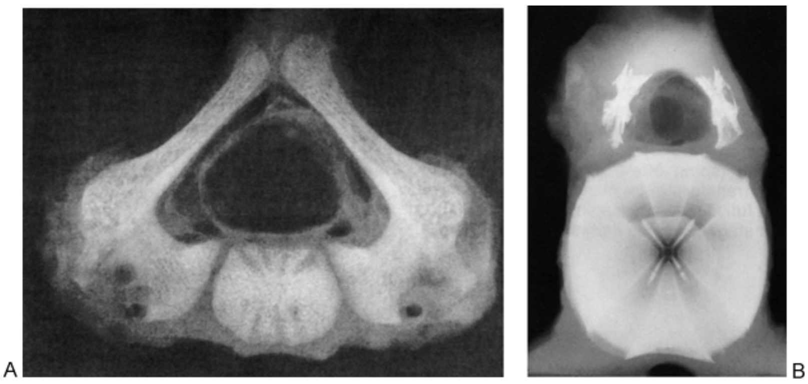

FIGURE 20. A: Irregular ossification of a cervical vertebral centrum. This variable ossification may be the basis for the concept of six ossification centers. **B:** Similar variable pattern of calcification in the thoracic vertebra of a shark seems to show four anterior regions and two posterior regions.

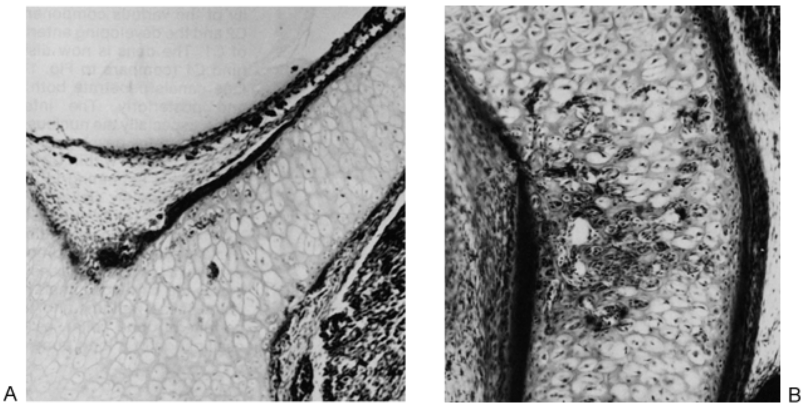

FIGURE 21. A: Early hypertrophy and eccentric bone collar formation in a posterior element. There is more definition of the bone collar on the canal side than on the muscle side. **B:** Subsequent vascular penetration from the canal side to form the ossification center.

The intervertebral disc material becomes progressively defined in the embryonic period; more peripheral regions are characterized by greater cellularity (Fig. 22A). These peripheral regions differentiate and because of progressive motion develop a multilaminar appearance and an identity as the anulus fibrosus (Fig. 23A). Differentiating disc material is vascular and communicates with the contiguous vascular regions of the vertebral centrum and extraosseous circulations anterior and posterior to the vertebral body. The cells of the nucleus pulposus form a defined central cell grouping that is highly vascular in the fetus and child (Fig. 23B), a fact that may explain the concomitance of discitis, osteomyelitis, and eventual vertebral fusion among children.

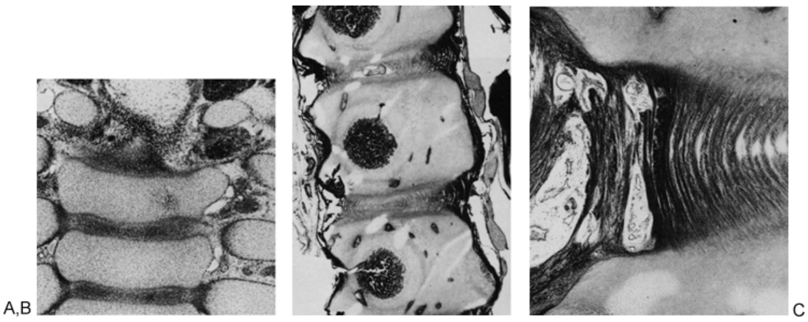

FIGURE 22. A: More defined condensation of disc tissue toward the end of the embryonic period. The cellular regions are more dense peripherally than centrally. **B:** As ossification begins in the fetal stage, the peripheral disc material assumes a multilaminar appearance. **C:** Maturation is associated with increased complexity of the laminations. This region also is extremely vascular.

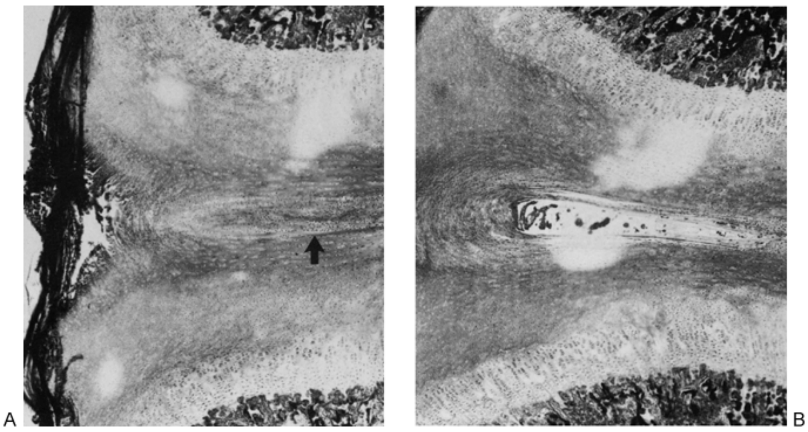

FIGURE 23. A: Central cellular condensation (*arrow*) in the region of the presumptive nucleus pulposus. The area is surrounded by hypertrophic cells that probably represent the developing epiphyseal analogue. **B:** This central disc region has considerable vascularity.

Postnatal Development

Normal postnatal development of the axial skeleton involves the progressive appearance of the characteristic curves (9,10), growth and expansion of the vertebral bodies (332), closure of the synchondroses, development of the ring apophysis, and changes in the longitudinal relations between the vertebrae and the spinal cord (262,349).

The diagnostic modalities used to examine the spines of adults must often be modified for children. On images of children, the presence of radiolucent cartilage produces large gaps between ossified parts, and ligamentous laxity allows greater motion during imaging, especially of the upper cervical spine (42,154,155,222,374).

Vertebral growth not only relies on genetic factors but also responds to epigenetic factors such as intrinsic tonicity in the paravertebral musculature, upright posture, and activity. Radiologic analysis of postnatal vertebral development among ambulatory and nonambulatory children supports a concept that vertebral body height in the midsagittal plane is relatively unaffected by mechanical factors and may even be primarily genetically determined (331). Latitudinal growth and peripheral vertebral growth are more dependent on upright posture. This differential growth response of the peripheral versus central portions may be a factor in the eccentric growth patterns that lead to development and progression of scoliosis and kyphosis.

Cord Growth

The spinal cord initially extends to the end of the vertebral canal, and the spinal nerves exit at or close to their respective levels of origin. Vettiveil (351) showed that there is rapid ascent of the conus medullaris relative to the vertebrae up to the 120-mm crown-rump length stage, when it reaches the fourth and sometimes the third lumbar vertebra. After that the ascent is fairly gradual; the cord terminates opposite the first or second lumbar vertebra in term neonates.

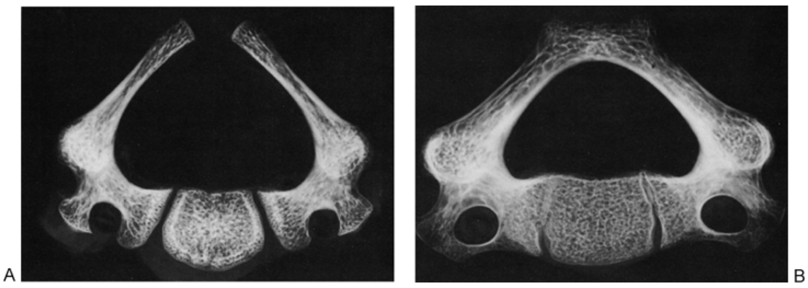

FIGURE 24. Differences of maturation of C3 at 1 year **(A)** and 6 years **(B)** of age. Posterior ossification is distinctly incomplete at 1 year of age. The neurocentral synchondroses are almost parallel and make up a large portion of the eventual vertebral body.

With postnatal growth, especially in the lumbar region during adolescence, the osteocartilaginous column elongates. Disparate rates of growth may occur between the vertebral bodies and the spinal cord. Positional changes cause the lumbosacral spinal roots to traverse more obliquely from the spinal cord to their respective neuroforamina and form an aggregate of nerve roots, the *cauda equina.* Some investigators believe that postnatal changes in cord level do not occur (15).

The filum terminale may attach as far as the first coccygeal vertebra and may cause progressive cord traction if elongation is not commensurate with the changing osseous-spinal cord relations (tethered cord syndrome). In diastematomyelia, differential growth may be a factor causing progressive development of neurologic abnormalities in a previously healthy child. The amount of disparate growth necessary to cause symptoms may be only a matter of millimeters.

Neurocentral Synchondroses

Progressive juxtaposition between the primary ossification centers of the anterior centrum and posterior arches occurs anteriorly to the anatomic pedicle, at the site of the neurocentral synchondrosis (Fig. 24). These regions are radiographically evident in the spines of infants and must not be interpreted as either congenital deformity or trauma (Fig. 25). It is also important to realize that as the most anterior portions of the neural arch contribute to vertebral body formation, a morphologic deformity such as fusion of adjacent posterior elements may affect the vertebral body to the margin of the neurocentral synchondrosis.

The cervical vertebrae, except for C1 and C2, and the thoracic and lumbar vertebrae follow this similar pattern of postnatal development with three ossification centers (two in the neural arches and one in the centrum) that meet within the vertebral body as the neurocentral synchondroses. Although the neurocentral synchondroses in the cervical vertebrae are almost parallel, such that the posterior centers contribute greatly to the lateral portions of each vertebral body, in the thoracic and lumbar vertebrae the posterior ossification centers contribute less and less to the final vertebral body (compare Figs. 25 and 26). The formation of unilateral bars in congenital scoliosis may include the variable anterior contribution. Thus an apparently posterior bar may extend anteriorly into a portion of the eventual vertebral body because of the segmental contribution of the posterior anlage. Such variable anterior extension of asymmetric fusions (congenital bars) affects the rate of progression of congenital scoliosis. The symmetric or asymmetric contribution of the posterior elements to the eventual vertebral body also affects the risk of progression.

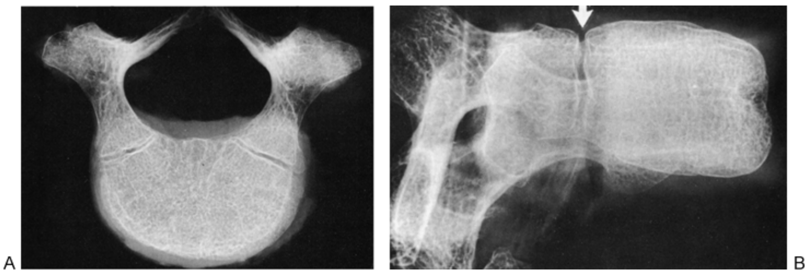

FIGURE 25. A: Radiograph of L3 at approximately 8 years. Compare the relative posterior contributions to the vertebral body with Figure 24. **B:** The neurocentral synchondrosis (*arrow*) is evident in this lateral view and should not be misconstrued as a fracture or congenital deformity.

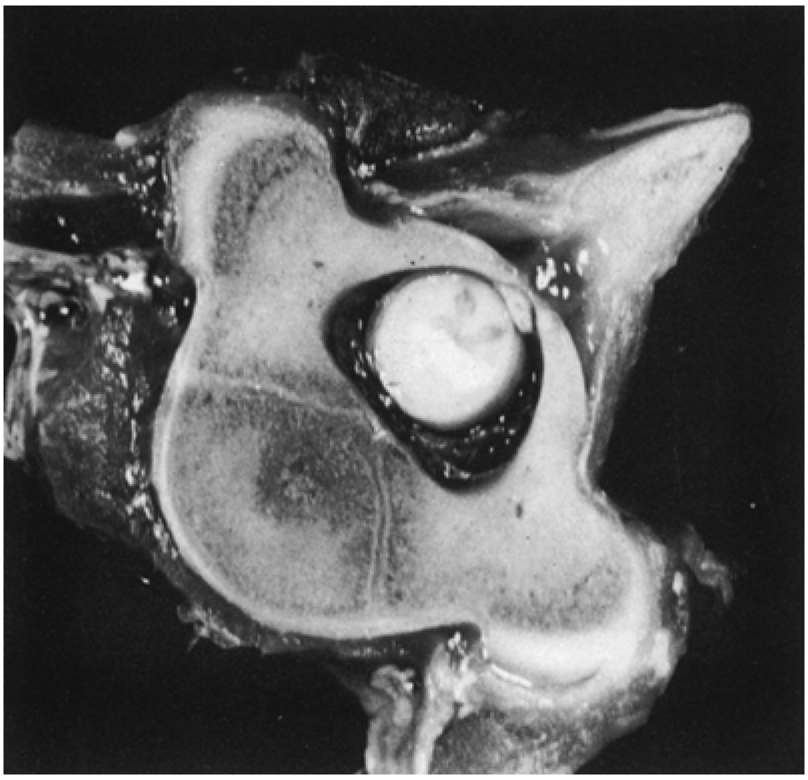

FIGURE 26. Closing neurocentral synchondroses in a lumbar vertebra of a greater kudu (antelope). In the same way that is common among humans, a small area of spina bifida occulta is evident. The spinous process is from the adjacent vertebra.

Because the neurocentral synchondroses are paired, growth in these regions must be equal if each vertebra is to develop normally. Experimental damage to one of the pair causes scoliosis (27,78,292). Subtle asymmetry of growth—one side versus the other—in these synchondroses may be a cause of scoliosis that affects the shape of the posterior elements and introduces asymmetric muscular function.

Canal Growth

The presence of three cartilaginous junctions within each composite vertebra allows progressive expansion of the spinal canal as the child grows. Conceptually these cartilaginous junctions are analogous to the triradiate cartilage in the acetabulum (347). Such multidimensional growth conglomerates are essential for enlarging three-dimensional morphologic features. Even if the posterior (spinous process) synchondrosis closes first, the paired neurocentral synchondroses still can grow longitudinally to allow further change in canal size.

Once the neurocentral synchondroses close (Figs. 26, 27), the spinal canal can no longer widen. Canal diameters throughout the spine appear to reach adult size by 6 to 8 years of age, after which little diametric canal growth occurs (112,154,155,374). Some remodeling and contour change in the spinal canal occurs through the periosteum on the inner and outer surfaces of the posterior elements. It is important to remember this early attainment of adult canal diameters.

A problem that may be caused by a decrease in the rate of growth or premature synchondrosis fusion is spinal stenosis. Either process, whether anterior or posterior, would lessen or preclude progressive canal widening. Because these are endochondral processes, failure to grow at a normal rate may impair proper diametric enlargement of the canal. Such growth impairment is a probable mechanism of spinal stenosis in skeletal dysplasia such as achondroplasia. Eccentric or asymmetric growth or closure of the neurocentral synchondroses also may play a role in the development of scoliosis.

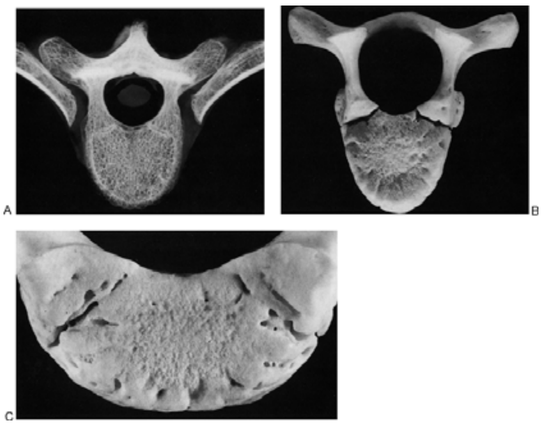

FIGURE 27. Closure stages of thoracic vertebra at 7 to 9 years. **A:** Radiograph of T6 at 9 years. **B:** Specimen of T5 at 7 years with open synchondroses. **C:** Closure of the synchondroses in T3 at 9 years. Anterior undulations counter shear stresses.

C1 (Atlas)

The anterior primary ossification center is present among fewer than 20% of neonates (Fig. 28). More commonly it appears 9 to 12 months after birth (range, 6 months to 2 years) (258). Usually this ossification center is unitary (Fig. 29). However, asymmetric, bifid, or multifocal ossification can occur (Fig. 29C) (258). The anterior center expands laterally toward each of the paired posterior ossification centers. The result is two cartilaginous gaps, which are defined as the *neurocentral synchondroses.* This anterior ossification center is called the *intercentraxium-1* (258). The anterior synchondroses are medial to the articular facets. In rare instances, the anterior center does not form, and the posterior centers progressively extend toward the centrum. By about 4 or 5 years of age, both the posterior synchondrosis and the anterior neurocentral synchondroses are fused. The spinal canal of C1 essentially reaches maximum (adult) size at a relatively early stage of postnatal development (5 to 6 years).

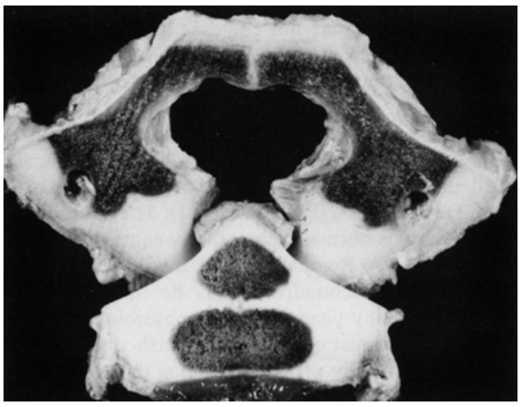

FIGURE 28. Development of C1 and C2 in a fetal Indian elephant. The anterior portion of C1, as in humans, is still cartilaginous. Only the posterior elements have ossified. Extensive confluence of cartilage of the dens and centrum of C2 is evident.

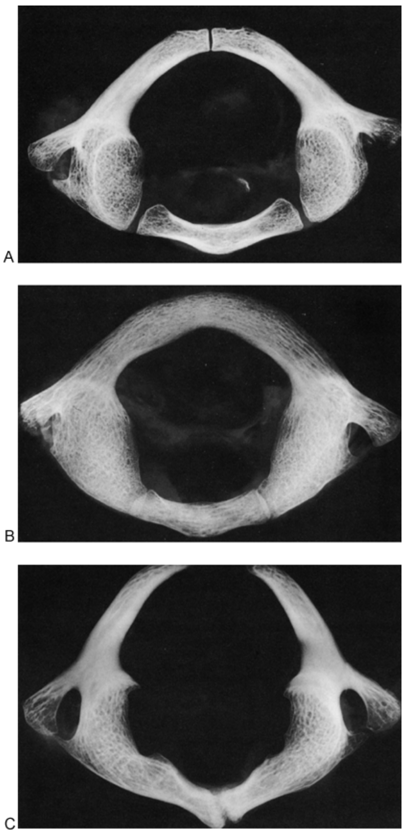

FIGURE 29. Postnatal development of C1. **A:** One and one half years. **B:** Five years. **C:** Anomalous development (8 years) with a single anterior synchondrosis (fusing) and spina bifida.

C2 (Axis)

The dens (odontoid process) develops two primary ossification centers that may not coalesce until 3 months after birth (Figs. 30, 31). This bifid nature is not the usual pattern in most mammals (259). The dens ossification is separated from the primary ossification center of the vertebral centrum by a cartilaginous region—the *dentocentral synchondrosis.* The dentocentral synchondrosis is below the level of the C1–2 articulations (Figs. 30, 31). The dentocentral synchondrosis normally closes between 5 and 7 years of age (Fig. 32). Remnants of the incompletely closed dentocentral synchondrosis may be evident on radiographs for many years after physiologic closure. The remnants must be differentiated from a fracture that can propagate along this structure as a physeal injury before skeletal maturity. The dens is a tubular bone analogue that forms a cartilaginous epiphysis at each end (chondrum terminale and dentocentral synchondrosis) and eventually forms a secondary ossification center in each end in most mammals (the os terminale and intercentraxium-2, respectively; Fig. 33). The centrum has superior and inferior epiphyses and secondary ossification centers. The inferior epiphysis of the dens and the superior epiphysis of the centrum fuse in embryos to form the dentocentral synchondrosis. The intercentraxium-2 is an analogue of secondary ossification in fused epiphyseal analogues. Humans appear unique in the absence of this secondary ossification in the dentocentral synchondrosis. There are no descriptions of this phenomenon in other higher primates.

Longitudinal growth of C2 occurs through three regions. First, the physis of the chondrum terminale contributes to the length of the dens. Failure of growth in this region may be a factor in the formation of a hypoplastic dens. Second, a small amount of longitudinal growth occurs within the dentocentral synchondrosis and contributes to both vertebral body height and dens length. Third, growth occurs inferiorly through the end plate physis.

The cartilaginous epiphysis at the tip of the dens may be transverse or form a cleft (*V* shape). This chondrum terminale at the superior end of the dens develops a secondary ossification center at 8 to 10 years of age—the os (ossiculum) terminale (Fig. 32B). Fusion of the os terminale with the rest of the dens occurs between 10 and 13 years of age (259). There is also an anterior acclivity, which is necessary to allow C1 to slide up and down during flexion and extension of the neck (325).

Mechanical Control of Growth

A factor involved in vertebral development is the exertion of physical forces on the tissues. Such forces are principally of two types. First, at the macromolecular level the developing musculature exert a force on the spinal column that increases as the tissue matures. Second, at the molecular level hydrodynamic forces are exerted on the cells as a result of retention of water within the extracellular matrix (129).

Carter and Wong and their coworkers (56,57,371) have shown that ossification centers appear in areas of high shear stresses, that the edge of the advancing ossification front is subject to high shear stresses, and that the intervertebral region is exposed to considerably hydrostatic compression. They believe that these observations support a general concept that shear stresses promote endochondral ossification and that intermittently applied hydrostatic compression inhibits or prevents cartilage degeneration and ossification.

Besides intrinsic limitations to cell division, there appears to be a mechanical restraint to elongation (275). This control factor is the periosteal sleeve, which is present to a limited degree in each vertebral body because of delayed development of the periosteum

as a discrete tissue around the vertebra. In contrast, the posterior elements develop a more typical periosteal sleeve. The sleeve has an intrinsic elasticity affected by a varying collagenous composition. When this intrinsic tension is disrupted, as in a fracture, overgrowth of the bone in relation the contralateral bone is a recognized clinical phenomenon (260). Although not as dramatic in a vertebral fracture as in long bone, the overgrowth may be a factor in recovery of vertebral height after an anterior wedge fracture in a child.

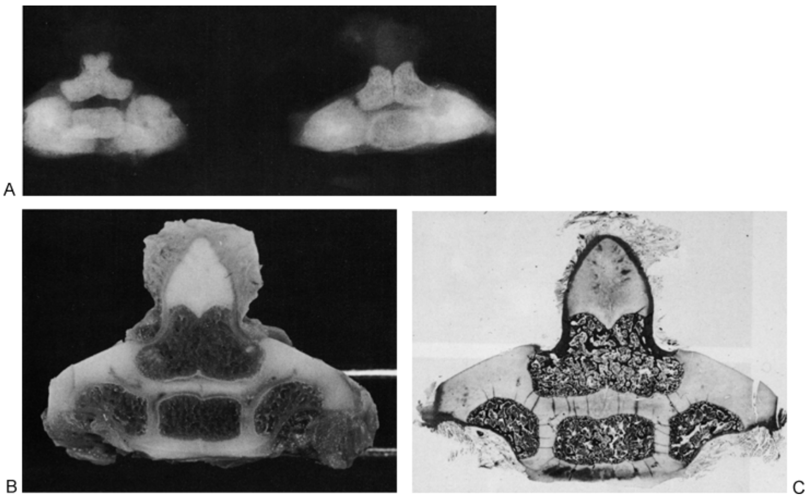

FIGURE 30. A: Radiographs of early development of C2 at term. The example on the *right* shows bifid ossification of the dens. **B:** Slab coronal section shows areas of cartilage and their continuities. **C:** Histologic appearance of C2. The dens ossification centers extend into the eventual vertebral body.

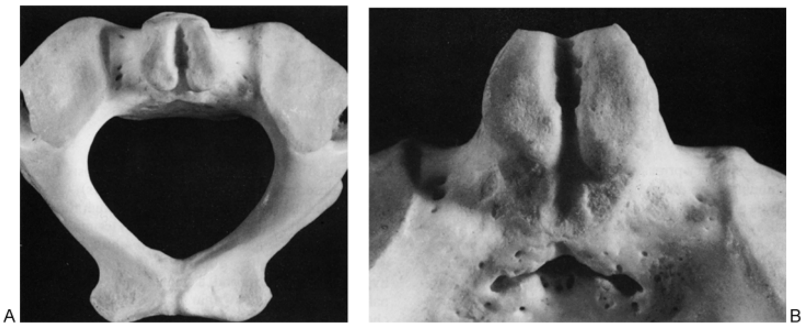

FIGURE 31. Specimen of C2 from a 10-year-old child with partial retention of the original bifid ossification process. **A:** Entire vertebra. **B:** Close-up view of dens. The underlying remnant of the dentocentral synchondrosis is also evident.

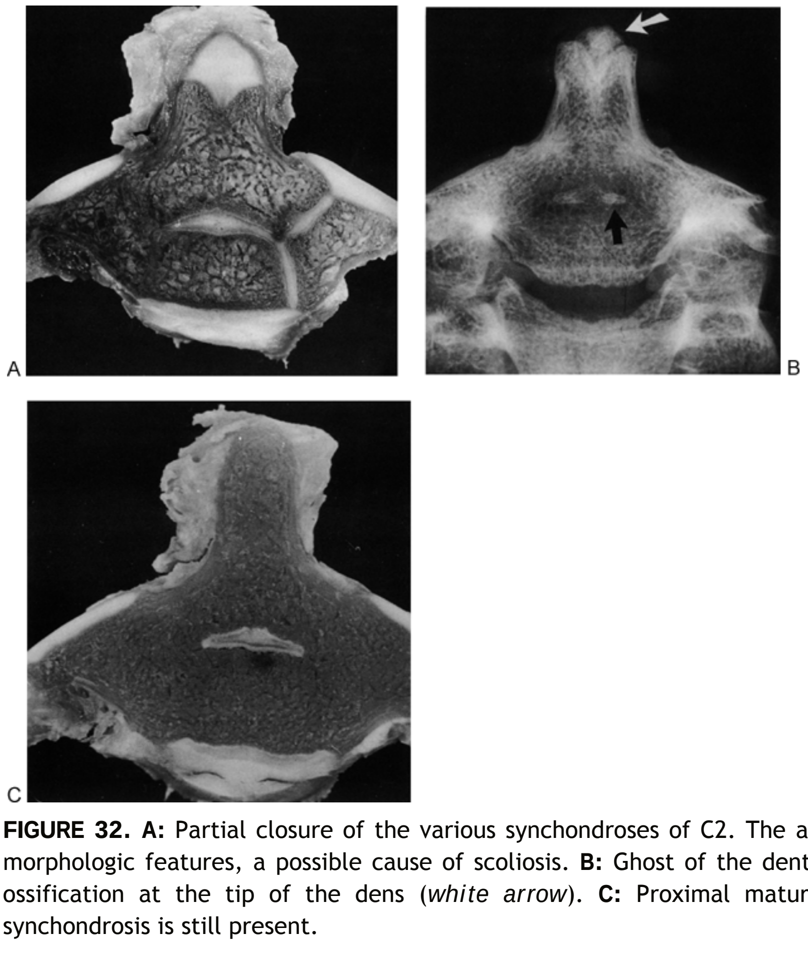

FIGURE 32. A: Partial closure of the various synchondroses of C2. The asymmetry of closure may be a factor in asymmetric morphologic features, a possible cause of scoliosis. **B:** Ghost of the dentocentral synchondrosis (*black arrow*) and secondary ossification at the tip of the dens (*white arrow*). **C:** Proximal maturation of ossification. A ghost of the dentocentral synchondrosis is still present.

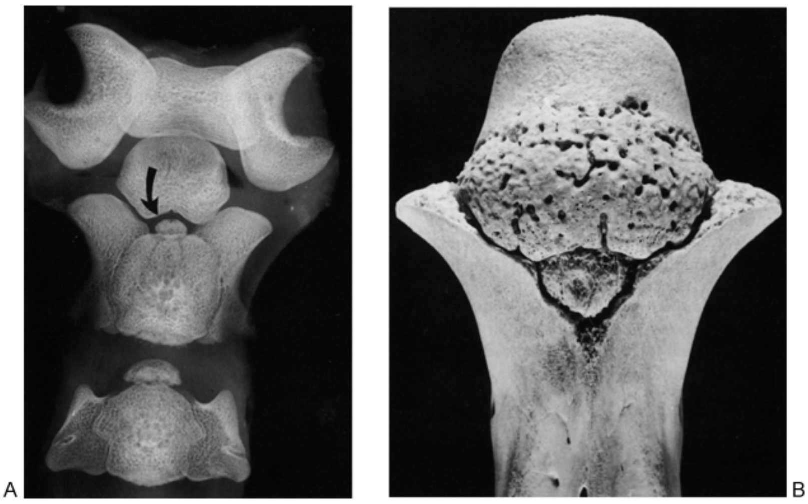

FIGURE 33. A: Radiograph shows upper cervical development in an addax (antelope). Secondary ossification (intercentraxium-2) is evident (*arrow*) within the dentocentral synchondrosis. **B:** Osseous specimen of C2 in a giraffe also contains the intercentraxium-2 and the multiple vascular penetrations of the lower dens. The more sclerotic cranial segment does not. A similar situation exists in humans and helps explain the problem of nonunion among adults with dens fractures.

Growth Mechanisms

Vertebral Growth

The primary ossification center of each vertebral body is initially associated with a spherical physis, as in epiphyseal ossification (Fig. 5). However, this center is not associated with extensive cortical bone formation, as would be expected with a metaphyseal-diaphyseal analogue. Thus ossification within the centrum resembles epiphyseal ossification, and in essence the ring apophyses are more like tertiary ossifications. After birth, the ossification center enlarges toward the sides of the vertebral mass (centrum) and the intervertebral discs (Fig. 34). Gradually the spherical growth center expands to demarcate increasingly parallel growth plates located superiorly and inferiorly. The situation is similar to, but not exactly the same as, that involving the tubular limb bones (95). Most animals have well-formed physes and epiphyses (epiphyseal ossification centers) in the superior and inferior aspects; humans and some other, but not all, large primates do not.

Longitudinal Growth

Physeal growth is the main mechanism by which each component of the axial skeleton enlarges (31,32,33). In the vertebral body, primary growth plates arise superiorly and inferiorly as a consequence of the formation of the enlarging primary ossification center (Fig. 34). These growth plates are characterized by an area of rapidly maturing cartilage that grades imperceptibly into the other cartilage of the chondroepiphysis. Although the primary function of the physis is to provide a mechanism for longitudinal growth, it also contributes greatly to circumferential expansion of the vertebral centrum. These physes change to variably undulated structures as the centrum increases in height and postnatal biomechanical demands change (260). Measurements of static diaphyseal regions such as the entrance of the nutrient artery suggest relatively equal contributions of each end plate physis to the height of the individual vertebrae.

Many species better exploit longitudinal vertebral growth through the end plate physes. A thicker end plate epiphysis is present in most mammals, and within this epiphysis a true epiphyseal ossification center forms and progressively enlarges rather than forming a thin, peripheral ring apophysis, as in adolescent humans. These structures reinforce the similarity of the increase in length (longitudinal growth) between vertebral bodies and limb bones and provide a coaptive stability for extension. The giraffe particularly exemplifies this process. Giraffes have seven cervical vertebrae that form a neck that can attain a length of more than 6 feet (1.8 m) (Fig. 35). An interesting finding was that among the large number of fetal to subadult giraffes we studied in detail, minor structural deformities, asymmetric growth, and mild cervical scoliosis appeared to be quite common (Ogden and Ganey, unpublished observations).

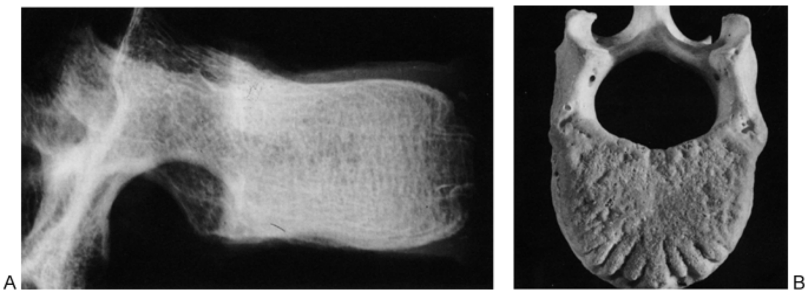

FIGURE 34. A: Characteristic lateral radiograph shows how the body often expands to the periphery in the central region first and then to the anterior and lateral "corners," leaving variable superior and inferior indentations where the remaining cartilage is present along the anterolateral margins. **B:** Osseous specimen shows how the cartilage of the end plate interdigitates with the expanding ossification center to counter shear forces as the trunk bends and twists. Anteriorly, these interdigitations have a radial (spokelike) appearance.

The contribution of the physes to longitudinal growth of the spine is important. Divided over approximately 20 to 25 vertebrae (40 to 50 growth plates), however, each physis makes a relatively small contribution to overall length. Longitudinal growth also occurs in each of the paired posterior elements. An anterior growth plate at each neurocentral synchondrosis and one posterior plate at the spinous process synchondrosis allow the laminar and pedicular regions to lengthen. As each posterior element elongates and grows away from the vertebral midline, the spinal canal enlarges. After the synchondroses close, usually at 5 to 8 years of age for most of the spine, the posterior elements are mature as far as longitudinal growth is concerned. In contrast, longitudinal growth of the anterior elements continues until 16 to 18 years of age. Asymmetric closure patterns of the neurocentral synchondroses (right versus left or longitudinally within a given synchondrosis) may be a subtle, yet predisposing factor in the eventual development of idiopathic scoliosis during adolescence.

Latitudinal Growth

Latitudinal growth of the vertebral body occurs in two ways. There is extensive latitudinal growth through the perichondrium, which surrounds most of the vertebral centrum during the first few years of development. There is also diametric growth in the physis and a thin, platelike epiphysis, both of which are responsive to physiologic stresses. As the spherical ossification center enlarges, there is an increase in appositional (membranous) bone along the sides where the ossification center extends to the periphery and induces discrete periosteum from the antecedent perichondrium (95,267,337). Individual vertebral bodies and even the posterior elements thus enlarge circumferentially by means of the combined processes of perichondral and periosteal apposition while they grow vertically (longitudinally) by means of endochondral ossification (Fig. 36). The vertebral physes enlarge in latitudinal directions by means of cell division and matrix expansion within the physis (interstitial growth). More important, they enlarge by means of cellular addition from the periphery. Interstitial growth in the transverse growth plate appears to be related to enlargement of the epiphyseal ossification center. When there is a chondroepiphysis, as there invariably is in a human vertebra, the cartilage of the epiphysis does not present a mechanical barrier to interstitial expansion within the juxtaposed growth plate.

While the physis is expanding latitudinally, the cortex of the vertebral centrum also must enlarge and serve as a peripheral structural support. This occurs through membranous bone formation, modeling, and remodeling (Fig. 37), all of which respond to biomechanical cues.

Histomorphology

The vertebral physis has a characteristic cytoarchitectural structure. The limited height of the vertebral physis after birth is a reflection of a relatively slow growth rate, especially in relation to the physis of a long bone.

In the zone of growth both longitudinal and diametric expansion of bone occurs. The reserve and dividing cells are associated

with blood vessels less in vertebrae than they are in long bones (Fig. 38A). However, large transphyseal vessels are more frequent than in a long bone (Fig. 38). The zone of Ranvier is much less evident in a vertebra, in part because of the restricted advance of the peripheral perichondrial collar. In the zone of matrix formation, increased extracellular matrix is established and undergoes the several important biochemical changes necessary for eventual ossification. The matrix calcifies, and the chondrocytes become hypertrophic, a reflection of their changing metabolic activity.

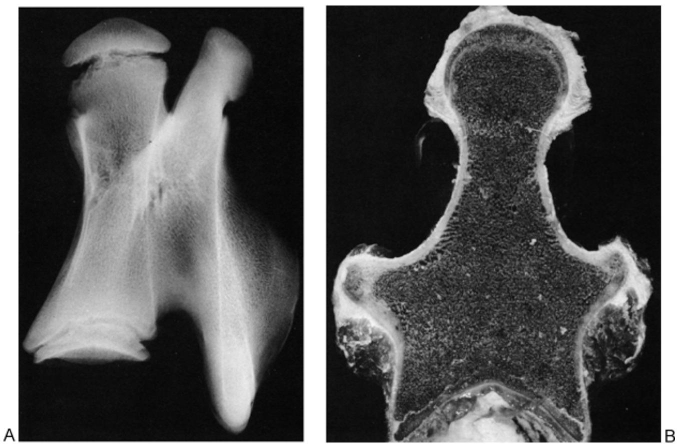

FIGURE 35. Development of a typical elongated cervical vertebra in a giraffe. In giraffes, the growth characteristics in the centrum are comparable with those of the long bones of a limb. A discrete physis and secondary epiphyseal ossification center are present at each end of the centrum. Such mechanisms are necessary to produce individual vertebrae that may attain heights of 6 to 10 inches (15 to 25 cm). **A:** Radiograph. **B:** Coronal slab section. Right-to-left asymmetry is evident. An interesting finding was that many cervical spines of giraffes studied had mild scoliosis.

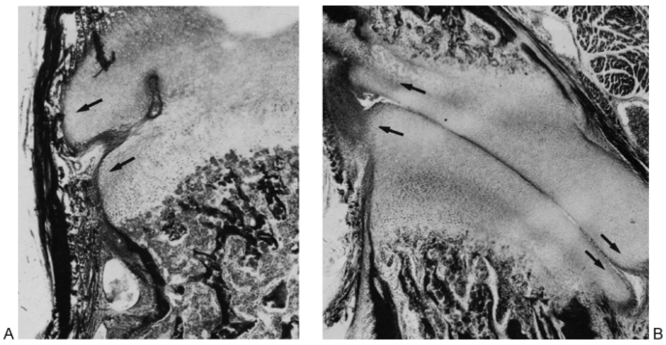

FIGURE 36. A: Area of latitudinal expansion of the vertebral centrum (*arrows*). **B:** Latitudinal expansion (*arrows*) of the posterior elements at the facet joint. These are analogous to the zone of Ranvier of a long bone and allow circumferential expansion of the centrum and latitudinal enlargement of the facet joint. As in the long bones, the peripheral membranous bone extends into this zone.

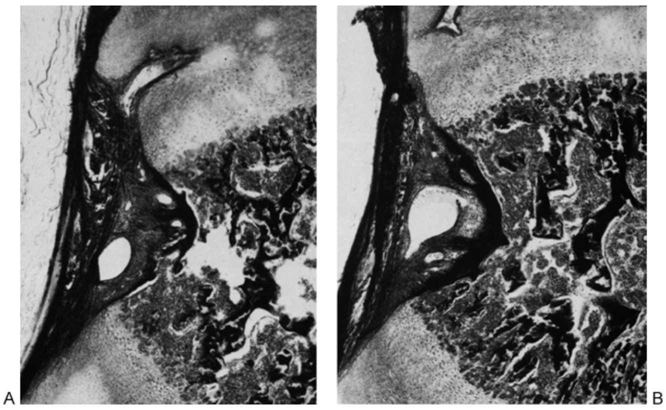

FIGURE 37. Varying degrees of cortical enlargement in thoracic **(A)** and lumbar **(B)** vertebrae. This process involves membranous bone formation, modeling, and remodeling, all of which are responsive to biomechanical demand.

In the last zone of cartilage transformation, the matrix (chondroid) is sufficiently calcified to allow vascular invasion by the metaphyseal sinusoidal loops. Endothelial cells and accompanying perivascular mesenchyme invade the space provided by hypertrophic cell apoptosis and provide cellular components for initial bone formation. Osteoblasts elaborate osteoid matrix directly on the preformed chondroid septa that are retained preferentially over the transverse septa that originally separated chondrocytes within hypertrophic columns.

This tissue is quickly mineralized to produce bone matrix, the primary spongiosa. By means of subsequent remodeling in the metaphyseal analogues, the initial bone is gradually removed and replaced by more mature secondary spongiosa that no longer contains remnants of the cartilaginous precursor. This process is abbreviated in the area around the centrum but is more evident in posterior elements (Fig. 1). Remodeling occurs throughout the growth period and after skeletal maturation. Failure to remodel in response to biomechanical stress may be a predisposing factor for microinjury and may lead to increased kyphosis.

“Ring” Apophysis

Because of ellipsoid enlargement of both the intervertebral disc and the primary ossification center in humans, the central epiphysis progressively thins and the lateral and anterior circumferential portions remain thick. The thickened periphery often is called *apophysis* (190,268), a term not completely appropriate. Most of the time these regions are subjected to compression and shear forces rather than pure tension, as befits the specific definition of an apophysis. On radiographs these regions may appear to be set in a groove extending around the upper and lower borders of the developing vertebral bodies. When this region is subjected to an increase in, if not pathologic, pressure, these indentations are accentuated, probably because of focal slowdown of endochondral ossification. The situation resembles formation of lateral irregularity and an increase in acetabular index in developmental dysplasia of the hip. This variation ossification may cause the vertebral changes usually called *Scheuermann* *disease.* This is not a disease but is a biomechanical response to abnormal stress in an actively growing and remodeling segment of the axial skeleton.

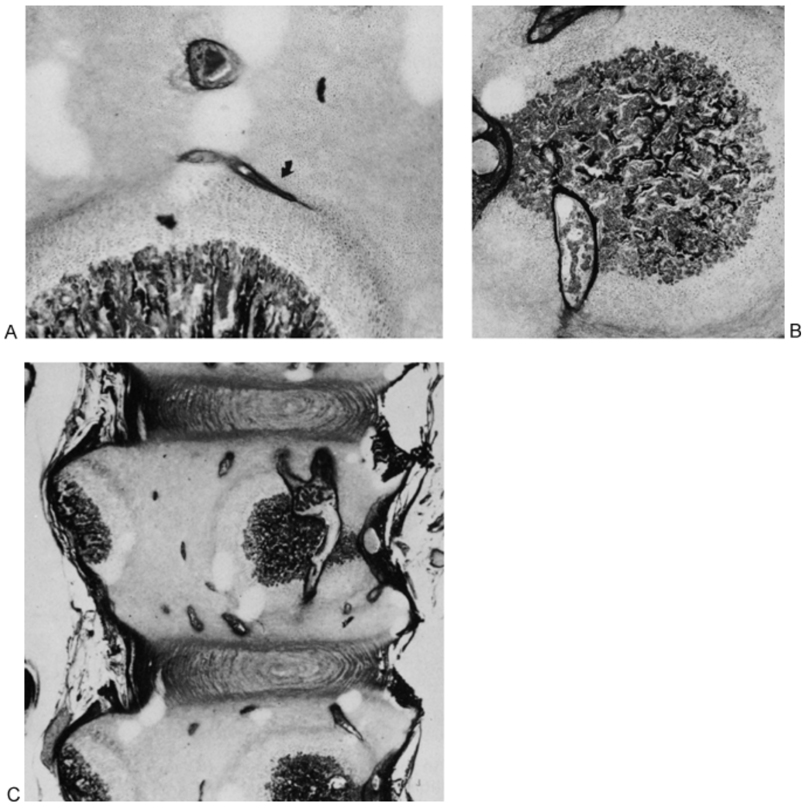

FIGURE 38. Vertebral vasculature. **A:** Epiphyseal (*E*) vessel (*arrow*) formation in the germinal zone comparable with that described for long bones. **B:** Large epiphyseal vessel (superiorly) and transphyseal vessel (inferiorly). The inferior vessel is surrounded by bone crossing the physis. However, in the absence of epiphyseal bone, impairment of growth does not occur. Such structures may be a defect that allows development of Schmorl nodules after skeletal maturation. **C:** Extensive vascular region extending across most of the vertebra and including both the superior and inferior physes.

Between 11 and 14 years of age, foci of ossification (Figs. 39, 40, 41) develop within the end plate epiphyses (31,33,156,190). By 12 to 15 years of age, these ossific foci form the radiologic "ring" analogous to the secondary ossification center of the tubular bones. This ring extends to and usually beyond the neurocentral synchondrosis (Fig. 41). The ring does not involve the entire circumference of the vertebral body, and as a secondary ossification manifestation does not greatly contribute to growth of the vertebral body. Growth occurs, instead, through the contiguous, previously described physes. In humans rings develop primarily in the periphery. Most other mammals have a plate-like epiphyseal ossification center (Fig. 42). Because spinal flexibility is generally has a juncture at the disc articulations of opposing vertebral bodies, a complete epiphyseal plate buffers the physes from shear forces. When the cant ilevered structure of the quadruped spine is taken into account, stress shielding offers a protective advantage in maintaining an aligned architecture and a balanced growth trajectory.

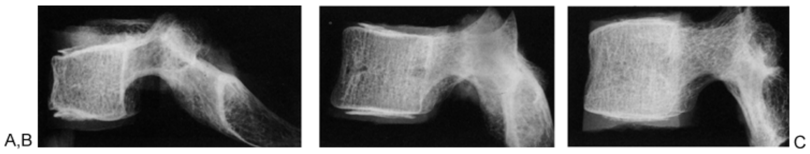

FIGURE 39. Variable stages of development of end plate and ring apophysis at T2 **(A)**, T8 **(B)**, and T12 **(C)** around 12 years of age. These form in the midthoracic region and extend cranially and caudally.

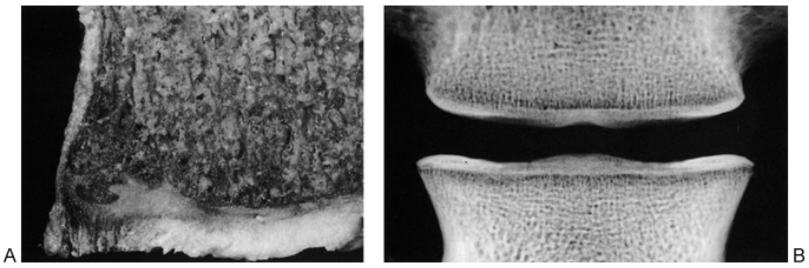

FIGURE 40. A: Appearance of a ring apophysis in L3 in a 16-year-old human. There is a very thin cartilage layer between the bone and the disc material. Impairment of growth and chondroosseous transformation in this region, comparable with impaired lateral acetabular development in hip dysplasia, is a likely cause of Scheuermann disease and thoracic kyphosis. **B:** Radiograph of fused ring apophyses in an adolescent baboon.

In deference to the prevalent morphologic features of mammals, axial loading of the human spine in most instances neutralizes the value of a spanning epiphysis in the vertebral centrum. However, the susceptibility of the human spine to focal damage from shear forces is an important consideration. Both postural influence and sensitivity to acute injury are enhanced by the lack of a full epiphyseal plate. In some mammals, the ossification centers unite anteriorly, effectively limiting further longitudinal growth (Fig. 43). The analogous structure in humans, the longitudinal epiphyseal bracket, is distinctly abnormal (217).

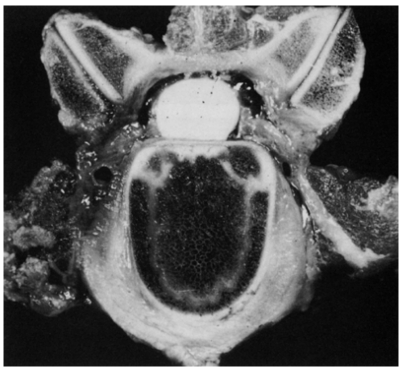

FIGURE 41. Transverse section of a cape water buffalo showing how the "ring" extends anterolaterally to the neurocentral synchondroses.

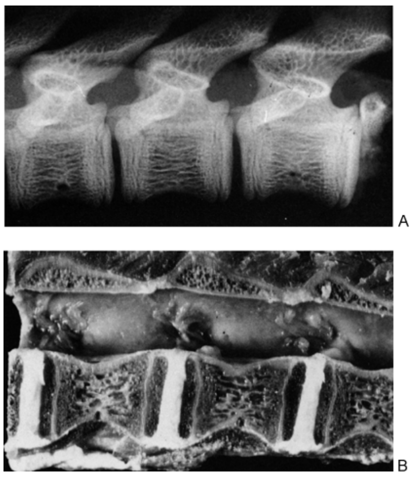

FIGURE 42. Most mammals have well-developed secondary ossification centers rather than ring apophyses. Radiograph **(A)** and midsagittal section **(B)** from an impala.

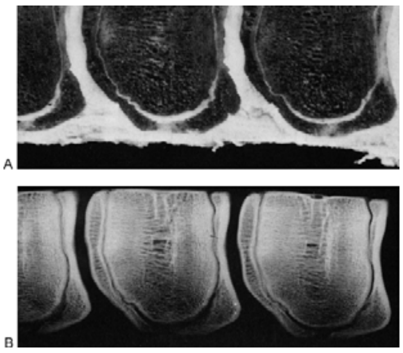

FIGURE 43. In some species, such as Grevy's zebra, the secondary centers grow toward each other anteriorly, producing a situation similar to the longitudinal epiphyseal bracket in humans. **A:** Midsagittal section. **B:** Radiograph. This process may direct the development of certain spinal curvatures in these animals. To our knowledge, this phenomenon has not been described for human vertebrae.

Physeal Undulation

Throughout prenatal development, the physis vertebral centrum is usually a spheroid structure. With increasing biomechanical demands, especially shear stresses from walking and running (upright stance), the physis progressively changes contour (56,57,317,376). Biologic demands on a given species may be assessed by means of evaluation of these contour changes, which undoubtedly are affected by both genotypic and phenotypic factors. These undulations are not as prominent in a vertebra as in a long bone, but they can be visualized on prepared specimens (Figs. 27 and 34). In certain mammalian species, such as dolphins, these undulations are almost like the spokes of a bicycle wheel. They afford biomechanical structural modeling and adaptation to considerable rotatory shear forces during sinusoidal swimming motions (268).

Segments of the growth plate may be left behind as the physis continues to grow away from the central reference point (Fig. 44). This commonly occurs in the long bones and is evident in enchondromatosis. A similar phenomenon in the developing spine may be the precursor of Schmorl nodules. Disc tissue extends into these osseous defects after skeletal maturation.

Growth Slowdown Lines

Special radiographic lines reflect alterations in the rate of longitudinal growth from a given physis. These lines, called *Harris growth arrest* or *slowdown lines*, are transversely oriented trabecular bands of increased radiodensity within the metaphyses and proximate diaphyses. Histologic examination shows these lines to be thickened, transversely interconnected trabecular networks with typical, longitudinally oriented trabecular bone on either side. The lines appear after a temporary slowdown of rapid longitudinal bone formation in the primary spongiosa and usually parallel the contours of the adjacent physis. At the interface of the advancing growth plate, bone formation yields a wake of longitudinally oriented trabeculae with interspersed marrow elements. When growth rates slow temporarily, trabeculae thicken in the hormonal milieu of differentiation and may fuse with each other transversely. When the abnormal process, such as a fracture or systemic illness, responsible for retarding growth subsides, rapid rates of endochondral growth and transformation resume, and the characteristic longitudinal trabecular orientation forms. As the bone elongates, these transverse lines are then progressively displaced from the physis. This phenomenon also occurs in the vertebral bodies (Fig. 45A), but it is not as easy to detect on clinical radiographs because of overlying tissue densities. As the metaphyseal bone remodels to diaphyseal bone, these trabecular lines gradually remodel and disappear completely by the time skeletal maturity is reached. This phenomenon may be present in a vertebra as a ghost or as a vertebra within a vertebra (Fig. 45B). No detailed studies of these lines in vertebrae have been undertaken.

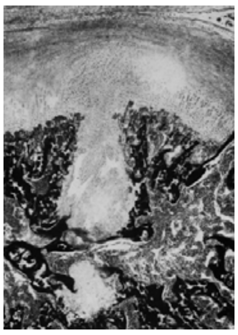

FIGURE 44. Retention of physeal tissue within the expanding ossification center. This may also be a precursor of a Schmorl nodule. Radiographically it would be of comparable appearance.

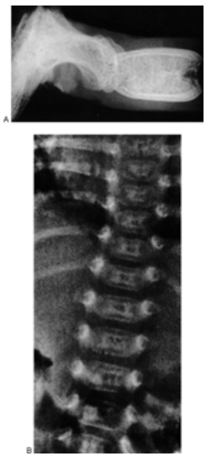

FIGURE 45. The spinal equivalent of Harris growth slowdown lines. **A:** Radiograph of T6 shows superior and inferior lines parallel to the end plate physes. **B:** Radiograph of a patient approximately 1 year of age shows vertebra-within-a-vertebra phenomenon. Patient had had severe sepsis in the neonatal period.

Growth Cessation

Once physiologic stimulation of growth has stopped, the physes regressively cease to be a dynamic element in tissue modeling. In the vertebral body this is concomitant with fusion of the secondary (ring) ossification center to the contiguous metaphysis. This process begins earlier in girls than in boys and like the appearance of primary and secondary ossification centers follows a reasonably predictable sequence. The earlier closure in girls may be due to the presence of estrogenic compounds that accelerate cartilage replacement and osseous maturation. Although the time of onset and completion of fusion are influenced by the sex hormones, the chronologic relations between individual bones is similar for both sexes.

Fusion of the end plate ossification center with the primary ossification center of the vertebral body begins at 14 to 15 years of age but may not be completed until 20 to 22 years in the lumbar region, especially among men. Figure 42 illustrates the comparable process in an animal forming distinct epiphyseal ossification centers.

The closure pattern of the physes at the facet joints has not been studied despite its potential role in asymmetric growth in idiopathic scoliosis. However, continuing data from our skeletal development laboratory suggest that this region is progressively replaced by bone by direct invasion, not unlike the process that occurs in the nonepiphyseal ends of the phalanges, metacarpals, and metatarsals (266).

Vasculature

The developing vertebral chondroosseous skeleton has a complex blood supply within the anterior and posterior anlagen and at the perichondrial surface (68,69,106,134). These various macrocirculatory and microcirculatory systems flux constantly and are essential to initial bone formation and remodeling (Fig. 46), neither of which can occur in the absence of these systems (44,216).

The circulation varies structurally with the appearance and growth of the ossification center. Vessels initially enter and distribute throughout the centrum within specialized structures called *cartilage canals* (Figs. 1B, 17B, 19B, and 46A). These canals grow into the centrum from both the anterior and posterior aspects. Unlike the long bones, canals communicate frequently across the physes (Fig. 47) to supply germinal regions and the intervertebral tissues. They are a potential route for spread of infection or tumor from the metaphysis into the epiphysis and disc. Unlike the centrum, the posterior elements are not characterized by the presence of extensive cartilage canal. The posterior elements ossify by means of eccentric vascular penetration from the periosteum with a progressively enlarging eccentric ossification center that expands from the inner surface toward the outer surface as well as anteriorly and posteriorly.

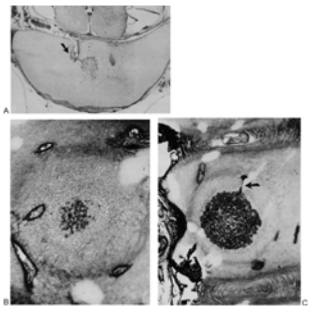

FIGURE 46. **A:** Extension of a cartilage canal (*arrow*) to reach the hypertrophic cells, a necessary step for ossification. **B:** Central hypertrophy and preossification surrounded by many cartilage canals. **C:** Further expansion ossification without peripheral bone collar. A contributing canal is evident (*arrow*).

Within the vertebral centrum, each cartilage canal contains a central artery and vein and a complex capillary network that surrounds the central vessels but stays within the confines of the canal and eventually forms a glomerular tuft as the end-arterial terminus of the canal system. Research has shown an absence of blood cells and, presumably, an absence of active circulation within these obvious anatomic structures before formation of the secondary ossification center (120). Calcification seems to enhance the activity of the circulation, as in the phenomenon of vascular invasion of the hypertrophic region of the calcified physis of a long bone. Such vascular invasion is impaired in calcium deficiency syndromes (rachitic disorders).

Cartilage canals serve several important functions. First, they supply discrete regions within the centrum with virtually no intraepiphyseal anastomoses between regions of the adjacent canalicular system. Second, the canals enter the centra at fairly regular intervals along each vertebra. Third, the canals serve as a cell conduit for additional chondroblastic and osteoblastic cells that facilitate continued chondroosseous maturation and enlargement of the ossification center.

The cartilage canals play a primary, essential role in the development of the ossification center of the centrum. The first sign of endochondral transformation is hypertrophy of the cartilage cells at the presumptive site of the ossification center (Fig. 46). This site, the preossification center, has both genetic and biomechanical determinants, a fact readily evident in the delayed secondary ossification of the capital femoral epiphysis of a subluxed or dislocated hip. The hypertrophic cells are brought into proximity with a cartilage canal system by means of progressive ingrowth. At first one and then multiple canals extend into this hypertrophic cell mass, but only after it has become analogous to the calcified, hypertrophic region of the physis. The ossification process enlarges, and a zone of hypertrophic and calcified cartilage cells (a spherical physis) surrounds it. One or two vessels from the anterior and posterior surfaces usually develop as the predominant blood supply.

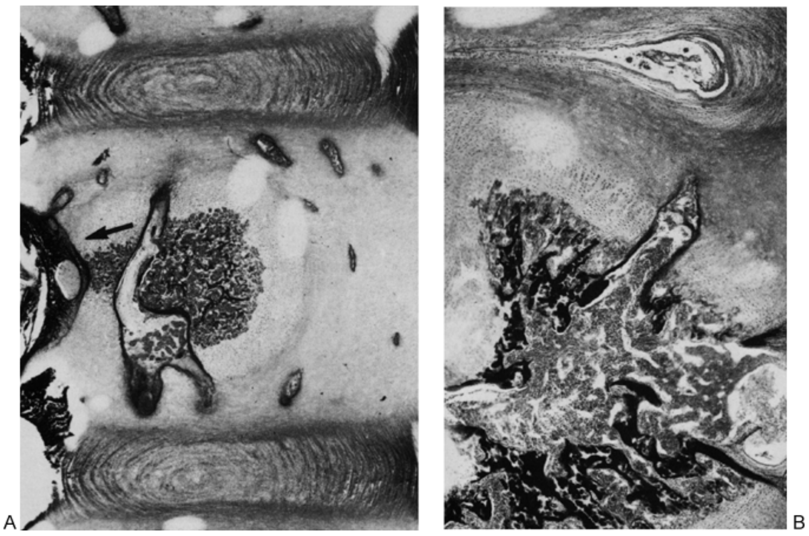

FIGURE 47. A: Anterior extension of the ossification center toward an early bone collar (*arrow*). A large vascular confluence is present. These appear to be relatively common in the developing centrum, unlike in the long bone epiphyseal-physeal vasculature. **B:** Extensions of vascularity and bone through the spherical physis toward the disc, which also has a large vascular region. This may be the anatomic explanation for combined osteomyelitis and discitis in childhood. The physis has well-demarcated regions similar to the physis of a long bone.

Guida et al. (134) studied the vascularization of the vertebral body at term. They demonstrated that each centrum has two anterolateral vessels stemming from the aorta and three or four posterior vessels that often originate from the same anterolateral vessels and transverse around the sides of the centrum and through the neuroforamen to reach the posterior centrum. Within the vertebral body there are multiple anastomoses.

Continued expansion of the centrum ossification center depend on the blood vessels (Figs. 47, 48, 49, 50). When normal flow is disrupted, osteocytes die rapidly. After recovery, the damaged bone must be replaced with viable bone. The initial bone in the secondary ossification center was biomechanically responsive in its trabecular orientation, but the rapidly formed new bone is not initially responsive and is thus susceptible to low-grade stress, especially at the interface of new and dead bone.

Within the vascularized chondroosseous epiphysis, the spherical growth plate expands centrifugally through rapid interstitial expansion and by means of radially directed longitudinal growth associated with metaphyseal ossification. Interstitial expansion of the spherical physis occurs almost throughout the existence of the ossification center. As the center expands toward the various surfaces of the vertebral body, the outer surface contains more and more platelike bone and fewer fenestrations. This delimits the amount of circulatory ingress, although, as demonstrated in Figs. 47 and 48, transphyseal circulation is frequent and may be an important source of epiphyseal circulation (germinal zone vascularity).

The enlargement of the centrum ossification center leads to juxtaposition of part of the spherical growth plate against the intervertebral tissues. The epiphyseal contribution is eventually replaced by a subchondral bone plate, but the remainder of the spherical growth plate may still be present at the interface of the epiphyseal margins and the peripheral boundary at the disc. This configuration allows continued osseous expansion commensurate with diametric expansion of the ossifying center. Actual latitudinal expansion of the centrum continues through the surrounding perichondrium and enlarges the cartilaginous antecedent model.

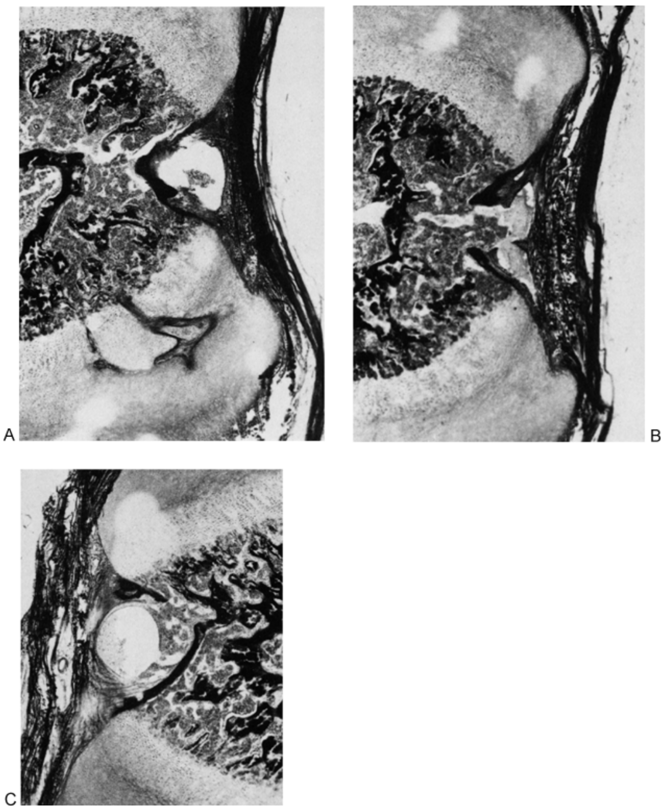

FIGURE 48. A–C: Variations in the posterior bone collar. This region is usually associated with a large vascular region (lakes). The vessels cross the physis in **A**.

As the ossification center forms and enlarges, the epiphyseal circulatory pattern changes. When the subchondral (cribiform) plate forms, small vessels cross this osseous plate and form vascular expansions that supply discrete regions of the physis and extend toward the intervertebral tissues.

Ferguson (106) emphasized the concept of dorsal (posterior) and ventral (anterior) blood lakes. Evident in Fig. 48, these lakes are closely associated with the developing peripheral ossification processes, although the exact role they play in hemodynamics is uncertain. These lakes can be disrupted with surgical exposure, and excessive bleeding can result.

Perichondrial Vessels

The perichondrial circulation shrouds each vertebral centrum, although with considerable anatomic variation, especially in relation to the vascular systems of the long bones. The most important derivation appears to be the system of small vessels within the zone of Ranvier (Fig. 48). The functional integrity of these vessels in the zone is essential to continued appositional growth at the periphery of the centrum and posterior element growth plates. Disruption of the perichondrial system may produce isolated areas of ischemia along the periphery and subsequent eccentric growth. Circulatory patterns in both the perichondrial circulation and its intraepiphyseal contributions change gradually and affect the susceptibility of a region to ischemic damage. Impairment of this circulation in the anterolateral regions may seriously affect chondroosseous transition and may be a factor in irregular radiographic appearances.

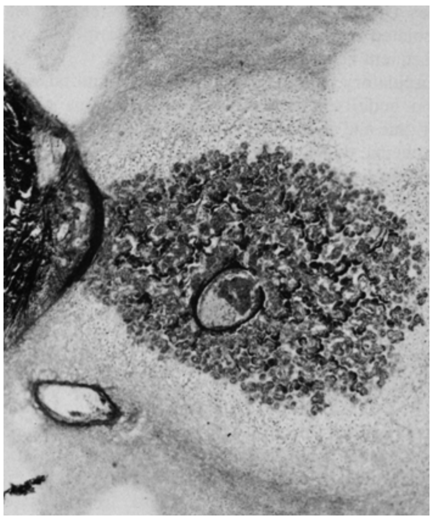

FIGURE 49. Vascular lake within the ossification center.

Circulation in the Posterior Elements

The posterior elements derive their blood supply from branches of the same arteries that supply the centrum (93). These vessels proceed dorsally to reach each of the paired posterior elements. As such, compromise of an anterior parent vessel can compromise posterior and anterior circulation and accentuate the progression of scoliosis because of asymmetric vascular insufficiency.

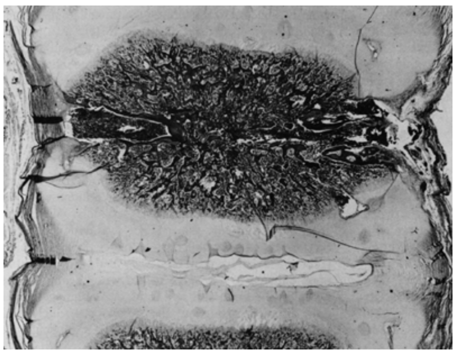

FIGURE 50. Image from near the end of gestation shows established fetal vertebral centrum and maturing anterior and posterior vascular contributions.

Vascular Disruption

When a region of the epiphyseal vasculature is either temporarily or permanently compromised, the zones of growth and transformation associated with these vessels cannot undergo appropriate cell division and maturation. Unaffected regions of the physis continue their longitudinal growth, and the affected region is left behind. The growth rate of the cells adjacent to the infarcted area is more mechanically compromised than that of cells farther away (277). If the involved area is peripheral, an angular deformity may occur. This may be a mechanism involved in Scheuermann disease.

Because vascular disruptions may be transient, the physis has a certain amount of recovery capacity. However, when circulation is restored, the cells most responsive are those that encircle the physis in and adjacent to the zone of Ranvier. DeSalis et al. (78) showed that circulatory disruption of one of the neurocentral synchondroses over several vertebrae caused scoliosis. Histologic studies showed that the neurocentral synchondroses on the convex side stayed open longer than those subject to vascular compromise. They also showed contiguous damage to the spinal cord preferentially on the side of the vascular damage rather than diffused throughout the spinal cord. Such cord changes may affect the segmented spinal musculature and further contribute to asymmetry of growth.

Clinical Application

It is extremely important to thoroughly assess all components of the spine and spinal cord and not to concentrate on only the radiologically obvious, that is, osseous, skeletal deformities when planning treatment, particularly when a patient has congenital spinal abnormalities. Deformities still in a cartilaginous phase may not be readily evident until sufficient postnatal growth and chondroosseous transformation have occurred to allow definition with routine radiography. Progression of deformity tends to be slower in the cartilaginous phase but becomes more evident with increasing ossification, not unlike the slow and later rapid progression of angular deformity in a limb bone from an osseous bridge after trauma or infection. The treating physician must be prepared to alter concepts of deformity and treatment, actual or intended, on the basis of the evolving anatomic deformity.

Arbitrary standards for values of various degrees of motion, distances, and so forth that are commonly applied to the evaluation of adult spines are not always applicable in the treatment of children. Nonossified cartilage can exaggerate a discrete measurement, placing it in the range that is pathologic for adults. It is important to base treatment decisions on the normal radiographic values for children rather than on those for adults (42,49,154,222).

The morphologic variations of congenital and acquired deformities, diseases, and trauma involving the spines of patients with immature skeletons are logically and clinically approached through an appreciation of prenatal and postnatal developmental biologic mechanisms at the molecular and cellular levels. Equally important is how the constantly changing microscopic and macroscopic anatomic differences of growing children compare with the relatively static skeletal components of adults (100). It is essential to realize the wide variation of basic steps in prenatal and postnatal skeletal development that may manifest in deformity despite initial radiographic similarity (286).

Congenital deformities invariably affect more than the evident osseous axial skeleton, especially among children younger than 5 years. Radiolucent cartilaginous, vascular, and neuromuscular structures may be altered or deficient and may thwart well-planned attempts at improvement if treatment is based only on radiologically evident changes (62). Acquired diseases and injuries can alter normal patterns of growth and necessitate modification of otherwise standard approaches, especially if the principles of adult surgery are applied. Deformities may recur among children because of inability to correct the causal (whether genetic or acquired) growth aberration. The biologically fluid (plastic), constantly remodeling skeleton does not always require the same types of prolonged immobilization and rigid fixation used for comparable treatment of adults.

Congenital spinal anomalies range from those so frequent that they should be considered normal variants, such as spina bifida occulta of L5, to major structural defects. Many major defects are related to somite malformations; these include block (unsegmented) vertebrae, wedge vertebrae (hemivertebrae and butterfly vertebrae), incomplete neural arch fusion, spina bifida, congenital bars, block vertebrae, absence of pedicle formation, and asymmetric pedicular enlargement. Limb abnormalities, such as radial hemimelia, often occur concomitantly with spinal abnormalities. There also is a relatively high incidence of renal, genitourinary, and gastrointestinal deficits. The following sections briefly correlate developmental morphologic features with potential treatments and the usual course of the condition.

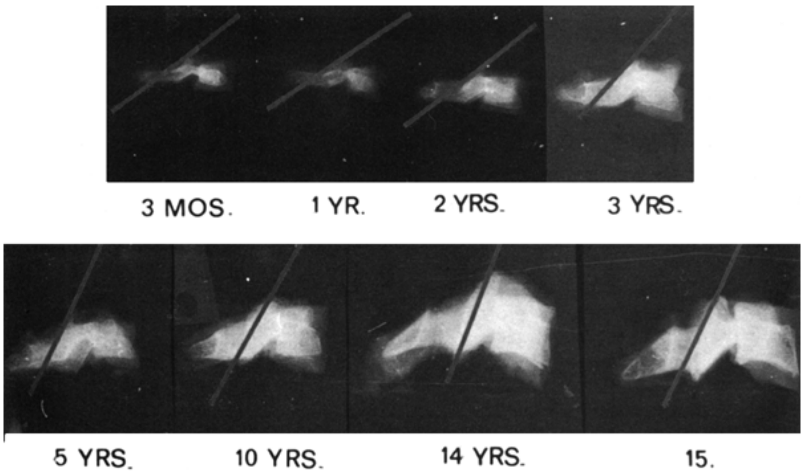

FIGURE 51. Changing pattern of angulation of the superior facet joint of C3 between 3 months and 15 years of age.

Hydromyelia and Syringomyelia

Hydromyelia occurs when the neural canal is retained (Fig. 19). This diagnosis is being made increasingly with the use of magnetic resonance imaging (324). Hydromyelia may be limited to only a few segments or extend for most of the cord. In most patients it is probably a structural variation rather than a definitive pathologic condition. Interpretation must be based on and correlated with the findings at clinical examination.

Syringomyelia can originate through slow dilation of the retained neural tube (canal). In children with spina bifida, syrinx enlargement may be caused by obstruction in the ventricular system. Syringes also may have posttraumatic or postischemic causes. Although most syringes appear stable, some may rapidly accumulate fluid, expand, and compress spinal cord tissue between the syrinx and the inner walls of the vertebral arch. Such a syrinx may be associated with the rapid onset and progression of scoliosis.

Cervical Hypermobility

The facet joints of the upper cervical spine are less oblique (more horizontal) than those of the lower cervical spine of young children (Fig. 51) (260). This allows considerable forward motion in flexion, especially at the C2–3 and C3–4 joints, and causes the phenomenon of pseudosubluxation (58,323). As the upper cervical spine matures, the facet angles become more oblique (more vertical) and subluxation becomes less accentuated (260). The thoracic and lumbar vertebrae follow similar developmental patterns of changes in facet orientation, but the phenomenon of pseudosubluxation is not as readily evident. Rotational changes in the orientation of the planes of the thoracolumbar facet joints also can occur. Asymmetric changes may be a subtle predisposing factor in idiopathic scoliosis. Such a predisposition to scoliosis with asymmetric development of the thoracic vertebrae has been found in rodents (172).

Congenital Scoliosis

Pathogenesis occurs very early in development, commonly before 6 weeks after ovulation (85,89,94,142,151,287,329). The deformity may occur by means of failure of formation. Typical patterns are unilateral hypoplasia (wedge vertebra) and aplasia (block vertebra or hemivertebra; Fig. 12). An alternative explanation is failure of segmentation that which leads to bar formation and affects anterior elements, posterior elements, or both. A combination of these deformities also may be present (Figs. 52, 53).

The anomalous vertebrae may or may not be radiographically evident at birth, depending on the extent of the abnormality and how much of the area has ossified (Fig. 53). For example, a hemivertebra may be represented by an asymmetric ossific center. Early definition of the exact structural defect may not be easy (Fig. 53). However, the earlier a specific deformity is properly classified, the sooner can appropriate treatment be instituted.

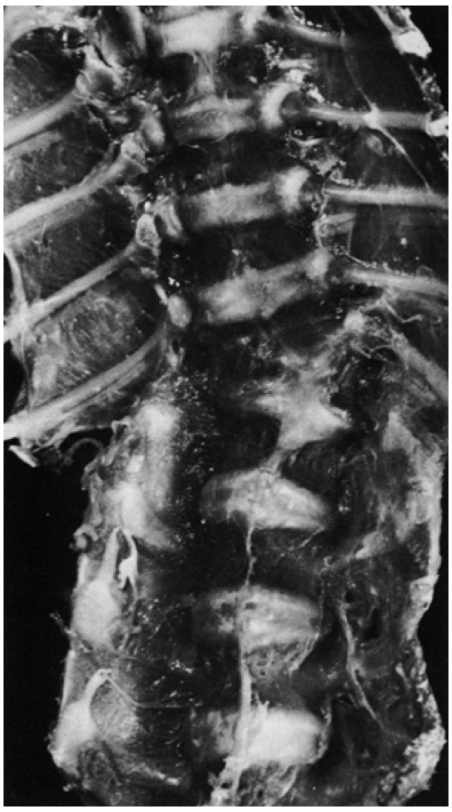

FIGURE 52. Congenital scoliosis in a greater kudu (antelope). The animal was stillborn.

Longitudinal growth of the vertebral column occurs at each end plate anteriorly and by means of periosteal apposition posteriorly. If growth is tethered unilaterally by a bar, a deformity is likely because normal development occurs contralaterally. Conversely, absence of growth potential may lead to increasing deformity because of the present of normal posterior growth coupled with anterior deficiency. Congenital vertebral anomalies thus cause progressive curvature. The rate of progression, however, is highly variable.

Congenital Kyphosis

Congenital kyphosis often is caused by a hemivertebra located within the posterior aspect of the centrum. The size of the hemivertebra and whether it is attached by cartilage to an adjacent vertebra determine the rapidity of progression. A congenital kyphosis may not be clinically evident at birth, even with an evident hemivertebra. It manifests, however, as the vertebral column undergoes chondroosseous maturation and spinal elongation and particularly after the patient assumes an upright posture, whether sitting or standing.

The spinal cord appears to be much more susceptible to injury in congenital kyphosis than it is in congenital scoliosis. Any evidence of cord dysfunction necessitates urgent treatment to stop or reverse progression. Parents need to be warned of the risk of neurologic worsening, even with in situ, noninstrumented spinal fusions.

Klippel-Feil Syndrome

The Klippel-Feil syndrome involves variable portions of the cervical spine (Fig. 54), particularly fusions of several levels of the anterior and posterior components of the cervical and on occasion the upper thoracic spine (11,28,130,135,152,153,165,188,192,239,265). Spina bifida and Sprengel deformity (omovertebral bone) are frequently present. The extent of deformity is not always evident in the first year or two of life. Many patients do not come to medical attention until adolescence, when they are being evaluated for neck pain after an evocative situation, such as football or wrestling (260).

Perhaps the most serious problem is the insidious impingement on the cord that occurs when limited motion segments begin to move excessively, especially during adolescence. For example, in cases of C1–3 and C4–7 fusion, there is only one important flexion-extension region, namely the C3-4 articulation. Forward motion (flexion) may chronically impinge on the cord and slowly lead to long-tract symptoms consequent to subtle, progressive spinal cord damage. Complete fusion of this "remaining motion" segment may be necessary to alleviate not only the symptoms but also cord damage.

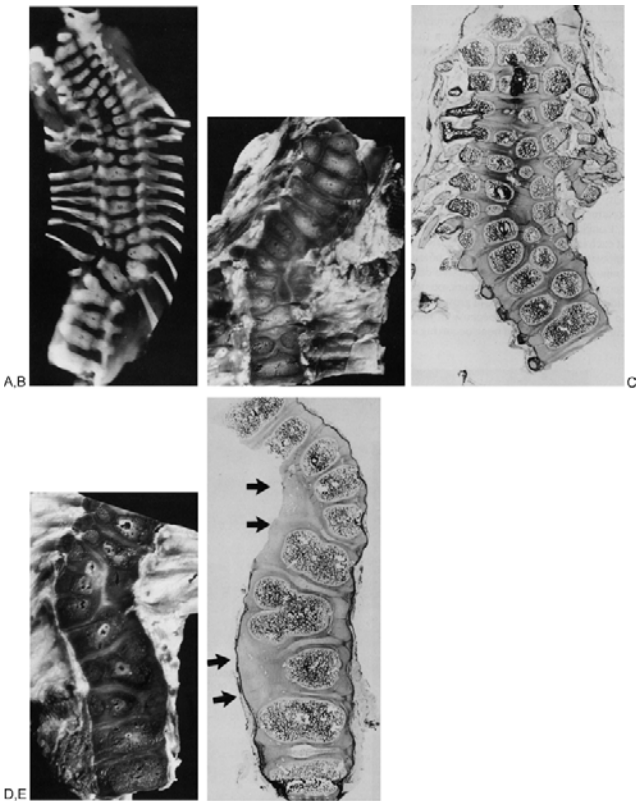

FIGURE 53. Multiple congenital vertebral anomalies in a human stillborn with congenital scoliosis. **A:** Radiograph of the entire spine. **B**, **C:** Morphologic and histologic sections of the cervical and upper thoracic regions. **D, E:** Morphologic and histologic sections of the lower thoracic and lumbar regions. Of particular importance is the cartilaginous continuity over several deformed segments (*arrows*). This would have been radiolucent at first, but it eventually formed a multilevel bar.

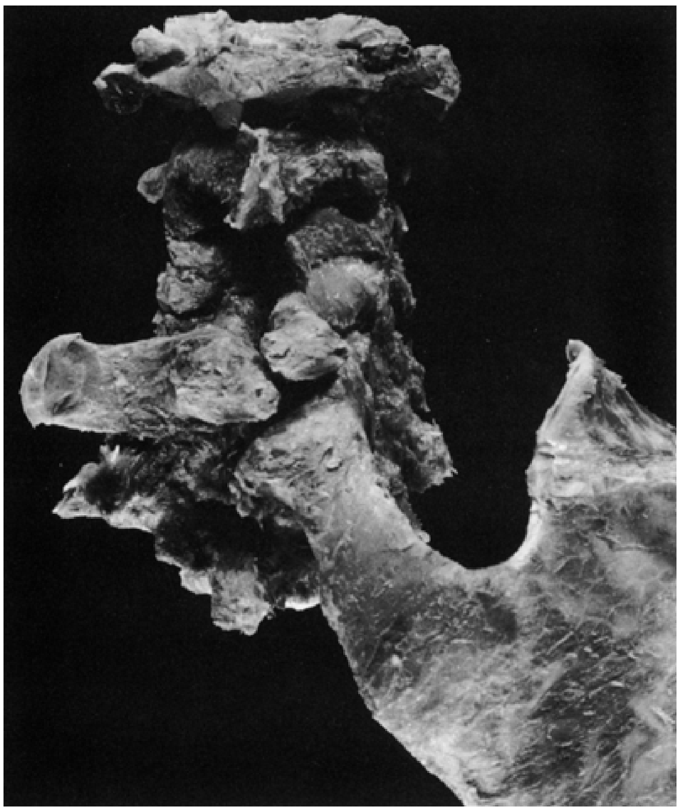

FIGURE 54. Spina bifida of the cervical spine of a patient with Klippel-Feil and Sprengel deformities.

Spina Bifida and Dysraphism Complexes

Dysraphism is failure of fusion of posterior midline vertebral structures. In rare instances the anterior structures are affected. The spectrum of spina bifida, the most obvious form of spinal dysraphism, ranges from myeloschisis to myelomeningocele, meningocele, and spina bifida occulta (Fig. 55 ; see also Fig. 18). Myeloschisis and myelomeningocele probably occur during the embryonic period. Meningocele and spina bifida occulta more likely develop during the fetal period because of incomplete chondroosseous transformation. A minor defect in the spinal cord or meninges may prevent development of the normal amalgamation of the posterior element. However, the converse is not true. That is, an abnormal posterior arch can occur in the absence of a neurologic problem.

The posterior elements may be incompletely formed and oriented laterally (Fig. 56). This redirects the spinal extensor musculature anteriorly such that the muscles act as flexors and contribute to increased kyphosis at the level of the bifida defect. Failure of proper formation of the posterior elements contributes a great deal to the difficulty of instrumented spinal fusion. For example, pedicle screw placement is challenging if not impossible.

Lumbosacral Agenesis

The incidence of lumbosacral agenesis is high among prediabetic and diabetic mothers, yet the exact role of the metabolic abnormality as a causal factor has not been elucidated. The syndrome involves a spectrum of morphologic disorders ranging from mild dysplasia to complete absence of components of the lumbar or sacral spine or both. The most extreme manifestation is sirenomelia.

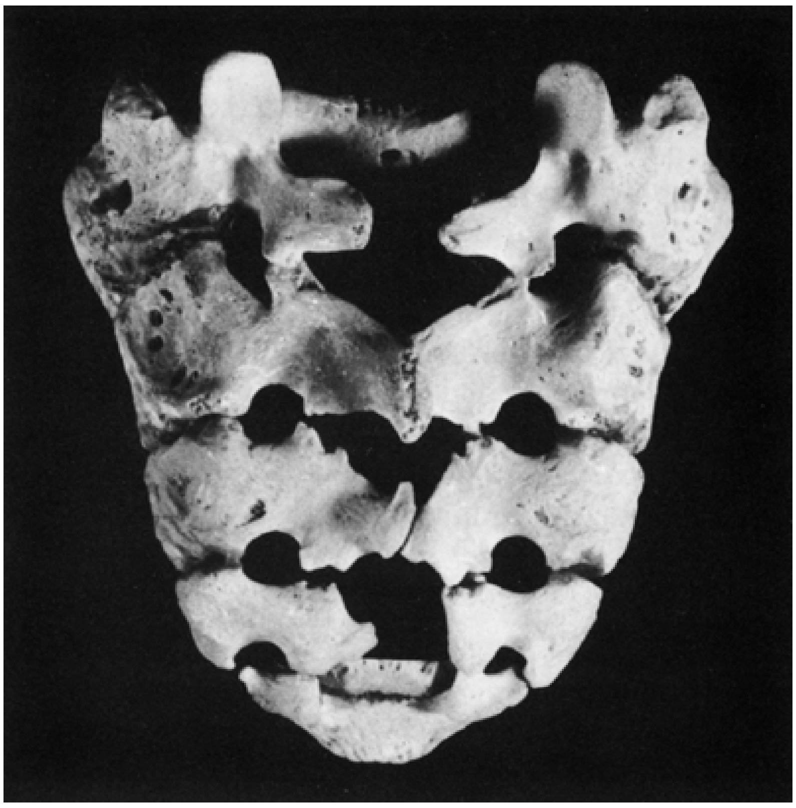

FIGURE 55. Spina bifida of the sacrum.

Diastematomyelia

Excessive width between pedicles may be associated with the presence of an osseous or cartilaginous mass extending from the vertebral body into the vertebral canal (62,91). The spinal cord or cauda equina is divided (cleft) around this fixed mass, which essentially transfixes the cord. Because of disparate longitudinal development of the spinal cord relative to the lengthening spine, children with this defect characteristically does not have neurologic symptoms until they are several years of age,

It had been assumed that the ascent of the spinal cord within the osseous vertebral canal has a progressive tethering effect. Barson (15) challenged this concept when showed in anatomic studies that the cord normally reaches the adult level (L1–2) within the canal by 2 months of age. Barson suggested that the normal ascent of the cord is unusually retarded in children with diastematomyelia or that the neurologic signs lack a simplistic mechanical explanation. In theory, one would expect a severe neurologic deficit at birth because most of the ascent, according to the usual concepts, occurs before this time.

Tethered Cord

Normally the filum terminale either elongates or detaches from its most distal (sacral) attachments during the fetal or early postnatal period to allow the aforementioned proximal migration. Failure to do so may produce progressive traction on the spinal cord or roots. The resulting change in neurologic function may necessitate intervention. The problem is fairly frequent among patients with spina bifida, either as a primary problem or as a secondary consequence (scarring) of primary closure of the defect in the neonatal period (235). The presence of tethered cord or another accompanying defect is not an indication for surgery; neurologic deterioration should be the basis for intervention.

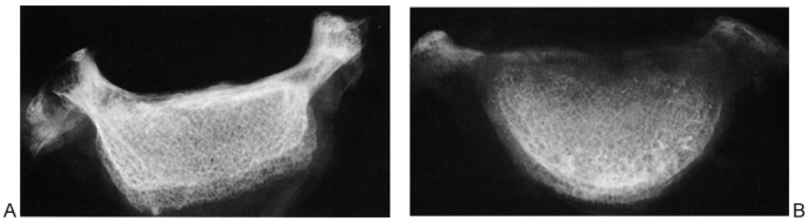

FIGURE 56. Representative myelomeningocele vertebra resected during kyphectomy. The amount of posterior element formation is limited in **A** and markedly lateralized in **B**.

Idiopathic Scoliosis

The origin of idiopathic scoliosis remains controversial (7,191,247,300,333,335). Theories include neuromuscular imbalance, subtle growth abnormalities, and dysfunction at the cord or brain tissue level. Like slipped capital femoral epiphysis, three-dimensional alteration of the structure of the spine and curvature undoubtedly are outcomes that may have been derived from any one of several pathways.

Rönning and Kylämarkula (292) found that the potential of the neurocentral synchondroses to fuse at discrete times could be altered by changing biomechanical conditions. Altered muscular dynamics could feasibly allow asymmetric closure. Bequiristain and Cañadell et al. (27,52) showed that unilateral fusion with screws of several levels of the porcine thoracic spine produced scoliosis, They concluded that if symmetric growth of the neurocentral synchondroses was disturbed, rotation of the vertebral body would occur because of eccentric growth. Such eccentric development of the neurocentral synchondroses has been found in a large number of spines from cadavers of newborn infant (Ogden JA, unpublished observations). The asymmetric growth would produce three-dimensional change, as in Blount disease of a long bone or altered acetabular development in hip dysplasia.

The facet joint has a chondroosseous growth mechanism. In essence, each vertebra has four such facet physes (two superior, two inferior). Growth must be equal, right and left, to allow symmetric bone formation. Alteration of rates of growth can affect the shape of the posterior elements and secondarily affect muscle function, which can affect growth rates (loop effect).

Spinal Osteochondrosis and Scheuermann Disease

The cartilaginous plates appear to be relatively weaker mechanically where they are penetrated by vertebral vessels. These areas conceptually have a decrease in resistance to the continuous pressure of the nucleus pulposus. Portions of the nucleus may be forced through the end plate into the vertebral body (Schmorl nodule). However, as shown in Fig. 44, the tissue in the radiolucent region may be unossified cartilage rather than disc material per se. During active growth this is a gradual process.

Multiple prolapse resulting in irregular end plates, associated with loss of anterior vertebral height in adolescents, is known as *Scheuermann kyphosis.* The specific cause of this sequence of events is not known. It is likely that some kyphosis occurs first, and then increased anterior pressure propagates the deformity (Hueter-Volkmann law) and allows uneven growth of the vertebral body, particularly with wedging. This produces a climate for variable growth similar to alteration of lateral acetabular growth in hip dysplasia. The narrowness of the intervertebral discs combined with the kyphosis contributes to abnormal biomechanical loading. This deformity can be corrected during further growth when these forces are mollified, as by bracing. The relatively dependable and rapid response to bracing supports a biomechanical cause rather than an intrinsic biologic (molecular) abnormality.

Chordoma

In normal development, notochordal cells progressively disappear from the vertebral centrum during the cartilaginous period of embryonic development. Persistence of the notochord, however, can form a mucoid streak (Fig. 15), a finding not uncommon among neonates. On radiographs these often appear as radiolucent depressions extending from the nucleus pulposus. Cohen et al. (66) described a number of patients with irregular radiolucencies in the vertebral centra due to retained segments of notochord that apparently impeded complete coalescence of ossific regions. During postmortem examinations, notochordal tissue remnants were found in 2% of cases. Notochordal cells may persist in the nucleus pulposus until term and may even be found in the nucleus as late as 10 years of age (331). Most are found in the region of the clivus (base of the skull) and in the sacrococcygeal region, where most chordomas occur. Chordomas are thought to arise from altered growth of these notochordal cells (331).

Canal Tumors

An excessively high sagittal diameter or excessive width between the pedicles during development suggests the presence of an expanding lesion within the spinal canal. A large vertebral foramen likewise should point to the possibility of the presence of a pathologic lesion (such as a neurofibroma). Many types of tumors affect the developing spine. Management is essentially the same as in other regions, but with an emphasis on preserving spinal stability and cord function. Tumors such as eosinophilic granuloma are associated with trabecular collapse (vertebra plana); recovery of vertebral height is variable.

The spine often is the initial site of malignant disease in children. Leukemia must be included in the differential diagnosis of back pain among children. Expansion of leukemia infiltrates within the trabecular bone may cause microstructural failure and painful symptoms. Wedging of the vertebrae may occur.

The spine may be the site of metastasis, especially of neuroblastoma. Radiation therapy for malignant tumors can alter growth if only a portion of the spine receives radiation exposure. The cord also is susceptible; radiation-induced fibrosis often develops. This may put the patient at risk of ischemic change if fusion is undertaken for the spinal deformity.

Os Odontoideum

The mechanism of formation of os odontoideum is reasonably well accepted (109,110,136,150,240,284,309,370). Fielding and Griffin (109) discovered that 17 of 35 cases of os odontoideum occurred an average of 3.5 years after initial trauma. In most cases, the radiograph obtained immediately after the trauma showed an intact dens.

Examination of radiographs that show antecedent os odontoideum clearly associated with C1 and some of the terminal ligaments allows easy postulation of a causal traumatic injury. Because of a lack of or minimal treatment, constant motion can contribute to the development of a pseudarthrosis that interferes with the blood supply to the distal part of the dens ossification center and causes progressive atrophy in the distal portion (290). The chondrum terminale, however, remains intact with all of its ligaments and vascularity attached (304). It then undergoes normal secondary ossification, which appears as a radiographically separate structure. Because the blood supply is cut off, there is minimal possibility of distal endochondral bone formation. However, the physis of the chondrum terminale, which has an intact circulation, enlarges, and if some blood gets into the proximal metaphysis, the ossiculum may enlarge.

End Plate Fractures

The expanding chondroosseous interface of the vertebral body, and possibly the posterior elements, presents a mechanically susceptible region analogous to the equivalent region of a long bone. The interface thus is susceptible to fractures that separate the physis and epiphysis from the ossification center of the centrum. These injuries may be subtle and often reduce spontaneously after the injury mechanism dissipates (260,261). Partial fractures of the end plate (Figs. 57, 58) frequently involve the cervical spine anteriorly (210) and the lumbar spine posteriorly (260,262,291). In the latter instance, a lesion equivalent to a herniated disc develops. The cartilaginous cap may be avulsed as a physeal injury. The chondroosseous growth mechanism of the facet likewise may be disrupted and cause acute as well as long-term growth alteration.

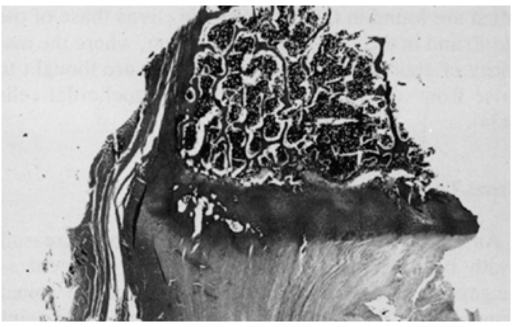

FIGURE 57. Avulsion of the corner lumbar fragment sustained through weight lifting.

Spondylolysis

No prenatal pattern of development of ossification centers in the lumbar neural arches suggests that the pars interarticularis defect in spondylolysis is the congenital result of failure of fusion of the posterior primary ossification centers. There is only one ossification center in each posterior element. The initial site of this onset of ossification also is the region involved in the spondylolytic defect. The normal site of ossific fusion of the centrum with the neural arches is well anterior to the pathologic defect, within the vertebral body. Any pars defect must be an acquired, traumatically incurred failure within the primary ossification center of the neural arch (214).

There are infrequent situations in which sacral spina bifida is associated with loss of the normal interspinous ligament support for the lumbar spine. Over a sufficient biomechanical time span, such an anatomic arrangement can lead to a more horizontal direction of the facets and attenuation of the developing pars interarticularis by plastic deformation of the bone (bone may be acutely stretched 3% to 7% of its length before fracturing). However, in most cases of spondylolysis, the pars is attenuated or broken by chronic, repetitive, often minimally or asymptomatic trauma, as in competitive gymnastics or figure skating. When both sides fail, biomechanical stability is affected, and spondylolisthesis may result.

Apparent spondylolytic defects can involve the upper cervical vertebra (66,260). These probably arise from variations in ossification of the region of the posterior element that contribute to the final vertebral body, which is more extensive in the cervical region than it is in other regions.

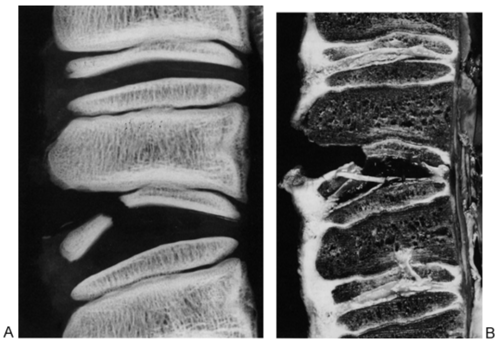

FIGURE 58. Spontaneously occurring end plate fracture in a zebra. **A:** Radiograph. **B:** Sagittal section.

Spondylolisthesis

Spondylolisthesis most often is an acquired disorder that requires antecedent bilateral spondylolysis (246,343,367). As mentioned earlier, a congenital deficiency also may allow the progressive forward slipping of one vertebral bone on another that typifies this lesion. In the most severe form, complete displacement occurs and the superior vertebra is located anterior to the inferior vertebra.

Dysplasia

The ossification center of the dens has both a proximal and a distal physis. In diseases that affect longitudinal growth, such as achondroplasia, the dens may not grow normally, leading to hypoplasia of the dens. This can occur with any skeletal dysplasia. *The shape and stability of this region always must be assessed for any child with dysplastic skeletal abnormalities* (293,355). Fusion, when necessary, should be performed with the patient's own bone because of the high risk of lysis of allografts among children (321).

In achondroplasia the vertebral canal may be narrowed throughout its length. Hence the normal spinal cord and cauda equina are housed in an inadequate bony canal. This abnormality is caused by a lack of growth in the pedicles and laminae. The sagittal width also is less than normal. The resultant spinal stenosis can cause severe neurologic problems in adulthood (97). Kyphosis with or without wedging at the thoracolumbar junction is frequent (226).

Spondyloepiphyseal dysplasia affects the vertebral epiphyses of the spine as well as those of long bones (270). End plate ossification becomes irregular. Abnormalities of the vertebrae include irregular end plates, platyspondylia, and the appearance of a central tongue in the lumbar area. The end plates may manifest as multiple Schmorl nodules. However, these are more likely unossified dysplastic cartilage remnants similar to those shown in Fig. 44 .

Several mucopolysaccharidosis syndromes include progressive abnormal development of the vertebral column (196,219). Ovoid vertebral bodies with wedging and kyphosis at the thoracolumbar junction are characteristic. The accumulation of abnormal molecular (metabolic) products in the trabecular spaces affects chondroosseous transformation and biomechanics. Thus the ability to grow normally is hindered by microstructural failure and variable collapse, especially in the anterior aspect. Platyspondylia is frequent in Morquio syndrome.

In Down syndrome, hypoplasia of the dens is common. However, a more difficult problem is increased joint laxity, which may particularly affect the atlantoaxial region (47,72,281,288). If instability persists, progressive myelopathy can damage the upper cord (Fig. 59) (355).

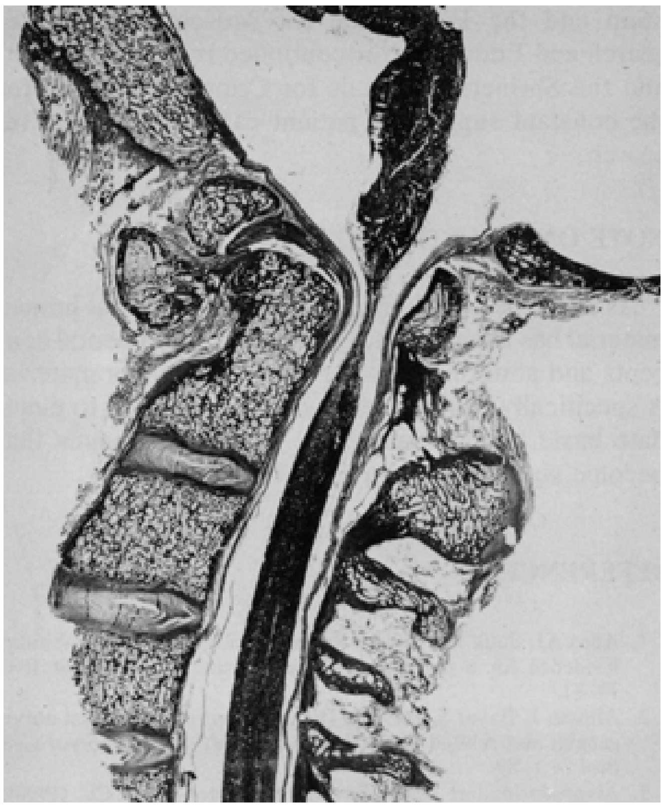

FIGURE 59. Cord compression due to instability of C1–2 in a patient with Down syndrome.

Acknowledgments

The authors thank the Human Developmental Anatomy Center, National Museum of Health and Medicine, and the Armed Forces Institute of Pathology for making human embryonic and fetal material, especially that of the Carnegie collection, available for study; Busch Gardens Zoologic Park for providing a wide array of comparative animal material; and the Skeletal Educational Association for continued research support.

Section II Biomechanics

2

Spinal Biomechanics

Ian A. F. Stokes

I. A. F. Stokes: University of Vermont, Burlington, Vermont 05405.

This chapter surveys the biomechanics of the pediatric spine, especially the relation between forces and movements in the spine and the relation between forces and injury. These principles can be used to gain a better understanding of the spine from the point of view of growth and development, development of deformities, causes of injury to the spine, and the principles used in both conservative and surgical treatment. In describing the relation between forces and motion and between forces and tissue damage, properties of the spine must be described in mechanical terms. The spine can be considered a mechanical system that has geometric properties and tissue material properties. Together these characteristics determine the structural properties. First some basic mechanical concepts are reviewed.

The geometric characteristics of the spine—size, shape, motion, and the direction of forces applied to it—must be defined in three dimensions. This conventionally is done by means of a cartesian coordinate system. A cartesian coordinate system is uniquely defined according to the position of its origin and the direction of at least two of the three axes. The third axis by definition is perpendicular to the other two. Because the spine is flexible and moves, the definition of an axis system is not simple. Depending on the point of view, axes can be defined by reference to landmarks on an individual vertebra, by reference to the end vertebrae of the spine, or by reference to the position of the person's entire body (Fig. 1). The choice of axis system can be quite important, because measurements of spinal deformity and motion differ depending on whether a local, spinal, or global reference is used, if these axes systems are not coincident.

Once an axis system is selected, motion of the spine or motion of vertebrae can be considered as a combination of translations and rotations within this coordinate system. Forces, which produce primarily translation, and torques, which produce primarily rotations, can be considered to have components along and around the same set of axes. Because translations and rotations are fundamentally different, motion of the spine is considered to have six degrees of freedom (three translations and three rotations), and the force system acting on the spine has the same six degrees of freedom (91) (Fig. 2).

To simplify consideration of its biomechanics, the spine is often broken down into mechanical units called *motion segments* or *functional spinal units.* Each motion segment consists of two vertebrae and all the passive structures (disc, ligaments, joint capsules, and so on) that link these two vertebrae (Fig. 2). The mechanical properties of the motion segment depend on its physical dimensions and proportions and the tissue material properties. Most investigations of properties of motion segments have been performed with aged specimens. How can these results be scaled or otherwise adapted to describe properties of the pediatric spine? During growth, the shape of vertebrae changes substantially. The dimensions of the neural canal approach adult size at an early age (109,143), but the vertebral bodies continue to grow (33). At the same time, there are probably age-related changes in tissue material properties. Because of the complex behavior of biologic tissues, numerous terms including those used in Fig. 3 must be used to describe the response.

Stress and Strain Relations of Tissues

Deformation of tissue in response to applied load usually is displayed by means of a stress-strain graph (Fig. 3). Stress is a standardized measure of applied load in a particular direction (load divided by area of specimen), and strain is a standardized measure of the deformation in a specified direction (elongation divided by original length for direct strain, and shear deformation divided by specimen thickness for shear strain). In a stress-strain curve, numerous tissue characteristics are displayed and can be quantified. The elastic range is the range of deformation from which complete recovery is possible after unloading. Biologic tissues often have an initial region of laxity, an approximately linear elastic range, and a nonlinear elastic range. After the elastic limit, plastic deformation can occur. After a specimen that has been taken into the plastic range is unloaded, a permanent, plastic deformation remains. After the ultimate or maximum stress is passed, failure occurs. All these properties are illustrated in Fig. 3 . Time-dependent properties are a function of the history of loading. These properties are illustrated in Fig. 4, which also shows how materials with time-dependent properties can be conveniently visualized and represented by equivalent structures consisting of springs and dampers. An example of time-dependent behavior is the decline in force magnitude in Harrington instrumentation that occurs over a period of hours after the operation (39,93).

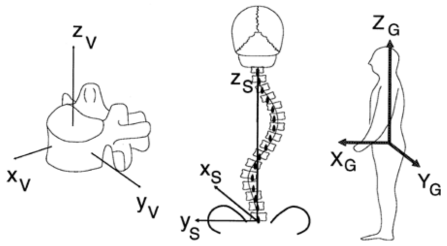

FIGURE 1. *Left to right*, Vertebral, spinal (spine with scoliosis), and global (body) axis systems. When making clinical measurements, such as from plain radiographs or computed tomographic sections, the axis systems should always be specified.

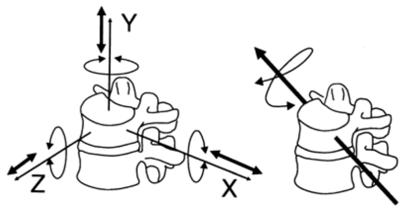

FIGURE 2. A motion segment, which consists of two vertebrae and the structures (disc and ligaments) that connect them, has six degrees of freedom. These produce six distinct components of motion (*left*)— three translations and three rotations. An alternative (*right*) is to express the six components of motion as motion along and around a helical axis. (Adapted from

, with permission.)

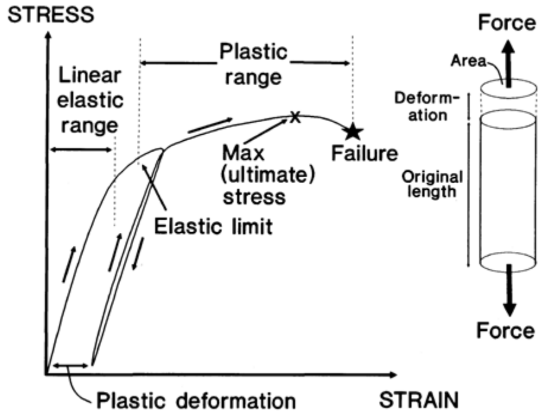

FIGURE 3. Stress-strain graph of typical material. A sample was loaded past its elastic limit, unloaded to demonstrate plastic deformation, and then loaded again to failure. Stress and strain are standardized measures of load and deformation. Representation of load and deformation as stress and strain allows comparison between tissue samples of different sizes.

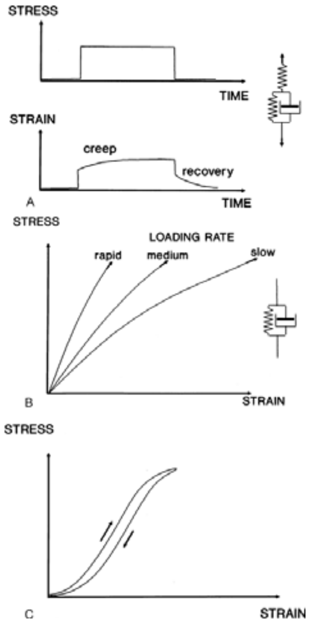

FIGURE 4. Three types of material behavior illustrated by stress and strain response and by equivalent spring and damper systems. **A:** Viscoelastic behavior. A step load produces a gradual increase in deformation, and unloading initiates slow recovery. **B:** Load-rate-dependent behavior. **C:** Hysteresis (unloading path different from loading path). Energy is absorbed in each load-unload cycle.

The acute and time-dependent behavior of the ligaments, vertebrae, discs, and other spinal structures during normal in vivo function, trauma, and treatment is a complex interaction between the tissue material properties and the sizes and shapes of these structures. In the same way as tissue properties can be displayed with a stress-strain graph, a load-deformation graph is used to display structural properties (Fig. 5).

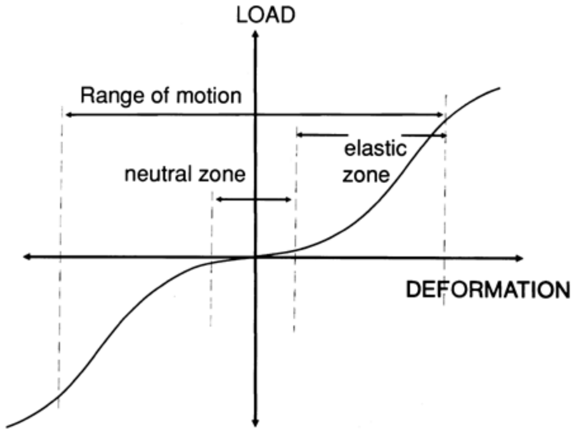

FIGURE 5. Idealized load-deformation behavior of a motion segment for loading along one axis, and the corresponding deformation along that axis. The motion segment displays nonlinear behavior that has been characterized by Panjabi (100) as having an initial region of minimal stiffness (neutral zone) followed by an elastic zone.

Loading and Deformation of the Spinal Motion Segment

The motion segment (Fig. 2) seldom moves in a single direction or even in a single plane. As described earlier, there are six degrees of freedom, but these normally occur in combination. In general, application of a single force or torque does not produce a single translation or rotation and may often produce all six translations and rotations in varying amounts. The tendency of certain degrees of freedom to be associated with each other, especially axial rotation and lateral bending, is called *coupling* (101). This complex mechanical behavior is difficult to visualize. One helpful concept is the instantaneous helical axis of rotation: for any instantaneous increment of motion, one vertebra can be considered rotating about and translating along an axis of rotation that is fixed relative to the other vertebra. If motion is considered planar, the point at which the axis of rotation cuts this plane is the center of rotation. However, the instantaneous axis of rotation is not fixed and depends on the direction of the applied forces and torques and on the position of the motion segment within its range of motion. The deformation of any tissue or structure depends on how far it is from the axis of rotation. Because the axis of rotation usually passes through the intervertebral disc, this minimizes the magnitudes of strains of tissues within the disc.

An experimental determination of the characteristics of the motion segment can be summarized in a load-deformation graph (Fig. 5). These graphs show a nonlinear relation between load and deformation. There typically is a region, called the *neutral zone*, of large deformation for small positive and negative loads (100). This region can be considered a region of laxity and is thought to place the spine at risk for instability. With increasing deformation, stiffness increases (elastic zone). With deformation beyond the elastic zone, damage can occur. Therefore the neutral zone and the elastic zone together constitute the functional range of motion. Although these characteristics of the motion segment can be defined for cadaver spinal specimens, at present there is no way to determine their properties in vivo.

Injuries to the Motion Segment

All the components of the motion segment contribute to flexibility and may contribute to ultimate strength, depending on the failure mechanism. This depends on the direction of loading. White and Panjabi (153) introduced the concept of major injuring vector to describe the predominant direction of loading during an injury. This leads to the idea that fractures and other injuries can be classified according to the magnitude and direction of forces acting at the time of injury. Fortunately, spinal injuries are somewhat rare in childhood and adolescence (18). Birney and Hanley (18) reviewed 84 injuries and found that the most common cause was falling from a height. Most of the others had recreational and athletic causes or were traffic and pedestrian injuries. Birney and Hanley drew attention to a problem that may be more common among children: spinal cord injury without radiologic evidence of injury or subluxation in the spinal column. In these cases it is difficult to establish the cause of injury or the necessary treatment.

Mechanisms of Injuries to the Spinal Cord

Each of the various tissues of the spine has a maximum strain beyond which injury occurs. Normal motion of the spine occurs around axes of motion that lie toward the posterior part of the intervertebral disc and maintaining acceptable ranges of deformation of the anterior disc and of the spinal cord and neural structures. It appears that direct trauma and sustained ischemia often combine to produce a neural deficit. Compression of short duration (71) and tension (95,96) on the spinal cord can produce irreversible ischemic damage. Sudden transverse deformation of the spinal cord produces a complex pattern of internal strain. For instance, anteroposterior compression tends to produce tension in the transverse direction (20,21). Standardized animal models for studying direct trauma to the spinal cord rely on dropping a standard weight from a standard height onto the exposed cord of an animal such as a rat (35,98,104). The effect of such trauma depends on many variables, including the shape of the dropped object, its mass, and the height from which it falls. The change of momentum of the dropped mass correlates better with the extent of the injury than does the kinetic energy of the mass before impact (98,104). Among patients the degree of spinal instability after injury indicates the probable degree of deformation of the cord at the time of the initial trauma but gives no indication of the duration of deformation. Thus the degree of spinal instability may not correlate with the degree of neurologic damage.

Contribution of the Intervertebral Disc to Flexibility and Strength

The intervertebral disc has a special mechanical role in transmitting large compressive forces and provides flexibility for rotations about all three axes. In compression loading, large pressures are generated in the nucleus pulposus, and these pressures are contained by tensile stresses in the anulus. Compression stiffness is relatively high initially, about 1 mm deflection per 1,000 N of compressive force, and it increases at greater forces. Disc compression (reduction in height) is accompanied by a similar amount of disc bulging (increase in disc radius). The high swelling pressure of the nucleus allows it to sustain high pressures without rapid loss of fluid. Although it has little effect on the compressive behavior of the disc (81), removal of the nucleus has a great effect on motion in other planes (102). Deformation causes a flow of fluid within the disc and causes changes in fluid content (volumetric changes). These are also apparent as diurnal changes in disc height. Whether these fluid fluxes augment the nutrition of intervertebral discs by means of a pumping mechanism is unclear (60,145), because diffusion may predominate. The vertebral end plates and the disc periphery are pathways for diffusion of nutrients and metabolites in and out of the avascular disc. The rates of diffusion of nutrients and metabolites along these pathways differ as a function of molecular weight (145).

Intervertebral discs can be subjected to quite large rotations without damage. Axial rotation allows the smallest range before damage occurs. Thus twisting has been considered a common source of injury to intervertebral discs (43), especially repetitive small injuries that cause disc degeneration in later life.

Contributions of the Vertebral Bodies To Flexibility and Strength

Vertebral bodies deform under compressive loading, and the end plates become more concave under the influence of intradiscal pressure (22). The end plate deformation at its center is of similar magnitude to the amount of radial bulging of the disc. Microscopic damage to the trabeculae (55) and herniation of the disc through the end plate (Schmorl nodule) apparently can occur at any age.

Contributions of the Posterior Elements and Ligaments to Flexibility and Strength

Depending on their orientation, which varies along the length of the spine, facet joints can contribute to resisting compressive loading, shear loading, and torsion loading (Fig. 6). However, probably because of flexibility in the neural arch, neither removing nor transfixing the facets has a great effect on the flexibility of the motion segment, except in torsion (132). Farfan (42) progressively cut away the posterior structures of lumbar motion segments and showed that the each facet joint contributes about 18% of the torsion stiffness. A large part of the remaining flexibility is provided by the intervertebral disc (Fig. 7). A similar experiment was conducted by Panjabi et al. (103) to investigate displacement in cervical motion segments in response to a posteriorly directed shear force (Fig. 8). When motion segment components were transected starting posteriorly (Fig. 2A), the largest increases in both rotational and translational displacements occurred with cutting of the disc and anterior ligament. When cutting was started anteriorly (Fig. 8B), sectioning of each structure produced a large increase in rotation and translation. Overall it appears that the intervertebral disc is the most crucial structure for the mechanical integrity of the motion segment, but posterior structures help guide the motion segment and protect the disc from injury.

Special Considerations in the Immature Skeleton

Nearly all the information about mechanical properties of the motion segment and how they contribute to flexibility and strength of the spine comes from adult material tested in vitro. It is almost impossible to make measurements for living subjects, and very little material from young subjects has been tested. Ashton-Miller and Schultz (9) found that a child's spine is 5 to 10 times less stiff than the average adult spine. There is a loss of stiffness in both material (tissue) properties and mechanical (structural) properties of knee ligaments with age (158), which probably is paralleled by similar changes in other soft tissues, including those of the spine.

In Vivo Loading of the Spine: Moments of Lifted Objects and Muscles

The spine is loaded by a combination of externally applied forces, body weight forces, and muscular forces. Because the moment arms of the muscles around the spine usually are smaller (73) than those of lifted weights and body weight contributions, the forces in muscles are correspondingly high. Figure 9 illustrates a case in which compressive load on the spine approaches 5,000 N (about one-half ton). This is close to the ultimate compressive strength of the adult spine. The weight being lifted together with the weights of body segments above the level of the spine being considered produce moments about the spine. The magnitude of each moment is the product of the force (weight) and its distance from the spine. These moments must be countered by moments generated by muscle and ligamentous forces. For any position of the body and for given external loading, the internal forces and moments acting on the spine can be estimated by means of considering the equilibrium between internal and external forces and torques around the spine with the help of a biomechanical model (4). When the trunk is at rest, all the forces and moments must balance to prevent motion. Free body analysis (Fig. 9) is an equilibrium analysis in which a system is split into real or imagined component parts (free bodies) to check that each part is in equilibrium. It can therefore be used to measure the internal stresses in joints and muscles when a body segment is subjected to external loads.

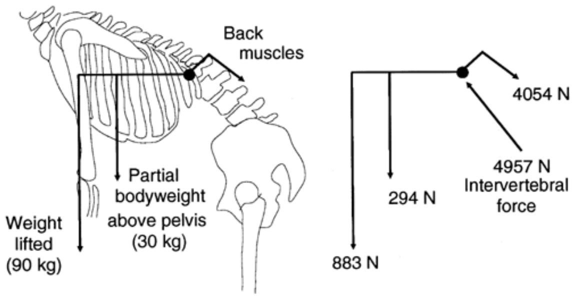

FIGURE 9. Simplified model of lifting mechanics. Deep muscles of the back provide extension moments to counteract flexion moments of the weight of the head, arms, and trunk and of the lifted weight. Possible effects of intraabdominal pressure are neglected in this model. (Adapted from Morris JM, Lucas DB, Bresler MS (1961): The role of the trunk in stability of the spine. *J Bone Joint Surg Am* 43:327–351, with permission.)

Biomechanical Models

Biomechanical analysis of spinal forces seldom has a unique solution because the redundant number of spinal muscles provides many combinations of synergistic and antagonistic muscle forces that can satisfy equilibrium. To resolve this redundancy in a model, the pattern of coactivation of muscles can be obtained from experimental electromyographic (EMG) recordings. However, the EMG-to-force conversion is always approximate, and the number of muscles that can be recorded is limited. Biomechanical models can be used to make assumptions about rules that govern muscle recruitment, that is, which muscles are active and which control strategies are used to activate them. This usually requires a presumed physiologic cost function, such as total muscle stress or intervertebral forces, that is considered to be minimized by the muscle control strategy. In simple sagittal-plane lifting tasks, it appears that both muscular activation levels and spinal compressive loadings are minimized but subject to increases in both muscle activation and spinal loading produced by antagonistic muscle forces. For example, in lifting tasks, antagonistic abdominal muscles are activated to produce a counterproductive flexion moment. This also produces intraabdominal pressure, which once was thought to augment the extension moments about the spine (92) and thus help to reduce compressive loading on the spine. This effect is now considered negligible (56,85,139), and it appears that abdominal muscle activation is important for maintaining the structural stability of the spine (4,47).

Another complicating factor in biomechanical models of the trunk is the contribution of ligamentous structures. These passive structures contribute to the forces acting on the spine only when they are in a tightened position. In lifting tasks performed with a flexed spine, the erector spinae muscles are electrically silent (120), and the ligaments provide a major contribution to the force. However, whether it is better to lift with the spine in a lordotic, kyphotic, or neutral position is unresolved (3,36).

Spinal Stability and Instability

Stability means that a system returns to equilibrium position after a perturbation. Buckling is a kind of instability in which a structure suddenly bends and collapses when a certain critical load is exceeded. The term *stability* unfortunately has been used in many different meanings in the context of the spine to refer to both clinical and biomechanical aspects. Biomechanical instability should not be confused with (a) large elastic deformation of the spine (high flexibility), (b) hypermobility of a spinal segment relative to its neighbors, (c) abnormal coupling of components of spinal motion, such as increased anterior shear motion accompanying flexion, (d) sudden and unpredictable changes in painful symptoms, or (e) slowly progressing posttraumatic or scoliotic deformity (9).

Equilibrium is a stable position of minimum potential energy. Because potential energy increases with deformation in an elastic structure, increased stiffness of a structure usually provides greater stability, but stiffness and stability are not equivalent. The spine consists of a column of vertebrae linked by relatively flexible articulations, so it is probably at risk of buckling when loaded by external forces and muscle forces. For equilibrium, all muscle tensions must be carefully balanced to prevent large deformations at individual articulations. Muscle stiffness is required to stabilize the spine. Because muscle stiffness increases with muscle activation, increased muscle coactivation can help to stabilize the spinal column. These ideas have been investigated analytically (16,31,47), and the results suggest a stabilizing role for antagonistic muscle activity, for muscles that cross several segments, and for the shorter muscles, such as the multifidus. Spinal instability is difficult to demonstrate in vivo. If it occurs, instability is most likely transient and unlikely to be recorded on an x-ray film.

Biomechanics of Painful Conditions of the Spine

There is much disagreement about the role of biomechanical factors in the causation of low back pain among adults. When it occurs among children, low back pain should be taken seriously (116). The cause of low back pain in children is seldom mechanical (traumatic) or disc herniation or degeneration, and the underlying pathologic condition may be more ominous. An exception is spondylolysis, which is a risk among children who participate in certain sports (77). Although usually asymptomatic among children (124), spondylolysis may develop into spondylolisthesis during the adolescent growth spurt (157). Spondylolysis is more common among gymnasts (62) and football players (84,124) than it is among other children. Spondylolysis is reported to be present among 4.4% of the population at 6 years of age. The prevalence increases to 6% in adulthood (44). Important epidemiologic observations emerged from studies of skeletons removed from the graves of Alaskan natives (131). Four percent of the skeletons of 6-year-old children had this defect, which increased to 34% in adulthood. These observations led to the idea that spondylolysis is a fatigue fracture caused by repetitive loading. Cyron and Hutton (32) reproduced a spondylolysis fracture in cadaver vertebrae subjected to repetitive loading of the posterior elements. Their experiments were complemented by a simple mechanical model that showed how facet joint loading, combined with tension from the extensor muscles, produced bending moments in the neural arch. Rosenberg et al. (115) reported no instances of spondylolysis among persons with spinal paralysis. Their findings provide additional evidence of a mechanical cause of spondylolysis.

Spinal Deformities

Simple mechanical consideration of the structural stability of the spine suggests that spinal deformities should be common. There are excellent controls over the growth and development of the spine in most persons, except when there is muscular weakness. The apparently spontaneous development of scoliosis and abnormal kyphosis is difficult to explain (113). Spinal growth and development are important factors in the progression of spinal deformities (19,150), but it is not clear whether abnormal growth initiates the deformity (135). Growth and maturation apparently are disturbed in idiopathic scoliosis. There are few indications why idiopathic scoliosis is more common among girls, except that their vertebrae might be slightly more slender (148) and there are differences in the development of the sagittal spinal curvatures (156). A set of subtle mechanical factors, including abnormal growth (13,38,51,76,127,141,144,154,155), joint laxity (17), sagittal spinal curvature (156), and neurologic factors (57) may play a part (94).

Etiology and Progression of Scoliosis

The exact biomechanical mechanisms responsible for idiopathic scoliosis, especially the transverse plane rotations of the vertebrae, are not well understood. A number of biomechanical factors have been invoked to explain the biomechanics of scoliosis. These include intervertebral motion coupling, spinal tethering and buckling, and mechanical influences on growth.

It appears unlikely that coupling of rotational motion in intervertebral segments controls the development of vertebral rotation in scoliosis. Both lateral bending of the spine and scoliotic deformities show rotation in the transverse plane. However, the normal kinematic relations between lateral bending and axial rotation are different from those in scoliosis (133,151,152) and do not explain the pattern of deformity that develops in scoliosis with maximal vertebral rotation at the curve apex. Spinal tethering by posterior structures of the spine (33,63,130) also has been invoked to explain the spinal shape in scoliosis and its causation. There are several parts to this theory. Tethering is thought to prevent flexion of the spine and lead to a hypokyphotic or lordotic shape, which then has a greater tendency toward instability (34). Second, the tether is thought to maintain a straighter alignment of the posterior elements than of the vertebral bodies, thus rotating the vertebrae in the curve. That the sagittal plane of the spine is flattest in the early teen years (156) supports the idea that this shape places the spine at risk of development of scoliosis. The shape of the spine in scoliosis is reminiscent of that of a buckled beam, but buckling may not explain the development of lateral curvatures because buckling of the ligamentous spine first exaggerates the sagittal curvature.

It has been proposed that a small lateral curvature of the spine would load the vertebrae asymmetrically and cause asymmetric growth in the vertebral physes (106) and acceleration of the deformity in a vicious circle (111,136) after a certain threshold of spinal deformity has been reached. This theory of spinal growth sensitivity to loading asymmetry must explain why the normal spinal curvatures (kyphosis and lordosis) in the sagittal plane do not progress into hyperkyphosis and hyperlordosis by the same mechanism, although progressive deformity in Scheuermann kyphosis has been attributed to a similar mechanism (123). This concept of the mode of progression of deformity is attractive intuitively and is incorporated into the rationale for use of braces and other treatments. The concept cannot be quantified, however, without better knowledge of the normal spinal loading and of loading in the presence of scoliosis and knowledge of the sensitivity of growth to mechanical load magnitude and the time course of loading. Development of the rotational deformity in the spine complicates this process. The growth plates of long bones also are responsive to torsional loads (6,91), but the origin of such forces in the spine during progression of scoliosis is not clear. The clinical observation (79) that the risk of progression of scoliosis is a combination of both curve magnitude and amount of residual growth cannot be explained quantitatively with mechanical principles.

Spinal Biomechanics and Growth

Regulation of bone growth is complex. Genetic, vascular (66,129,142), hormonal (13,26,110), and biomechanical (24,50,58,136) factors all play a role. Because the dimensions of the neural canal develop at such a young age, factors such as diet and health status in the perinatal period can influence spinal growth and subsequent health (29,108,109). Longitudinal growth in the vertebral body occurs in the cartilage of the end plates (33) and is influenced by biomechanical loading (87,136). Roaf (112) developed a rationale for local epiphysiodesis in the treatment of patients with scoliosis with varying degrees of kyphosis and lordosis. It appears that the technique of vertebral growth arrest and stapling may be unsuccessful because it has been used when too little residual spinal growth has been present. The relation between mechanical factors and growth (modeling) is not well understood, and much of what is known about the interaction between mechanical forces and bone metabolism relates to remodeling of mature bone as opposed to the modeling of growing bone (24,78). The discs are implicated in scoliosis (106), and very little is known about the mechanical influences on the development and growth of the discs. Diaphyseal remodeling may not respond to mechanical loading in the same way as growth in physes. For example, the diaphyseal remodeling that straightens malunion of a long bone would require that the concave (compression) side experience apposition of bone and that the tension side experience resorption, the opposite of the growth modulation in physes.

Arkin and Katz (6) reported a sensitive response of long bone growth to compressive loading in rabbits. They found no evidence of a threshold level of load to produce growth modulation. They also found that limbs that were immobilized and relieved of weight bearing were elongated. Tension forces applied across the long-bone growth plates of sheep accelerated growth (107). Gooding and Neuhauser (49) found “tall vertebrae” in patients with paralysis and in younger patients who had been treated surgically with posterior fusion of the spine. Gooding and Neuhauser argued that the unloading of the spine increased longitudinal growth.

Clinical application of these principles of growth modulation implies direct application of loads to the skeleton or alteration of ambient loads with therapies such as exercises or brace wearing. Stapling of growth plates is thought to influence growth because of forces generated in the staples by growth of the underlying physis. Staples have been shown to have profound effects on growth (53) and the growth plate cells (41,59). However, other compensatory mechanisms may come into play. Hall-Craggs and Lawrence (52,53) found that rabbit tibia that had been stapled at one growth cartilage had accelerated growth at the growth cartilage at the other end of the bone.

Lack of understanding of the exact physiologic response of growing vertebrae to force has led to uncertainties about the efficacy of braces to manage idiopathic scoliosis. The relative timing of stimulus and response is unknown. Night bracing (overcorrection with a brace during the night) seemed intuitively attractive, because it is successful in orthodontic bracing. Clinical trials are showing, however, that night bracing is inferior to full-time use of a Boston brace for scoliosis (61,69). It may be that night bracing applies loading to the spine but in a way that does not influence growth. Bone metabolism also is known to have diurnal variations with greater mineralization activity at night but greater synthesis of collagen by day. The intuitively attractive idea of using electrical stimulation to treat scoliosis also failed, possibly because of insufficient understanding of the underlying physiologic mechanisms. Unknown factors include the muscle forces generated by the stimulation, the resulting adaptive changes in the muscles, the forces imposed on the spine by stimulation, and the growth response.

Mechanical Considerations in the Management of Spinal Deformities

In both conservative and surgical treatment of patients with spinal deformities, forces are applied to the spine. In the case of surgery, the desired forces usually can be applied more directly. Just as the motion segment has six degrees of freedom, there are, in general, six distinct components to any deformity of the spine, and forces can be applied to correct each of these components. Thus mechanical treatment of spinal deformities can involve horizontal forces in the frontal or sagittal planes, distraction forces, lateral bending or flexion-extension moments, or moments in the transverse plane (Fig. 10). In practice, precise control over the applied forces is difficult to achieve. However, both brace and surgical treatments are evolving in an attempt to address the three-dimensional components of spinal deformities.

Conservative Treatment

Brace treatment usually involves the principle of a three-point application of forces. The middle force is directed at the region of maximal deformity while equilibrium is provided by two additional forces at the extremes of the deformity (Fig. 10A). The present trend in bracing for scoliosis is to attempt to control both sagittal and frontal plane curvatures at the same time. The magnitude of scoliosis curves may be the best predictor of success of this treatment (89,90), but it is unclear why this treatment is not always successful. Changes in skeletal configuration (spine and rib cage) with the Boston brace among 40 patients with right thoracic idiopathic scoliosis were recorded with stereoradiography (75). It was found that both the frontal and the sagittal plane curvatures were reduced, leaving the plane of maximum curvature almost unchanged. There was no significant improvement in vertebral rotation, but the ribs on the right (convex) side became angled more downward. Chase et al. (27) measured interface pressure between a Boston brace and 14 patients with adolescent scoliosis. The total force exerted through the brace averaged 58 ± 18 N and was associated with an initial curve correction of 37% ± 21%. The mean force level was maintained throughout the 6-month study, although the mean curve correction at 6 months had reduced to 15% ± 14%.

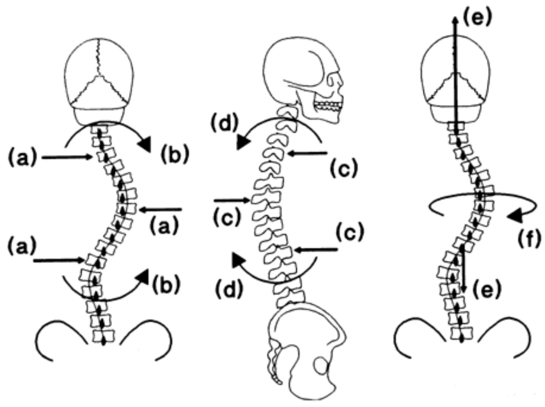

FIGURE 10. Forces that can be applied by means of instrumentation to correct scoliosis. *a*, lateral force; *b*, coronal moment; *c*, sagittal force; *d*, sagittal moment; *e*, distraction force; *f*, axial moment

Braces apply forces directly to the trunk, and patients may be encouraged to recruit their own muscles in a beneficial way (passive and active theories of brace function). Wynarsky and Schultz (160) recorded muscular activity within a Boston brace and found little evidence of the second (active) mechanism.

Electrical stimulation of muscles for correction of scoliosis (11,12), although intuitively attractive as a way to load the growing skeleton, has not been successful (40). The treatment initially appeared promising and was used only at night, but the idea of night-brace treatment also has produced disappointing results (61,69). Night treatment raises the fundamental question about how a spinal deformity responds to the application of force. There are two possible modes of action. The brace or the electrical stimulation may apply forces directly that then modify the growth and development of the deformity. An alternative explanation is that the chronic stimulation or lengthening of muscles may change the resting length or tension of the muscles and prevent progression. Although the activity of bone cells has diurnal variation, it seems that providing a stimulus during the night is sufficient to produce marked differential growth. Unanswered questions remain about the biologic characteristics of bone and muscle.

Surgical Treatment

Instrumentation used in surgical treatment of spinal deformities has two separate mechanical roles. The first is to apply forces to correct or reduce the spinal deformity. The second is to produce the correct mechanical environment for spinal fusion by means of immobilizing the spine until fusion has occurred.

Control of the shape of the spine in three dimensions with instrumentation has proved to be challenging. The distraction forces applied to the spine with Harrington instrumentation were found to cause the flat-back complication (2,88,138). Curved rods were recommended to prevent this loss of curvature (25,67). Curving the rod can prevent its contacting intermediate vertebrae, but the forces at the end of the rod where the hook connects to the vertebrae are probably unchanged. Because of force equilibrium, the predominant forces at the instrumentation hooks must be equal and opposite along the line joining the saddles of the hooks in the absence of appreciable additional forces between the rod and the spine. With distraction instrumentation, there is a diminishing return with increasing distraction because the moment of the distraction force decreases as correction proceeds (Fig. 11). Distraction instrumentation can be augmented with segmental wires, which are attached to the posterior part of the vertebrae. In a scoliosis curve, they might be expected to pull the posterior parts of the vertebrae into the concavity of the curve and worsen the vertebral rotation. However, this does not appear to be an important effect (140).

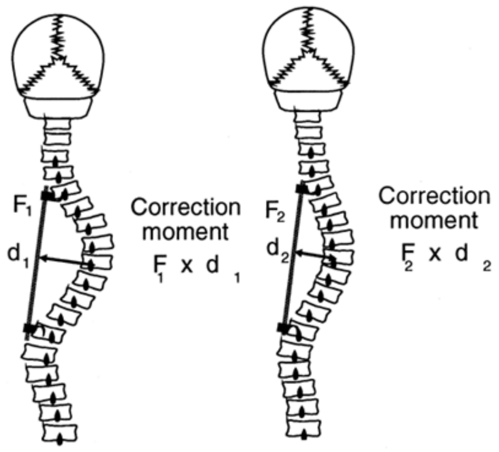

FIGURE 11. Distraction instrumentation produces decreasing increments of correction moment for increasing increments of force as correction proceeds.

There is little change in vertebral rotation after Harrington surgery (1,15,37,45,149), and there are small changes in the surface asymmetry of the back (65,149). This is not unexpected, considering that the distraction rod does not apply moments around the vertical axis. In contrast, the derotation maneuver used in the Cotrel-Dubousset procedure is intended to address the three-dimensional deformity of scoliosis by rotating the spine from a scoliosis curvature into kyphosis. However, the resulting derotation of the apical vertebrae and of the surface asymmetry of the back is quite small (14,159). The biomechanics of the Cotrel-Dubousset procedure are complicated because the operation can apply both distraction forces and lateral forces. The effects on the transverse plane should depend on the direction of the forces applied relative to the positions of the vertebrae in the deformed region of the spine (Fig. 12). This geometric configuration changes continually during the derotation maneuver (46). In theory, anterior instrumentation may be better placed to provide correction of both the lateral curvature and the vertebral rotation by means of pulling the spine toward the convexity of the curve (54). Anterior instrumentation also holds the promise of allowing shorter fusion while allowing fine surgical control over the fused part of the spine. The challenge of controlling the postoperative shape of unfused regions of the spine is even greater than that of manipulating the spinal shape within the bounds of the instrumentation. The control of posture and shape and balance of the spine is complex and is a poorly understood area of biomechanics of the spine and trunk.

Insights into the exact sequence of geometric changes in the spine during instrumentation are coming from intraoperative measurements. These measurements are technically demanding and necessitate tracking the motion of landmarks on the spine by means of photogrammetry (118) or with sensors of magnetic fields (74). These measurements have shown that the proportion of curve correction of idiopathic scoliosis produced by distraction is almost equal to the proportion produced by the derotation maneuver of segmental instrumentation (36,94,97,101,121). The curvature of the surgically exposed spine of a patient under anesthesia before instrumentation is substantially less than that present on preoperative radiographs.

After the operation, the process of graft incorporation and arthrodesis begins. More rigid fixation promotes more rapid fusion (68,82,83). There has been concern that extremely rigid fixation techniques would also produce stress shielding of bone and osteopenia. This was found among dogs (83,128) but not goats (68), and it does not appear to be important among humans.

In the spines of children, the question of graft placement is especially important in arthrodesis in the presence of continuing growth. The tethering effect of posterior fusion can produce continuing development of deformity of the vertebral column around the axis of the instrumentation. This is known as the *crankshaft phenomenon* (125). Very rigid fixation (anterior and posterior) may be able to arrest growth and prevent this from occurring (70). An alternative strategy is internal fixation without fusion, which allows continued growth while deformity is controlled. This method is associated with instrumentation problems because in the absence of fusion, the instrumentation is liable to fatigue failure due to the continued loading caused by patient activity.

It is suspected that the presence of a fused region results in greater everyday motion of the unfused motion segments, especially those adjacent to the fusion. This certainly appears to be true for the lumbosacral joints of patients with fusion that extends to L5 (30). Much of the clinical follow-up information about adjacent segments comes from patients who underwent fusion for degenerative conditions. It is not clear whether the adjacent segment degeneration is a result of natural history or whether the process is accelerated by the presence of the fusion.

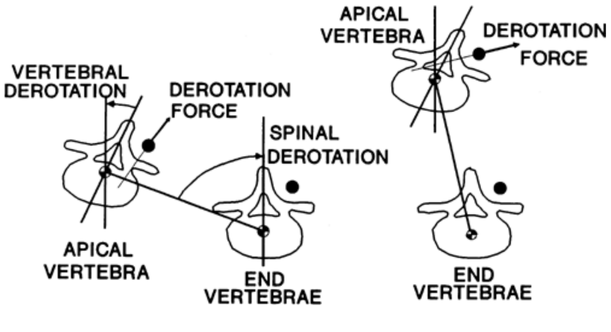

FIGURE 12. Transverse plane diagram of a spine with scoliosis before (*left*) and after (*right*) a derotation maneuver with a Cotrel-Dubousset rod on the concave side of the curve. The line of the force applied through the hook to the apical vertebra relative to its center of rotation determines the direction of the moment tending to reduce the axial rotation of the apical vertebra. These diagrams show that the derotation force tends first to derotate but then to rotate the apical vertebra.

Biomechanical Aspects of Surgical Planning

A surgeon planning surgical therapy for a spinal deformity has many variables to consider when using modern segmental instrumentation. These variables include the design of the instrumentation system, the number and location of vertebrae on which instrumentation is to be performed, rod shape (curvature), interconnections between instrumentation components, and the extent of the operative maneuvers. All of these factors can influence the correction of the deformity and the rigidity of the final construct. Surgical management of deformities must be viewed in three dimensions, which increases the challenges involved in surgical planning. There are four sources of information to help in decision making. First is empirical experience based on treatment of a large series of patients. Second, biomechanical studies in the laboratory provide information on the strength and flexibility of constructs applied to animal or human cadaveric spines. Third, animal experiments have been used to gain insight into the fate of both the instrumentation and the spinal fusion in vivo. Fourth, biomechanical analysis and biomechanical models can be used to predict the outcome of surgery on the basis of the underlying biomechanical principles.

Radiographic Assessment

Lateral bending radiographs may used in preoperative planning. The principle is that the amount of preoperative curve correction achieved by means of active of passive lateral bending or traction is predictive of the amount of change curvature during surgical treatment (28,147). Unfortunately, the amount of change in curvature with lateral bending is somewhat unrepeatable. It seems that fulcrum bending (side lying with a pad under the curve apex) produces the greatest change in curvature, which is quite predictive of surgical correction (80). In a study of the degree of vertebral rotational correction in lateral bending, spinal instrumentation markedly corrected the Cobb angle but minimally corrected apical vertebral rotation. In contrast, preoperative lateral bending produced a similar proportional correction of both (7).

Lateral bending radiographs also are used to help select the extent of fusion and the vertebrae for attachment of instrumentation (hook level selection). These rules are mostly empirical and based on qualitative concepts of spinal biomechanics, such as the neutral vertebra.

Mechanical Simulation of Surgical Maneuvers

In theory, if the mechanical properties of both the spine and the instrumentation were understood completely, biomechanical models can be used to predict the outcome of surgical therapy. There have been a number of attempts to develop and validate such models. Schultz and Hirsch (121,122) used a three-dimensional model adjusted to fit the frontal plane spinal deformity of six different patients to investigate the extent to which distraction forces from Harrington rods might alter the spinal deformity. These simulations demonstrated a nonlinear relation between the distraction force and correction, because the moment of the distraction force decreased as correction proceeded (Fig. 11). These models also helped predict that distraction forces would produce very little derotation of vertebrae about the longitudinal axis. A similar model was used to study correction of deformity by means of electrical stimulation (119) and with braces (161).

One of the difficulties in using a mechanical model to predict the outcome of surgery for an individual patient is the unknown flexibility of each motion segment. Meade and Patwardhan et al. (86,105) developed a model that was used to estimate intervertebral stiffness by means of comparing predictions made with a two-dimensional model of the spine with the observed outcome of surgery. The results of these analyses indicated that motion segments near the apex have a flexibility similar to that of segments elsewhere in the curve (146). Subbaraj et al. (137) used a two-dimensional model of a patient's spine to simulate variations in surgical procedure. They estimated the flexibility of each motion segment based on radiographic measurements before and after application of traction. A three-dimensional model developed by Jayaraman et al. (64) was used for a similar purpose. Individualized simulation of six patients before and after Harrington rod surgery compared with the measured shape of each patient recorded with stereoradiography showed that model-predicted spinal curvature agreed better in the frontal plane than in the sagittal plane (134). The latter was sensitive to the properties of the intervertebral motion segments. Another problem in these simulations is incorporating nonlinear elastic and time-dependent material properties of the spine. These are known to be important in vivo, because the forces in instrumentation immediately postoperatively decay as much as one half in a few hours (39,93).

Segmental instrumentation offers surgeons many variables and multistep maneuvers to adapt to individual patients' needs. It also, however, produces many unknown inputs for the biomechanical analysis and difficulties in validation of predictions from models. To simulate these procedures, the surgical maneuvers for the concave-side rod of segmental instrumentation can be represented in four steps: (a) install the rod passively to the end hooks, then approximate the intermediate hooks to the rod; (b) displace the hooks along the rod to their final positions (hook distraction); (c) rotate the concave-side rod; (d) lock the hooks to the rod and relax the applied torque (spring-back). It has proved very difficult to quantify the required magnitude and direction of all these displacement inputs in the simulation.

Another possibility offered by analytical modeling is the ability to calculate stresses at selected sites in the spine and instrumentation. A finite element analyses were used to estimate stresses in internal fixation devices (48,126). These models have provided estimates of the change in bone stress for different vertebral injury situations with inclusion of plastic washers in the construct and after incorporation of bone graft. Biomechanical analyses also have been used to investigate the consequences of surgical variables, such as angulation of pedicle screws, on the rigidity of the construct (72,117).

Evaluation of Spinal Instrumentation

Much of the understanding about results of spinal fusion is empirical and based on results of follow-up studies. Biomechanical principles should provide additional information. The use of surgical instrumentation has a direct mechanical effect on the fused part of the spine and an indirect effect on the unfused region. It remains a challenge to biomechanics to further our understanding of the interactions between the spine, the instrumentation, and the muscular and other forces. The muscles and their control present the greatest difficulties, because central nervous system control of trunk balance is so poorly understood.

Mechanical Testing of Implants

There are three basic types of spinal implant construct testing—tests of individual implant components, such as hooks and rods; tests of the connections between an implant and the spine, such as hooks and pedicle screws; and tests of complete instrumentation assemblies. The performance of all constructs can all be evaluated tested in simulations of in vivo conditions. Laboratory testing of a spinal construct, which consists of test instrumentation applied to a standardized spinal specimen, can provide information about flexibility, strength, and fatigue life. Components such as pedicle screws can be tested in pull-out (72). The challenge in all these tests is to establish conditions that are representative of the in vivo situation. A test of strength (failure test) can be considered a test of instrumentation safety, and a test of stiffness can be considered a test of efficacy, because it is generally considered that stiffer fixation is more effective in achieving the goal of spinal arthrodesis. Thus strength and stiffness are desirable properties of instrumentation. Failure tests can be performed only once per specimen, whereas a stiffness or flexibility test can be repeated, provided that the installation of the instrumentation and the test itself do not greatly change the mechanical properties of the specimen. This may explain why there are a preponderance of reports of stiffness-flexibility tests over failure tests.

In a typical construct test, instrumentation is applied to a spine specimen, which is loaded. The resulting deformations are measured. A rare alternative is to test a construct by means of applying a displacement and measuring the necessary forces—a stiffness test. This test is the inverse of the flexibility test. In a typical flexibility test, a pure moment is applied with a coupling that consists of two equal parallel forces. The magnitude of the moment (torque) is the force magnitude multiplied by the distance between the parallel forces (Fig. 13A). As an alternative, offset compression loading (Fig. 13B) is intended to be more physiologically realistic because the spine is compressed axially at the same time as a bending moment is produced. The latter kind of loading is more difficult to control, because it can cause buckling. Another problem is that as the specimen deforms, the loading position and direction can move relative to the specimen and alter the components of force and moments acting on it. Most reports give the resulting rotations about the same axis as the applied torque or collinear with the applied load. If additional rotations or displacements about other axes are recorded, these provide information about the coupled (as opposed to direct) stiffnesses. The motion typically is recorded by means of mechanical or optoelectronic methods or with magnetic sensors of position and orientation. For the motion measurements to be valid, it is important that the segments be firmly embedded at their ends.

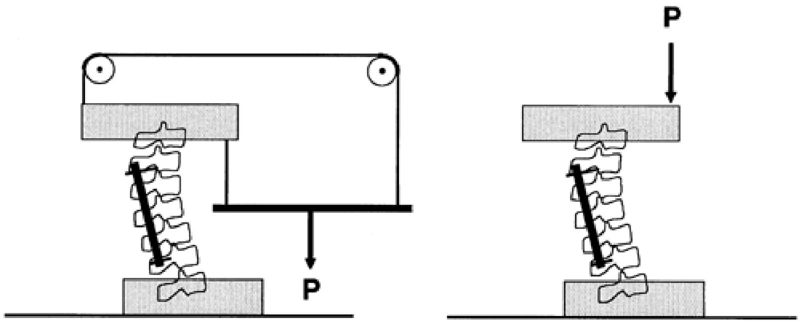

FIGURE 13. A: Mechanical test of an instrumentation construct with a pure moment that imposes flexion-extension by means of a coupling (equal parallel forces). **B:** Mechanical test with offset compression loading.

If linear forces are used as applied loads, great care must be taken to define the axis system. Linear force can produce rotational moment that depends on the point at which it is applied and on the direction of force. Therefore an advantage of testing a construct by using applied couples and recording rotations is simplicity: the measured flexibility is sensitive only to the axis of testing, and this facilitates comparisons between tests of various construct designs. The disadvantage is that such testing ignores direct forces and linear displacement components, thus it may lose realism while gaining simplicity. This may explain why many reports give only the three rotational modes of testing and omit the other three (translational) degrees of freedom. The results for individual degrees of freedom usually are reported separately. Because these are referenced to an arbitrary axis system, it may be preferable to refer the resulting motion to a structure of anatomic interest, such as the motion occurring at the site of arthrodesis.

In the real in vivo biomechanical situation, the spine has six complex degrees of freedom that interact structurally. Because the stiffness of the lumbosacral spine increases with axial loading, testing under laboratory conditions without such preloading may lead to underestimation of the spinal contribution to stiffness. The spine is subject to complex muscular, ligamentous, and gravitational forces that we do not understand very well. Therefore, ideally we would first identify which combination of forces and moments is pertinent and then perform instrumentation tests that simulate this realistic combination of muscular, ligamentous, and gravitational forces with six degrees of freedom. Then we should record the resulting motion in a way that gives an indication of the probability of rapid fusion and the chances of failure of the metallic or biologic structures. The applicable loadings have not yet been determined, nor have the pertinent specimen deformations. Information about in vivo loading of internal fixators has been provided by means of telemetry of signals from force transducers built into the instrumentation (114). These show forces on the order of 250 N and moments on the order of 6 Nm transmitted through the instrumentation during walking, but this constitutes an unknown proportion of the total load carried by the spine and the instrumentation. For comparison, Cappozzo (23) calculated that the cyclic component of the compressive force in the spine during walking typically is 700 N, approximately body weight.

Fatigue testing is important to establish whether instrumentation will fail with repetitive loading. This kind of testing usually is conducted only on individual components of instrumentation or on constructs applied to inert fixtures, such as plastic blocks, because on the order of one million cycles of loading must be applied to ensure that failure would not occur under in vivo conditions. These tests provide values for the maximum safe loads under test conditions that must then be interpreted in terms of expected in vivo loading. Because this kind of test is time consuming, an alternative is to analyze expected loads in vivo to determine from a stress analysis whether the highest calculated stresses all are within the limits of those to which the instrumentation materials are resistant to fatigue. In this kind of analysis it is very important to ensure that small radii and features with other shapes that can produce stress concentrations (stress raisers) are taken into account.

Many instrumentation tests are performed on animal spines because human spines representative of the target population (persons who need implants) are difficult to obtain. Specimens of human spines also are more variable in their mechanical properties than are animal spines of similar ages taken from animals of the same breed. Bovine calf and pig spines have been shown to be a reasonable choice because they have vertebral dimensions and flexibility properties similar to those of humans.

Standardized protocols for testing of instrumentation should facilitate comparisons between tests performed in different laboratories (8,99). However, standardization is difficult. In addition to defining the exact conditions for the tests, standardization has to take into account the difficulty of obtaining suitable human cadaveric material or the appropriateness of using animal spines. Standardization has been elusive. To date only the testing of instrumentation systems attached to plastic blocks (corpectomy model) has been provisionally standardized by the American Society for Testing and Materials (5). If a greater degree of standardization could be achieved, there is no guarantee that the results of the tests would be predictive of clinical outcome.

It remains unclear how surgeons who operate on the spine should interpret the information in reports of stiffness and strength testing of spinal implants. Also unclear is what information is helpful in selecting an instrumentation system and adapting it to the needs of a particular patient. It appears that the stiffer instrumentation the better are the results, providing the size of the instrumentation components is not excessive. Given that there are six degrees of freedom possible in a stiffness test, it is not known which components of rotation and translational stiffness are most important. Biomechanical information can be used in conjunction with other information in making surgical decisions. Biomechanical testing ought to be used with the goal of reducing the need for empiricism in the development of knowledge about the outcomes of different surgical strategies.

Conclusions

The spine is a complex, flexible structure the biomechanics of which are difficult to understand. Each motion segment has six degrees of freedom that interact with one another. This interaction, combined with the inherent curvatures of the spine and the complex anatomic features of the muscles and ligaments, produces biomechanical behavior that is difficult to predict. The spines of children present additional challenges because the biomechanical behavior interacts with growth and continuing development. If, however, the underlying biologic characteristics that relate mechanical factors to biologic responses were better understood, new possibilities would emerge for effective treatments that are not possible on the spines adults, which no longer have growth potential. Because much of the pediatric management of spinal problems is based on biomechanical principles, biomechanical considerations are important in most clinical and surgical decisions.

The spine of a child is not simply a scaled-down version of the spine of an adult. Although axiomatic, this concept is frequently forgotten in the management of pediatric spinal disorders. Making treatment decisions without knowing the unique features of the pediatric spine is akin to prescribing a medication without knowing the mechanism of action of the drug or the side effects. A physician treating a child with a disorder of the spine usually has a general understanding of the structural features unique to the pediatric spine. It also, however, is incumbent on the physician to have a firm understanding of the unique functional features of a child's spine. This chapter is intended to bring the specific functional features of children's spines into clinical perspective.

Knowledge of the biomechanical characteristics of the pediatric spine and the changes with age is particularly important in dealing with pediatric spinal instability and deformity. An understanding of these unique biomechanical features is the cornerstone in the decisions about nonoperative or operative treatment. To achieve a successful outcome, it usually is necessary to address the biomechanical derangements present in the pediatric spinal column. An understanding of the biomechanical principles of the normal and altered pediatric spines with consideration of biologic factors leads to rational treatment decisions for individual patients. Although knowledge of the biomechanics of the pediatric spine remains incomplete, certain principles can be ascertained with our current knowledge.

Clinical error, including inaccurate diagnosis, suboptimal timing of treatment, and poor selection of treatment, may be the result of deviation from biomechanical principles. For example, physicians may diagnose pathologic C2-3 subluxation more often than it actually occurs if they are not aware that pseudosubluxation of C2 on C3 can be caused by the increase in ligamentous laxity and facet orientation that is normal in childhood (27). Conversely, true instability of C2 on C3 may be missed if the limits of physiologic ligamentous laxity are not realized.

The physician must select the procedure with the greatest likelihood of success in dealing with the primary pathologic condition and the fewest potential complications. These two goals are not always met with a given surgical procedure. For example, cervical or thoracic laminectomy provides the most direct approach to spinal cord lesions. However, this procedure on a preadolescent patient is likely to cause progressive kyphosis at the level of the laminectomy (71). Knowledge of ligamentous laxity and the importance of the posterior tension band in these patients would lead to a decision to fuse the vertebrae at the level of the laminectomy. Knowledge of the plasticity of an immature posterior fusion mass in very young patients may lead to a decision to use localized instrumentation or a postoperative orthosis until the fusion consolidates. These examples highlight the clinical problems that can occur when there is no strong biomechanical or biologic rationale for treatment selection and implementation. The rest of this chapter describes basic biomechanical principles of the normal and pathologic pediatric spine and how these principles can be applied to clinical decision making.

Biomechanical Principles Specific to the Pediatric Spine

One cannot understand specific pathologic conditions without understanding the biomechanical features that differentiate the normal spine of a child from the normal spine of an adult. These features are closely related to basic tissue differences and to capacity for growth and remodeling. The clinical utility of these principles also is discussed. Table 1 lists the basic biomechanical features typical of the pediatric spine. The following sections present a thesis for understanding the biomechanics of the pediatric spine.

Growth

A clear difference between the pediatric and the adult spine is that the pediatric spine is actively growing. Growth applies forces to the spine, the magnitude of which varies with the rate of growth. Because the growth velocity is highest in infant and adolescents, it is expected that the resulting forces applied to the spine are greatest at these ages. Even though they are not great, the forces that result from growth may change spinal structure because they are applied over long periods of time. In normal spinal growth, anterior and posterior growth and side to side growth are balanced. The result is lengthening of the spinal column with relatively small change in its gross contours. If, however, a pathologic condition causes asymmetric growth, the force vectors change and cause deformity. This is exemplified by anterior fusion, congenital or surgically induced, in a child. Because the anterior structures no longer grow but the posterior structures continue to grow, a progressive kyphotic deformity results (114).

TABLE 1. Biomechanical Features of Pediatric Spines that Differtiate Them from Adult Spines

Growth
Adaptability
Malleability
Hypermobility
Growth plate as weak link
Changes in mechanical properties with age
Development of structural sagittal contours with age
Changes in applied forces with age
Regenerative capability
Immature neuromuscular control

The forces applied by asymmetric growth can be used to produce the progressive correction of congenital scoliotic curvature. This is the rationale for convex hemiepiphysiodesis for congenital scoliosis (115). Any correction obtained depends on the magnitude and rate of remaining growth on the concave side. Defects of segmentation lack concave growth, and convex hemiepiphysiodesis does not correct the deformity if the procedure is limited to the area of congenital anomaly. In contrast, a defect of formation can have considerable remaining growth potential, and the possibility exists that curve correction can be obtained with this technique. The often difficult to determine remaining spinal growth must be carefully considered in the management of pediatric spinal disorders. The ultimate goal should be to achieve a balanced spine.

The crankshaft phenomenon, which causes a progressive increase in curvature and rotational deformity, is an example of how spinal growth complicates the management of deformities of the pediatric spine. This phenomenon occurs in patients with immature skeletons who undergo isolated posterior fusion for the management of scoliosis. Despite solid fusion, progressive bending of the plastic posterior fusion mass can be caused by continued anterior growth of the spine at the fused levels (37). As expected, the risk of progression after posterior fusion is related to the amount of anterior growth remaining. Risk factors include being younger than 10 years of age at the time of fusion, Risser sign 0, or the presence of open triradiate cartilage (48,69,95,98). Progressive bending is common under these circumstances and can occur despite the presence of a thick fusion mass and rigid instrumentation. Anterior and posterior fusion often is recommended to prevent the crankshaft phenomenon among this population (68). Congenital scoliosis appears to carry lower risk of the crankshaft phenomenon than does idiopathic scoliosis, likely because of the limited growth potential remaining among many children with congenital scoliosis (37).

Adaptability

The pediatric spine can adapt to applied stresses much more readily than can the adult spine. This is related to growth potential, the lower modulus of elasticity, and prominent remodeling capability. The result of this adaptability is that a child often can maintain a functional level in the presence of a serious pathologic condition. For example, a large thoracic scoliosis curvature in a child is likely to be associated with a compensatory lumbar curve that causes net balance of the head over the pelvis. Despite this considerable spinal deformity, a child often continues to function well because of the compensatory mechanisms (63). Although immature musculoskeletal tissues have considerable capability to adapt and remodel, neural tissues do not have the same capability; this disparity can cause serious clinical problems (see later).

Malleability

In addition to being adaptable, which implies an active process, the pediatric spine also is substantially malleable. *Malleability*, a passive process, implies that the spine may be deformed with the application of a force external to the spinal column. One adverse outcome related to malleability is the scoliosis that often rapidly occurs after unilateral rib resection in a child (31). The same procedure is unlikely to cause progressive deformity in an adult. Malleability is a reflection of the intrinsic elasticity of ligamentous tissues and the modulus of bone. With maturation of these tissues, malleability decreases rapidly. This is one of the reasons the use of orthotic devices for the correction of deformities loses effectiveness with maturation (26). Malleability also is an important quality of the bony elements, as in spondylolisthesis, in which the pars interarticularis may undergo extensive elongation before fracture (57).

A corollary to malleability is that the pediatric spine is able to absorb considerable energy before failure. This partially accounts for the lower incidence of fractures of the spine among children than among adults (55). A spinal cord injury also can occur in a child without radiographic abnormality (*SCIWORA*) (62,65,89). In many cases, spinal cord injury is caused by overdistraction of the spinal cord, which is less elastic than young ligamentous tissues. Injury also may be caused by transient subluxation of vertebrae even though the ligamentous and bony elements are structurally intact.

Hypermobility

The physiologic range of motion of the pediatric spine is considerably greater than that of the adult spines. This is the result of differences in ligamentous restraints and orientation of the facet joint (110). In athletic activities such as gymnastics this hypermobility can be beneficial, but it generally is of questionable functional value. For example, among female gymnasts, spinal hypermobility can be accentuated to an extreme, as exemplified by the hyperextension used in back walkovers. This, however, exceeds the physiologic hypermobility of childhood, and the concentrated extension forces cause a high frequency of stress fractures of the susceptible pars interarticularis (58). Hypermobility must be appreciated in the assessment of patients with disorders such as pseudosubluxation of C2 on C3 (27). Physiologic hypermobility does not cause pathologic conditions when subjected to normal forces. Thus pseudosubluxation does not cause narrowing of the spinal canal. In general, physiologic hypermobility of the axial skeleton generally parallels that of the appendicular joints. These features can be used to assist in differentiating physiologic from pathologic hypermobility.

Weak Growth Plate

The growth plate is the weakest link in the axial skeleton when it is subjected to tensile forces. This has important implications for the types of injury most likely to occur in the pediatric spine. Odontoid injuries usually occur through the physeal plate, located near the base of the odontoid process (100). These are often in a position nearly equivalent to that of type II odontoid fractures in adults and are similarly unstable. However, because the pediatric injury occurs through the growth plate, the healing potential is high, and nonunion is infrequent. Because the spine does not have posterior column growth plates that can absorb traumatic force, injuries to the ligamentous and bony elements of the posterior column do occur. Physeal injuries frequently accompany disc protrusions among children. As an anular fragment protrudes from the disc space, traction through the ring apophysis avulses a fragment of bony end plate. This accounts for the present of extruded bony fragments on radiographs of the spines of these patients (8).

Changing Spinal Contours

The sagittal spinal contour begins as a gentle *C* arc. Secondary lordotic cervical and lumbar curves are added to this kyphotic curve with development. The development of these secondary curves has considerable biomechanical relevance, because the transitional regions between lordotic and kyphotic curvatures are regions of stress concentration and are susceptible to deformation. The predominance of burst fractures at the thoracolumbar junction is related to this stress concentration (110). It appears that the sagittal curve partially stabilizes the spine against the development of rotational and coronal plane deformity. With rapid spinal growth, as occurs during the adolescent growth spurt, anterior spinal growth appears to exceed posterior growth in many instances and to decrease thoracic lordosis. This may leave the spine susceptible to both rotational and coronal plane deformities, which cause scoliosis (103).

Changing Applied Forces

The forces to which the spine is subjected are important in the initiation, perpetuation, or exacerbation of various spinal diseases. These day-to-day forces change substantially during the process of growth and development. In infancy, the child is generally protected from large forces, partially as a result of a low level of activity. However, the head of an infant is large in relation to body mass; this is a potential source of considerable force during acceleration or deceleration. The force that this applies to the cervical spine can have devastating consequences (32,51). This vulnerability decreases with age with the decrease in the proportion of head to body mass, stabilization of the neck lever arm, and maturation of neuromusculoskeletal defenses against injury. The importance of lengthening spinal lever arms with growth is well known to physicians experienced in bracing. It is difficult to obtain adequate curve control with orthoses for very young patients with short spinal lever arms and abundant body fat (21).

The day-to-day forces to which a child is subjected usually increase through early childhood as play becomes more vigorous. Play is random at first, but as children become involved with organized sports they are more likely to be exposed to repetitive stress. It is at this time that the child becomes vulnerable to spinal disorders due to fatigue (34). These include spondylolisthesis, spondylolysis, disc protrusion, and muscle strain.

Immature Neuromuscular Control System

Myelination of the central nervous system is completed during the first 2 years of life. Balance and coordinated neuromuscular activities, however, continue to develop throughout childhood. The implications of this immaturity are, first, that the skeletal system, including the spine, is exposed to increased risk of injury. Second, immature motor control may predispose the child to conditions such as scoliosis (124). Postural equilibrium and balance require the complex integration of sensory stimuli from the proprioceptive, visual, and vestibular systems with control of the motor systems. Subtle abnormalities of this system may underlie at least some cases of idiopathic scoliosis (99,112).

Application of Biomechanical Principles to Clinical Practice

The importance of biomechanical principles depends on the specific clinical scenario. The rest of this chapter focuses on the application of basic biomechanical principles to the management of specific spinal disorders. Because biomechanical knowledge has its most profound effect on the management of spinal instabilities and deformities, the discussion is limited to these entities.

Scoliosis

Three-Dimensional Assessment of the Spine

The clinically important biomechanical features of scoliosis can be divided into those that are important in the initiation, progression, and management of curves. The three-dimensional nature of the deformity has been recognized because the original anatomic descriptions of scoliosis. Despite this, it is only in the last decade that the importance of the associated deformities in planes other than the coronal has come to light. The noncoronal plane components of the deformity appear to have both etiologic and therapeutic significance. Evidence suggests that decreased thoracic kyphosis and rotational deformity are important in the initiation of scoliotic curves. The importance of rotational deformity of the spine as a potential complication also has been stressed. It is essential that a physician managing scoliosis be adept at performing three-dimensional assessment of the spine, trunk, and entire body (Table 2). The findings must then be used in conjunction with biologic information and knowledge of the biomechanics of treatment modalities to arrive at the best therapeutic approach for a given patient.

TABLE 2. Biomechanical Features Important in Evaluations for Scoliosis

- Spine
  - Coronal curves

  - Temporal analysis
- Thoracic cage
  - Paravertebral prominence
  - Pulmonary function
- Entire body
  - Leg length
  - Pelvic inclination
  - Trunk shift
  - Shoulder inclination
  - C7 balance
  - Occipital balance

A detailed clinical and radiographic assessment of a patient with scoliosis focuses not only on the various components of the spinal deformity but also on the resulting biomechanical alterations that occur in the trunk and the rest of the body. The spine must be evaluated to determine the magnitude and rigidity of the coronal, sagittal, and rotational deformities. This information must then be correlated with the effect of the spinal deformity on the function of the entire patient to assist in determining the best treatment.

The most obvious spinal deformity in scoliosis usually is curvature in the coronal plane. Radiographic evaluation of the magnitude of this curve has been standardized with the Cobb method. However, attempts to predict associated spinal and other deformities on the basis of the Cobb angle have met with little success (52). The magnitude of associated sagittal and rotational deformities does not correlate with the magnitude of the Cobb angle. This indicates that other factors are implicated in the development of the associated deformities. Despite poor correlation, there is excellent biomechanical evidence that spinal motions in different planes are coupled—deformity in the coronal plane affects the spinal configuration in the other planes (109). In the midthoracic spine, however, coupling is not entirely predictable. Ohlen et al. (87) showed that thoracic kyphosis among patients with idiopathic scoliosis was less than that among controls with normal spines. However, the degree of kyphosis or lordosis did not correlate with the Cobb angles.

Among most patients with thoracic scoliosis, rotation occurs and causes the spinous processes at the apex of the curve to rotate toward the concavity of the curve. However, nonstandard vertebral rotation is present in many patients with scoliosis. Most commonly this involves rotation that extends more than one segment beyond the end vertebra. Armstrong et al. (6) showed that rotation of the vertebral bodies to the side opposite the major curve occurred among 7% of the patients in their series. As a result of this variability, the three-dimensional nature of curves must be assessed individually to determine optimal treatment regimens. These associated deformities may have a considerable functional effect on the patient. Rotation of the spine influences the perception of the sagittal and coronal plane deformities; this occurs because a lateral curvature is rotated out of the frontal plane. If there is substantial curve rotation, a spine that is lordotic may appear kyphotic on a standard lateral radiograph. For this reason, Stagnara et al. (104) described radiographs in the true plane of the deformity to assess scoliosis with a marked rotational component. These radiographs are not used frequently in scoliosis management in North America; however, the influence of rotational deformities on the assessment of coronal and frontal plane deformities should be kept in mind.

Assessment of spinal rotation with plain radiographs has been shown to be of limited accuracy. Both the Moe and Pedriolle methods have been shown to have measurement errors greater than 5 degrees. Assessment of vertebral rotation with plain radiographs is further complicated for curves greater than 50 degrees, with which deformities of the vertebral elements are common (3). For this reason, transverse computed tomographic sections with the vertebrae referenced to the thorax have been used for research. Accuracy within 0.3 degrees with vertebrae tilted up to 20 degrees in the sagittal and frontal planes has been reported with this technique (2). Aaro and Dhalborn (3) also found that vertebral rotation correlates roughly with the size of the lateral curve but not with the location or length of the curve.

Surgical improvement of vertebral rotation with instrumentation in idiopathic scoliosis is unpredictable at best (4). Wojcik et al. (119) found that the rotational correction obtained with Cotrel-Dubousset instrumentation is inconsistent. Wood et al. (120) pointed out that studies of rotational correction should reference vertebral correction to the pelvis, not to other vertebrae. These authors found that the entire vertebropelvic axis rotated around the frontal plane and that no selective derotation of the apical vertebrae occurred after Cotrel-Dubousset instrumentation. Wojcik et al. (119) also found no consistent rotational correction of the apical vertebrae of thoracic curves when segmental sublaminar wiring was used. These results were confirmed by Hullin et al. (56), who found that the rib hump often worsened with sublaminar wiring of thoracic curves. Hullin et al. found Luque wiring effective in achieving three-dimensional correction of thoracolumbar and lumbar curves. The reason for the difference in rotational correction according to curve location is unknown, but it may be related to the sequence of application of the Luque rods. Further therapeutic implications of spinal deformities outside the coronal plane are discussed later.

Static three-dimensional analysis of spinal deformity should be supplemented with an analysis of the flexibility of or ability to correct any deformities. General assessment of spinal flexibility can be made by means of clinical examination, but a more precise evaluation includes radiographic assessment. Supine side-bending radiographs have been used most frequently to assess spinal flexibility. The comparative value of standing, side-bending radiographs, manual pressure over curve apexes, and traction radiographs has not been scientifically assessed. These technical variations in the assessment of spinal flexibility may affect the magnitude of measured flexibility. Biomechanical data certainly indicate that longitudinal forces are more effective than transverse forces in achieving correction of curves greater than 55 degrees (110). This suggests the usefulness of traction in assessing large curves. The viscoelastic properties of the spine have not been accounted for in any of these assessments, so the bending time before radiography has not been standardized. Current methods for evaluating the flexibility of a curve are imprecise but are useful in patient care.

Bending radiographs contribute several factors to the biomechanical assessment of scoliosis, including assessment of the flexibility of major and compensatory curves, evaluation of the mobile disc spaces, and determination of which vertebrae become horizontal and come into the stable zone with side bending. Assessment of the flexibility of the curve provides a rough guide to the potential responsiveness to bracing and suggests the curve correction that can be obtained with surgery. The correlation between predicted preoperative correction based on bending radiographs and ultimate curve correction generally is good. However, the force generation that may be applied segmentally with Cotrel-Dubousset instrumentation and newer segmental devices often produces greater correction than predicted preoperatively. Overcorrection can cause postoperative decompensation and should be avoided (107). The lowest vertebra to become horizontal and stabilize with side bending and is adjacent to a mobile disc space determines the lowest level for Cotrel-Dubousset instrumentation. When a large and rigid lumbar curve is present, it is important that the distal end vertebra involved in instrumentation meet these criteria (10). This provides a stable and well-aligned caudal foundation for instrumentation and correction of the proximal curves and minimizes the risk of decompensation of the coronal plane with instrumentation.

In addition to the static and dynamic assessment of the three-dimensional spinal deformity, the clinical evaluation should define the chest wall deformity. This involves evaluation of the appearance of the paravertebral prominence and functional evaluation of thoracic capacity and pulmonary function. The paravertebral prominence in scoliosis is composed of the transverse processes, posterior aspects of the ribs, scapula, and overlying muscles on the convexity of the curve. The magnitude of the paravertebral prominence does not correlate well with the measured Cobb angle or with measured vertebral rotation at the curve apex. Aaro and Dahlborn (2) found that patients with early scoliosis often have clinically apparent posterior thoracic prominences, despite the absence of rotational deformity of the vertebrae. It appears that deformities of the ribs may play an important part in the development of rib humps (108). In addition, changes in the costovertebral joints may contribute to the rib prominence. The costovertebral joints allow motion, primarily in the coronal plane, as occurs with respiration. Because the cross-sectional contour of the ribs changes considerably depending on the cranial-caudal angulation of the ribs, minor changes in this angulation may have considerable effect on the perceived magnitude of the paravertebral prominence (3). Other factors that may contribute to the incomplete coupling between the convex paravertebral prominence and the severity of spinal deformity include asymmetric rib growth and accompanying deformities of the transverse processes and scapula.

Decrease in the paravertebral prominence can occur as a result of coronal plane correction with minimal rotational correction of the spine, because the convex ribs may change from a horizontal to a more vertical pattern. This likely accounts for the often marked improvement in the paravertebral prominence with Cotrel-Dubousset instrumentation in the management of adolescent idiopathic scoliosis, despite only inconsistent rotational correction. However, clinical studies of instrumentation for scoliosis have shown that the posterior thoracic prominences may persist despite excellent correction of the spinal deformity (23,85,93). This has been demonstrated for Harrington, Harrington-Luque, and Cotrel-Dubousset instrumentation. Wojcik et al. (119) showed that the convex rib drooping present in idiopathic scoliosis usually is not corrected with segmental sublaminar wiring or Cotrel-Dubousset instrumentation. This may contribute to residual rib prominence. Persistent thoracic deformity may be caused by convex rib deformities (108), which may be managed best with spinal instrumentation and fusion combined with thoracoplasty. Although the main concern about the paravertebral prominence has been appearance, there is potential for biomechanical derangement of the scapulothoracic articulation. Some of our patients have had convex scapulothoracic pain or clicking with motion in association with a large convex paravertebral prominence. The functional importance of the paravertebral prominence to the scapulothoracic articulation remains unclear.

An important aspect of thoracic deformity is thoracic volume and, closely associated with this, dynamic pulmonary function. Thoracic volume is a complex measurement obtained with sophisticated techniques—either digitized radiography or computed tomography (86)—generally not performed in the clinic. Calculated thoracic volume is a reflection of the spinal deformities in the coronal and sagittal planes, the decrease in thoracic height, rib deformities, and elevation of the diaphragm. Ogilvie and Schendel (86) found that loss of thoracic kyphosis is the factor that correlates most closely with decreased thoracic volume in idiopathic scoliosis. Although actual thoracic volume is not measured, the sagittal plane alignment has considerable influence on thoracic volume and must be accounted for in clinical decision making. Dynamic measurements of pulmonary function in scoliosis obtained with spirometry must be interpreted with full knowledge that this measurement depends on patient effort and may have limited reproducibility. Despite the limitations, pulmonary function testing is frequently used (66). Pulmonary function is related to thoracic volume and thoracic muscle activity, both of which may be limited in scoliosis. Because the respiratory capacity of the thoracic musculature in scoliosis may be limited, particularly in neuromuscular scoliosis, improvement of thoracic volume may not produce similar improvement in pulmonary function. This appears to be particularly true with operative correction of curves greater than 90 degrees (66).

The final component of biomechanical assessment of the deformity in scoliosis involves determining how the spinal and thoracic deformities relate to the structure and balance of the entire patient. This often is the most functionally important portion of the assessment and requires knowledge of leg length discrepancy, pelvic inclination and rotation, lateral trunk shift, shoulder tilting, and C7 and occipital balance in both the coronal and sagittal planes. Understanding how the spinal deformity relates to the lower extremities, pelvic and shoulder girdles, and head position allows planning of treatment to address the most important components of the deformity for a given patient. Patients with large curves may be well balanced in the coronal and sagittal planes, and balance may be impaired with inadequately planned surgery (75). A patient's main concern may be related to shoulder obliquity or rotation of the shoulder girdle with respect to the pelvic girdle. If these concerns are not addressed with treatment, the patient may be dissatisfied despite excellent correction of the spinal deformity. The relations of structures at the cranial end of the spine to those at the caudal end often is more functionally important than the intervening scoliotic curves. The complex nature of the spinal deformity and the associated deformity of the body necessitates individualized assessment and management of scoliosis.

Leg length discrepancy may affect the pelvis and the spine. It appears that a leg length discrepancy greater than 2.5 cm is associated with a high incidence of scoliosis, often in the lumbar region, that usually is of small magnitude and is nonprogressive (90). A leg length discrepancy probably exerts its influence on the spine as a result of righting reflexes that act to maintain the patient's center of gravity in a stable position. Correction of the leg length discrepancy can resolve the curvature; however, Papaioannou et al. (90) showed that appreciable, although minor, lumbar scoliosis remains in many patients after neutralization of the discrepancy. Because leg length discrepancy causes pelvic obliquity that can be reversed initially with sitting, the patient's coronal plane balance may shift considerably between the standing and sitting positions. As the spine becomes more rigid with time, the ability to compensate for shifting balance becomes limited. As a result, it is important to attempt to account for the shifts in C7 or occipital balance that can occur with correction of a limb length discrepancy in a patient with scoliosis.

Pelvic obliquity can be caused by infrapelvic or suprapelvic problems (114). Infrapelvic problems include leg length discrepancy and iliotibial band contracture. Suprapelvic causes include neuromuscular imbalance and the fractional lumbosacral curve in scoliosis. The forces that contribute to the development of the pelvic obliquity also frequently cause an associated scoliotic deformity, particularly in the lumbar spine. Marked fixed pelvic obliquity in association with lumbar scoliosis may necessitate fusion to the pelvis with possible correction of the pelvic inclination with respect to the lumbar spine. If pelvic obliquity in this scenario is not addressed, the potential for producing an unbalanced spine is high.

Asymmetry of shoulder levels often is a problem among patients with scoliosis, particularly those with high thoracic curves. Most children without scoliosis have some normal shoulder asymmetry, mainly depression of the dominant shoulder. In any case, it is desirable to obtain reasonably level shoulders at the completion of treatment, because this is a potential source of patient dissatisfaction.

The combination of leg length discrepancy and pelvic inclination with the spinal curves determines whether the spine and the patient are balanced with the head centered over the pelvis. Although the relation of the occiput to the sacrum in the coronal and sagittal planes may be the most meaningful measurement, the relation of C7 to the sacrum is more commonly measured because this can be done readily measured on standing anteroposterior radiographs of the spine. It is important to realize that the occipital shift, which may be more important to the patient's perception of balance, may be substantially different from the C7 shift, particularly when curves extend into the cervical spine. In the frontal plane, the C7 plumb line should fall close to the midsacral line. Healthy children may show up to 2 cm of lateral shift from the midsacral line in neutral standing; this tends to decrease with age, possibly as a result of neural maturation (7). The mechanisms controlling spinal balance are poorly understood, as are the specific functional limitations caused by coronal imbalance.

In the sagittal plane, C7 is normally centered over the body of S2. Iatrogenic loss of lumbar lordosis (surgical flat back) often is associated with anterior displacement of C7 relative to S2 (67). The patient may be able to partially compensate and maintain C7 balance by means of extensor spinae contraction, hyperlordosis of the cervical spine, and knee flexion. Further implications of flat back syndrome are discussed later.

Initiation of Scoliosis

Numerous theories of the cause of idiopathic scoliosis have been presented in the literature over the past 50 years. Most of these have been disproved. Produced of melatonin by the pineal gland has been implicated as a possible etiologic factor. What is known is that melatonin deficiency caused by pinealectomy among chickens causes scoliosis. Machida (74) found lower melatonin levels among children with progressive curves than among children with normal spines. Hilibrand et al. (53), however, found no correlation when they compared children with and without scoliosis.

Subtle abnormalities of neuromuscular balance may be an important cause of idiopathic scoliosis. In much of the research in this area, it is difficult to differentiate primary from secondary abnormalities (124); however, abnormalities of postural control identified in the siblings without scoliosis of patients with scoliosis suggest that these may be of etiologic importance. Abnormal otolithic vestibular function has been found among children with scoliosis (112). Asymmetry of paraspinous muscle activity among patients with scoliosis also has been identified, but there is no evidence to suggest that this asymmetry is of primary importance in scoliosis.

Studies have emphasized biomechanical and structural changes early in the scoliotic process that may be of etiologic importance (Table 3). Experimental and clinical studies indicate that loss of normal thoracic kyphosis can cause a situation in which the spine is unstable during rotation and lateral bending (33). Using derotated views of the spine, Deacon et al. (29) showed with radiographs that patients with idiopathic scoliosis have less thoracic kyphosis than do children with normal spines. Although routine lateral views erroneously indicated a mean thoracic kyphosis of 41 degrees, derotated views showed actual lordosis of 14 degrees on average. Loss of thoracic kyphosis may occur if posterior spinal growth lags behind growth in the anterior spinal column. A linked column such as the spine loses stability when it is lengthened and straightened (110). This may allow rotational and coronal plane deformities to develop.

TABLE 3. Biomechanical Factors in the Initiation and Progression of Idiopathic Scoliosis

- Initiation
  - Immature balance
  - Hypokyphosis and rotational instability
  - Nonstandard vertebral rotation
  - Muscle imbalance
- Progression
  - Gravity effects
  - Decrease in concave growth (Hueter-Volkmann law)

Another observation of potential etiologic importance in idiopathic scoliosis is that the direction of coupled rotation in the midthoracic spine is opposite that which occurs in other regions of the spine. With lateral bending in the midthoracic spine, the spinous processes rotate into the concavity of the curvature. Such nonstandard coupling of rotation and lateral bending may produce a rotationally unstable situation that may progress to the complete deformity of scoliosis (6). These theories must be described as interesting but speculative. They do not explain why certain persons and families are more prone to develop scoliosis than are others. Although the cause of idiopathic scoliosis remains unknown, it appears likely that biomechanical factors combine to produce a spine that lacks the stability to prevent axial rotation and bending in the coronal plane.

Progression of the Curve

The same factors that are involved in the initiation of scoliosis may be important in progression of the curve. Additional factors of probable importance in the progression of the deformity, particularly with larger curves, are the effects of gravity and asymmetric spinal growth. Biomechanical models have shown that the effects of gravity are more important than asymmetric functional capabilities of muscles in determining curve progression (45). As curves become larger, gravity applies an increasing bending force to the curvature in the upright posture. The deforming forces of gravity theoretically are more important in longer curves, in which there is a longer lever arm. Increasing deformity also is associated with increasing asymmetry of the force applied to the spinal growth plates. The increased concave pressure inhibits growth on this side of the spine, in accordance with the Hueter-Volkmann law. The result is progression of the deformity. Mente and Stokes et al. (80,105) applied the Hueter-Volkmann law experimentally in a rat tail model and found vertebrae loaded asymmetrically produced vertebral wedging due to asymmetric growth in the physis.

Biomechanics of the Management of Scoliosis

The primary goal in treating patients with scoliosis is to stabilize the curves to prevent further progression of the deformity (Table 4). Closely related to this is the goal of achieving correction of spinal deformity, although this is not part of the therapeutic regimen for every patient. The optimal treatment in a specific situation achieves the primary goal of prevention of curve progression and addresses as many secondary goals as possible. Treatment that neglects secondary goals can produce the unacceptable biomechanical situation of impaired function and possibly cause late pain.

TABLE 4. Biomechanical Principles of Management of Scoliosis

- Primary goals
  - Prevent progression of deformity
  - Correct spinal deformity
- Secondary goals
  - Balance spine, pelvis, and shoulders (coronal, sagittal, and rotational)
  - Maintain mobile low lumbar segments
  - Restore and maintain sagittal contours
- Tertiary goals
  - Increase truncal height
  - Achieve cosmetic correction

The prevention of curve progression must counter the forces that tend to cause progression. The force causing progression is greatest in large curves in which gravity applies a bending force (45) and in young patients, among whom asymmetric spinal growth can accentuate the deformity. Methods for decreasing curve progression include decreasing the deforming force, applying a compensatory force, or a combination of these methods. Decreasing the deforming force can be achieved by means of decreasing the magnitude of curves with casting, bracing, or instrumentation. Decreasing the deforming force induced by asymmetric growth can be achieved by means of decreasing curve size or fusing the growing segments.

The compensatory force that can be applied by external devices usually is limited. External devices often are successful in neutralizing the deforming forces of small to moderate-sized curves (less than 40 degrees). In larger curves (40 to 50 degrees) the effectiveness of orthotic devices depends on achieving a substantial decrease in curve size and deforming forces (26).

Curve correction is not necessarily the primary goal in surgical treatment of patients with scoliosis. Correction of curves in the coronal plane may be useful for decreasing the deforming forces on the spine and for improving some aspects of appearance, but curve correction must be carefully coordinated with an overall plan to maintain the coronal, sagittal, and rotational balance of the patient. The issue of how much correction is appropriate for a patient is based on a risk to benefit analysis. With a rigid curve, correction may necessitate combined anterior and posterior procedures or may place undue stress on the instrumentation. In such cases, the benefits of curve correction may not be justified. The risk of traction on neural elements also must be accounted for in obtaining curve correction. There is no specific level of residual curvature that is best for all patients; this must be decided on an individual basis.

The biomechanics of obtaining curve correction have been studied extensively (110). The forces applied can include transverse loading, longitudinal traction on the curve concavity, compression on the curve convexity, and rotational forces (Fig. 1). With curves less than 55 degrees, transverse loading forces are the most effective in reducing the magnitude of the curve. For curves larger than 55 degrees, the force vectors change appreciably, making concave longitudinal distraction more effective than transverse loading. The usefulness of convex compression in correcting the deformity is substantially limited by the short lever arms provided by the transverse processes. Convex compression of large curves may actually apply a force that worsens the deformity, because the compressive force vector passes through the curve concavity. Rotational forces may improve the contours in both the coronal and the sagittal plane, but the actual rotational correction obtained with current instrumentation systems is limited. Correction with these systems may occur through a combination of transverse loading and longitudinal distraction.

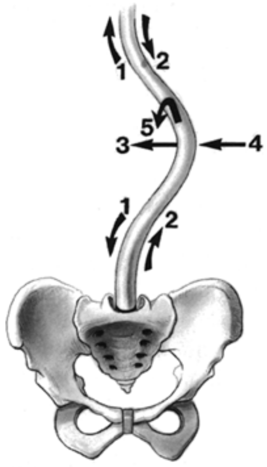

FIGURE 1. Schematic representation of force vectors that can affect correction of a spinal deformity. *1*, Concave distraction; *2*, convex compression; *3*, transverse force pulling the curve toward concavity; *4*, transverse force applied at curve apex; *5*, rotation of curve from coronal to sagittal plane.

Spinal deformities combine with the positions of the pelvis, shoulders, and head to determine whether the patient is balanced in the coronal and sagittal planes. A double curve in which there is a rigid and poorly aligned low lumbar curve often causes imbalance when the thoracic curve is corrected. This cause, at least in part, is inability of the rigid, caudal regions of the spine to compensate for changes induced in the midthoracic and thoracolumbar regions. Loss of spinal balance may produce an appearance that is worse than the initial deformity. Maintenance of sagittal contours also considerably improves the likelihood of a successful results of treatment.

An attempt must be made to preserve mobile motion segments in the lower lumbar spine. It is ideal that at least three healthy, mobile segments in the lower lumbar spine be preserved to avoid inordinate stresses on the remaining motion segments. Cochran and Nachemson (28) found that the incidence of serious low back pain increases from about 20% with fusion that extends to L3 to 80% with fusion that extends down to L5. Maintenance of mobile distal lumbar segments is a problem with large lumbar curves in which instrumentation must be extended into the lower lumbar spine. The distal extent of fusion can be minimized with the use of anterior instrumentation or posterior segmental instrumentation supplemented with pedicle screws.

A basic component of many scoliosis curves is decreased thoracic kyphosis. One surgical goal in this population is to increase thoracic kyphosis. This may be achieved through the use of Luque instrumentation with sublaminar wiring that pulls the vertebrae posteriorly to contact the contoured rods (60). The use of segmental instrumentation devices may achieve increased thoracic kyphosis with less neurologic risk than that of sublaminar wiring. Kalen and Conklin (60) showed that correction of thoracic kyphosis does not increase lordosis in the lumbar spine on which instrumentation is not performed.

The importance of preventing iatrogenic flat-back deformity should be emphasized. As the name implies, flat-back deformity consists of loss of lumbar lordosis. Normal lumbar lordosis broadly ranges from 20 to 80 degrees (11). Iatrogenic flat-back syndrome is defined as a loss of lumbar lordosis that causes low back pain, upper and middle thoracic pain, cervical muscular strain, and knee pain (30). Lagrone et al. (67) found that the flat-back syndrome is most common when distraction instrumentation is extended into the lower lumbar spine or the sacrum. The next most common predisposing factor is preoperative thoracolumbar junctional kyphosis greater than 15 degrees. It appears that this complication can be minimized with knowledge of the sagittal plane contours and avoidance of the use of distraction instrumentation in the lower lumbar spine (106). Because surgical correction of flat-back deformity is a major procedure that necessitates an osteotomy such as a Smith-Peterson or pedicle subtraction osteotomy, avoidance of this complication is paramount.

Biomechanics of Orthotic Treatment

The effectiveness of orthotic treatment in preventing progression or achieving correction of a deformity is determined primarily on the basis of the factors in Table 5 . The deforming force vectors interact with the orthotically applied force vectors to give a resultant or net force that determines the tendency of the spine to undergo correction or further deformation. This interaction can be represented as a balance with deforming forces on one side and applied or correcting forces on the other. The resistance to change represents spinal malleability or rigidity. This resistance decreases the effects of the resultant force on the spine. Greater forces are needed to effect changes in less malleable curves.

TABLE 5. Factors that Determine the Effectiveness of Orthotics

- Deforming force, which depends on
  - Spinal growth
  - Severity of deformity
- Applied force properties
  - Magnitude
  - Location
  - Direction
  - Temporal aspects
- Spinal malleability or rigidity

The primary factors determining the deforming forces are the rate of spinal growth (application of asymmetric forces to the spine) and the size of the curve (increasing the deforming effect of gravity). This biomechanical model is supported by results of clinical studies, which indicate that the remaining spinal growth and magnitude of the curve are most important in determining whether a curve progresses (72). The directional component of the applied force may be complex and three-dimensional, complicating this model.

There are several important aspects to the corrective forces applied by an orthotic device, including magnitude, location, direction, and temporal qualities. The magnitude of the corrective forces depends on the type and fit of the brace. These forces can be produced by passive correction by the brace or by the patient's active postural reaction to the brace. Passive correction is limited by patient tolerance of the direct pressure applied by the brace. Active correction is limited by the muscular forces that the patient can exert for prolonged periods. Studies have suggested that a patient's active postural reaction in the brace may be the most important force leading to correction (5,83). In either case, the applied forces usually are not large.

Traditional orthoses rely on the principle of three-point fixation to apply corrective forces to a deformity (21). Adequate force generation with this system depends on separation of the two end points from the central (apical) point of pressure application (Fig. 2). This creates adequate lever arms for force generation. The Milwaukee brace is a cervicothoracolumbosacral orthosis that is capable of producing adequate lever arms for the management of most curves, except those in the high thoracic region. Successful use of a thoracolumbosacral orthosis (TLSO) is restricted to curves with apexes below T7 (39); this is likely related to the shorter lever arm produced when cervical extension is not used.

It appears that bracing may provide some rotational correction of the scoliotic spine. Aaro et al. (1) showed that an average of 38% correction of rotation was achieved with the use of the Boston brace. However, the amount of correction varied dramatically among patients. Because it is unpredictable, rotational correction cannot be a prime goal of orthotic treatment. The ability of the Milwaukee brace to achieve correction of spinal decompensation was studied by Rudicel and Renshaw (97). The braces used were found to be inadequate for correction of spinal balance. It remains unclear whether adding trochanteric extensions to the brace improves decompensation correction.

The forces applied can be further limited if they are not directed in the appropriate plane for the deformation. Because it has a posterolateral apical pad, the Milwaukee brace produces lordosis in the thoracic spine; this effect can be minimized with optimal pad placement. Loss of thoracic kyphosis decreases thoracic volume and may impair pulmonary function (86). The presence of true lordosis of the thoracic spine is a contraindication to the use of a Milwaukee brace. Orthotic design also influences the location of maximal applied force, which should be at the curve apex to optimize the corrective force. The magnitude, direction, and location of force must be optimized in the orthotic design for application of a suitable corrective, or counterprogressive, force.

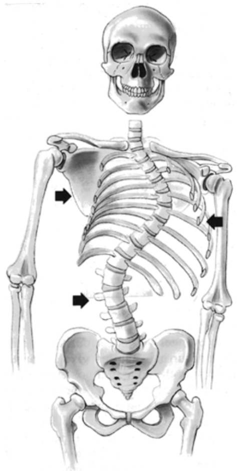

FIGURE 2. Three-point application of force (*arrows*) for orthotic correction of scoliosis. Correction of high thoracic curves is limited by the short lever arm achieved with an infraaxillary pad.

The temporal characteristics of the force applied by an orthotic device also influence the ultimate magnitude of the curve. To have an optimal effect in countering the progressive forces, the force should be applied when the progressive forces are expected to be maximal. Maximal deforming forces generally occur when a patient is in an upright rather than prone or supine posture. For this reason, orthotic devices that are used only at night (92) probable function at a biomechanical disadvantage compared with braces that are prescribed for full-time use. Howard et al. (54) in a retrospective cohort study found the TLSO superior to the brace worn at night for preventing progression of the curve among adolescents with idiopathic scoliosis. Other investigators have found similar results with full-time brace wearing (41,61,96). Night bracing may be most useful during weaning from full-time brace wear.

The other important temporal characteristic of the applied force is its total duration of application. The application of force ideally should be continued until either the deforming force or spinal malleability decreases to a suitable level. Clinical experience has determined that both of these events generally occur around the time of skeletal maturity (26). Therefore it is biomechanically sound to continue orthotic treatment until skeletal maturity. Although the deforming force caused by spinal growth is no longer present in adults, the deforming force as a result of gravity is still present. This may cause continued curve progression after skeletal maturity, although such progression usually is slow because of decreased spinal malleability. The rate of progression may increase in later adult life with the increased overall spinal malleability that accompanies osteoporosis.

The decision to use an orthotic device for the management of a specific curve should be made when the applied forces can reasonably compensate for the deforming forces in a spine that is still malleable. Orthotic devices generally should not be used if the deforming forces are excessive (curves greater than 50 degrees), if the applied forces are minimal (because of skin problems or lack of patient compliance), or if the spine is rigid.

Biomechanics of Instrumentation and Fusion

The biomechanical goals for the surgical management of scoliosis include the general therapeutic goals for scoliosis described earlier and optimization of the biomechanical environment for fusion and minimization of complications related to instrumentation. The optimal biomechanical environment for fusion should place any bone graft under compressive stresses and minimize tensile stresses. Compression of an immature fusion mass promotes consolidation of bone. Conversely, tension promotes formation of fibrous tissue. The concave side of a scoliotic curve is the most desirable location for bone grafting, because this is the compressive side. Zagra et al. (125) used computed tomographic scans to follow consolidation of the fusion mass after posterior fusion for idiopathic scoliosis. Fusion consolidation was most pronounced on the concave side of the curve, as would be predicted with the Wolff law.

The importance of achieving relative immobilization of the spinal segments during fusion has been emphasized (79). Studies have shown that the rate of pseudarthrosis decreases from about 25% with a Risser cast to 15% with Harrington rods. This effect may be partially attributable to improved correction with Harrington rods. With current instrumentation systems, much of the compressive and tensile force is loaded through the instrumentation rather than through the spine. This appears to be particularly true of rigid pedicle-screw devices that may act in a load-bearing capacity. Use of such implants has the theoretical disadvantage of stress shielding of the immature fusion mass, possibly causing problems with fusion consolidation. However, these theoretical concerns have not been supported by either clinical or basic research. In an animal study, Johnston et al. (59) found that cross-linking and large diameter rods produce the stiffest fusion mass and no apparent stress shielding of the fusion. It does not appear that use of load-sharing devices has any substantial advantage over use of load-bearing devices in terms of fusion consolidation in the spine. Immobilization of the fused segments seems to be more important than cyclic loading to promote spinal fusion.

The anterior column of the spine is normally subjected to greater compressive forces than is the posterior column (110). This also is true of the scoliotic spine, particularly if residual thoracic kyphosis is present. Thus anterior fusion has a biomechanical advantage over posterior fusion. Anterior fusion also has the biologic advantage of a large, well-vascularized fusion bed. The advantages of anterior fusion are particularly useful when the anticipated pseudarthrosis rate with posterior fusion alone would be high, as in long fusions involving the thoracolumbar spine in which the transverse processes are relatively small and weak fusion often results. Anterior approaches in the management of spinal deformities should be used when needed to improve fusion rate, to improve correction of deformity, to allow anterior decompression of neural elements, or to prevent the crankshaft phenomenon.

Minimizing Complications of Instrumentation

Complications related to instrumentation include failure of instrumentation, iatrogenic fracture, decompensation, and neurologic complications. These problems can be minimized with knowledge of the biomechanical limitations of instrumentation systems. Because the spine has considerable viscoelasticity, the deformation that can be induced with a given applied force increases with the duration of application. This means that a given degree of correction of the curve can be achieved with small forces applied slowly. Minimizing the amount of force needed for curve correction is desirable, because this minimizes the risk of fracture of the posterior elements at the site of application of force. It is judicious to correct spinal deformities slowly and sequentially to take advantage of the viscoelastic properties of the spine during the correction process. Sequential correction with a minimum of 5 to 10 minutes between stages may be optimal (38). Stress relaxation occurs during this time, and little change occurs after this, if the force application is constant. With the advent of posterior instrumentation systems capable of applying large forces to the spine, the need to minimize the correcting force is even more important. The risk of iatrogenic spinal fracture can be decreased by respecting the inflection point of the spine. The inflection point is the point on the load deformation curve at which the amount of force needed for a given deformation increases dramatically. The inflection point may be palpably detected and should be interpreted as an indication that failure of the bony elements is imminent if the applied force is increased (110).

In a well-designed study, Nachemson and Elfstrom (84) used telemetrized Harrington rods to measure the forces to which the instrumentation was subjected in the postoperative period. These forces were found to vary considerably during routine daily activities. Forces during standing and walking were about 60% higher than those in the supine position. Axial forces were high when the patient lay on the convex side of the curve. The axial forces decreased considerably when a Milwaukee brace was used in the postoperative period. The investigators did not measure rotational and bending forces, which may be more important than axial forces as a predisposing factor for failure of instrumentation. Nevertheless, when Harrington rods were used, it was prudent to have patients avoid lying on the convex side, and care was taken to minimize the stress produced by Valsalva maneuvers (such as violent coughing and vomiting) during the immediately postoperative period. Segmentation fixation systems provide higher end-point fixation strength than the Harrington system; however, if there is uncertainty about the fixation, use of a postoperative brace and the aforementioned principles may decrease the risk of instrumentation failure.

Failure of the instrumentation used to manage idiopathic scoliosis most commonly occurs as the result of fatigue. Erwin et al. (40) found that fractures of Harrington rods occurred an average of 3.4 years postoperatively. As might be expected, larger curves had a higher rate of rod fracture and fractured earlier. These authors also identified rod fracture in the presence of a solid fusion; this is likely the result of repetitive elastic deformation of an immature fusion mass. Spinal fusion possesses considerable elasticity until 18 to 24 months after the operation. It is during this time that a rod is vulnerable to fracture, even though a bridging fusion is present. Segmental instrumentation has improved strength with fewer stress risers than has use of the Harrington system. As a result, fracture is less likely with the segmented systems.

Neurologic complications of the management of scoliosis are caused by cord compression, overdistraction, or purely vascular factors. Bridwell et al. (24) retrospectively identified 4 of 1,090 patients with intraoperative neurologic deficits; 3 of the 4 defects were purely vascular. Risk factors were anterior-posterior fusion and the presence of hyperkyphosis. Distraction of more rigid spinal segments causes rapid loss of spinal evoked potentials; this occurs more slowly in more flexible segments (88). Results of histologic studies suggest that actual structural damage to the cord occurs with distraction of stiff regions of the spine. It appears that ischemia rather than direct trauma is the cause of damage in more flexible regions. These important findings suggest the possibility of immediate onset of irreversible cord damage with distraction in rigid regions and must be carefully considered when correction of a severe and rigid spinal deformity is planned.

Kyphosis

Unlike the complex, multiplanar deformity of scoliosis, the deformity of kyphosis is confined to the sagittal plane. Because forward bending in pure kyphosis is symmetric relative to the facet joints, coupled deformities generally do not occur. To some extent, this simplifies the approach to the biomechanics of kyphosis. However, the biomechanical complications of neurologic compression and pseudarthrosis are of particular concern with kyphotic deformities.

Normal thoracic kyphosis tends to increase progressively with maturation until near the end of adolescence, but the normal range of kyphosis is large. Among older adolescents, the normal range of thoracic kyphosis is about 20 to 50 degrees (11,14). The presence of physiologic thoracic kyphosis allows for spinal balance, maximal thoracic volume, and spinal stability. Normal thoracic kyphosis combines with cervical and lumbar lordosis to keep the head centered over the sacrum in the sagittal plane. If the thoracic kyphosis increases in a child, there usually is enough flexibility in the cervical and lumbar spines to maintain spinal balance. Among older adolescents and adults, loss of sagittal balance is more likely to be a clinical problem.

Initiation and Progression

Initiation of a kyphotic deformity can be caused by asymmetric growth, loss of the anterior buttress, loss of the posterior ligamentous tension band, or a combination of these factors (111). When posterior growth markedly exceeds anterior growth, the result is a tendency toward a kyphotic deformity. Congenital or acquired conditions can cause the loss of anterior growth potential in the vertebral column and progressive kyphotic deformity. As in any physis, the active cells are highly susceptible to damage (94); this biologic effect gradually is converted into the biomechanically significant deformity of kyphosis.

Loss of the posterior ligamentous restraints is of particular concern in the immature spine, because the remaining structural elements often are malleable enough to allow rapid progression of the deformity. In the thoracic spine, normal kyphosis produces a lever arm that tends toward progressive kyphosis. For this reason, laminectomy in the immature thoracic spine carries a particularly high risk of progressive kyphosis (71,122,123). With removal of several contiguous thoracic laminae, rounded kyphosis tends to develop with the addition of levels adjacent to those that were originally involved. When bilateral facetectomy is included with laminectomy, a more localized gibbus-type deformity tends to develop. The development of kyphotic deformities is predictable among patients younger than 10 years who are treated with these procedures.

Loss of the structural integrity of the anterior column of the spine causes loss of the ability of the spine to withstand anterior compressive loads; progressive kyphotic deformity often develops. Loss of the anterior buttress of the spine causes loss of the anterior pivot point for spinal motion and weakens the ability of the posterior ligamentous restraints to resist kyphotic forces. The combination of these factors causes loss of the anterior spinal buttress, which can lead to progressive kyphotic deformity. This situation can occur with burst fractures that cause greater than 50% loss of vertebral body height (78), neoplastic or infectious vertebral destruction, and congenital vertebral malformation involving anterior failure of formation of a vertebral body (type I). In the case of type I congenital kyphosis, the deficient anterior buttress combines with excessive posterior growth relative to anterior growth. The likely result is progressive kyphosis (46,81,114). When a kyphotic deformity has been initiated, the patient's center of gravity is displaced anteriorly, resulting in a larger lever arm for the body weight acting on the apex of the kyphosis (64). This tends to increase the kyphotic deformity.

Structural Features

The clinical distinction between flexible and rigid kyphosis has important implications for patient care. At the extreme of flexibility, a postural round-back deformity straightens completely with voluntary extension; the lack of any structural component of these curves makes treatment other than exercise superfluous (21). Flexible structural kyphosis gradually becomes more rigid.

This occurs as a result of thickening and lack of longitudinal growth of ligamentous structures, loss of disc height and mobility, and vertebral wedging (14). In the thoracic spine, loss of flexibility may be accentuated by severe deformities caused by shortening and deformity of the anterior chest wall, including the ribs, sternum, and intercostal muscles. The flexibility of the kyphosis determines whether bracing is likely to be successful. Curves that can be reduced to less than 50 degrees in the brace are much more likely to have a favorable outcome than curves that cannot be reduced to less than 60 degrees in the brace (22). Curves that can be corrected to less than 55 degrees likewise probably can be managed by means of posterior instrumentation alone (see later). Larger and less flexible curves usually are best managed with combined anterior release and posterior instrumentation and fusion to minimize instrumentation failure and pseudarthrosis.

Neurologic Impairment

Kyphotic deformities have a particular tendency toward neurologic impairment. The spinal cord is most susceptible to injury with direct transverse compression (43). For this reason, most cases of neurologic deterioration with kyphosis are the direct result of tethering of the cord over a large kyphotic deformity (73), particularly if a gibbus deformity is present. Because the cord has considerable inherent elasticity, isolated longitudinal distraction of the cord is less likely than is transverse compression to cause neurologic problems. However, longitudinal distraction of the cord in the presence of anterior compression increases the compressive effects on the cord (43). Thus the use of halo traction or instrumentation to distract the spine in the presence of a fixed kyphotic deformity without initial anterior decompression of the spinal cord poses considerable neurologic risk (117). If the spinal cord is already tented over a kyphotic deformity, a relatively small disc protrusion can have major effects on increasing spinal cord compression and neurologic deficit (18,121).

Orthotic Treatment

There is agreement that bracing can be effective for controlling and even correcting many cases of kyphosis. The uniplanar deformity of kyphosis is well suited to sagittal plane corrective forces applied through a Milwaukee brace. The principle of three-point fixation is used to apply posteriorly directed forces at the chin, sternum, and anterior pelvis and anteriorly directed forces at the apex of the kyphotic deformity. The success of bracing depends on reducing the deforming forces to an acceptably low magnitude. This necessitates that the kyphosis be flexible enough to achieve in-brace correction to less than 60 degrees and that the posterior growth potential not greatly exceed that in the anterior column (22). In the case of congenital kyphosis, particularly cases caused by failure of anterior vertebral formation, posterior growth continues in the brace, resulting in a high probability of progressive kyphosis (114). Results of clinical studies of the effectiveness of bracing in the management of Scheuermann kyphosis have indicated that this entity can be controlled or corrected in many cases. However, patients with kyphosis of greater than 70 degrees, vertebral wedging that averages more than 10 degrees, or skeletal maturity are unlikely to have a good result with bracing (22).

Biomechanics of Surgical Treatment

The goals of surgical management of kyphotic deformities are to obtain a solid arthrodesis over the length of the kyphosis, to attain some deformity correction, and to minimize risk to the neural elements. Correction of deformity is a goal only if it does not pose an inordinate risk to the patient. Correction of kyphotic deformity may be biomechanically desirable, because it may achieve improved balance in the sagittal plane and provide a biomechanical environment with increased compressive forces that favor fusion (17). However, the biomechanics of correction deformity always must be considered in conjunction with the previously discussed biomechanics and biologic characteristics of spinal cord compromise.

Achieving solid arthrodesis in kyphotic deformities is determined by several biomechanical factors. The entire length of the applicable segments optimally would be under compression to favor arthrodesis. This would require a direct line of weight transfer from each end of the segment. In the presence of substantial residual kyphosis, the posterior elements are in tension, tending toward formation of pseudarthroses (111). If the kyphosis is not flexible enough to correct to less than 55 degrees, anterior fusion should be added to achieve a graft in compression (17). Among a group of patients with congenital kyphosis greater than 50 degrees, Winter et al. (117) found a 55% rate of pseudarthrosis with posterior procedures alone. The rate of pseudarthrosis with combined anterior and posterior procedures was 15%.

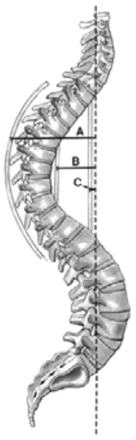

FIGURE 3. Limitations of posterior devices in stabilizing large kyphotic deformities. The moment arm *A* of force on a posterior implant is substantially greater than that on a short anterior strut *B*. The shortest moment arm is represented by a long strut graft *C*, which extends from vertebrae close to the weight-bearing axis (*dotted line*). Because the axis of rotation is anterior to the vertebral bodies, the strut grafts are under compression, and the posterior construct is subjected to biomechanically less favorable tensile forces.

If severe residual kyphosis is present, addition of anterior strut grafts across the length of the kyphosis can be used to achieve a more direct line of compressive force transfer and to relieve some of the posterior tensile forces (Fig. 3). The compressive strength of strut grafts depends on the type of graft selected. Fibular struts have the greatest strength followed by iliac crest; rib struts are weakest. Rib struts are highly susceptible to fracture if they are placed more than 4 cm anterior to the apex of the deformity. Graft fracture often occurs 6 to 12 months after the operation (17), presumably during the period of revascularization, in which the compressive strength is compromised. Vascularized rib grafts have been used successfully to reduce the fracture rate by avoiding the revascularization period (16). Regardless of the method of arthrodesis used, it is important to extend fusion over the length of the kyphosis (21). If fusion stops short of the end vertebra or a vertebra in the neutral weight-bearing axis, the kyphosing force is concentrated on the motion segment adjacent to the fusion. There is a considerable tendency for this segment to fall off and cause junctional kyphosis proximal or distal to the fusion.

Spondylolysis and Spondylolisthesis

Solid biomechanical knowledge is important in the management of spondylolisthesis, because this condition is the combination of deformity and instability. The deformity of spondylolisthesis is forward displacement of one vertebra on another. The instability of spondylolisthesis is shown by the tendency for some cases to undergo progressive slipping. This section discusses the biomechanical features important in the causation of spondylolysis and those that are important in the progression and management of spondylolisthesis.

Etiology of Isthmic Spondylolysis

Spondylolysis has been rarely documented among persons younger than 6 years. The incidence increases between the ages of 6 and 14 years, when it approximates the 5% incidence among adults (9,49). It has been hypothesized that the involvement of children in organized athletic activities when they reach school age may account for the increased incidence during these years (113).

Isthmic spondylolysis is caused by repetitive stress, which produces a stress fracture of the pars interarticularis (113). The stresses to which the posterior elements are subjected are highest in the lumbosacral region. This large amount of stress is caused by the combination of lumbar lordosis that concentrates stress in the posterior elements, the long trunk lever arm in the lumbosacral region, and the transition between the mobile lumbar segments and the immobile sacral segments (34). The concentration of stress at the L5 lamina largely accounts for the predominance of spondylolysis at L5 compared with other vertebral levels (57). Less commonly, L4 may be involved with a spondylolytic defect, particularly if L5 is a transitional vertebra (sacralized). The result is stress concentration in the posterior elements of L4. In anatomic studies, the pars interarticularis of children is thin and elongated. This relative weakness of the region may contribute to the development of stress fractures here (70).

In normal erect stance and gait, the posterior elements bear only about 20% of the weight transmitted through the spine. However, the force transmitted through the lumbar spine increases to about 50% when the spine is in a hyperlordotic position (111). When the lumbar spine is in a hyperextended position, the inferior facet of L4 impinges and levers on the posterior elements of L5 in the region of the pars interarticularis; this phenomenon has been disputed (57). This may cause direct transmission of force through this vulnerable region. Activities associated with accentuated lumbar lordosis place the pars interarticularis region of L5 at particularly high risk of spondylolysis. Activities that involve alternating flexion and extension produce large stress reversals in the pars and create the potential for stress failure (44). Participation in gymnastics, weight lifting, hockey, platform diving, and interior line football corresponds to a high incidence of spondylolysis (58,70).

The clinical importance of these biomechanical factors is that they provide the basis for ascertaining who is at risk of spondylolysis and appropriately minimizing that risk. Avoidance of repetitive, forceful lumbar hyperextension by children may greatly decrease the risk of development of spondylolysis; however, controlled studies have not been performed. In gymnastics, back walkovers should be avoided, because they place the L5 pars interarticularis at particularly high risk of stress fracture. Lumbar braces and corsets do not have an established role in minimizing the risk of spondylolysis in high-risk activities.

Biomechanics of Progression of Spondylolisthesis

Spondylolisthesis involves forward subluxation or slipping of a vertebra relative to its subjacent vertebra. The potential for progressive slipping is an important factor that may influence the decision to perform fusion. Progression of spondylolisthesis is a form of chronic instability and can be analyzed through the use of biomechanical principles. In normal spines, forces that tend to displace L5 anteriorly relative to the sacrum are balanced by forces that resist this translation. The deforming forces are those applied by body weight and muscle actions. The resistive forces are supplied by the posterior osteoligamentous tether and the anterior osseous buttress. Deficiencies of either of the columns that resist translation can produce a tendency toward progressive slipping and segmental kyphosis.

The posterior osseoligamentous tether is formed by the intact laminae, facet joints, spinous processes, and intervening ligamentous structures. When this column is anatomically intact, it can resist physiologic forces to prevent abnormal translation of the vertebral elements. Loss of the structural continuity of this column occurs with spondylolysis or with hypoplasia of

S1 facets (dysplastic spondylolisthesis). However, even in these situations, some resistance to displacement is provided by the posterior ligamentous structures and the anterior bony buttress to prevent immediate, catastrophic displacement of L5 on the sacrum. Laxity of ligamentous tissues may allow accelerated progression of spondylolisthesis. This may account for the considerably higher incidence of progression to severe spondylolisthesis among girls than boys and among younger than older children (9). Laminectomy and decompression of the neural elements in spondylolisthesis remove ligamentous and scar tissues that provide some residual resistance to the anterior translation of L5 on the sacrum. In the presence of this iatrogenic worsening of instability, it is advisable to perform fusion to decrease the risk of progression of the slip (20).

The intact anterior lip of the sacrum forms a buttress to prevent displacement and kyphotic angulation of L5. This buttress is deficient if the sacrum is substantially rounded, if L5 is wedged, if L5 has levered into kyphosis over the sacral promontory, or if L5 has translated more than 50% anteriorly relative to the sacrum. Natural history studies show that the combination of these features, which indicate a deficient anterior buttressing effect, increases the risk of progressive slipping (12,50).

For progression of spondylolisthesis to occur, the deforming forces must exceed the resisting forces supplied by the posterior tether and the anterior buttress. The force tending to displace the superior vertebra anteriorly increases when kyphosis is present at the spondylolisthetic level, resulting in an increased slip angle (Fig. 4). In this situation, the patient's center of gravity is displaced anteriorly relative to the level of the slip. This increases the moment arm for force transmission through the level of spondylolisthesis. The result is a net increase in the deforming force.

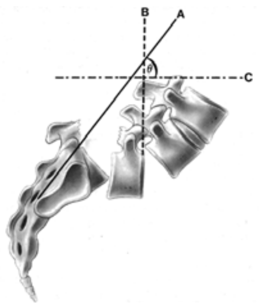

FIGURE 4. The slip angle (angle of lumbosacral kyphosis) is the angle formed by lines parallel to the posterior cortex of the sacrum *A* and the line perpendicular *C* to the superior end plate of L5 *B*. This measurement is biomechanically important because it is strongly related to the risk of progression of spondylolisthesis.

The presence of marked local kyphosis in spondylolisthesis is accompanied by compensatory changes in the rest of the spine that act to maintain balance in the sagittal plane. In the lumbar spine, this involves lumbar hyperlordosis; in the thoracic spine, hypokyphosis is commonly. It has been hypothesized that the decrease in thoracic kyphosis that accompanies spondylolisthesis may be associated with a tendency toward development of deformities in the coronal plane. This may account for the higher incidence of idiopathic-like scoliosis in association with spondylolisthesis than exists among the general population (101).

Mechanics of Neural Impairment

Although most neural deficits that occur with spondylolisthesis involve L5 radiculopathy, cauda equina compression can occur. Cauda equina syndromes most commonly are caused by a greater than 50% slip of dysplastic spondylolisthesis (76). Because the posterior elements of the slipping vertebra are intact, compression of the cauda between the lamina and vertebral body of S1 occurs. The biomechanics of cauda equina compression with spondylolytic spondylolisthesis are not well defined. One theory is that the cauda is stretched over the dome of the sacrum and that the stretching causes neural dysfunction; however, there is a poor correlation between the degree of the slip, radiographic cauda equina impingement, and a clinical cauda equina syndrome. It appears that in this scenario, other factors such as the rate of slip progression and presence of associated disc protrusions are important.

Biomechanics of Fusion for Spondylolisthesis

The surgical management of spondylolisthesis requires techniques that have a high likelihood of achieving solid arthrodesis while minimizing slip progression. By necessity, this means that the graft should be placed in a compressive mode and that the applicable levels should be immobilized. With less than 50% translation of one vertebra on the other, an intertransverse fusion between L5 and S1 is under acceptable compression. Slips greater than 50% cause anterior and inferior movement of the transverse processes of L5 toward the sacral ala. The result is inadequate area for posterior grafting that also is subjected to relative tensile forces (12). In this situation, including the transverse processes of L4 in the arthrodesis not only improves the graft bed available but also improves the compressive characteristics of the fusion (12,42). However, when there also is a substantial kyphotic deformity (slip angle greater than 45 degrees) at the spondylolisthetic level, even fusion to the transverse processes of L4 may not produce acceptable graft compression (Fig. 5). In this case, a more acceptable biomechanical environment for fusion can be obtained by means of using anterior-posterior arthrodesis, using a transsacral fibula, or reducing the slip angle (13,102). Anterior arthrodesis is anterior to the axis of rotation of the spondylolisthetic vertebra and therefore is under compression (15,19). Reduction of the slip angle can be achieved by means of casting, instrumentation, or total excision of the spondylolisthetic vertebra. Reducing the slip angle causes a posterior change in the patient's center of gravity, so that a posterolateral graft is under increased compressive force. Reduction improves the contours of the sagittal plane and sagittal balance for many patients (13). Despite this, the surgeon's enthusiasm for reducing the slip angle and improving the biomechanical milieu for fusion must be tempered with the knowledge that reduction techniques, particularly those that involve instrumentation, carry considerable risk of iatrogenic neural deficits (15).

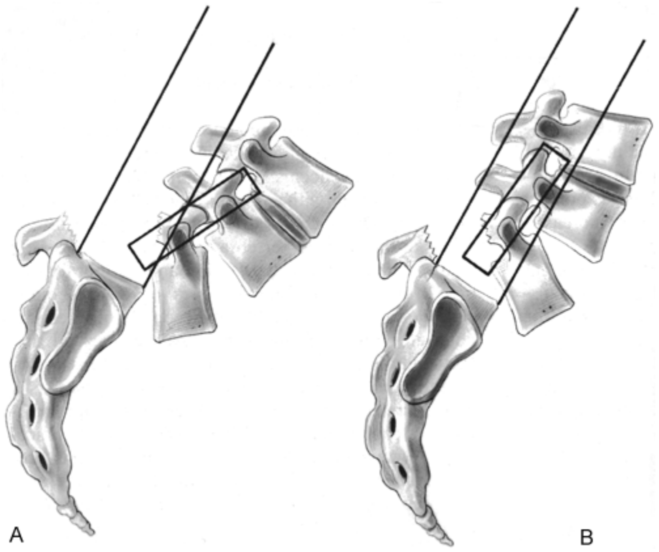

FIGURE 5. Effects of anterior translation and slip angle on intertransverse fusion biomechanics in spondylolisthesis. **A:** With greater than 50% slippage and a large slip angle, the fusion (*black box*) is not within the compressive zone over the ala of the sacrum (*black lines* projected parallel to the walls of the sacrum). This places the fusion under tensile forces that are predisposing factors for pseudarthrosis. **B:** With reduction of the slip angle, a transverse process fusion comes into the compressive zone despite greater than 50% residual translation.

Among children, the posterior spinal fusion mass retains considerable plasticity, despite the presence of an apparently solid arthrodesis. Plasticity is most pronounced during the first 24 postoperative months but persists until maturity. Because of this plasticity, progression of the slip can occur despite the presence of a radiographically solid arthrodesis. Progression is most likely to occur with a large slip angle or extensive posterior decompression (13). In these situations, the potential for worsening of the spondylolisthesis should be recognized, and it may be prudent to institute use of an orthotic device.

As in fusion of joints in the extremities, achieving a high probability of successful arthrodesis in spondylolisthesis necessitates immobilization of the levels to be fused. To be effective in immobilizing the lumbosacral joint, an external device should incorporate at least one thigh in an extended position; this achieves relative immobilization of the pelvis and sacrum relative to the lumbar spine. Immobilization can be more rigidly obtained with internal fixation. The most rigid constructs are pedicle screw–rod devices with rigid cross linking. This rigid immobilization may reduce the rate of pseudarthrosis, but studies with pediatric populations have not been performed. Except for older adolescents, the small pedicle size of these patients poses technical problems for the placement of pedicle screws.

Conclusions

Understanding the biomechanical characteristics of the pediatric spine provides a rational basis for the management of pediatric spinal disorders. Complete biomechanical analysis of this complicated, composite structure requires sophisticated inquiry. This chapter presents basic principles that can be applied to the normal and diseased spine to predict general biomechanical behavior. The analysis of scoliosis centers on the three-dimensional aspect of the deformity and how this influences treatment. In contrast, the deformity of kyphosis is confined to a single plane. This concentrates tensile forces on the posterior spine and predisposes the patient to pseudarthrosis and spinal cord injury. The combination of deformity and instability in spondylolisthesis makes biomechanical analysis essential to understanding the risk of progression and the basis for treatment.

Radiography

Wilhelm Conrad Roentgen discovered x-rays in 1895, for which he won the Nobel Prize for physics in 1901. Any physician can understand the basic physical principles of radiography, which are crucial for obtaining high-quality diagnostic examinations and protecting patients and medical staff from radiation exposure. Diagnostic imaging has recently advanced in giant leaps; nevertheless, radiography continues to be the mainstay of any diagnostic investigation. This fact is easily forgotten in the hospital environment, where physicians are surrounded by high-technology equipment. A radiographic examination should always precede any complex imaging procedure, and the interpretation of these complex studies should be undertaken only with the plain film examination at hand. Radiographs provide important information about the alignment of the vertebral bodies, disc space height, facet joint integrity, trabecular pattern, and cortical bone destruction.

Physical Principles

X-rays are a form of radiation belonging to the electromagnetic spectrum (Fig. 1) (40). Electromagnetic radiation consists of electric and magnetic fields that are perpendicular to each other. Electromagnetic radiation has a dual nature, behaving under some circumstances as waves and under different circumstances as particles or photons. The two concepts of wave and particle have been postulated to explain the variety of physical characteristics associated with electromagnetic radiation (9).

In diagnostic radiology, the most useful parts of the electromagnetic spectrum are x-rays and radio waves, both of which can travel through the human body (Fig. 1) (14). Under proper and predetermined conditions, x-rays and radio waves may carry useful diagnostic information that can be captured by appropriate receptors and recorded on films or displayed on television screens for viewing by physicians. X-rays can be either generated in x-ray tubes or emitted from radioactive nuclei. Those generated in x-ray tubes are generally used in radiography, fluoroscopy, conventional tomography, and computed tomography (CT). X-rays emitted from radioactive isotopes are used in nuclear medicine and radiation therapy. Radio waves are much less energetic than x-rays and are used extensively in magnetic resonance imaging (MRI) (14).

In diagnostic x-ray tubes (Fig. 2), x-rays are produced when a fast stream of electrons is suddenly stopped by the target or anode (positive terminal). The electrons originate on the negative terminal of the tube, which is also called the *cathode* or *filament* (9,40). On the cathode side, x-ray tubes are typically equipped with two filaments—one large and one small; the large filament is used for large exposures. The area of the target bombarded by electrons is referred to as the *focal spot.* Ideally, the focal spot should be as small as possible in order to produce a sharper image on the film (Fig. 3), although a large focal spot allows greater heat loading and therefore less damage to the target. The ability of the x-ray tube to achieve high x-ray outputs is limited by the heat generated at the target or anode. To overcome this problem, the rotating anode was developed, which allows the tube to withstand huge accumulations of heat generated during large exposures (Fig. 2) (9,26). In addition, both the filament and the target are made of tungsten, which has a very high melting point. To limit lack of image sharpness, the focal spot should not exceed 1.2 mm in size, and the spine should be placed as close as possible to the film. Patient motion during the exposure could also result in unsharp images; therefore, patients are instructed to remain perfectly still during the exposure.

With every exposure, an x-ray beam is emitted consisting of a wide spectrum of energies (7,26). The quantity of x-rays emitted from the x-ray tube is proportional to the number of electrons flowing from the filament (cathode) to the target (anode); this is measured in milliamperes. The milliampere setting on the control panel is preselected by the technologist. The quality, or penetrating power, of the x-rays is inversely related to the wavelengths of the x-rays emerging from the tube and is determined by the energy of the electrons striking the target (Fig. 1). More energetic electrons produce a preponderance of x-rays in the beam with shorter wavelengths (high-energy x-rays) and more penetrating qualities. The energy of the electrons bombarding the target is predetermined before the exposure by adjusting the kilovolt setting or potential difference between the cathode and anode. Therefore, with any particular milliampere and kilovolt settings, a spectrum of x-rays of different wavelengths (polychromatic) and energies emerges from the x-ray tube (9,26). Very low-energy x-rays are not diagnostically useful and are actually harmful to the patient because most are absorbed by the first few centimeters of tissue; these low-energy x-rays fail to reach the film or detector with diagnostic information. X-ray tube casings are designed with filters to remove low-energy radiation. Filtration is extremely useful for changing the composition of x-rays in the beam. Aluminum (1 to 3 mm thickness) is the most commonly used general-purpose filter. Filtration increases the ratio of x-rays in the beam that are useful for imaging to those that increase only the patient's dose of radiation. High-energy x-rays pass through the patient, carrying information, and are diagnostically useful (9).

All the components of the tube are designed to withstand high temperatures generated by changing the kinetic energy of the electrons into x-rays. This is not an efficient process; only 1% to 2% of the kinetic energy of the electrons is transformed into x-rays, and the rest changes to heat.

A physical principle of practical importance in scoliosis examinations is called the heel effect, which becomes detectable when exposing long films (6 inches or longer). The intensity, or concentration, of x-rays within the beam is not uniform throughout all portions of the beam; it is less toward the anode side of the tube (Fig. 4) (9,26). This fact is exploited to obtain balanced photographic densities on radiographs of body parts with different thicknesses. Ideally, when obtaining an anteroposterior view of the entire spine, the thicker body parts (abdomen) should be placed in the intense portion of the x-ray beam or toward the cathode side of the x-ray tube, and the thinner body parts (chest and neck) should be placed toward the anode side of the tube.

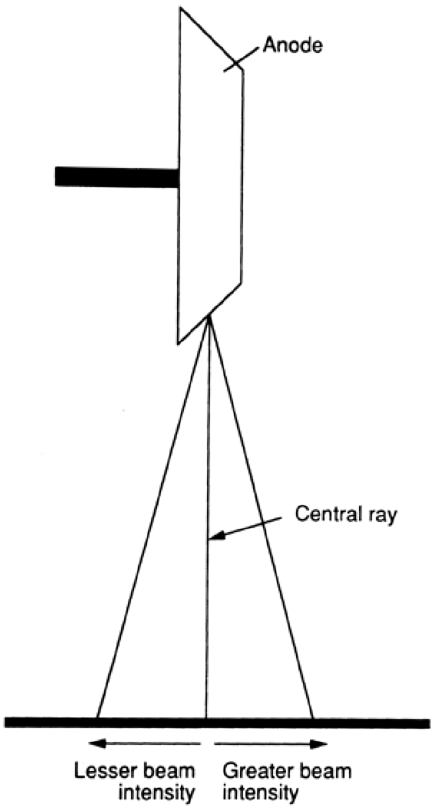

FIGURE 4. Beam intensity. The x-ray beam is more intense toward the anode side of the tube. This fact is put to practical use in the radiography of structures of uneven thickness.

Principles governing the interaction of x-rays with matter are beyond the scope of this chapter. Generally, however, the interaction of x-rays with living or nonliving matter is dependent on the energy of the radiation. Low-energy diagnostic x-rays generate less scatter radiation and produce radiographs with good tissue contrast when compared with high-energy x-rays (20). Much of the low-energy radiation, however, is absorbed by thick body parts, and its clinical use is limited (40). High-energy diagnostic x-rays, produced by high kilovolt settings, are generally favored because less radiation is absorbed by the patient; however, they generate significant scatter, resulting in foggy images and diminished tissue contrast on radiographs. Without scatter control, the information content of x-ray images is severely compromised (Fig. 5). To control scatter and improve image quality, radiographic grids are used. The grid is the most common way of controlling scatter in medical radiography. Grids consist of lead strips separated by x-ray–transparent spacers. Primary x-rays travel in a straight line from the tube to the image receptor (Fig. 6A). X-rays that interact with the tissues and bounce off other atoms or electrons are deflected from a straight path and give rise to scattered radiation (Fig. 6B) (2). The amount of scatter is also proportional to the patient thickness and field size used. Thicker body parts produce much more scatter than thinner parts. Larger field size again results in more scatter and less tissue contrast on images (20). Limiting the field size—in other words, restricting the size of the beam to the area of interest—achieves two very important objectives: It reduces scatter and cuts radiation to the patient by limiting radiation to body parts of clinical interest.

The grid is positioned between the patient and the image receptor; the x-rays traveling in a straight line carry useful information and, for the most part, pass through the lucent portion of the grid (Fig. 6). About 85% to 95% of the scattered x-rays are absorbed by the grid (2). Radiographic examinations of the thoracic and lumbar spine in older children cannot be performed without grids. One disadvantage of grids is that they absorb some of the primary radiation emerging from the patient as well as most of the scattered radiation; therefore, it becomes necessary to increase the radiation to the patient in order to maintain the proper photographic density on the film, which is the price paid to produce high-quality images when radiographing thick body parts (2). Controlling scatter therefore results in increasing patient dose and x-ray tube load. Equipment manufacturers and physicists continually strive to control scatter efficiently by trying to maximize image contrast and minimize radiation dose. Thin body parts, such as the cervical spine, produce little scattered radiation and can be radiographed without grids. One caution regarding the use of grids relates to the fact that grids are focused; therefore, proper alignment and proper distance from the x-ray tube should always be maintained, or the image quality will deteriorate quickly (2,9). This could become a serious problem in examinations performed in bed or in the operating room using portable x-ray machines.

Concepts controlling image formation are the key to the interpretation of radiographic examinations. Photons from the x-ray source interact with tissues and pass through the patient. Variations in tissue composition give rise to differences in attenuation and spatial variation in the x-ray beam exiting the patient. Most of the x-rays in a beam pass through air-containing tissues, such as the lung, with only minimal attenuation; however, most of the beam is absorbed or markedly attenuated as it passes through bone. Fat attenuates x-rays more than air, and water and soft tissues attenuate x-rays more than fat but less than bone. These alterations in the x-ray beam produce differences in the response and the light output of the intensifying screen in the film cassette (Fig. 7). As more x-rays pass through the patient and reach the intensifying screen, more visible light is generated by the screen, and the radiographic film becomes darker. Intensifying screens are used because the sensitivity of film to x-rays is low compared with its sensitivity to visible light. Intensifying screens are placed within x-ray cassettes to convert x-rays into visible light, which in turn exposes the film (Fig. 7). The efficiency of the intensifying screen in converting x-rays to visible light is important in reducing the radiation dose to the patient. State-of-the art radiography relies almost exclusively on the use of rare earth screen systems, which are more efficient than the old calcium tungstate screens (9,26,40).

The same physical principles of radiography apply to fluoroscopy except that the images are displayed on a television screen instead of films. Fluoroscopy plays a limited but important role in selected patients with spine problems. Needle biopsies of the vertebrae and discs are typically performed with biplane fluoroscopy.

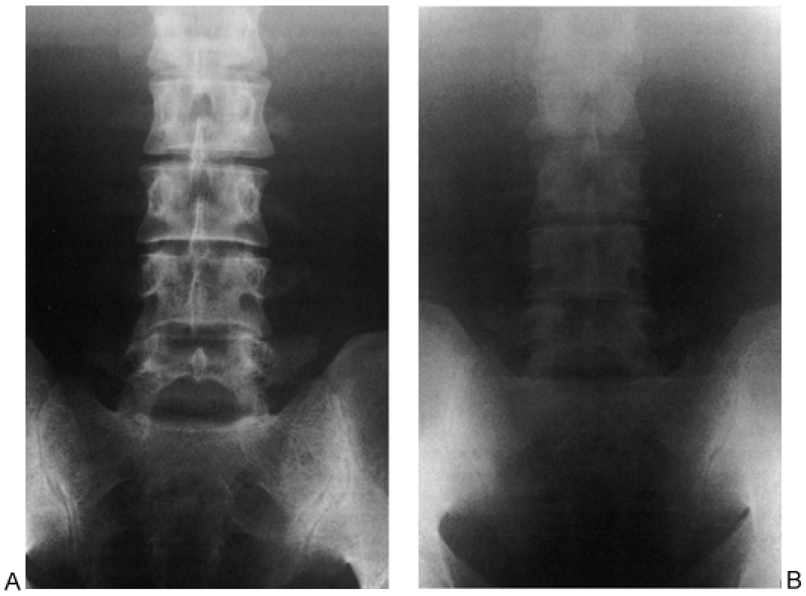

FIGURE 5. A: Anteroposterior radiograph of a lumbar spine phantom performed with a moving grid (Bucky) shows excellent trabecular detail and good contrast because most of the scattered radiation has been absorbed by the grid. **B:** The same spine phantom radiographed without a grid demonstrates inferior-quality image because of scatter.

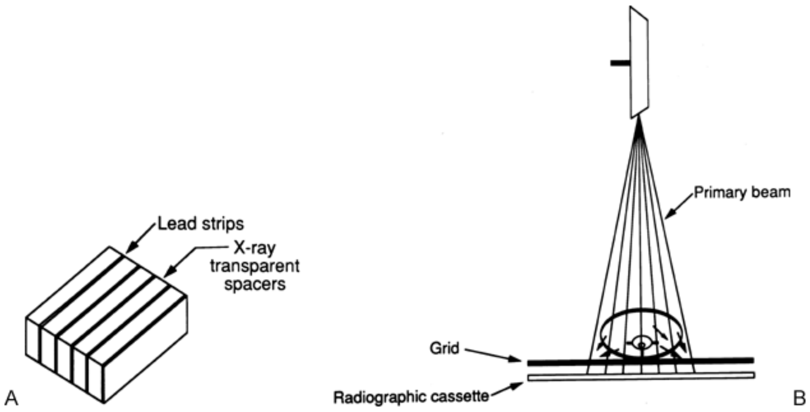

FIGURE 6. A: Cross section of a grid. **B:** Illustration of how the grid absorbs scattered radiation and allows the primary beam to pass through.

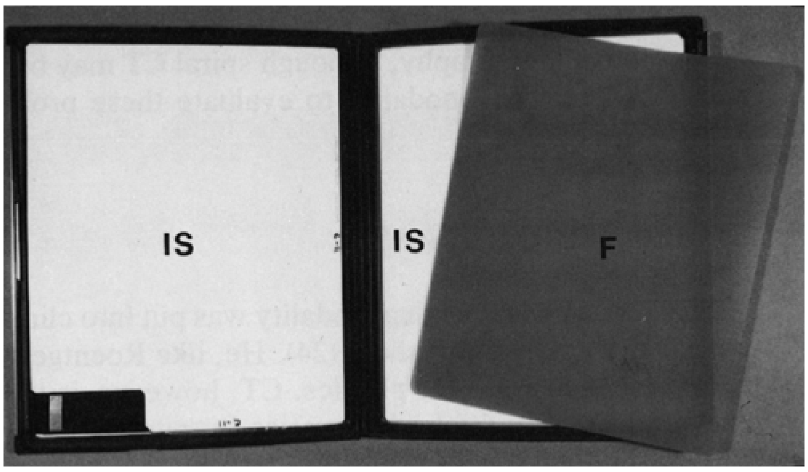

FIGURE 7. An opened cassette. On each side of the cassette, there is an intensifying screen (IS). When the cassette is closed, the film (F) is sandwiched between the two intensifying screens.

Technologic Advances

For more than 100 years, images have been captured on film. The era of filmless imaging is now here to stay. Digital radiography coupled with picture archiving and communications systems (PACS) is one of the fastest growing technologies in medicine. It is estimated that 66% of all hospitals in the United States will be using digital images that can be distributed to practitioners, both within and outside the hospital, using a PACS system by the year 2000. Factors promoting this change include faster and less expensive computers as well as memory storage devices with steadily increasing capacities. Another crucial component in this progress is the ease with which modern equipment manufactured by different companies can communicate digital information using standard protocols (e.g., Digital Imaging and Communication in Medicine [DICOM] standards).

Why do we need digital imaging? Digital imaging is more efficient to acquire and distribute than hard copies, and in the long run, digital images are less expensive to store and retrieve. Digital images can be made available to multiple physicians in different places at the same time. Digital images can be manipulated, that is, made darker or lighter, smaller or larger. Using Internet technologies, image distribution to distant locations can be easily accomplished at minimal cost.

Digital radiography is evolving. In the mid-1980s, indirect image capture was introduced and is still the dominant technology, although there is promise that direct electronic image capture may become the way of the future. With indirect image capture, the conventional screen-film system is replaced with a phosphor plate that can be stimulated, which stores a latent image (32). A laser image reader extracts the latent image from the phosphor plate, and data are handled by an image processor (20). Interactive workstations are connected to the image processor, replacing the light boxes for viewing the images. Direct electronic image capture was introduced in 1996. This technology used selenium or silicon detectors, which convert x-rays directly to electrons and subsequently to digital images.

The disadvantages of digital radiography include the high initial cost and complexity. The diagnostic quality of digital radiography is comparable to conventional screen-film radiography (28,32).

Conventional Tomography

The radiograph is a two-dimensional image of three-dimensional structures superimposed over each other. Conventional tomography, also known as *body section radiography*, is an x-ray technique used to blur out superimposed structures and bring into focus structures of interest. The components of any tomographic unit are an x-ray tube and film cassette connected to a rigid arm. When the tube moves in one direction, the film moves in the opposite direction around a fulcrum or focal plane (Fig. 8). The amplitude (distance) of tube travel is measured in degrees and is referred to as the *tomographic angle.* The plane of interest within the patient is positioned at the level of the fulcrum and is the only plane that stays in sharp focus. Structures within the patient above or below the fulcrum are blurred (7,9).

There are several types of tube motions available, but the ones most commonly used in spine work are the circular motion and, to a lesser extent, the pluridirectional (or multidirectional) motion. Complex tube motions produce thorough blurring of structures outside the focal plane; however, complex motions expose the patient to more radiation and diminish image contrast (7).

Other factors to consider when planning tomographic examinations are section thickness and the interval between sections. The thickness of the section in sharp focus is inversely proportional to the amplitude (distance) of the tube travel measured in degrees. The more distance the tube travels, the thinner the section (7,9). The interval defines the distance between each tomographic section. The tube motion, travel, and interval are

predetermined for each examination depending on the size of the structure under evaluation. As an example, an osteoid osteoma within a pedicle is best studied with thin sections at intervals not exceeding 3 mm, whereas a large lytic or blastic lesion in the vertebral body can be studied with thicker sections at 5- to 10-mm intervals.

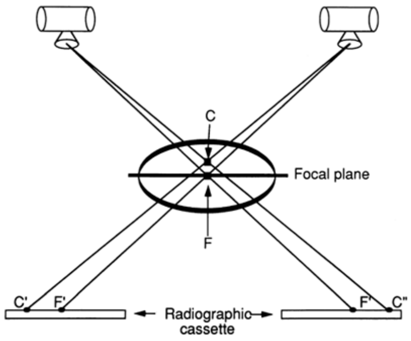

FIGURE 8. The basic principles of conventional tomography. During each exposure, the x-ray tube and radiographic cassette move in opposite directions. Structures above and below the fulcrum or focal plane become blurred, *C*. Only structures at the level of the focal plane stay in focus, *F*.

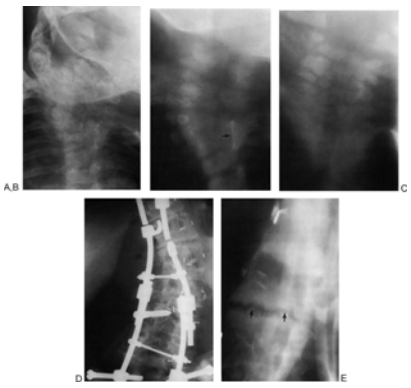

FIGURE 9. Three-month-old infant with congenital scoliosis. **A:** Anteroposterior radiograph demonstrates the scoliosis but fails to show in detail the multiple segmentation anomalies. **B:** Anteroposterior tomographic section at the level of the pedicles shows a pedicular bar on the left side (*arrow*). **C:** Another section through the vertebral bodies demonstrates multiple hemivertebrae. **D:** This 32-year-old woman presented with acute back pain, 3 years after posterior and anterior spine fusion. Plain films showed broken Cotrel-Dubousset rods. **E:** Conventional tomography demonstrates pseudarthrosis at the site of a previously fused disc (*arrow*).

The numbers that appear on the films in a tomographic series indicate the distance between the plane in focus or fulcrum and the film. When reviewing a tomographic study, the films should be arranged in the proper sequence.

Although conventional tomography has been replaced, for the most part, by CT, it continues to be an effective tool in the evaluation of the spine. It is the modality of choice for mapping segmentation anomalies of the spine (Fig. 9). Failure of spinal fusion is still best studied with conventional tomography, although spiral CT may become the preferred modality to evaluate these problems in the future.

Computed Tomography

The remarkable imaging modality of CT was put into clinical use in 1973 by Hounsfield (24). He, like Roentgen, won the Nobel Prize for physics. CT, however, is the end product of multiple discoveries by numerous investigators. The initial mathematical ideas were advanced as early as 1917 by the Austrian mathematician Radon. The basic principle behind CT is that the internal structure of an object can be reconstructed in the form of sections from multiple x-ray projections (9). CT, radiography, fluoroscopy, and conventional tomography use ionizing radiation to obtain images. The scanning gantry contains an x-ray tube, a series of detectors, and a couch with a precision positioning system. The x-ray beam is highly collimated, and the x-ray tube moves around the patient about 360 degrees during a single slice. The detectors capture the attenuated beam, and the resulting data are processed by a computer that displays the image on a matrix of 512 × 512 small squares, called *pixels.* Each pixel is given a CT number related to data obtained by the detectors. On the images, the CT numbers are displayed as various shades of gray, in which the lowest numbers appear black (e.g., air) and the highest numbers appear white (e.g., cortical bone) (7,41). The operator at the console can manipulate the window width (range of CT numbers in the gray scale) and the window level (center of the gray scale) to study either bone or soft tissue detail (Fig. 10) (40,41).

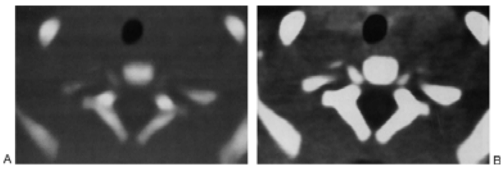

FIGURE 10. CT examination of the upper thoracic spine in an infant. The same section is filmed with a bone window (**A**) and a soft tissue window (**B**).

In planning a CT examination, the following parameters are selected: slice thickness, couch index or interval of slices (similar to conventional tomography), gantry angulation, proper window width and level for filming, and appropriate sagittal and coronal image reconstructions. For performing three-dimensional image reconstructions, a slice thickness of 3 mm with 1 mm of overlap is usually desirable.

Significant advances in CT technology have recently been made in the areas of image resolution, reduction of acquisition time, and software for three-dimensional reconstruction. Three-dimensional images do not add any new information that is not already available on axial images. CT actually displays complex anatomy and pathology in a more familiar and understandable fashion. In children, the complex problems of the craniovertebral junction have been appreciably simplified with the use of CT. Spiral or helical CT is a new technology that allows for faster image acquisition and for truly volumetric CT data. This has become possible because of technical refinements in the detector efficiency and greater tube cooling capability.

Three-Dimensional Computed Tomography

Traditionally, CT data have been presented in transaxial plane. With the advent of helical CT, volumetric data of a large area of interest, for example, the entire thoracolumbar spinal column, can be obtained in short period of time, about in 30 seconds. In helical CT, the volumetric data are obtained while the patient is translated continuously through a CT gantry in which the rotating x-ray tube is emitting x-ray without interruption. After the volumetric data are obtained, multiple overlapping axial images can be generated at arbitrary intervals, which provide superb source images for exquisite three-dimensional reconstruction (Fig. 11). These three-dimensional images can then be viewed from any direction without additional radiation to the patient. This is one of example of a postprocessing maneuver assisted by a graphic computer, which has become imminently important to present clinically pertinent information from vast amount of data obtained by newer CT and MRI technology.

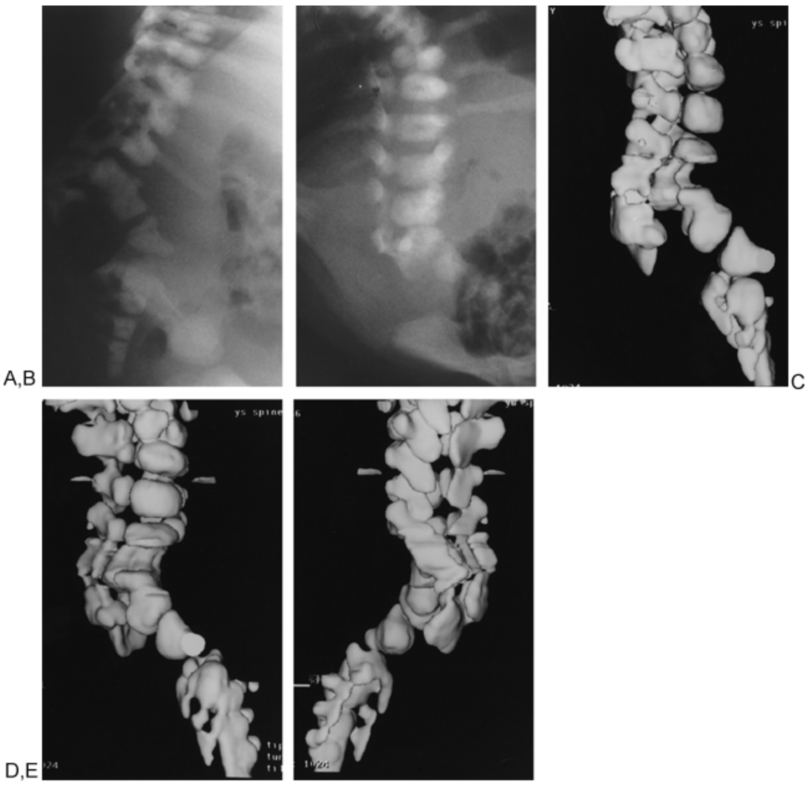

FIGURE 11. A neonate with occult dysraphism (myelocystocele). Lateral **(A)** and posteroanterior **(B)** plain radiographs show hypoplasia of lower lumbar vertebral bodies and marked kyphotic deformity. Three-dimensional computed tomography reconstructed images (**C**, lateral; **D**, anteroposterior; **E**, posteroanterior) clearly demonstrate deformed vertebral bodies and complete absence of the posterior elements.

Biologic Effects of Radiation

The use of x-ray examinations continues to increase in both the United States and other countries (17). In the evaluation of spine problems, radiographic examinations are often crucial in arriving at a specific diagnosis. Most physicians use ionizing radiation extensively in their diagnostic work; however, only a few are formally trained in handling ionizing radiation and radiation protection. Studies have shown that the lack of technical training results in excessive population exposure to ionizing radiation (10). The exposure of patients to medical x-rays continues to command increased attention by society and public health officials (22). If basic principles of radiation protection are followed, the same level of diagnostic information can be achieved with reduced risk to patients and health workers.

X-rays absorbed by tissues exert harmful effects on DNA by direct or indirect action. In direct action, dislodged electrons resulting from the absorption of x-rays interact with DNA to produce damage. In indirect action, the dislodged electrons interact with water molecules in the tissue, producing free radicals, which are highly reactive molecules. These, in turn, damage the DNA. With diagnostic x-rays, the dominant harmful effects on DNA are produced by indirect action. Whether the action of x-rays on DNA is direct or indirect, there are three principal biologic effects of ionizing radiation on humans: (a) genetic effects, in which radiation causes mutations in germ cells that will be expressed in some future generation; (b) carcinogenesis, in which radiation affects somatic cells, causing malignant mutations; and (c) cell killing, which affects embryogenesis because the resulting cell depletion can adversely affect the developing embryo and fetus (17).

In terms of the genetic effects of radiation, exposure to radiation does not produce bizarre or unique mutations, but it increases the frequency of mutations that occur naturally in the population (17,33). The radiation effects on a fetus depend on the stage of pregnancy. During preimplantation, or the first 10 days after conception, the main consequence is the death of the embryo. Radiation delivered during organogenesis, which occurs from 10 days to about 8 weeks after conception, leads to a broad spectrum of anomalies affecting organs and limbs. The natural prevalence of genetic disorders, however, is so high that small increments of fetal anomalies caused by radiation from diagnostic procedures are difficult to measure directly (17,33). There is evidence to suggest that irradiation of the fetus later in pregnancy can result in the future development of leukemia. Present data indicate that the risk for leukemia in a fetus exposed to more than 10 roentgens (R) increases from 1 in 3,000 to 1 in 2,000. To provide a basis for comparison, the average annual dose to the U.S. population from natural sources, or just from living in the United States, is 125 mR per year. The approximate fetal exposure from a chest x-ray to the mother is 1 mR, and an anteroposterior film of the lumbar spine is 50 mR (10,23). All estimates of the deleterious effects caused by radiologic procedures lead to the conclusion that the balance of risk versus benefit is heavily weighted in favor of benefits. If there is a valid medical indication to perform a diagnostic x-ray examination on a pregnant patient, the patient should not be denied the examination because of the pregnancy (43).

All health workers, including physicians, handling x-ray equipment should be familiar with the radiation protection guidelines at their institutions. The following are some general guidelines:

1. Appropriate personnel radiation-monitoring devices (PMDs) should be worn whenever there is a possibility of exposure to radiation.
2. PMDs should be worn only by the individual to whom they are assigned.
3. All exposure to the patient should be kept as low as reasonably possible by attempting to accomplish the following:
   a. Minimize the exposure time.
   b. Maximize the distance from the radiation source.
   c. Maximize filtration.
   d. Maximize film-screen speed (34).
   e. Use collimation.
   f. Use gonadal shielding.
   g. Eliminate unnecessary examination and views (36,37).

Magnetic Resonance Imaging

MRI is a new technology that uses no ionizing radiation. It produces sectional images in any desirable plane revealing excellent anatomic detail with high tissue contrast (30). The demand for spinal MRI examinations continues to increase rapidly. The full potential of MRI has not been reached; nevertheless, its impact on the evaluation of spinal diseases has already altered our approach to many diagnostic problems.

In 1945, Bloch and Purcell independently discovered the phenomenon of nuclear magnetic resonance (NMR). They found that certain nuclei are capable of interacting with discrete frequencies of the electromagnetic spectrum—in this case, radio waves—when these nuclei are placed in a strong magnetic field. NMR became an important tool in chemistry for determining molecular structure. In 1952, Bloch and and Purcell shared the Nobel Prize in physics for their work with NMR. In 1972, Lauterbur was able to use the principles of NMR to produce images; this heralded the birth of clinical MRI as we know it today.

MRI is conceptually different from other diagnostic modalities, and a basic understanding of its physical principles is essential for practicing state-of-the-art spinal surgery.

Physical Principles

Nuclei with an odd number of protons or neutrons (^{1}H, ^{31}P, ^{23}Na) exhibit a spin, and because these nuclei are charged particles in motion, they create a magnetic field around them, behaving like small magnets. The nucleus most commonly used for medical imaging is hydrogen, because of its abundance in biologic tissues and its favorable magnetic characteristics. Normally, these small magnets (nuclei) are randomly oriented; when placed in a strong magnetic field, however, they orient themselves in the direction of the external magnetic field and are considered to be in a state of equilibrium. In this state, the nuclei not only spin but also precess around the axis of the external field, in a manner similar to the wobble of a spinning top (Fig. 12). The frequency of precession is directly proportional to the strength of the external field. If a specific radiofrequency (RF) pulse that is resonant with (i.e., has a frequency equal to) the frequency of precession is applied to these nuclei, they deflect from their alignment with the external magnet. When the strength of the RF pulse is chosen to cause a 90-degree deflection, the nuclei tip 90 degrees and precess perpendicular to the external magnetic field. Magnetic moments perpendicular to the external field are capable of producing an alternating current or signal in a receiver coil or antenna placed adjacent to the part being examined. After the RF pulse stops, the nuclei gradually return from the tipped position to their equilibrium state (realigning with the external field), and the emitted signals diminish. The signals captured by the receiver coil are electronically transformed into clinically useful images, or *spectra* (1,8,18).

Definitions

Resonance

The nuclei precess at a frequency that is directly proportional to the strength of the external magnet. The external magnetic field is set at a gradient at which field strength gradually decreases across the scanned part, so that each slice or position is encoded with a known frequency of precession. In other words, the variation in the magnetic strength produces a corresponding variation in resonance frequencies across the sample volume. *Resonance* refers to the synchronization of the RF pulse with a specific precessing frequency of the nuclei in a particular slice (14,18).

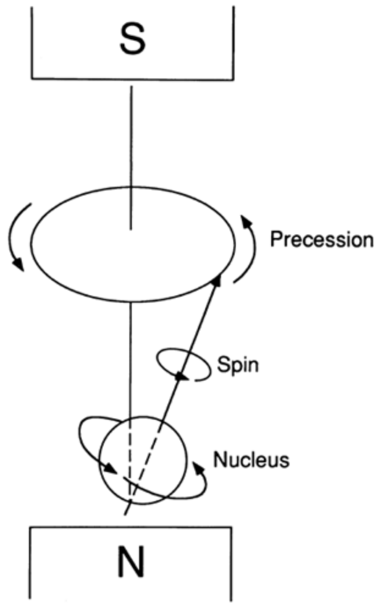

FIGURE 12. Nuclear spin and precession.

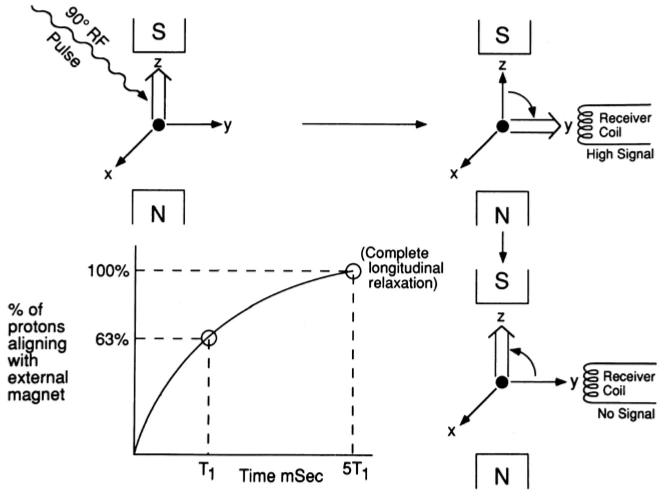

FIGURE 13. Sequence of events when a 90-degree radiofrequency pulse is applied. The magnetized hydrogen nuclei tip 90 degrees from the axis of the external magnet. The tipped nuclei then start to relax or realign with the external magnet at a rate defined by the T1 relaxation time of the tissue. By about five times the T1 relaxation time, all the tipped nuclei would have relaxed or realigned with the external magnetic field.

T1 and T2 Relaxation Time

The T1 relaxation time (longitudinal relaxation or spin-lattice relaxation time) is a tissue-specific time constant. It is the time required for 63% of the deflected nuclei to realign with the external magnetic field or return to the equilibrium state after the termination of a 90-degree RF pulse (Fig. 13) (1,8,14,18).

The T2 relaxation time (transverse relaxation or spin-spin relaxation time) is also a tissue-specific time constant describing the rate at which nuclei get out of phase or out of precessing as one unit and start to precess as individual nuclei. After the 90-degree RF pulse, all the deflected nuclei lying in the transverse plane precess in phase or as one unit. In a matter of milliseconds, they slip out of phase because of interactions with neighboring nuclei. As a result, transverse magnetization ceases, and the signal emitted from the scanned tissue diminishes. Maximum transverse magnetization is achieved immediately after the 90-degree RF pulse. Transverse magnetization decays exponentially at a time constant called T2. To put the nuclei back into phase or to make them spin as a unit, a 180-degree RF pulse is used (Fig. 14). This 90-degree RF pulse, followed by a 180-degree RF pulse, forms the basis for the commonly used spin-echo (SE) sequence, which is currently the workhorse for routine MRI (Fig. 14) (1,8,14,18).

T1 and T2 relaxation after the 90-degree RF pulse occur simultaneously. However, the T2 decay takes less time than T1 relaxation. For most soft tissues, the range of T1 is 220 to 3,000 msec; the range of T2 is 55 to 200 msec (35).

Pulse Sequence

A *pulse sequence* is a precisely defined pattern of RF pulses and listening times. The most commonly used pulse sequences in the study of the spine are the SE and gradient-refocused echo (GRE) or gradient echo sequences. A typical SE sequence consists of a 90-degree RF pulse, a pause, and then a 180-degree RF pulse. After an additional pause, the receiver coil is set to listen to a signal or echo emitted from the tissues; after a longer pause, the cycle of RF pulses and listening is repeated (Fig. 15). The SE sequence can be T1 weighted, accentuating the T1 properties of tissue, or T2 weighted, accentuating the T2 properties of tissue. T1-weighted sequences, sometimes called *partial saturation sequences*, have an echo time (TE) of less than 40 msec and a repetition time (TR) of less than 800 msec (Fig. 15). T2-weighted sequences have a TE of greater than 80 msec and a TR of greater than 1,500 msec (30,31,35). In general, T1-weighted images depict anatomy better, and T2-weighted images show pathology better. T2-weighted sequences tend to be lengthy and therefore costly. The other negative aspect of lengthy sequences has to do with patient motion because it is difficult for a patient to lie still for 30 minutes during image acquisition. Any motion during image acquisition results in marked deterioration of the images. Infants and young children who cannot remain still during the entire course of the procedure have to be sedated or put under general anesthesia before a spinal examination. Recently, a fast SE sequence has been developed that can cut the scanning time to one third the conventional SE sequence without any loss in diagnostic quality.

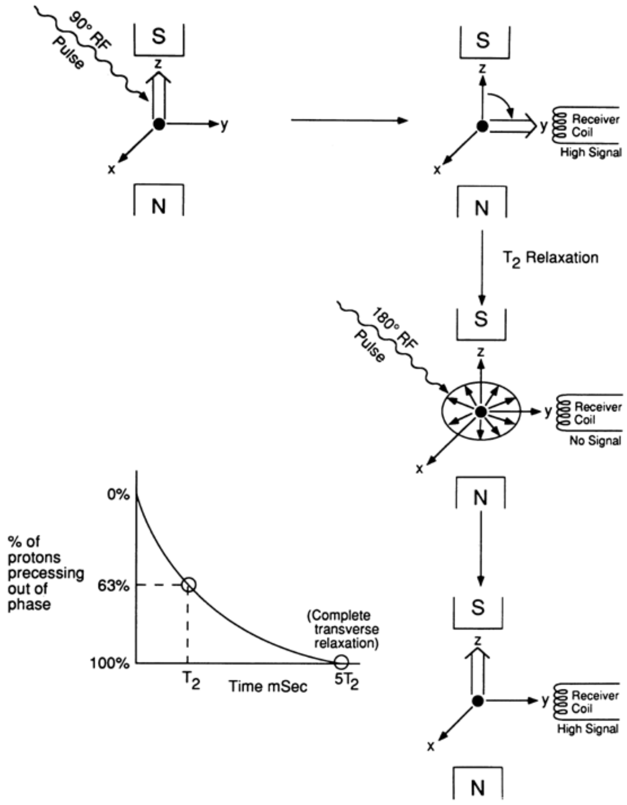

FIGURE 14. Sequence of events when a 90-degree radiofrequency pulse, followed by a 180-degree radiofrequency pulse, is applied. Note that the T2 relaxation time relates to the dephasing of the precessing nuclei, which occurs after they are tipped into the XY plane.

Other imaging sequences have been devised to reduce the examination time. GRE sequences are rapid sequences commonly used in the evaluation of the spine. Two characteristics distinguish GRE sequences from traditional SE imaging: GRE uses a partial flip angle for excitation less than 90 degrees, and GRE techniques lack the 180-degree refocusing RF pulse. Instead, refocusing is achieved by the reversal of a magnetic field gradient. The short imaging time of GRE techniques does not replace the conventional SE; however, it allows for some unique applications. The most notable is three-dimensional volume acquisition, which is based on the collection of data from a block or slab of tissue rather than one slice of tissue at a time. The excited block of tissue is partitioned into individual sections or images. With three-dimensional acquisition, structures can be studied with very thin sections, and data from the slab of tissue can be reconstructed in any desirable plane.

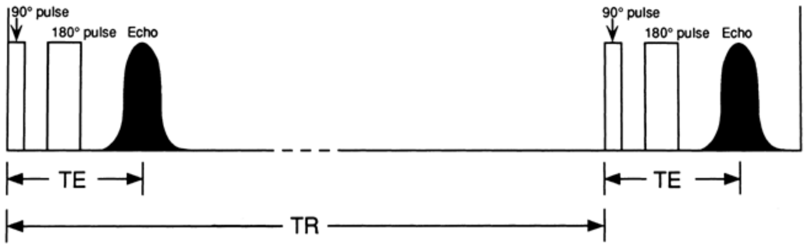

FIGURE 15. Typical T1-weighted spin-echo sequence.

When using the GRE sequence, the flip angle is the most important factor in determining the type of tissue contrast produced. In general, small flip angles, in the range of 5 to 20 degrees, produce T2-weighted images. Mildly prolonged TE, in the range of 25 to 30 msec, also potentiates T2 contrast (16).

Echo Time and Repetition Time

The TE is defined as the time between the initial RF pulse and echo production (Fig. 15). The TR is defined as the time between the beginning of a pulse sequence and the beginning of the succeeding pulse sequence (Fig. 15). The TE and TR values are printed on the film with other data to inform the physician interpreting the scans which pulse sequences were used.

Tissue Contrast

Why do certain tissues appear bright or dark with particular pulse sequences? Contrast depends on the following inherent tissue properties: free hydrogen in the tissue (also known as *proton density*), T1 and T2 relaxation times, and flow (30). Most soft tissues in the body have similar proton densities; therefore, proton density alone is not a major contributor to tissue contrast. Flowing tissue, such as blood within arteries, does not persist in a fixed place for scanning and therefore appears dark on both T1- and T2-weighted images. This is caused by the migration of the excited (stimulated by RF pulse sequences) cylinder of blood from the scanning field and replacement by unexcited blood. These flow principles are employed in magnetic resonance angiography (MRA), which is a noninvasive technique used to demonstrate vessels. This leaves T1 and T2 relaxation times of tissues as the most important factors in determining tissue contrast in images. Most clinical protocols are designed with pulse sequences that exploit both the T1 and T2 characteristics of the tissue, so that a range of pathologic features may be identified and characterized. With SE sequences, the variables that are manipulated to produce image contrast are the TR and TE. Sequences with short TR and TE produce images dominated by T1 effect; in long TR and TE sequences, the influence of T2 on image contrast is maximized (Table 1) (30,31).

On T1-weighted sequences (35), tissues with short T1 relaxation times have high signal intensity (bright)—for example, fat. Tissues with long T1 relaxation times have low signal intensity (dark)—for example, cerebrospinal fluid. On T2-weighted sequences (35), tissues with short T2 relaxation times have low signal intensity (dark)—for example, tendon or ligament. Tissues with long T2 relaxation times have high signal intensity (bright)—for example, cerebrospinal fluid.

Because of prolonged T1 and T2 relaxation times, inflamed tissue appears dark on T1-weighted images and bright on T2-weighted images when compared with healthy neighboring tissue. The increased water in the form of edema is offered as an explanation. Neoplasms generally increase the T1 and T2 relaxation times relative to the host tissue; therefore, they appear dark or signal intense on T1-weighted sequences and bright on T2-weighted sequences. This is also thought to be caused by an increase in the free water content within tumors (Table 2).

Surface Coils

A high signal-to-noise ratio is a critical factor in producing high-quality MRI scans. One important source of noise is the patient; therefore, it is important to optimize the interface between the patient and the coil receiving the signals from the patient. The standard body coil is built into the MRI machine and is relatively distant from the patient. When a coil is applied directly to the body of the patient, it is called a *surface coil.* Surface coils are sophisticated antennae designed to receive radio waves generated by the precessing nuclei. These radio waves impinge on the coil and generate an alternating current within it. The efficiency of this process depends on how closely the wires are applied to the body part being examined. The anatomic region determines the design of the surface coil. Therefore, a surface coil for the cervical spine is different in design from a lumbar spine coil or a knee coil (Fig. 16). Surface coils greatly improve the quality of the

image by increasing the signal-to-noise ratio. Using surface coils, however, limits the field of view. When selecting surface coil, the region of sensitivity of the coil should match in size the region of interest and the field of view. The smallest possible coil should be used (13,27).

TABLE 1. Relative Relaxation Times of Practical Value in the Spine

Normal Tissue	T1	T2
Water	Long (dark)	Long (bright)
Cerebrospinal fluid	Long (dark)	Long (bright)
Fat	Short (bright)	Medium (gray, bright)
Fibrous connective tissue	Long (dark)	Very short (dark)
Tendons and ligaments	Very long (dark)	Very short (dark)
Bone	Very long (dark)	Very short (dark)
Muscle	Medium (gray)	Medium (gray)
Cartilage		
Hyaline cartilage	Medium (gray)	Medium (gray)
Fibrocartilage	Long (dark)	Very short (dark)

TABLE 2. Relative Relaxation Times of some Pathologic Processes

Abnormal Process	T1	T2
Infection/Inflammation	Long (dark)	Long (bright)
Neoplasm	Long (dark) or medium (isointense)	Long (bright)
Fibrosis	Long (dark)	Very short (dark)
Fatty infiltration	Short (bright)	Medium (bright)
Hemorrhage (acute)	Long (dark)	Long (bright)

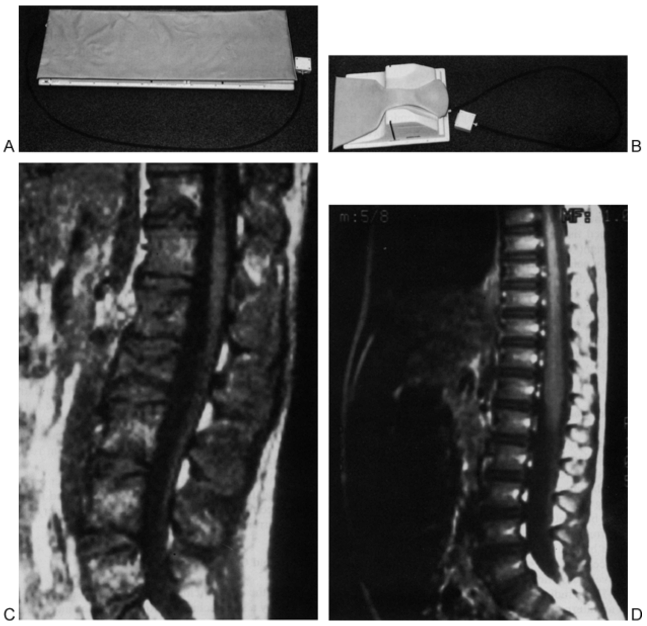

FIGURE 16. A: Surface coil used for magnetic resonance imaging (MRI) of the lumbar and thoracic spine. **B:** Surface coil for the cervical spine. **C:** A lumbar spine MRI study performed with a body coil that is built into the gantry and is not in direct contact with the patient. **D:** An MRI study performed with a surface coil shows significant improvement in the signal-to-noise ratio.

Phased-array coils (several surface coils combined to act as one) have the benefits of small surface coils (i.e., increased signal-to-noise ratio) yet provide a large field of view up to 48 cm in length. Both the thoracic and the lumbar spine can be imaged with this technique in about the same time as that required to image the lumbar spine alone (27).

Contrast Agents

The contrast agent presently approved by the U.S. Food and Drug Administration for clinical use is gadolinium diethylenetriamine pentaacetic acid (Gd-DTPA), which is a paramagnetic agent. Paramagnetic atoms possess unpaired electrons in their outer shells, thus creating their own small local magnetic field. Paramagnetic agents act in enhancing (shortening) the T1 and T2 relaxation times of surrounding hydrogen nuclei. T1 shortening produces higher (brighter) signals on T1-weighted images. Gd-DTPA displays pharmacokinetics similar to those of iodinated contrast media in that it penetrates highly vascularized areas and produces an increase in signal intensity in these areas on T1-weighted images. The paramagnetic properties of Gd-DTPA reduce the T1 relaxation time of penetrated tissues. In the musculoskeletal system, there is preliminary evidence that Gd-DTPA is useful in differentiating edema, cyst formation, and necrosis from the actual tumor and, therefore, helps in delineating the extent of a neoplastic process. It has also been used extensively in differentiating epidural scarring from recurrent disc herniation after disc surgery (3,45).

Nonionic gadolinium compounds with lower osmolality than that of Gd-DTPA are being developed. These newer compounds can be safely injected in larger doses than currently permitted with Gd-DTPA (3).

Safety and Contraindications

With the current clinical level of exposure, MRI is generally a safe technique. Recent studies indicate no interference with cardiac function or nerve conduction at 2 to 7 tesla magnet strength. The forceful attraction of ferromagnetic objects to the magnet is a definite risk. Caution must be exercised when there are ferromagnetic objects embedded in the patient, such as shrapnel, foreign bodies lodged within the eyes, or aneurysm clips in the brain. As a rule, MRI should not be performed on patients with cardiac pacemakers, aneurysm clips, or cochlear implants. Metallic orthopaedic appliances are generally not ferromagnetic, but they do create significant local artifacts that preclude scanning in the immediate vicinity of the appliance. MRI should be avoided during the first trimester of pregnancy (25,38).

Myelography

Myelography (5) has been replaced almost entirely by MRI, except on rare occasions, in the workup of pediatric spinal problems. When myelography is performed, low-osmolality, nonionic contrast material is used usually followed by a CT examination.

After adequate sedation and sterilization, the patient's back is anesthetized locally using 0.5% lidocaine (Xylocaine) at the L4–5 or L3–4 interspinous process. A 22-gauge spinal needle is inserted into the subarachnoid space, and contrast material is injected. If a complete block is suspected, a single drop of Pantopaque is injected. The table angle is changed so that the drop is moved to the level of the suspected block to identify it.

Indications for myelography include the following:

1. Identification of the exact anatomy of congenital anomalies, such as diastematomyelia, meningoceles, or other defects before corrective surgery
2. Documentation of drop metastases from such tumors as medulloblastomas, ependymomas, and pineal region tumors when the contrast-enhanced MRI study is negative
3. Confirmation of traumatic avulsion of the nerve sheath and posttraumatic pseudomeningocele

Major complications of myelography include death in association with anesthesia or sedation; respiratory arrest caused by tonsillar herniation or sedation; implantation epidermoid spinal abscess; chemical or infectious meningitis; and seizures.

Angiography

The indication for spinal angiography (15,21,29) in the pediatric age group is primarily for the transcatheter treatment of vascular malformations and preoperative embolization of vascular tumors (Fig. 17) (21).

The cervical spinal cord is supplied by anterior spinal arteries branching off from the vertebral arteries and radiculomedullary arteries of the deep cervical and costocervical trunk. The upper thoracic segment (T1 to T7) of the spinal cord is perfused by radiculomedullary branches arising from the fourth to fifth intercostal arteries. In the thoracic region, the anterior spinal artery is smaller in diameter than the one in the cervical or thoracolumbar region. The artery of Adamkiewicz (arteria radicularis anterior magna) supplies the spinal cord from T8 through the conus. In 85% of cases, this artery arises from the intercostal or lumbar artery accompanying a nerve root between T9 and L2 (Fig. 17E). In the remaining cases, it arises between T5 and T8.

Liberal use of the digital subtraction technique is essential in the spinal angiogram for the identification of the lesion and arteries supplying the cord, particularly the artery of Adamkiewicz. Diversion of the flow in a radiculomedullary artery to the artery of Adamkiewicz by opening a potential communication during embolization is well known; thus, intermittent verification of the flow pattern during the process of embolization is necessary to prevent inadvertent complications.

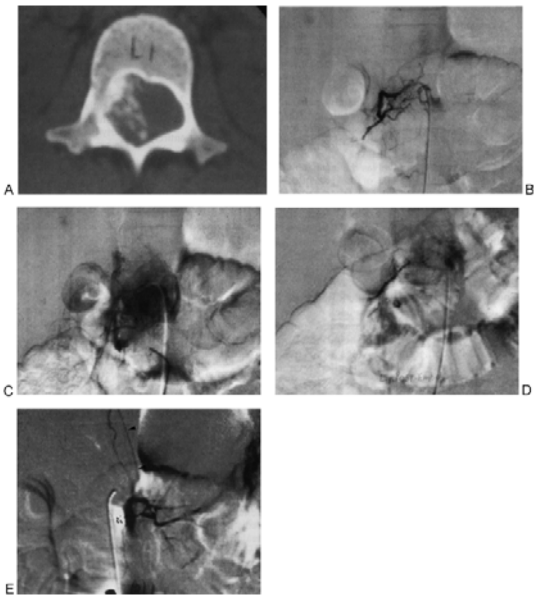

FIGURE 17. Chondrosarcoma arising from the right pedicle of L1. **A:** CT scan at the L1 vertebral body shows a calcified extradural mass eroding the posterior aspect of the vertebral body. **B** and **C:** Preembolization angiograms of the right L1 lumbar artery show a hypervascular mass. **D:** Postembolization angiogram shows obliteration of the tumor stain. **E:** Angiogram of the left L1 lumbar artery demonstrating the artery of Adamkiewicz (*arrowheads*).

Radionuclide Bone Imaging

A common indication for radionuclide bone imaging in children is low back pain. Back pain in children is different from that in adults. Most radionuclide bone scanning in adults is performed to evaluate metastatic bone disease, but this is not the case in children.

Technetium-99m methylene diphosphonate (^{99m}Tc-MDP) is given 2 to 4 hours before scanning. The dose of radionuclide is calculated according to the body weight of the child. Two other agents are used for the detection of infection: gallium-67 citrate and indium-111–labeled white blood cells. The use of indium-111 is widely accepted and involves the incubation of the radionuclide with a sample of the patient's blood, which is reinjected into the patient; scanning is performed 24 hours later.

Single photon emission computed tomography (SPECT) is frequently used in the evaluation of low back pain (Fig. 18). SPECT is thought to improve the identification and localization of bone lesions, but no controlled studies comparing SPECT with planar scintigraphy are available for the spine. As with all other imaging procedures, infants and young children must be adequately immobilized or sedated during image acquisition.

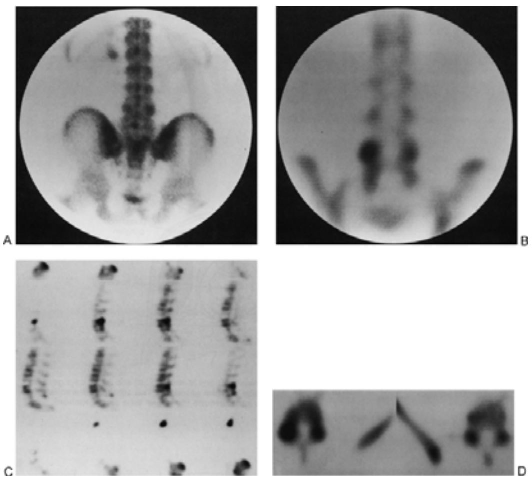

FIGURE 18. Nineteen-year-old athlete with low back pain. Radiographs were negative. Planar bone scintigraphy (**A**) is unremarkable. Coronal (**B**), sagittal (**C**), and axial (**D**) single photon emission computed tomography images show bilateral increased radiotracer uptake in the region of the pars interarticularis, more pronounced on the right side.

Bone scintigraphy is an excellent screening technique for young patients with low back pain. Because low back pain in children and adolescents is often associated with organic disease and should be vigorously pursued, bone scintigraphy provides a sensitive technique to exclude neoplasm, infection, fracture, or active spondylolysis (42).

Unique Features of the Developing Spine

Embryology of the Spine

A brief review of the basic embryology of vertebral column formation may help in the analysis of the radiologic appearance of the pediatric spine (11,19,39).

Development of the bony spine evolves around the notochord, which acts as a framework for the developing spine and induces and controls the formation of vertebral bodies. The notochord forms from Hensen's node, a rapidly proliferating group of cells in the primitive streak, and develops into a chain of cells between the neural tube dorsally and the entoderm (developing gut) ventrally (Fig. 19).

There are three stages in the development of the vertebral column: formation of the membranous, cartilaginous, and osseous vertebral column.

Formation of the Membranous Vertebral Column

The fetal vertebral column begins to form toward the end of the third week, when the notochord separates from the primitive gut and the neural tube, and somites are formed from paraxial mesoderm on either side of the neural tube (Fig. 19). The ventral medial aspect of the somite further differentiates into the sclerotome, the precursor of the centra, neural arches, and ribs. The dorsal-lateral aspect of the somite forms the dermatome, the precursor of skin. The dorsal-medial aspect of the somite forms the myotome, the precursor of the paraspinous musculature. The sclerotomes surround the notochord in the ventral aspect and the neural tube in the dorsal aspect, forming a continuous mesodermal sheath termed the *membranous vertebral column.* The sclerotome is then divided into cranial and caudal halves by an evanescent structure called the *sclerotomal fissure.* Adjacent halves of contiguous sclerotomes unite to form one vertebral body (Fig. 20). The intersegmental vessels that divided the sclerotomes now become incorporated within the center of the vertebral bodies, whereas segmental spinal nerves that originally related to the midpoint of the sclerotomal segment—site of the sclerotomal fissure—eventually relate to disc areas.

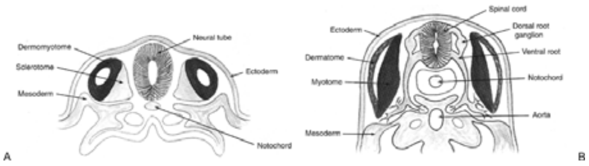

FIGURE 19. Early embryologic development. Axial sections at about 22 (**A**) and 30 (**B**) days' gestation. The notochord lies between the neural tube and the entoderm. The somites differentiate into sclerotomes, dermatomes, and myotomes and surround the neural tube and notochord.

Formation of the Cartilaginous Vertebral Column

At about the fourth fetal week, chondrification of the vertebral column starts, and the membranous vertebral column is succeeded by the cartilaginous vertebral column. Two cartilaginous centers appear on either side of the notochord, forming the cartilaginous vertebral bodies (Fig. 19). A short time later, additional cartilaginous centers appear in the neural arches and in the costal processes to form pedicles, laminae, and costal processes of the cervical spine and ribs.

Formation of the Osseous Vertebral Column

At about the eighth fetal week, ossification of the vertebral column starts from the thoracolumbar junction and extends cranially and caudally. Ossification centers are formed dorsally and ventrally in the vertebral body, one for each neural arch (Fig. 21). Ossification centers start to appear in the bodies of the lower dorsal and lumbar regions at about the third month of gestation and, by the end of the fifth month, are present in all vertebral bodies. Ossification proceeds rapidly craniad and more slowly caudad. By the fourth month, all the centra are ossified.

The notochord, which remained as a solid cord during the membranous stage, is progressively squeezed from the vertebral body into the intervertebral discs by the increased pressure caused by the rapid enlargement of the vertebral bodies during chondrification and ossification. The notochord in the intervertebral discs forms the nucleus pulposus after some mucoid degeneration and proliferation.

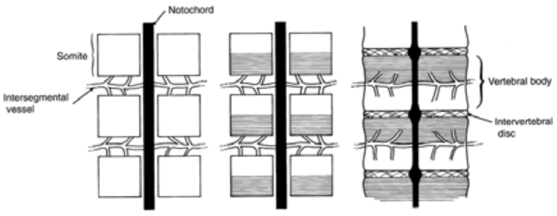

FIGURE 20. Development of the vertebral body and intervertebral disc. The vertebral bodies are formed by the fusion of the caudal segment with the cranial segment of the next somite. The intersegmental tissue containing intersegmental vessels becomes the center of the vertebral body. The intervertebral discs develop from the sclerotomes and remnants of the notochord.

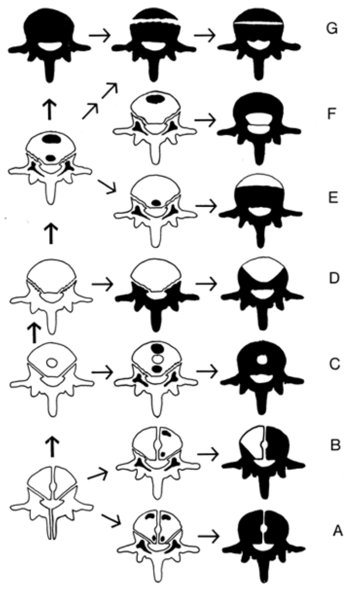

FIGURE 21. Development of the vertebral body and its variations. Cartilaginous formation is shown in white and osseous formation in black. Normal development is shown in the left row; variations and anomalies in the middle and right rows. *A*, sagittal cleft of body; *B*, hemivertebra; *C*, notochord remnant; *D*, absent vertebral body; *E*, hypoplastic vertebral body; *F, G*, coronal cleft (Adapted from Barnes GT (1991): Contrast and scatter in x-ray imaging. *Radiographics* 11:307–323 Links, with permission.)

General Development

The neonatal spine lacks the physiologic curvature of the adult spine (Fig. 22). At birth, the vertebral column is relatively straight and forms a single, long, shallow curve extending from the cervical to the lumbar segment with the convexity directed anteriorly. Cervical lordosis appears during the first year when the infant starts to have head control. Thoracic kyphosis and lumbar lordosis develop when the child starts to bear weight toward the latter half of the first year and gradually become more prominent during childhood. The complete loss of this physiologic curvature, however, may be pathologic even in neonates, suggesting conditions ranging from tumor to muscle spasms. In the neonatal period, the individual vertebral bodies are ovoid and wedge shaped when seen on lateral radiographs. They appear smaller in size relative to the intervertebral space, owing to the presence of nonossified cartilaginous zones on the superior and inferior surface. The "bone within a bone" appearance (Fig. 23) is normally seen, particularly in premature infants (4,19). The oval-shaped centrum has ventral and dorsal clefts, which are vascular channels (Fig. 22). The anterior notch is formed by a large sinusoidal blood space within the vertebral ossification center, whereas the posterior one is formed by a perforated indentation on the posterior wall of the vertebral body functioning as a conduit for basivertebral veins and nutrient arteries (39). Cartilaginous plates at the site of fusion of the sclerotome containing the intersegmental vessels can be observed routinely on MRI and occasionally on radiographs. The ventral channels gradually fade, but the dorsal channels may be seen even in adults (Fig. 24).

Neurocentral synchondroses, small nonossified parts of the attachment between ossification centers of the posterior neural arches and the vertebral body, are seen as radiolucent clefts in neonates and persist until the third to sixth years (Fig. 21). These should not be mistaken for fractures. The union of neurocentral synchondroses first occurs in the lumbar region shortly after birth, progresses cephalad, and reaches the cervical region by the second year. Clefts are also seen in the midline posteriorly between two ossification centers of the posterior neural arches and

appear as midsagittal radiolucencies on anteroposterior radiographs of the spine (Fig. 22D).

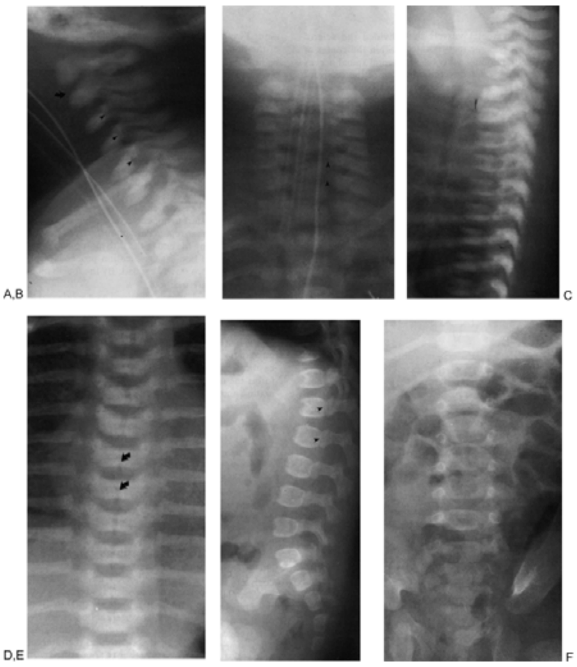

FIGURE 22. Neonatal spine. Cervical spine (**A and B**): Mid and lower cervical vertebral centra are round in shape and wedged anteriorly. Anterior arch of the atlas is not ossified and therefore cannot be seen. Physiologic kyphotic curvature is not developed. Neurocentral synchondrosis (*arrowheads*) between the centrum and neural arch is seen as a longitudinal radiolucency. The subdental synchondrosis (*curved arrow*) is not fused. Thoracic spine (**C and D**): Thoracic vertebral centra are more squared and show distinct anterior and posterior "notches." The midthoracic to upper lumbar region is the straightest segment. Central portions of the posterior arches, which are not ossified, are seen as a series of radiolucencies (*curved arrows*) in the midline. Lumbar spine (**E and F**): Mild kyphotic and lordotic curves are present in the upper lumbar and lumbosacral junction. Note the neurocentral synchondrosis (*arrowheads*).

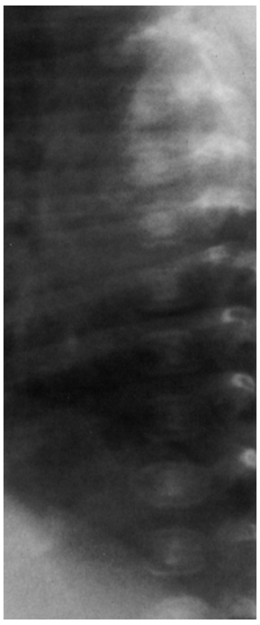

FIGURE 23. Neonatal spine. The "bone within a bone" appearance of the vertebrae is seen in the normal neonate.

Coronal cleft vertebrae are normally present, most commonly in the lumbar region and predominantly in boys (12). This variation of the vertebral body is probably caused by the incomplete fusion of the anterior and posterior ossification centers of the centrum (Fig. 19). This defect usually disappears in a few weeks to months. This variation occurs more commonly in association with skeletal dysplasias such as chondrodysplasia punctata (Fig. 25) (6).

As the child grows, the spinal column attains a more adult configuration (Fig. 26). Physiologic lordosis of the cervical spine becomes more evident once head control is gained. Lumbar lordosis becomes prominent with walking. The vertebral bodies become more rectangular.

Secondary ossification centers appear at the tips of the several bony processes attached to the neural arch (39): transverse, articulating, and spinous processes (Fig. 27). These ossification centers do not participate in the longitudinal growth of the spinal column. They all appear at about puberty and fuse to the main mass of the neural arch at about 25 years of age. The annular ossification (Figs. 28 and 29) marginating the superior and inferior corners of the vertebral body appears as early as the seventh year and fuses with the vertebral body at about 25 years of age. The ossification of the ring apophyses may not occur simultaneously in the upper and lower surfaces of the same vertebral body and may easily be mistaken for a fracture. Complete ossification

and incorporation into the vertebral bodies usually occur by 18 years of age. Ring apophyses may be seen in the lumbar vertebrae of patients even in their twenties. When seen on lateral radiographs, ossifying ring apophyses appear as thin sclerotic lines along the end plates. The vertebral bodies are slightly beaked or notched, owing to the apophyseal edges of the anterior borders.

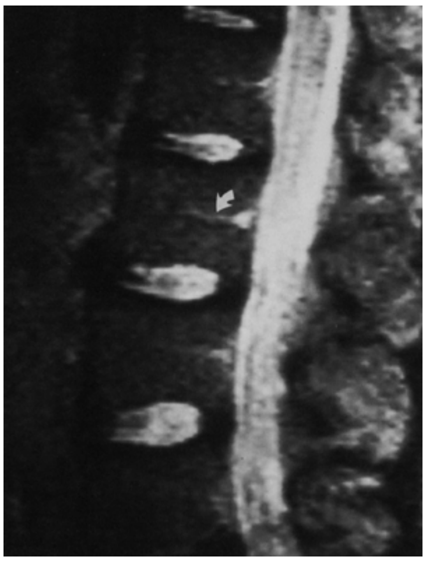

FIGURE 24. Dorsal vascular channel (*curved arrow*) is shown on a T2-weighted magnetic resonance image of a 25-year-old man.

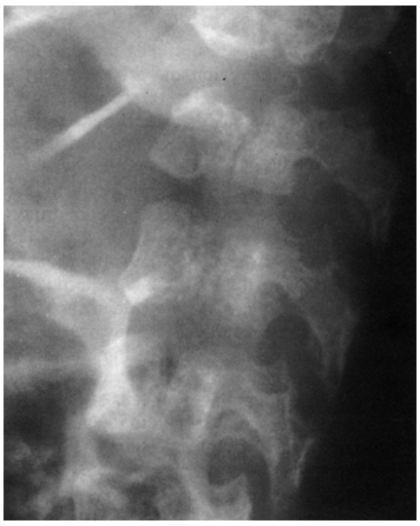

FIGURE 25. Coronal clefts of vertebral bodies. A coronal cleft is seen in multiple vertebral bodies in this infant with chondrodysplasia punctata. The cleft may be seen transiently in normal neonates.

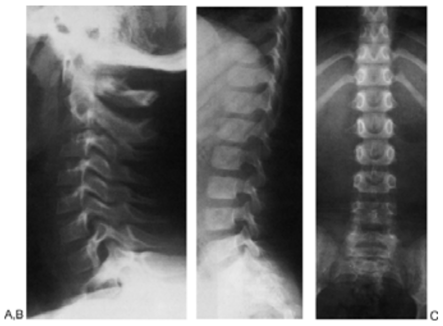

FIGURE 26. Normal 6-year-old cervical (**A**) and lumbar (**B and C**) vertebral column. Cervical and lumbar lordosis has developed, and the vertebral bodies have become more rectangular.

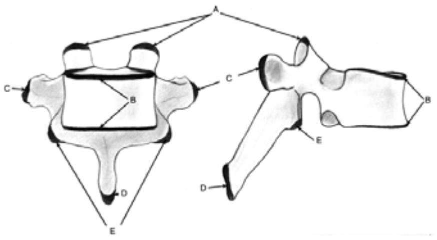

FIGURE 27. The secondary vertebral ossification centers. *A and E*, superior and inferior articular processes; *B*, annular ossification centers; *C*, transverse processes; *D*, spinous processes.

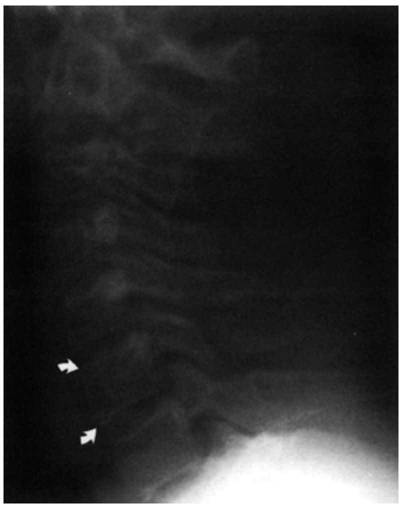

FIGURE 28. Annular ossification centers (*curved arrows*). Cervical spine in a 13-year-old boy.

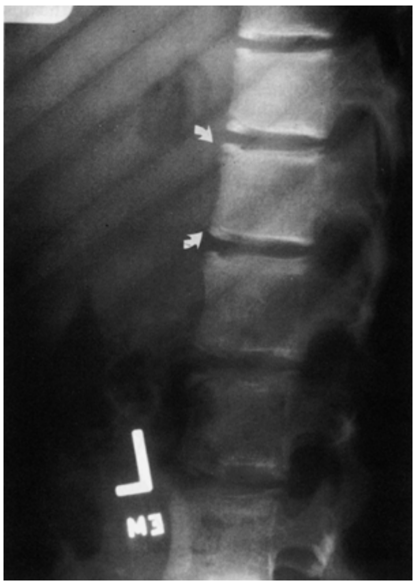

FIGURE 29. Annular ossification centers (*curved arrows*). Thoracolumbar junction in a 12-year-old girl.

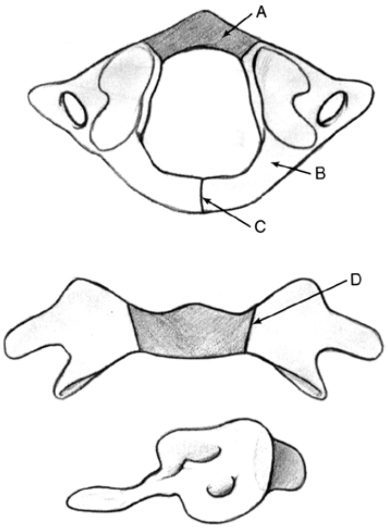

FIGURE 30. Development of the atlas. *A*, ossification center for the anterior arch; *B*, ossification center for the neural arch; *C*, the synchondrosis of the neural arches; *D*, the neurocentral synchondrosis.

The development of the atlas and axis requires special attention (Figs. 30, 31, 32, 33). At birth, the neural arches of the atlas are separated by cartilage in the midline dorsally. The arches fuse at about the fourth year. The anterior arch is cartilaginous at birth (Fig. 22A). Neurocentral synchondroses between the anterior arch and lateral masses fuse at about the eighth year of life. The failure of these fusions may cause confusion when evaluated in the context of trauma (Fig. 34). The transverse diameter of the atlas ring may be increased, causing lateral deviation of the lateral masses of the atlas in relation to the odontoid process, mimicking a Jefferson fracture.

The ossification of the axis is derived from five primary centers consisting of the centrum, neural arches, and dens; the latter two are paired (Fig. 31). The neural arches fuse dorsally at about the second year. The dens ossifies from two laterally placed centers that fuse before birth. Neurocentral and subdental synchondroses ossify between 4 and 7 years of age. Remnants of these synchrondoses should not be mistaken for fractures. The terminal *ossicle*, or “summit” ossification center, in the tip of the odontoid process appears between the second and sixth years; it then fuses with the main mass of the odontoid at 11 to 12 years of age.

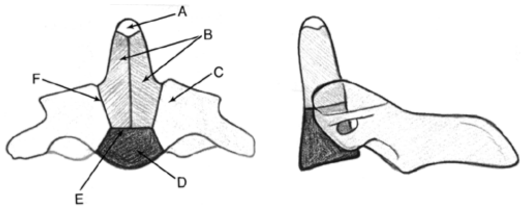

FIGURE 31. Development of the axis. *A*, ossification center for the os terminale; *B*, ossification centers for the odontoid process; *C*, ossification center for the neural arch; *D*, ossification center for the body of the axis; *E*, subdental synchondrosis; *F*, the neurocentral synchondrosis.

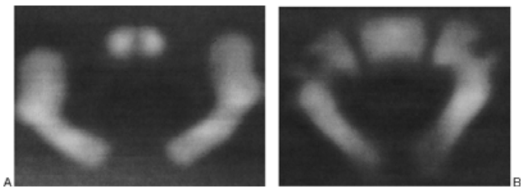

FIGURE 32. Computed tomography scans of the ossification centers of the atlas (**A**) and axis (**B**) in the neonate.

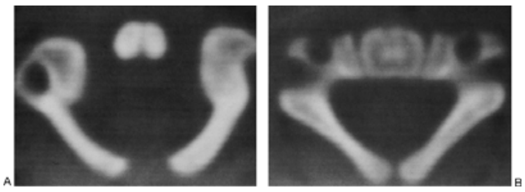

FIGURE 33. Computed tomography scan demonstrates the ossification centers of the atlas (**A**) and axis (**B**) in an 8-month-old infant.

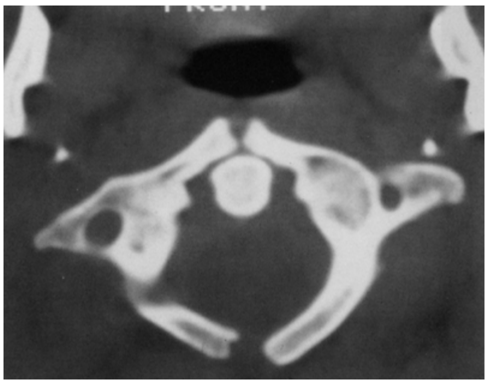

FIGURE 34. Nonfusion of anterior and posterior arches of the atlas in a 14-year-old boy. Open-mouth view (not shown) showed increased distance between the odontoid and lateral masses of the atlas. Jefferson fracture was suspected. Subsequent computed tomography scan revealed nonfusion (rachischisis) of both the anterior and posterior arches of the atlas.

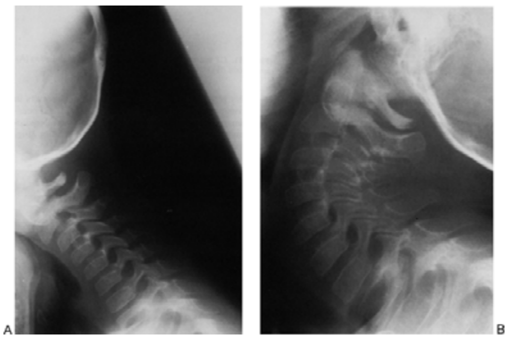

FIGURE 35. C2 to C3 pseudosubluxation. Lateral radiograph of a 6-year-old child in flexed neck position (**A**) shows prominent anterior movement of C2 to C3 and, to a lesser extent, C3 to C4, giving a subluxed appearance. On extension view (**B**), the alignment of the cervical spine is normal.

The upper cervical column has unique features in infants and young children. The upper cervical facet joints are oriented more horizontally, and vertebral bodies are wedged anteriorly. The fulcrum for maximal cervical flexion is higher, at the C2 to C3 level in this age group, as opposed to the C5 to C6 level in adults. This physiologic and anatomic uniqueness results in prominent anterior movement at the C2–3 and occasionally C3–4 spaces on flexed neck lateral radiographs, and it is often mistaken for a subluxation (Fig. 35).

Magnetic Resonance Imaging Signal Changes of the Developing Spine

MRI signal characteristics in the normal pediatric spine evolve dramatically with age (5,44). The signal characteristics of the bone marrow of vertebral bodies, cartilaginous end plates, and intervertebral discs may be summarized as follows.

From birth to 6 months of age, the bone marrow of the vertebral body is ovoid in shape and shows hypointense signal intensity on both T1- and T2-weighted images. The cartilaginous end plates are hyperintense on T1-weighted images and hypointense on T2-weighted images. The discs remain hypointense on T1-weighted images and hyperintense on T2-weighted images throughout growth (Fig. 36).

By 6 to 12 months of age, the bone marrow of the vertebral body becomes more rectangular, and its signal intensity becomes more intense compared with that of the cartilage and disc on T1-weighted images. This reflects the infiltration of lipid into the marrow space. The cartilaginous end plates become ossified by this age and demonstrate no signal on T1- or T2-weighted images (Fig. 37).

By 2 years of age, each part of the vertebra is more distinct, and normal spinal curvature is established. The marrow shows a more marked hyperintense signal on T1-weighted images and a hypointense signal on T2-weighted images. The end plates are ossified and demonstrate no signal on T1- or T2-weighted images (Figs. 38, 39, 40).

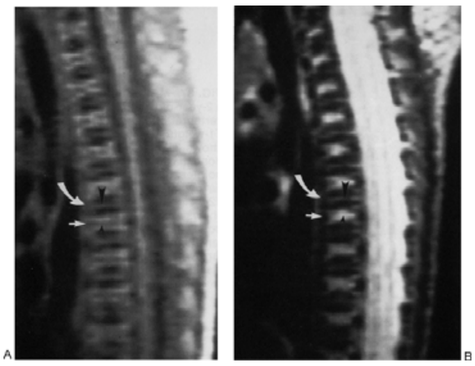

FIGURE 36. Magnetic resonance imaging of the spine in a newborn. The contour of the vertebral bodies is indistinct. **A:** T1-weighted image (SE 400/20) shows hypointensity of the bone marrow (*curved arrow*) with intersegmental vessels in the center (*arrowhead*), hyperintensity of the cartilaginous end plates (*arrow*), and hypointensity of the intervertebral discs (*small arrowhead*). **B:** T2-weighted image (SE 2,000/100) demonstrates hypointensity of the bone marrow (*curved arrow*) and the cartilaginous end plates (*arrow*) and hyperintensity of the discs (*small arrowhead*).

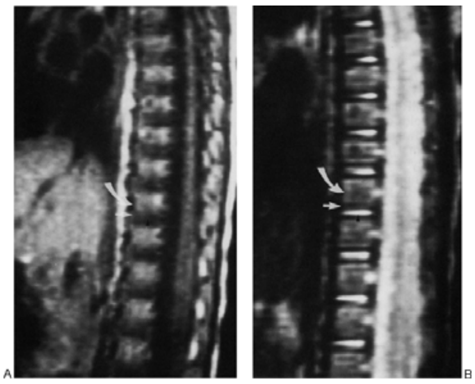

FIGURE 37. Magnetic resonance imaging of the spine in a 7-month-old infant. **A:** T1-weighted image (SE 400/20) shows slight hyperintensity of the bone marrow (*curved arrow*), hypointensity of the ossifying end plates (*arrow*), and hypointensity of the discs (*arrowhead*). **B:** T2-weighted (SE 2,000/100) image shows hypointensity of the bone marrow (*curved arrow*) and the cortical end plates (*arrow*) and hyperintensity of the discs (*arrowhead*).

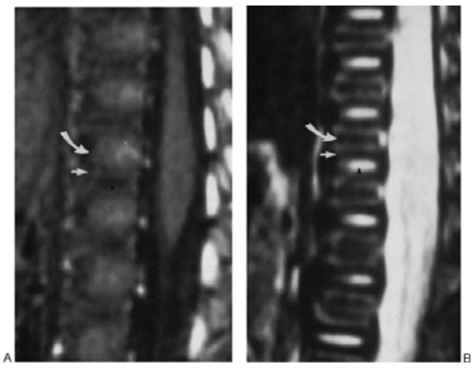

FIGURE 38. Magnetic resonance imaging of the spine in a 2-year-old child. The contour of the vertebral bodies is more distinct. **A:** T1-weighted (SE 400/10) image shows slight hyperintensity of the bone marrow (*curved arrow*) and hypointensity of the cortical end plates (*arrow*) and the discs (*arrowhead*). **B:** T2-weighted (SE 2,000/90) image shows slight hypointensity of the bone marrow (*curved arrow*), hypointensity of the cortical end plates (*arrow*), and hyperintensity of the discs (*arrowhead*).

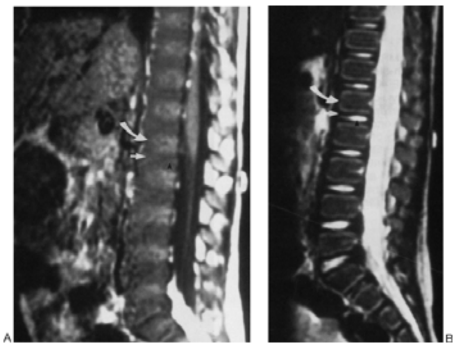

FIGURE 39. Magnetic resonance imaging of the spine in a 5-year-old child. **A:** T1-weighted image shows slight hyperintensity of the bone marrow (*curved arrow*), hypointensity of the cortical end plates (*arrow*), and isointensity of the discs (*arrowhead*). **B:** T2-weighted image shows slight hypointensity of the bone marrow (*curved arrow*), marked hypointensity of the cortical end plates (*arrow*), and marked hyperintensity of the discs (*arrowhead*).

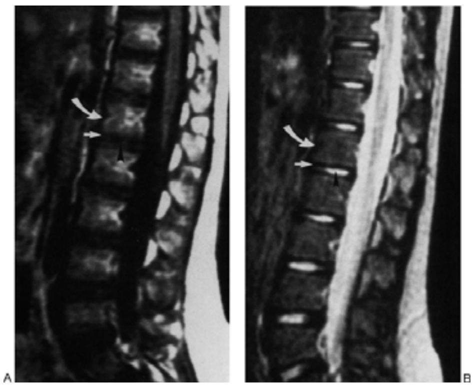

FIGURE 40. Magnetic resonance imaging of the spine in a 9-year-old child. **A:** T1-weighted (SE 500/11) image shows marked hyperintensity of the bone marrow (*curved arrow*), marked hypointensity of the cortical end plates (*arrow*), and isointensity of the discs (*arrowhead*). **B:** T2-weighted (SE 2,000/90) image shows isointensity of the bone marrow (*curved arrow*), marked hypointensity of the cortical end plates (*arrow*), and marked hyperintensity of the discs (*arrowhead*).

Summary

Familiarity with the developing spine, as well as the imaging modalities to evaluate it, is essential for diagnosing spinal disease. This chapter briefly discusses these issues and points out some of the technical developments that are looming on the horizon.

Section IV Patient Evaluation

5

Back Pain in Children

Howard A. King

H. A. King: St. Lukes Regional Medical Center, Boise, Idaho 83702.

The problem of evaluating back pain in adults has been carefully studied, with numerous papers written that document the incidence of pain and symptoms. Treatment of the adult with back pain remains controversial, but the incidence and rate of pain have been well documented. In general, the literature suggests that in most adults with back pain, there is no definable cause of the symptoms, and symptoms resolve with time in most patients. The clinician generally has a grasp of those problems that will respond well to surgical treatment if the symptoms do not resolve with conservative management (e.g., spinal deformity, spinal stenosis, spondylolisthesis, disc herniation). We know far less about the incidence of back pain in children and the adolescent group. Reports suggest that the incidence of back pain in the younger age groups may be higher than once thought (1 ,8 ,15 ,19 ,25 ,26 ,29 ,33 ,36 ,40). Turner and colleagues (43) reported that less than 2% of patients younger than 15 years of age had been seen by a physician for an evaluation of back pain. Grantham (18), however, noted in a review of school children that 11.5% of adolescent boys were seen by a physician for low back pain. Fairbanks and associates (12) showed that 26% of students in English schools reported back pain on a questionnaire, and yet very few had sought medical attention for the symptoms. Olsen and coworkers (33) reported that complaints of back pain are rare before 10 years of age but increase between 12 and 15 years of age. Olsen and coworkers' data suggested that by 15 years of age, 36% of adolescents could be expected to have experienced back pain. Their data, however, showed that only 2% of their study group sought medical attention for their symptoms. Balague and colleagues (1) using a validated questionnaire found that 27% of Swiss schoolchildren had experienced back pain, but as in other studies, few of the study group had gone to see a physician. These investigators also noted that 23.6% of competitive and 15.8% of recreational athletes had low back pain.

Review of the current literature suggests that the incidence of back pain in children and adolescents is higher than earlier literature would suggest (1 ,2 ,3 ,4 ,5 ,6 ,7 ,8 ,9 ,10 ,11 ,12 ,13 ,14 ,15 ,16 ,17 ,18 ,19 ,20 ,21 ,22 ,23 ,24 ,25 ,26 ,27 ,28 ,29 ,30 ,31 ,32 ,33 ,35). Young patients, however, rarely have symptoms severe enough to warrant medical attention. Micheli and Wood (29) have shown that young athletes who present with back pain have a high incidence of spondylolysis as the cause of their symptoms. Turner and colleagues (43) and I (21 ,22 ,23) have shown that children presenting to a physician with back pain frequently have a cause of their symptoms.

Physicians who see young people in their practices should be prepared to evaluate these patients if they present with symptoms of back pain. The physician should be prepared to take a detailed history, perform a thorough physical examination, and order appropriate radiographic examinations. If the physician is uncomfortable in performing this evaluation, an early referral to someone experienced is appropriate. It is ill advised to make the diagnosis of stress or psychosocial problems until all other organic causes have been excluded. Likewise, the diagnosis of “growing pains” should not be made; even when all other causes have been excluded, the diagnosis is more likely to be related to activity or overuse than growth.

The evaluation of the child with back pain requires a detailed history and physical examination. When appropriate, radiographs, laboratory tests, and special diagnostic imaging studies may be necessary to complete the workup. It is useful for the evaluating physician to have a good understanding of the differential diagnoses and studies that are appropriate to do a thoughtful and detailed evaluation.

Medical History

The initial step in evaluating a child with back pain is a careful, detailed history. Both the child and the parent should be present to provide optimal information. Frequently, even adolescents are not good historians, and a parent can usually help fill in the details. A thorough history offers insight into the problem and how it affects the patient and family. The initial evaluation should take place in a well-lit and comfortable environment that is conducive to the development of a good rapport with the patient. It is also appropriate to study the interaction of the child with family members. Subtle comments and movements may hold keys to the underlying problem. Frequently, what is said is not as revealing as what is observed.

The history should start with general questions regarding the onset of symptoms, location, frequency, duration, and intensity. Acute traumatic symptoms must be distinguished from those with a slow insidious onset. It is important to inquire about sports and other specific activities. Spondylolysis is frequently seen in patients actively engaged in football, dance, or gymnastics (2 ,7 ,13 ,17 ,21 ,22 ,23 ,24 ,30 ,31 ,39 ,42 ,44). Inquiring about these activities may help direct attention to possible “overuse” syndromes. It is also important to inquire about the frequency and intensity of these activities. Many young athletes may offer that they play a sport, but specific questions may reveal that they participate at a very high level and practice for many hours, supporting the diagnosis of stress fracture or overuse syndrome. Any abrupt changes or increase in activity may be associated with the onset of back symptoms. How the symptoms are interfering with the child's normal activities is a significant factor. Symptoms that are only occasionally present with home chores are not as worrisome as symptoms that cause a child to stop participating in a sport or pleasurable activity. Any child who has voluntarily given up a pleasurable activity because of back pain is by definition disabled and has severe symptoms. These complaints alone are adequate to proceed with an aggressive workup regardless of initial findings.

It is appropriate to inquire about frequency, duration, location, and intensity of the symptoms. Movements or activities that aggravate or relieve the symptoms should be identified. It is also important to inquire about night pain. Night pain is a worrisome symptom that can be associated with tumors, infections, and inflammatory conditions. Generally, problems such as spondylolysis, spondylolisthesis, Scheuermann disease, muscle pulls, or overuse are improved by bed rest. If a family or child reports night symptoms, the physician's level of concern should be heightened. Nighttime back pain mandates a complete and meticulous workup.

The nature of the pain is frequently difficult to determine. It is, however, helpful to inquire about localized, diffuse, or radiating pain. Localized pain may be seen with spondylolysis and tumors. Generalized pain or pain over a fairly wide anatomic region is frequently seen with overuse problems, Scheuermann disease, or inflammatory conditions. Radiating pain into the upper or lower extremities or complaints of numbness, tingling, or weakness suggest neurocompression and warrant the appropriate studies.

The patient and family should be questioned about alterations in neurologic function. It is important to inquire about changes in bowel and bladder habits. Families are frequently embarrassed to discuss issues of bed-wetting or incontinence; hence, the information may not be volunteered unless specifically addressed. These symptoms may be subtle and should therefore be thoroughly discussed. Inquiries about changes in balance and coordination must also be made. Families may not place any significance on the fact that a child falls or stumbles more frequently than other children, unless the right questions are asked. Mild changes in gain and coordination suggest subtle neurologic changes and warrant the appropriate evaluation.

Finally, inquiries must be made about similar symptoms in other family members or role models. Even though the diagnosis of conversion reaction is a diagnosis of exclusion, children do mimic complaints they see and hear from others, including parents, grandparents, siblings, or friends. These symptoms may not seem to correlate with the child's problems, and many families will not associate the two problems unless specifically asked. Even if the symptoms and complaints appear to mimic a role model, a detailed workup should be performed before the diagnosis of a conversion reaction can be made.

A general systems review should be included in the evaluation. Other medical problems can present with a chief complaint of back pain. Weight loss, fever, lethargy, skin rashes, and joint pain and swelling should be noted. Any family history of genetic conditions should also be reviewed. Lymphomas, infections, and rheumatologic conditions have presented with the primary complaint of back pain. The clinician must be aware of the myriad diagnoses that may present as back pain.

Physical Examination

The physical examination should be carried out in comfortable, well-lit surroundings. The examination must be thorough, and the patient should wear only underpants and a hospital gown. Boys frequently prefer the use of gym trunks. Modesty should be maintained but not at the cost of being able to see the patient. Observation of the torso and limbs is basic to a thorough back evaluation.

The initial step is a general screening examination, which should include a review of the head, neck, upper and lower limbs, and gait pattern. This allows the physician to watch the patient move and observe the torso and limbs for symmetry; abnormalities in the patient's gait might suggest a neurologic problem.

The spinal examination should start with a general review of posture, alignment, and skin patterns. It is important to look for obvious spinal deformities, trunk decompensation, and evidence of muscle spasm. Midline skin defects, café-au-lait spots, and cysts can indicate serious underlying problems and should be carefully reviewed. Midline cysts, hemangiomas, and lipomas frequently communicate with the underlying nerve structures; therefore, any evidence of midline skin defect should be noted and worked up aggressively to exclude a neural defect or lesion.

The forward-bending test is a crucial part of the examination (Fig. 1A, B). Things to look for include thoracic and lumbar asymmetry and evidence of limited or asymmetric movement of the spine. The amount of movement is a sensitive sign of possible problems. When the child has listing and dysrhythmia or a rigid lumbar lordosis on forward bending, a cause of the back pain is frequently found. An abnormal positive forward-bending test is nearly always a sign of underlying pathology. A positive examination is not pathognomonic of a specific condition but is almost always associated with a documentable diagnosis (Fig. 1A–IB).

The neurologic examination should be thorough. Careful study of the gait provides valuable information, especially when spinal cord or cauda equina pathology is suspected. Motor, sensory, and reflex testing should also be performed and recorded. A sensory examination may not be reliable in young children, however. It is important to look for clonus and the Babinski sign. Evaluation of the abdominal reflexes should also routinely be performed. An abnormal abdominal reflex is a subtle sign of spinal cord pathology. Asymmetry or absence of the reflex has been associated with syringomyelia and spinal cord tumors. Straight-leg raising and crossed straight-leg raising may indicate the presence of radiculopathy. If positive neurologic findings are noted, pediatric neurologic consultation may be indicated.

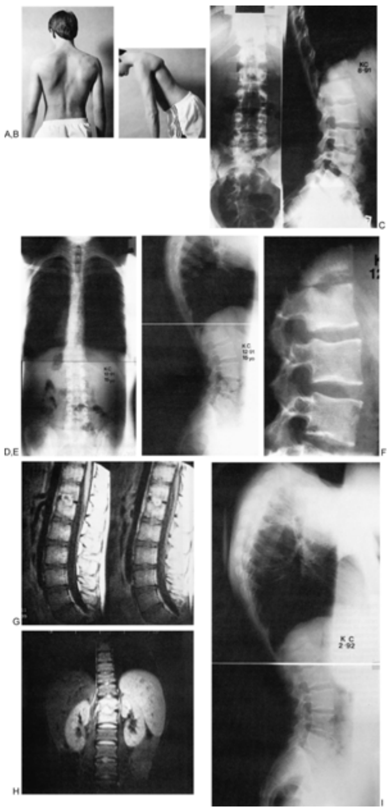

FIGURE 1. A and B: This 15-year-old boy presented with a 4-month history of midthoracolumbar back pain and stiffness. This forward-bending test demonstrates severe limitation of motion on forward bending. Note that the patient's lumbar lordosis does not flatten with forward bending. These findings invariably occur when a patient has a true organic cause for back pain. **C:** Anteroposterior and lateral radiographs in the same patient. There is some early narrowing of the T12–L1 disc space. These films were, however, interpreted as normal. **D to F:** Radiographs obtained 4 months after the initial onset of back symptoms. The T12-L1 disc space shows marked narrowing and erosive changes of the end plates, suggesting the diagnosis of hematogenous discitis. **G**and **H:** The physical examination and radiographs were suggestive of discitis. Because of the severe symptoms, a magnetic resonance imaging scan was obtained, which confirmed the diagnosis of discitis. The patient's sedimentation rate was elevated. He was treated with thoracolumbosacral orthoses and intravenous antibiotics. **I:** This radiograph was obtained after 6 weeks of brace and intravenous antibiotic therapy. The patient was completely free of symptoms and had regained normal back motion. The film demonstrates residual changes at the T12-L1 disc space.

Radiographic Evaluation

Every child who presents with back pain should have at least an anteroposterior and lateral radiograph of the spine (Fig. 1C, D). Oblique radiographs are not necessary on a routine basis but can be useful if the initial films are negative or equivocal. Good-quality films are important, especially when looking for tumors and stress fractures. If the findings are subtle, they may be missed on a poor-quality study. It is also important to visualize fully the area of maximal symptoms. Communicating with the radiology technologist regarding location of symptoms and maximal area of interest will ensure adequate visualization. Experience suggests that spondylolisthesis and spondylolysis are the most common causes of low back pain. Generally, the pars interarticularis defect can be seen on the lateral film. In addition, oblique views and caudocephalic views may be useful in better defining the pathology if the anteroposterior and lateral views are equivocal or nondiagnostic.

Imaging Studies

Bone Scan

If a child is having significant symptoms and the plain radiographs are not diagnostic, a bone scan using technetium-99m should be done (Fig. 2D). If the symptoms have lasted less than 1 month and the physical examination is unremarkable, the decision to do a scan may be delayed. In a patient with severe symptoms or a highly suspicious examination, however, a bone scan should be done promptly. The scan has been useful in finding tumors, discitis, and stress fractures. The radioactive material is more readily absorbed in areas with increased vascularity.

It is important to outline the specific information hoped to be obtained from the scan. The nuclear medicine team can do various views to help define a suspicious area. For example, pinhole images may be useful to give better detail around a tumor nidus or pars interarticularis stress fracture. Generally, the scan is performed 2 to 3 hours after injection of a radioactive tracer. If the vascularity of the lesion is a concern, a three-phase scan can be performed, consisting of an initial-phase dynamic flow study (nuclear angiography), an immediate postflow image, and then the usual delayed blood pool image (28). Generally, however, the standard delayed study is of most benefit.

The bone scan studies should include the entire spine and pelvis. A total-body scan is generally not necessary unless a tumor or a suspicious lesion has been identified. Under these circumstances, a total-body scan is performed to exclude metastatic or multifocal disease. It is most important to include the pelvis because lesions in the pelvis can present as and mimic lumbar symptoms. Lesions around the ischium and greater sciatic notch may even cause the patient to present with radicular-type symptoms. Even though there is no neural compression, the symptoms may closely resemble sciatica. Lesions or a stress reaction around the sacroiliac joints may cause symptoms similar to those of spondylolisthesis and spondylolysis. It is important to realize that a positive scan may be a nonspecific finding and must be correlated with symptoms, plain radiographs, and other studies, such as computed tomography (CT) and magnetic resonance imaging (MRI) scans.

Occasionally, the bone scan does not show focal increased activity, yet the symptoms and plain radiographs may suggest a suspicious lesion. Lowe and associates (27), in a prospective study of 53 military recruits with low back pain and spondylolysis, confirmed an increased incidence of positive bone scan and active symptoms. Papanicolaou and colleagues (34) found that although bone scans were useful in evaluating patients with spondylolysis, plain radiographs were better for making the diagnosis; bone scans may be more useful in determining the activity level of a pars fracture.

Single photon emission computed tomography (SPECT) is a technique that links the bone scan with CT techniques. This technology dates back to the early 1980s but has only recently been integrated into routine scanning studies (3 ,14). The technique is basically CT of a conventional scan. Collier and coworkers (9) and Bellah and associates (2) have shown that SPECT imaging is more sensitive in looking for stress fractures than plain scanning techniques (Fig. 2D, E). Bodner and colleagues (3) have shown that SPECT scans are more sensitive in identifying stress fractures in the lumbar spine and have more precision in locating lesions. They believe that by using axial images, they can be more precise in locating the exact anatomic area involved. SPECT studies can be useful when the plain bone scan is negative or equivocal. The SPECT image can help locate stress fractures and differentiate unilateral from bilateral pars fractures when the plain bone scan shows only a unilateral lesion (Fig. 2D, E).

Computed Tomography Scan

CT scans can be useful in evaluating low back pain. CT can be used as an adjunct in the evaluation of suspicious bony lesions seen on x-ray or bone scan. Although CT is not much help as a screening study, it is useful in evaluating tumors, fractures, and disc herniations. CT may also be used to evaluate spondylitic lesions in the lumbar spine. If brace or cast immobilization has been used, CT scans may be used to determine whether healing has occurred in the pars area.

CT scans are also used to evaluate neural compression after myelography. Although MRI has decreased the number of myelograms performed, CT can be effective in enhancing a myelographic study, especially in adolescent patients with difficult-to-evaluate disc herniation. Using CT-enhanced myelograms is an effective way of outlining the pathology. CT is an accurate tool when MRI shows multiple levels of disc pathology or when there are equivocal studies that do not match the symptoms.

Magnetic Resonance Imaging

MRI scanning techniques have revolutionized the evaluation of children's spines. MRI techniques are extremely useful in evaluating the spinal cord and neural elements, and tumors and syringomyelia have been much more accurately evaluated with MRI.

One caution, however, involves the tendency to overread MRI scans positive for disc pathology as the cause of low back pain. Tertti and associates (42) studied two groups of young adolescents—one with back pain and the other free of symptoms. They found that 38% of the patients with back pain and 26% of the symptom-free patients had disc degeneration by 15 years of age. They were unable to find any statistical significance in their data. They concluded that by 15 years of age, disc degeneration is already a common finding on MRI scans and may not correlate with back symptoms.

Although MRI studies are excellent diagnostic tools, they should not be used as a “shotgun” screening examination and should not be performed before a thorough examination and plain radiographs are obtained. Because of their cost and inconvenience, MRI studies must be reserved for those cases in which clinical signs and symptoms deem them appropriate. Specifically, MRI has been extremely useful in evaluating the spine when neurologic findings or symptoms are present. It is invaluable in diagnosing spinal cord tumors, syringomyelia, bone tumors, discitis, and other conditions. However, it does not seem as effective as some other diagnostic modalities for diagnosing stress fractures and should not replace a careful history and physical examination.

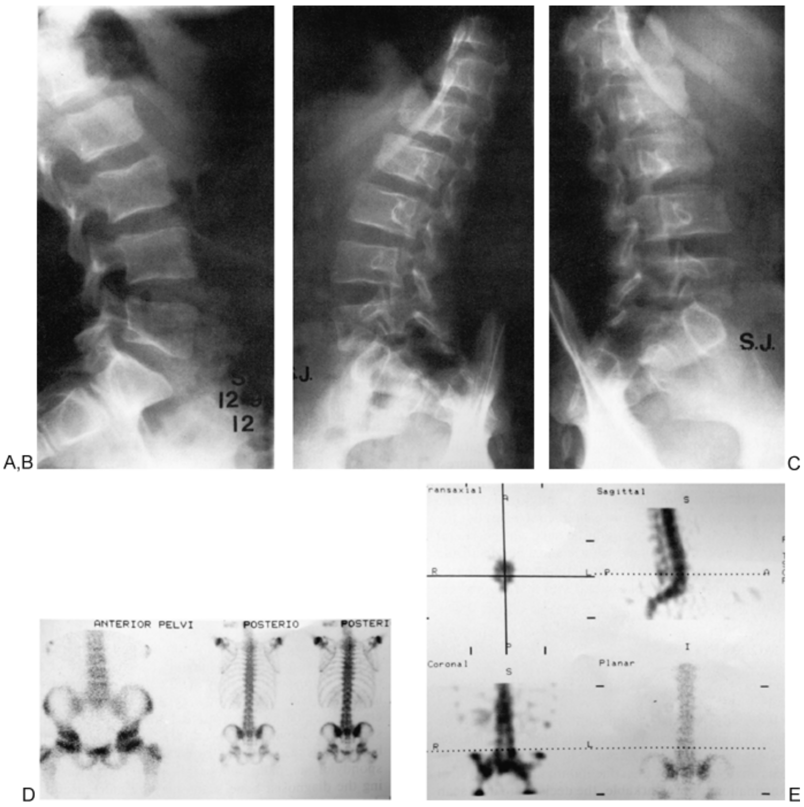

FIGURE 2. A: Lateral radiograph in a 12-year-old competitive runner. This patient had a 3-week history of low back pain localized to the left side at the lumbosacral junction. A high index of suspicion for spondylolysis was noted because of the patient's high level of sports activity. The anteroposterior and lateral radiographs were interpreted as normal. **B and C:** These oblique radiographs were used to evaluate the sacs interarticularis. They were interpreted as showing no evidence of fracture. **D:** A bone scan was obtained. The initial planar study did not demonstrate uptake in the spine or pelvis. **E:** This image, using single photon emission computed tomography techniques, demonstrates an area of increased activity at the L5–S1 pars interarticularis on the left. This area was compatible with the patient's symptoms, which subsided with brace immobilization.

When using MRI, physicians must communicate their suspicions to the radiologists. Because many radiologists are more familiar with adult conditions, some extra prescan planning can be useful in getting maximal value from the studies, especially in young children for whom sedation or general anesthesia is necessary to obtain an optimal study.

Laboratory Evaluation

A careful laboratory evaluation may be indicated based on the complaints and clinical findings. In cases in which infection, rheumatologic disease, lymphoma, or leukemia are included in the differential diagnosis, laboratory studies are useful. A complete blood count, sedimentation rate, urinalysis, electrolytes, and enzymes can be used to screen for general medical conditions. HLA-B27, rheumatoid factor, antinuclear antibody, and Lyme titers can be obtained if a rheumatologic condition is suspected.

Because numerous medical conditions can present with back pain as one of the early symptoms, physicians must never forget the importance of evaluating the entire patient. Diagnostic tests and imaging cannot replace a thoughtful physician who understand the many conditions that might bring a child with back pain in for evaluation.

Differential Diagnosis

The differential diagnosis can generally be established after a careful history and physical examination. The imaging and laboratory studies may be diagnostic or add to the clinical information to help establish a diagnosis.

Bunnell (7) has divided back pain in children into four categories (Table 1):

1. Mechanical disorders
2. Developmental disorders
3. Inflammatory disorders
4. Neoplastic disorders

I have suggested a fifth category, conversion reaction, be added to the list (21 ,22). The categories outlined by Bunnell are an invaluable guide in helping the physician's thinking process as the evaluation of the child with back pain begins.

After the initial history and physical examination, a working differential diagnosis can be established. Radiographs and laboratory studies can be added to complete the workup and help confirm a diagnosis. The child should not be compared with the adult, and the diagnosis of overuse and lumbar strain can be included after all other possible causes of the symptoms have been excluded. If the diagnosis is not obvious despite a thorough evaluation, it is appropriate to repeat periodic examinations until the symptoms resolve or the diagnosis becomes apparent. It is fair to assume that serious problems do not resolve spontaneously.

TABLE 1. Categories of Causes of Back Pain

- Mechanical disorders
  - Postural problems
  - Muscular disorders
    - Overuse syndromes
  - Herniated nucleus pulposus
- Developmental disorders
  - Spondylolysis/spondylolisthesis
  - Scheuermann disease
- Inflammatory disorders
  - Discitis
  - Disc space calcification
  - Osteomyelitis
  - Rheumatologic conditions
    - Juvenile rheumatoid arthritis
    - Ankylosing spondylitis
- Neoplastic disorders
  - Vertebral column
  - Spinal cord/canal
  - Muscle
  - Metastatic tumors
- Conversion reaction
  - Psychosomatic back pain

Turner and coworkers (43) have shown that more than half of children 15 years of age or younger with nontraumatic back complaints were diagnosed with a problem thought to be compatible with the presenting symptoms. Tufel and I (23) reported on a prospective study of 54 children presenting to a spine clinic at a regional children's hospital. None of the patients presented with a confirmed diagnosis. This study demonstrated that 34 of 54 patients were found to have a diagnosis that was thought to be the cause of the presenting symptoms. It is important to keep in mind that both of these studies were done in a specialty clinic at tertiary referral centers. The incidence of positive findings may be less in a primary care setting, but in specialized centers, back pain is frequently associated with physical problems. It is also important to realize that our study was a prospective study done on patients who were referred and had no diagnosis at the time of initial evaluation. The most alarming finding in our study was the high incidence of tumors found in the study patients. In our series (23), 6 of 54 (11%) patients, and in Turner's series (43), 4 of 61 (6%) patients were found to have tumors around the spine.

The age at presentation can frequently be helpful in developing a differential diagnosis. In my experience, patients younger than 10 years of age at presentation are more likely to have discitis or a tumor, and patients older than 10 years of age at presentation are more likely to have spondylolysis, spondylolisthesis, or Scheuermann disease as a causes of symptoms.

Spondylolysis and Spondylolisthesis

Both Turner and colleagues (43) and I (21 ,22 ,23) showed that spondylolysis and spondylolisthesis were the most common causes of back pain in the study groups in children 10 years of age or older. Spondylolysis appears to be uncommon in children 5 years of age or younger. The fracture of the pars interarticularis appears to occur in activities that accentuate lumbar lordosis and with repeated movement create the stress fracture. Jackson and coworkers (20) have demonstrated an 11% incidence of spondylolysis in young gymnasts. Kono and associates (24) reported a 10.9% incidence of spondylolysis in athletic Japanese boys. Ferguson and coauthors (13) have shown an increased incidence of spondylolysis in college football linemen. Teitz (41) reported a 5% to 20% incidence of spondylolysis in dancers who presented with symptoms of back pain. These studies would suggest that certain activities appear to have an increased incidence of stress fracture in the lumbar spine. Numerous studies have suggested that there is a definite heritable association with spondylolysis (31 ,32 ,45).

Patients with symptomatic spondylolysis usually complain of pain with strenuous activity that is usually relieved with rest. The symptoms may be acute or, more frequently, insidious in onset. Some patients present with lumbosacral pain only. The symptoms may vary from mild without limitations in activity to more severe, causing the elimination of all strenuous activities.

The diagnosis can frequently be made on radiographs by obtaining anteroposterior, lateral, and oblique views. When the radiographs are inconclusive, a bone scan with SPECT imaging can be done. If the x-rays and bone scan are equivocal, fine-cut 1-mm CT scans can be done. In my experience, MRI scans have not been useful in establishing the diagnosis of spondylolysis.

The initial treatment of symptomatic patients with spondylolysis is usually modification of activities and the use nonsteroidal antiinflammatory drugs. In patients who persist in having symptoms despite a conservative treatment program, the use of thoracolumbosacral orthosis may be helpful. I generally immobilize the spine for 6 to 12 weeks. Morita and colleagues (30) have shown that about 73% of patients with early defects heal with brace immobilization. In patients with more chronic defects, healing was much less likely. My experience has shown that healing is not as common, but brace immobilization has led to relief of symptoms with subsequent return to normal activities.

Surgical treatment for spondylolysis has been reserved for patients whose symptoms do not respond to nonoperative therapies. In L5- to S1-level spondylolysis, a posterolateral fusion would be recommended. For pars defects at L4 to L5 or above, a pars defect repair can be considered. In my experience, surgical treatment is rarely needed because most patients respond well to conservative programs.

Wiltse (45) has categorized spondylolisthesis into five types: (1) isthmic, which is the most common cause seen in adolescents; (2) dysplastic; (3) traumatic; (4) degenerative; and (5) pathologic. The degree of slip has been categorized by the amount of displacement of one vertebral body on the other: grade 1, 0 to 25% slip; grade 2, 25% to 50% slip; grade 3, 50% to 75% slip; grade 4, 75% to 100% slip. In mild grade 1 to 2 slips, conservative treatment is generally all that is necessary to allow these children to resume their sports and activities. In those with progressive slips and in growing children with grade 3 and above slips, a posterolateral fusion is probably indicated. Controversy exists about the need for instrumentation and reduction in the management of spondylolisthesis.

Scheuermann Disease

In the series reported by Turner and colleagues (43) and myself (21 ,22 ,23), Scheuermann disease was the second most common cause of back pain. Patients generally present with pain that starts later in the day or after strenuous activity. Frequently, these patients also complain of poor posture, with the development of thoracic kyphosis. Rarely are the symptoms so severe that the patients have voluntarily halted activities. The symptoms are usually described as aggravating but not limiting. The physical examination is generally nonspecific unless a deformity is present. The forward-bending test may reveal an obvious kyphosis, with sloping of the ribs and an increase in the anteroposterior dimensions of the chest. A lateral radiograph of the spine shows the typical findings of end plate irregularities and wedging of three or more vertebral bodies. Generally, the diagnosis can be established by physical examination and radiographs. If the symptoms and history do not match the radiographic findings, bone scans can be done to exclude other concomitant causes of symptoms. Bone scans are generally not useful in diagnosing Scheuermann disease unless a fracture has recently occurred. A fracture or avulsion of the end plate may occur in addition to the typical Scheuermann findings.

Osteomyelitis and Discitis

Vertebral osteomyelitis and discitis tend to occur in patients between 1 and 12 years of age, with the mean age of presentation being 6 years (5 ,38 ,44). These conditions can occur at any age, however. These patients usually have had symptoms of a fairly long duration. They may or may not be febrile, but they generally appear ill. They may present with back pain, but it is not uncommon for a young child to present with refusal to walk. It is possible to confuse this condition with a septic hip or pelvic osteomyelitis.

Radiographs can frequently confirm the diagnosis, but early in the course of the disease, a bone scan may be more useful, especially if disc narrowing has not yet occurred. Sedimentation rates and white blood cell counts are frequently elevated and can help establish the diagnosis. MRI studies may also be useful in localizing the lesion and defining the extent of bone and soft tissue involvement. Even though tuberculosis of the spine is rare in the United States, there are several new cases each year. It is important to consider this condition when a child presents with back pain and radiographs show vertebral collapse and soft tissue mass. In addition, a careful neurologic evaluation should be done to document the possibility of cord compression.

In the early stages of discitis, the white blood cell count may not be elevated. Wenger and associates (44) have shown that blood cultures were positive in 9 of 32 patients and were more useful in the acute period. Disc space biopsy has been shown to have 25% accuracy factor and, when positive, usually shows *Staphylococcus aureus* as the organism. Because of the low yield of disc space biopsy, blood cultures are obtained, and the patients are treated as though they have *S. aureus* infection. Treatment includes brace or cast immobilization and parenteral antibiotics, especially in patients who present with fever and systemic symptoms. Most patients respond to brace and antibiotic treatment. Rarely is surgery indicated in these patients.

Disc Herniation

Although disc herniation is not a common cause of back and leg pain in children, it does occur (4 ,5 ,6 ,11 ,16). Children and adolescents account for about 1% to 2% of all patients who present with disc herniations (9). These patients generally tend to present with a paucity of neurologic signs, yet most have positive straight-leg raising signs. DeLuca and colleagues (10) noted that 98% of children with disc herniation presented with back pain, some with and some without sciatica. Epstein and associates (11) reported on 25 patients with disc herniation and noted trauma as a precipitating cause in more than half. All patients had straight-leg raising signs, and 17 patients had positive crossed straight-leg raising signs. Epstein and others (11) have noted a high incidence of other anomalies along the spine in addition to the herniated disc. Such anomalies as transitional vertebra, spondylolisthesis, congenital spinal stenosis, and lateral recess narrowing have been noted.

The evaluation should include imaging studies. MRI and CT-enhanced myelograms are the two best means for confirming the diagnosis. The MRI scan, however, can be overly sensitive and may lead to false-positive results. DeLuca and colleagues (10) have shown that most herniations occur at L4–5 or L5–S1 levels.

A displacement of the posterior growth apophysis can occur in young patients. These patients frequently present acutely after trauma. Clinical symptoms and presentation can otherwise mimic disc herniation. CT scans and MRI studies do a good job of demonstrating the displacement of the vertebral apophysis and frequently a piece of adjacent bone. The history and physical examination can be suggestive of the problem, but radiographs and imaging studies are necessary to confirm the diagnosis and differentiate the condition from a more typical disc herniation. Differentiation of a disc herniation from apophyseal separation is useful because surgical treatment may vary, depending on the location and size of the fragments.

Tumor

Studies have shown that children with back pain can and do present with tumors (21 ,22 ,43). These lesions can occur in the bone or along the spinal cord and soft tissues, and they may be difficult to identify and diagnose. Tachdjian and Matson (39) showed that the diagnosis of cord tumors may take a long time because of the unusual presentation. When these lesions present with marked neurologic deficits, it is easy to proceed with a prompt diagnostic workup. Frequently, however, these patients present with nonspecific complaints of back pain or a constellation of unusual symptoms. They may present with complaints of night pain or pain unrelated to any activity. Although the history may be specific for changes in coordination and bowel and bladder habits, the children frequently have no neurologic signs or changes. On occasion, patients with cord lesions have presented with such unusual complaints that their symptoms have been attributed to hysteria. As mentioned previously, the diagnosis of psychosomatic back pain can be made only when all organic causes have been excluded.

The clinical examination may reveal back listing or atypical scoliosis. Left thoracic scoliosis or scoliosis extending into the cervical spine has been associated with tumors. A careful neurologic examination should be done, paying careful attention to reflexes, especially the abdominal reflexes. Reflex changes of clonus, Babinski sign, or asymmetry of the abdominal reflex may indicate a subtle myelopathy. Any hard neurologic finding demands a prompt evaluation, including sophisticated spinal imaging. MRI scans with and without gadolinium appear to be the best techniques for evaluating spinal cord and soft tissue tumors.

Psychosomatic Pain

Throughout this chapter, it has been stressed that psychosomatic back pain in children should be a diagnosis of exclusion. There are times, however, when careful diagnostic evaluations are done and no firm diagnosis can be made. In patients whose symptoms appear to exceed the findings and who may be subject to other home or school factors, psychosomatic reactions must be considered. These patients often present after relatively minor trauma. They generally report severe incapacitating symptoms but rarely have positive physical findings. During the initial evaluation, it is important to learn about the patient's social and family situations. Children are under great pressure to do well at school, be model citizens, and compete in athletics. When these stresses are masked outwardly, they may result in a myriad of symptoms, including back pain. It is also not uncommon to find that another family member has similar problems and that the child has subconsciously taken on those symptoms. The clinician must be aware of these potential problems and inquire about them.

One study analyzed the experience of managing 17 patients who presented to a clinic with symptoms and findings compatible with the diagnosis of reflex neurovascular dystrophy (37). The clinic program included a careful medical evaluation to exclude organic causes of symptoms. If the symptoms seemed to exceed those related to normal overuse, the patients underwent a careful psychological evaluation, which generally revealed other symptoms or predisposing problems. In that series, role modeling was noted in 71%, hyperesthesias in 59%, parental marital discord in 47%, headache in 41%, abdominal pain in 41%, and conversion symptoms in 41%. Half the patients complained of minor preceding trauma. These patients and their parents viewed themselves as quite ill. In fact, these patients viewed themselves as more ill than did a group of patients newly diagnosed with juvenile rheumatoid arthritis.

The diagnostic studies included a Family Environment Scale, Brief Symptoms Inventory, and Childhood Depressive Inventory. These are standardized tests that can be useful in adding objective data toward the establishment of a diagnosis. Family environment scales demonstrated two family types: one with a highly cohesive, low conflict, high intellectual and recreational orientation; the other with high levels of conflict and low intellectual orientation. Brief Symptoms Inventory studies showed a high level of conflict in 41% of families, especially in the cohesive family type. Only one patient was noted to be depressed based on the Childhood Depressive Inventory. The common denominator for most of these patients was a stressful environment with a fairly high level of family conflict. As a general rule, these patients were not clinically depressed.

Treatment in these patients included aggressive psychological and physical therapy. In patients with severe incapacitating symptoms or a chaotic home situation, hospital admission may be appropriate. Aggressive management has achieved a 94% recovery rate.

Psychosocial elements can play a large role in children's back pain; however, only when a detailed medical evaluation is negative for physical causes should one consider the possibility of psychosocial problems as the cause of symptoms. It is useful to consult colleagues who are familiar with childhood psychosocial problems to aid in the workup and evaluation of these patients. A team approach appears to give optimal long-term results.

Summary

Back pain in children is a fascinating area of pediatric orthopedics. The incidence of back pain in children is fairly high when a large group is screened by questionnaire. Most of these patients never seek medical advice or present for consultation. In patients who do seek medical attention, however, the incidence of a definable cause of symptoms is high. Careful, detailed medical and radiographic evaluations must be performed. Imaging studies should be used when indicated. With diligent workup and evaluation, one can expect to find a cause of the symptoms in more than half of patients. Psychosocial problems may also be masked as low back pain in children and cannot be overlooked when doing an initial evaluation. Even with all our modern technology, nothing replaces the watchful eye of a caring and knowledgeable physician.

Evaluation of the Patient with Deformity

Richard E. McCarthy

R. E. McCarthy: Arkansas Spine Center, Little Rock, Arkansas 72205.

Screening

Concept of Screening

Screening has been defined as the presumptive identification of unrecognized disease or a defect by the application of tests, examinations, or other procedures that can be applied rapidly to sort out apparently well people who have the disease from those who probably do not. A screening test is not intended to be diagnostic; rather, physicians can establish a diagnosis after appropriate referrals are made (13). Screening can be undertaken to determine the frequency or natural history of a condition or, as in the case of scoliosis, can be directed toward the early detection of the disease process or its precursors as a guide to the management of individuals (42). Certain presumptions regarding the disease are made regarding the risk or occurrence of the disease and the management of that disease. Some have debated the value of screening for scoliosis based on these presumptions.

The detection of spinal deformities for most patients begins soon after birth. There are, however, cases in which prenatal ultrasounds have detected the presence of spinal deformities, as in the case of spina bifida. The benefit of prenatal detection with myelodysplasia is realized at birth when preparations may be necessary for a cesarean birth or the availability of specialists such as pediatric neurosurgeons for prenatal sac closure. Certainly, there is a benefit derived from the early anticipation of that birth and the emotional adjustment of the parents.

Initial inspection of the newborn in the nursery may identify early signs of spinal dysraphism associated with cutaneous sinuses, midline hairy patches, or other cutaneous lesions. Truncal asymmetries can be detected within the first few years of life, with some congenital deformities, such as a hemivertebra, causing scoliosis or kyphosis. It is important that pediatricians keep this in mind during their routine physical examinations of newborns and toddlers. Developmental changes marked by a delay in reaching milestones or an abnormal gait may reflect early signs of neuromuscular diseases that, late in the course of the disease, may be associated with spinal deformities.

An examination for spinal deformities during the juvenile years should be part of the routine physical in the pediatrician's office. This may elicit early signs of coronal or sagittal plane deformities associated with congenital or idiopathic causes. Children with known congenital or acquired diseases associated with known higher incidence of spinal deformities should be examined and, in some cases, radiographs taken on a yearly basis in an effort to detect those deformities early. Children with myelodysplasia and high neurologic levels should be reviewed with a radiograph yearly to look for scoliosis. The purpose of early detection of any spinal deformity is to institute a timely plan of care and intervention for treatment. For juveniles, this may mean observation, for some bracing, and for others surgery. Surgery may mean the insertion of “growing rods,” in situ fusions, excision of hemivertebra, or merely a diagnostic test such as a muscle biopsy. For most, after documentation of the magnitude of the deformity is established, close observation is the mainstay of treatment.

Early detection of spinal deformities during adolescence has been shown to affect the ultimate outcome of this disorder significantly by decreasing the number of cases detected late and allowing for better treatment plans (23 ,26 ,32 ,48).

School Screening

Population

Most school screening in North America has been performed in grades 5 to 9, that is, in the 10- to 14-year-old age group, as recommended by the Scoliosis Research Society (35). The differential prevalence of this disease in girls has prompted some locations to recommend that boys be screened less frequently (2).

Screening Technique

Before the initiation of the screening process, training programs have been established in most locales for the proper training and education of the primary screeners. The primary screeners often consist of nurses, interested teachers, educated laity, physical therapists, and occasionally physicians. Letters are sent out to the parents before the screening day advising them of the process to take place. Schools have traditionally cooperated with preventive care programs for screening of other medical problems (hearing and vision). Examining the students in the school setting generally allows for an efficient use of the students' and the examiners' time with a minimal amount of actual on-site cost. The support of the school administration is essential, as is the proper training of the screeners. Medical advisors have often served as consultants to screening programs in the United States. At times, slide shows and movies have helped to educate both students and parents by increasing their awareness of scoliosis (22 ,32). The screening should take place in the school nurse's office, a physical education class, or some other suitable location, to provide a reasonable degree of privacy. Boys and girls should be examined separately, and girls should be screened by or in the presence of a female examiner. Boys should take their shirts off; girls should be encouraged to wear a bathing suit or bra to preserve modesty.

The actual examination begins with the student standing in a straight but relaxed posture while the examiner observes from behind (Fig. 1). Asymmetries of the neck, shoulder, rib margins, waist, flank, or hips can be noted. Defects in postural balance may be noted as poor positioning of the head and shoulders over the center of the pelvis. A prominence of the scapula on the side of a convex curve or elevation of the shoulder on that side may reflect a thoracic scoliosis. Unequal distances between the torso and the hanging arms may reflect a truncal shift, whereas an unequal waistline or a high hip may reflect a pelvic obliquity in addition to truncal shift. The limb length inequality may be noted in the standing position by an asymmetry of the top of the underwear or in the forward-bending position with an elevation in the hemipelvis on the long side. The child is then asked to bend forward with the arms hanging freely rather than joined exactly together (37). The feet are together and the knees straight; the child is asked to bend at the hip to nearly 90 degrees (Fig. 2). If hamstring tightness does not allow for full forward flexion, a slight symmetric bend to the knee will allow for further hip flexion. The child can be then observed from the head or back looking for truncal asymmetries. These are seen as a prominence in the rib height (hump) associated with a thoracic scoliosis or a prominence of the paraspinal muscle mass associated with rotation of a lumbar curve (Fig. 3). These deformities are caused by vertebral rotations associated with scoliosis. Not uncommonly, ipsilateral prominences are be noted. The right thoracic idiopathic curve is often noted as a right-sided rib hump with a left-sided lumbar prominence. Any asymmetries in this position can be measured with the use of an inclinometer device such as recommended by Bunnell (5) to better establish the angle of truncal rotation (ATR) (Fig. 4). Readings can be taken with this device on those areas of the spine that are horizontal to the ground, fixing the center of the scoliometer over the spinous process. Further forward flexion of the hips is necessary to place the lumbar prominence in a horizontal position, and then less flexion for measurement of the high thoracic curves. Wherever asymmetries of truncal rotation are noted, measurements should be taken and recorded.

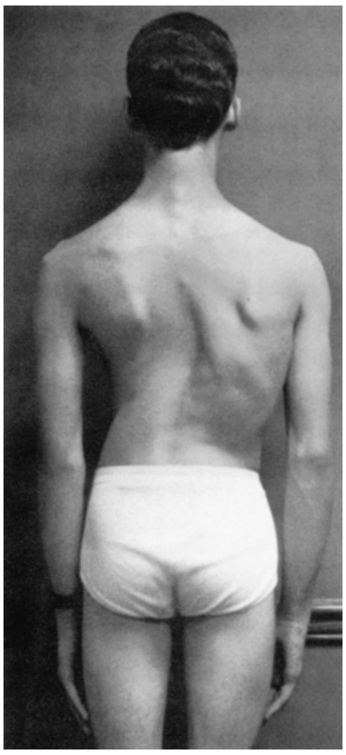

FIGURE 1. Asymmetries of the back can be noted in this 15-year-old boy, distinguished by elevation of the left shoulder area, lateral trunk shift to the right, and prominence of the right-sided rib hump.

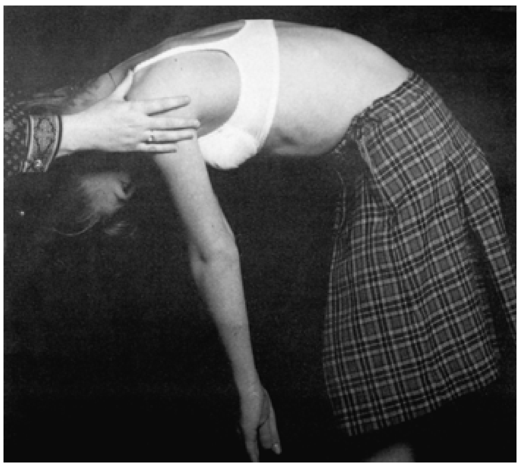

FIGURE 2. The Adams forward-bending test for school screening.

The child should be viewed from the side in both the forward-bending and standing positions. The long sloping curve of postural kyphosis will be noted differently from the acute gibbous deformity of a congenital kyphosis (Fig. 5), or the abnormal kyphosis of Scheuermann disease (Fig. 6). The findings should be recorded for each student and kept in his or her school health record. Most screening programs across the United States have reported carrying out their screening with the aid of an inclinometer (2). These have been found by many to be helpful in establishing specific criteria for referral of patients. The scoliometer is inexpensive, portable, and allows for a number to be recorded for those youngsters thought to be at risk for scoliosis. The criteria for referral in many centers has been based heavily on the ATR. It has been suggested that an ATR of 5 degrees should be referred for further follow-up (5 ,6 ,7). Ashworth has pointed out that an ATR of 5 degrees supplies 100% sensitivity but only 47% of specificity, whereas an ATR of 7 degrees has a sensitivity of 83% but a specificity of 86%, thereby minimizing referrals based on false-positive test results (3). Based on those recommendations adopted in each of the screening programs, appropriate referrals are made.

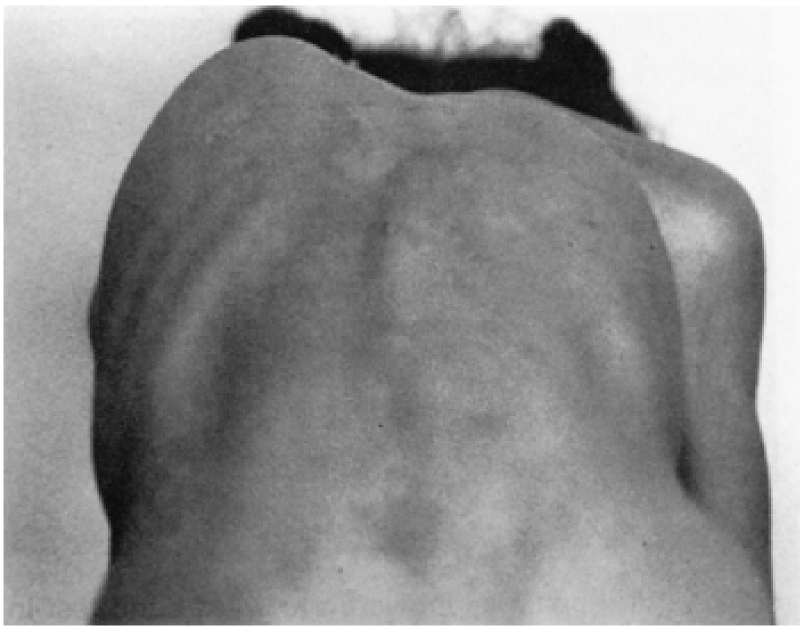

FIGURE 3. The forward-bending test gives the best visualization of truncal asymmetries.

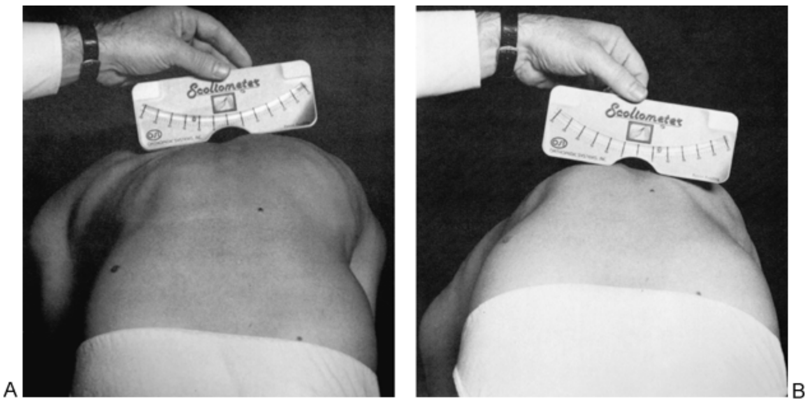

FIGURE 4. Measurement of angle of truncal rotation with scoliometer in forward-bending position with measurements of both thoracic (**A**) and lumbar (**B**) curves in the same patient. The maximal reading for each curve is recorded.

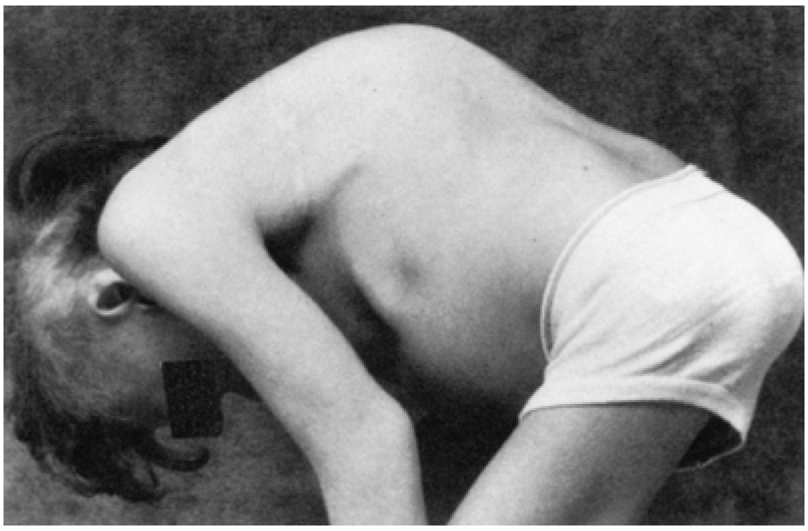

FIGURE 5. Congenital kyphosis on forward-bending test in an 11-year-old boy.

It is generally thought that a second screening should be carried out to confirm the findings for those students considered at risk for spinal deformities. Many centers have found the use of the inclinometer especially helpful during this second screening session. Usually, this second screening is carried out by a more experienced screener or a physician to confirm the presence of criteria for referral and keep low the incidence of false positive referrals. After the criteria have been met, the child's parents should be informed of the results and a recommendation made for a timely follow-up examination by the child's physician. Those youngsters at greater risk with large degrees of truncal rotation (ATR of 8 degrees or greater) should be referred directly to an orthopaedist. A follow-up telephone call can insure that the family is aware of the recommendation and the importance of compliance.

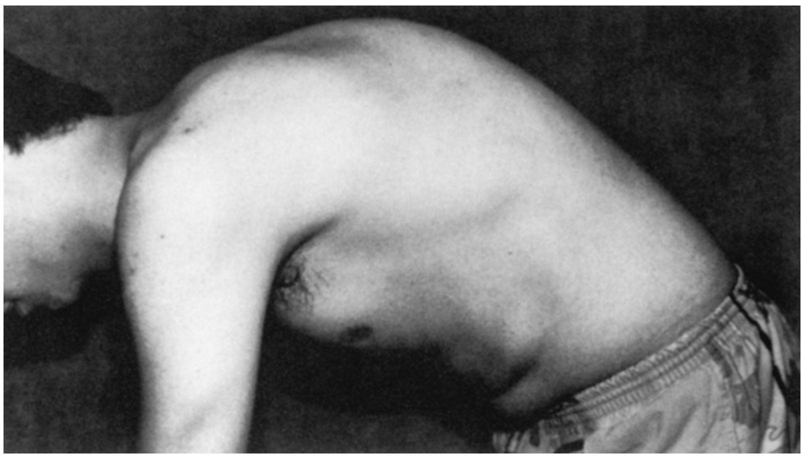

FIGURE 6. Scheuermann kyphosis on forward-bending test in a 17-year-old boy.

Upon referral to the primary care physician, the child is carefully assessed to confirm the asymmetry, to eliminate other causes of scoliosis, and to evaluate maturity. At times, referrals are made to a physician's offices for an elevation of the scapula not associated with any truncal rotation. Elevations of the scapula can occur with mild forms of Sprengel deformity. Leg length inequality may produce a truncal rotation in the standing position, but with examination in the sitting position, the asymmetry is eliminated (8). Referral to an orthopaedist may or may not be in order depending on the magnitude of limb length inequality. Painful scoliosis may or may not be associated with an abnormal neurologic examination, but painful scoliosis should raise a “red flag” for further assessment to exclude intraspinal pathology (24). Signs of other medical problems may also be elicited by the primary care physician, such as café-au-lait skin pigmentations (possible neurofibromatosis), midline hairy patches (possible spinal dysraphism), abnormalities in height indicative of dwarfism or Marfan disease, or other possible illnesses. An assessment of skeletal maturity at the time of that visit would be most helpful in determining both the risk of progression and the urgency of referral. The Tanner grading system offers signs of secondary sex characteristics with which pediatricians are the most familiar (38). These are based on the presence or absence of breast tissue, pubic hair, and development of the genitalia in assessing maturity.

For many physicians, the confirmation of a curvature merely confirms the need to refer the child to an orthopaedist who cares for scoliosis. If that is the case, then a radiograph is not necessary. If the primary physician wishes to participate in the decision making and assessment, then a standing radiograph of the spine on either a 36-inch film or a 14- × 17-inch film may be appropriate. This may be helpful for the early identification of congenital curves that cannot be differentiated from idiopathic curves on physical examination alone. The importance of this lies in the increased incidence of renal anomalies that accompany this defect. Workup with renal ultrasound or intravenous pyelogram (IVP) may be indicated (32). The film should be positioned so that the entire spine appears on the one film with the lower end of the cassette positioned at the level of the anterosuperior iliac spine and with the child in the erect position. Posteroanterior projections minimize breast radiation dosages. Based on his examination, the primary care physician will then make a further referral, continue to observe the patient himself, or discharge the patient (29). Some record of that evaluation should then be returned to the school, where data can be collected and an analysis carried out by the screening program, to keep records of the prevalence of the disease and the results of the screening program.

One of the dilemmas facing physicians specializing in the care of patients with scoliosis and spinal deformities is the question of how to minimize the delay in transfer of appropriate patients to them. This should be done to minimize the involvement in the medical care system of those patients who need observation only or no form of treatment at all. Hopefully, as each branch of the decision making tree learns the importance of its role in either holding onto or expediting the referral of those patients, the dilemma faced by the patient in the accompanying figure will not be repeated (Fig. 7).

Scoliometer

Since 1948, a number of diagnostic techniques have been used to describe the rib hump deformity characteristic of scoliosis. The level and ruler described by Cobb (10) have the time-honored tradition of being used by all the spine surgeons trained at the Twin Cities Scoliosis Center (4) (Fig. 8). Other contour-describing devices have been introduced by Willner, Rogala, Burwell, and Thulbourne (8 ,34 ,39 ,43 ,44 ,45 ,46). None of these devices has gained widespread use, and compared with the scoliometer, they are somewhat inconvenient. Bunnell (6) introduced an inclinometer in 1984 that has become known as the *scoliometer.* The idea for this device came from his experiences as a sailor with a similar on-board device used to measure inclination of the sailboat in a strong wind.

An inclinometer is designed to measure the rotational deformity by better defining the angle of thoracic inclination. That angle is the construct between the horizontal and a plane across the posterior rib cage at the greatest prominence of the rib (5). Bunnell chose to apply this device to rotational deformity occurring throughout the spine as it describes the angle of trunk rotation. He defined this angle as that which occurs between the horizontal plane and the plane across the posterior aspect of the trunk at the point of maximal deformity, when that section of the spine is observed in the horizontal plane. Patients are placed in the forward-bending position (Adams test), and the degree of hip flexion is adjusted to place either the thoracic or the lumbar spine in the horizontal position (Fig. 4). The scoliometer has a false-negative result rate of 0.1% and a high degree of sensitivity (6). It has been reported as an effective screening tool in the identification of children at risk for significant scoliosis (more than 10 degrees) (1 ,3 ,19 ,25 ,41). Ashworth (3) found that adding the scoliometer to the Adams test increased the specificity of that test from 56% to 86%. Bunnell (6) found that the mean Cobb angle in patients with 5 degrees of truncal rotation was 11 degrees of scoliosis, and for a truncal rotation of 7 degrees, the mean Cobb angle was 20 degrees. The recommendation was made, therefore, to refer all patients with an ATR of 5 degrees or greater because they are in the at-risk population for spinal deformity. Some authors have recommended increasing this cutoff to 7 degrees, but at the same time, concern has been expressed that some patients with curves greater than 20 degrees will not be picked up on initial screening (3 ,19). Others believe that the scoliometer is insufficient to use as the sole method of patient diagnosis and management. It remains a worthwhile tool for school screening, however (1 ,7 ,28).

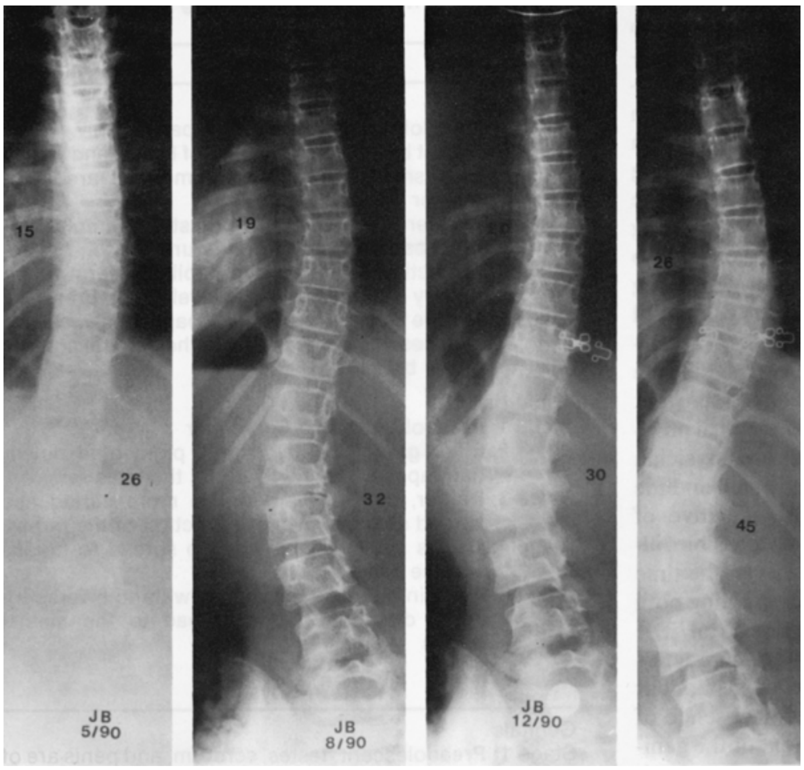

FIGURE 7. Scoliosis noted at age 11 years and followed without intervention until age 13 years, at which time the patient was referred for evaluation and treatment.

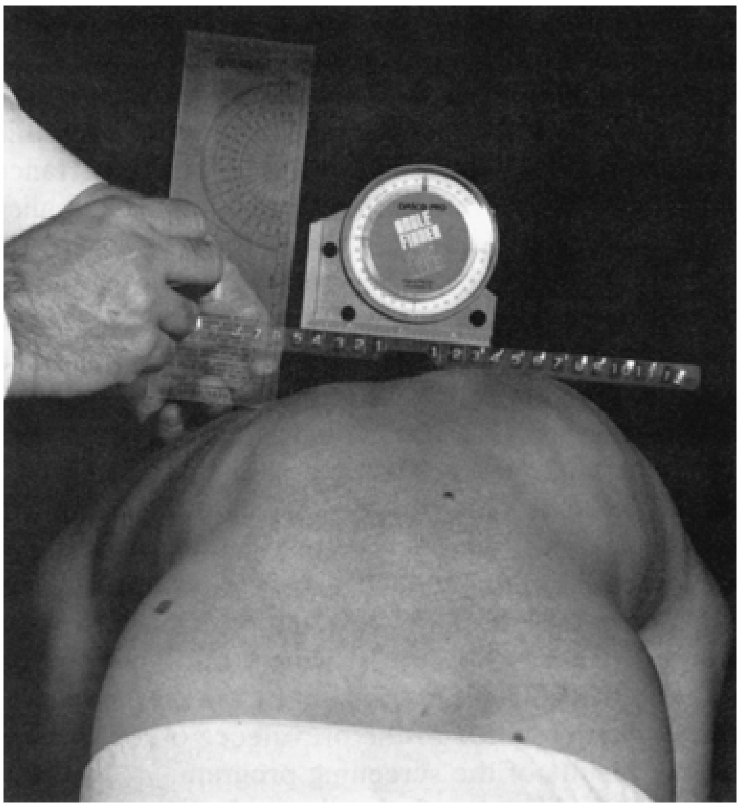

FIGURE 8. Truncal rotation measured by the spirit ruler.

General Evaluation for Deformity

History

Disorders of the renal or nervous system may reflect scoliosis associated with a number of possible syndromes (47).

It is important to establish developmental milestones, especially any delays during the first 2 years of life or the presence of any protracted hospitalizations or illnesses. Abnormalities in gait, difficulties in learning, hearing abnormalities, visual problems, cleft lips, cardiac murmurs, extremity disorders, genitourinary problems, and certainly neurologic disorders all may be pieces of the puzzle to establish the diagnosis. For many children, scoliosis is merely one piece of a syndrome, all of which must be considered when any correction of the deformities is contemplated. General questions regarding previous operations or illnesses may elicit a history of disorders in other organ systems.

It is a good discipline to force oneself to ask all the questions regarding other organ systems before the obvious history of the spinal deformity. In this manner, the possibility of missing an associated disorder is minimized. Questions regarding the spinal deformity itself can then be directed toward how the deformity was detected, whether it was known from many years before and forgotten, picked up on a recent visit to the pediatrician's office, or identified in school screening. At times, the patients themselves have noticed asymmetries in their clothing but have delayed the referral until a friend or parent brings it to their attention. At times, the parents notice asymmetries in the torso while making clothing for their children. The question of who detected the deformity is an important one, and feedback should be provided to the school screening program, if that is the source of the referral, so that the school screening programs can improve their screening techniques.

The presence or absence of pain is an important piece of the history and has been discussed previously. Has there been any previous treatment of this disorder? If so, what type of bracing or surgery was carried out? How reliably was the brace worn? Or exactly what kind of surgery was done? Records of those procedures are very helpful in the proper evaluation of these patients. All of the details related to the previous course of treatment, and the patient's interpretation of that course, are important in assessing both the physical and psychological situation.

An assessment of maturity can be carried out by questions related to the onset of menarche in girls, which generally signals the beginning of slowdown of growth. The amount of growth remaining after menarche is generally 2 years. For boys, the appearance of axillary hair and the initiation of shaving are generally signs that are equivalent to menarche and, therefore, growth slowdown. It is well known that the general range of maturity is varied for different adolescents, and boys may continue growing into their late teens. The 6 months before and immediately after these peak markers form the period of most rapid growth. It is during these times that youngsters with spinal deformities are at greatest risk for progression of curvature.

Physical Examination

It has been stated that “more mistakes are made from want of proper examination than for any other reason” (27). In the area of spinal disorders, the physical examination and an excellent history are essentials to proper diagnosis (27). Patients should be examined without clothing in a hospital gown that opens in the back.

The examiner begins his observations upon entering the room, first noting the posture of the child and the ability and manner of interactions with the parent or care provider. Then he notices the ability or inability of the child to interact with the examiner. These first impressions may have important consequences not only for diagnosis but also for the outcome of any treatment recommendations. Adolescents who are able to confront the reality of their spinal disorder and deal with it directly in a mature manner are more likely to have a successful outcome, both physically and psychologically, from whatever treatment modalities are recommended. Wherever possible, adolescents and children should be directly involved in the history taking and questions, in order to set the stage for a comfortable physical examination.

The physical examination of the spine begins with a general inspection in the standing position (Fig. 1). Boys can leave off the hospital gown, and girls can have the back of the gown moved aside for proper examination while maintaining modesty. At some time during the evaluation, however, the chest should be examined. Body habitus should be noted. The presence of obesity can mask the early signs of spinal deformities, and these patients present later in the course with a larger curve. Extremely tall, thin individuals may manifest the body habitus of Marfan disease; if this is suspected, examination of the oropharynx may reveal a high-arched palate. Increased arm span may also be noted. Patients with dwarfism should be checked for corneal clouding characteristic of mucopolysaccharidosis or limb deformities (40). Obvious asymmetries should then be noted along the contours of the back, especially elevation of the shoulder, prominence of the scapula, an uneven waistline, and the presence of rib humps. Cutaneous lesions may be noted across the back with midline hairy patches, sinuses, or clefts indicative of spinal dysraphism (Fig. 9). Café-au-lait spots can masquerade as simple birth marks, but when they occur as large blotches or are greater than five in number, they are thought to represent early signs of neurofibromatosis (14). A characteristic area for café-au-lait spots to appear is the axilla.

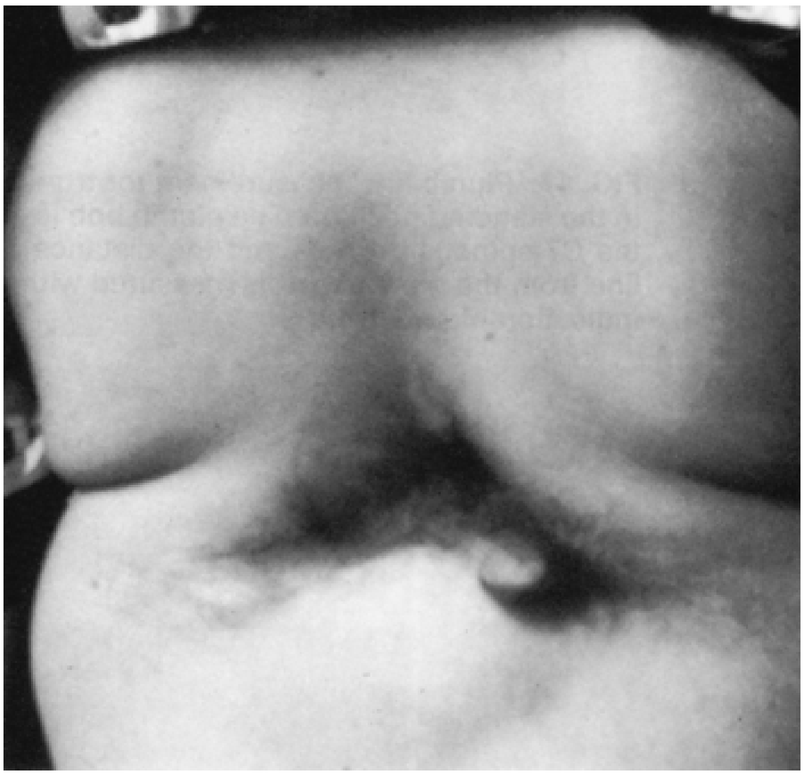

FIGURE 9. Lumbar midline hairy patch indicative of spinal dysraphism. (Courtesy of Tom Dempsey, M.D.)

The head should be directly aligned over the sacrum, and any deviation from midline may reflect a spinal deformity. This can be demonstrated by dropping a plumb line from the spinous process of C7 down to and beyond the gluteal crease. The distance of that plumb line from the gluteal crease can be recorded in centimeters for future reference (Fig. 10). If a leg length discrepancy is suspected, small wooden blocks underneath the shortened extremity will eliminate the contribution of the leg length discrepancy to any pelvic obliquity (Fig. 11). Performing the forward-bending test in the sitting position eliminates the effect of the leg length discrepancy on the spine (Fig. 12). By viewing the patient from the side, the sagittal curves can be noted between the occiput and the sacrum, including a normal cervical lordosis, thoracic kyphosis, and lumbar lordosis, which generally maintain a proper balance of the head and trunk over the pelvic girdle (20) (Fig. 13).

In this same position, the range of motion of the spine can be tested in flexion, extension, and the side-bending position. Passive side bending is often necessary to visualize the maximal amount of flexibility in a curve (Fig. 14). Clinical bending tests may be necessary in the supine position with three-point bending using a hand over the apex of the curve to be tested and contralateral forces over the shoulder and iliac crest during forced correction (Fig. 15). Flexibility can also be tested by grasping the head in the area of the mastoid processes and lifting the patient from the standing or sitting posture (4) (Fig. 16). Tests of clinical and radiographic flexibility supply important information for the planning of surgical instrumentation in order to balance thoracic curves properly over the flexible lumbar spine and pelvis. In severe curves, deformities are exaggerated and should be noted. For instance, if a large lumbar curve is present, it can produce a protrusion of the lower rib cage that abuts the pelvis. This usually accompanies a markedly shortened torso out of proportion to arm length.

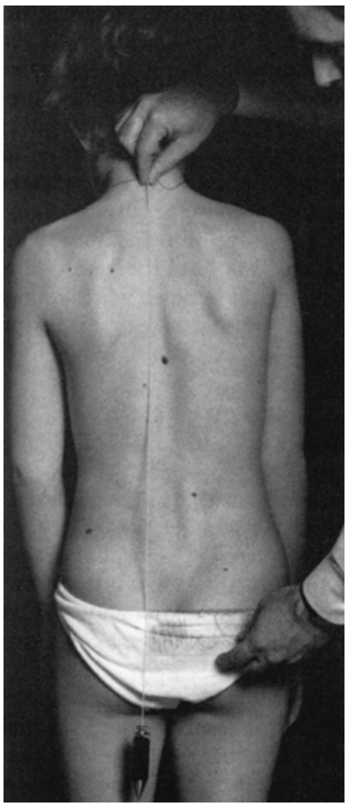

FIGURE 10. Plumb-line measurement for truncal asymmetry in the standing position. The plumb bob is dropped from the C7 spinous process, and the distance of the plumb line from the gluteal cleft is measured with a ruler as an indication of balance.

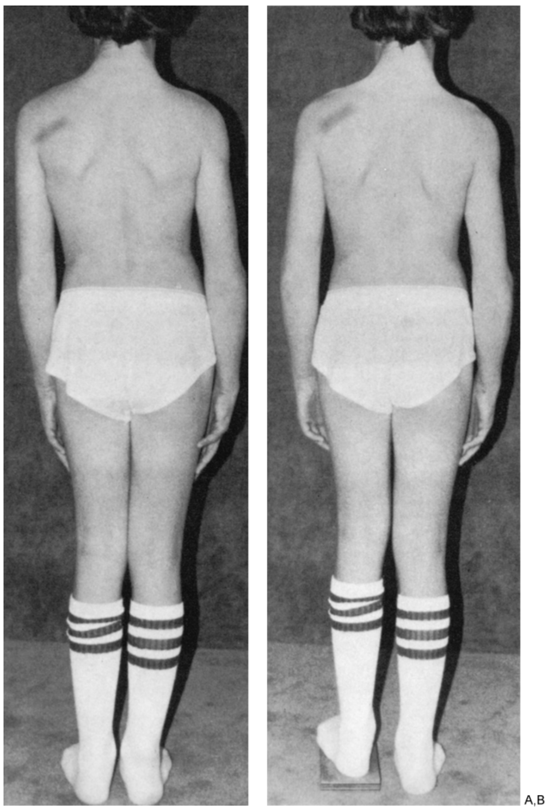

FIGURE 11. Scoliosis can occur secondary to leg length discrepancy (**A**) and is corrected by a ¾-inch block beneath the short extremity (**B**).

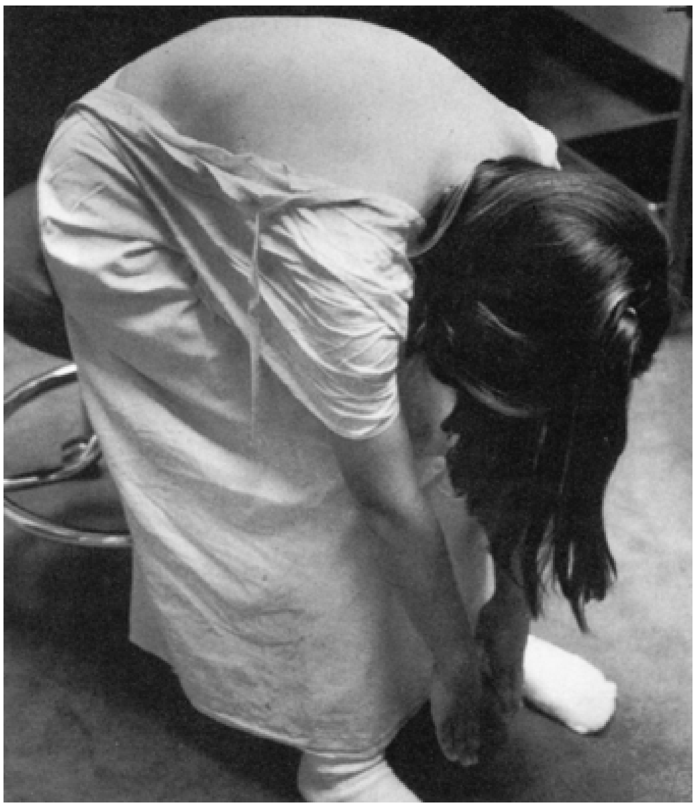

FIGURE 12. Sitting forward-bending test: truncal asymmetries viewed from the sitting position eliminate the effect of leg length discrepancies.

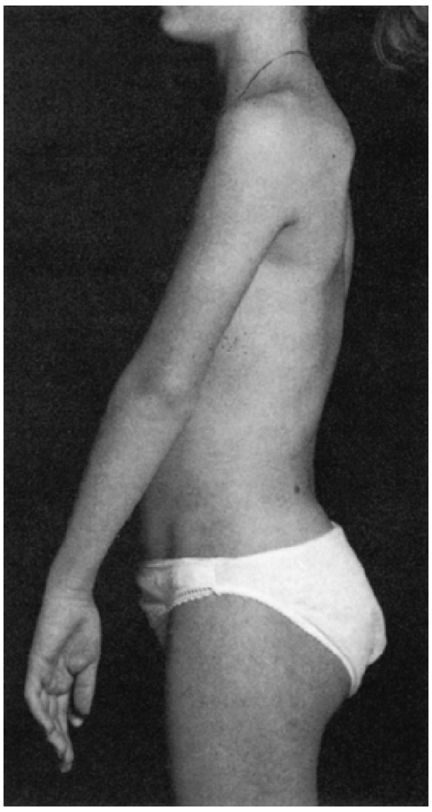

FIGURE 13. Standing lateral position to check for presence of abnormal sagittal curves noted here as the hypokyphosis often seen in idiopathic scoliosis.

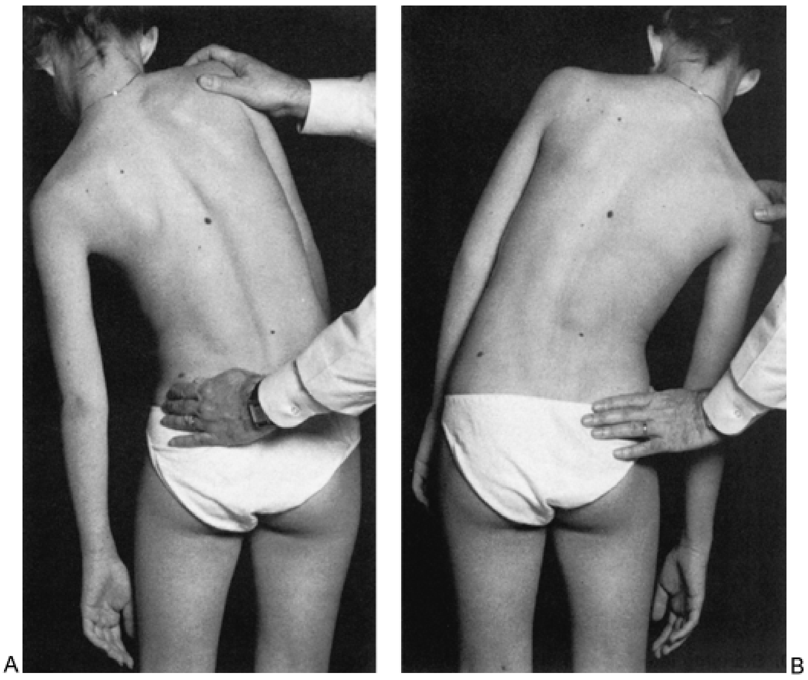

FIGURE 14. A and B: Passive standing side-bend test.

While in the standing position, palpation of the lower lumbar spine posteriorly may reveal a palpable step-off felt at the level of the slip in spondylolisthesis (Fig. 17). In its exaggerated forms, the characteristic lumbosacral kyphotic deformity can be seen in the standing position, but this is not common. Careful palpation of the spinous processes may be the only finding on physical examination besides tight hamstrings.

The forward-bending test is carried out with the patient's feet placed together, the knees straight, and flexion through the hips. The patient is instructed to touch the toes with the hands thrust forward at the same level (Fig. 18). Some authors have pointed out that asymmetries in arm lengths may lead to some confusion when the hands are joined together during the Adams test. The back should be viewed both from the head and the bottom end to maximize visualization of the truncal rotation, especially in cases in which the youngster is unable to bend fully forward because of tight hamstrings. When visualized from the bottom end, deviations to one side or the other on forward bending may be indicative of a painful scoliosis (Fig. 19). Asymmetries in truncal rotation should be defined in some manner (6 ,39). The most commonly used devices are the scoliometer to determine the ATR and the spirit level to measure in centimeters the height of the rib hump or lumbar prominence (Figs. 4 and 8). The scoliometer should be placed over the maximal area of the paraspinal prominence where it is positioned horizontal to the floor. The maximal reading of the scoliometer is recorded after multiple readings are taken both superiorly and inferiorly to the side of the apex; this number represents the ATR. The ATR for each curve identified should be recorded (6).

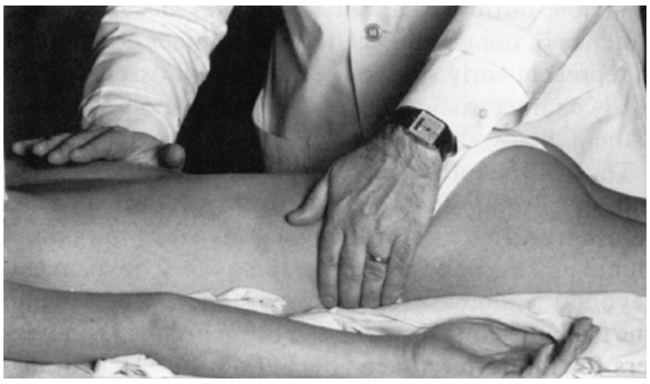

FIGURE 15. Prone three-point flexibility testing.

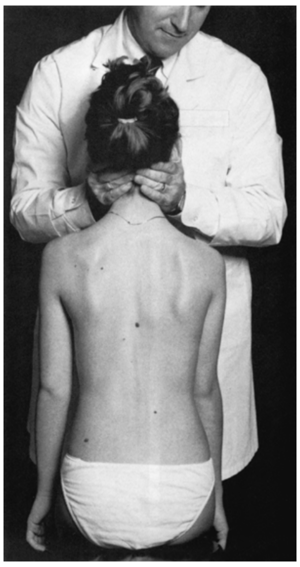

FIGURE 16. Sitting passive traction test for flexibility.

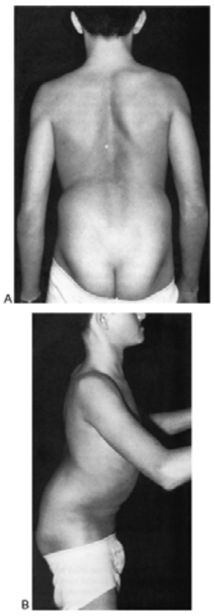

FIGURE 17. A and B: Clinical appearance of 16-year-old boy with isthmic spondylolisthesis, grade IV.

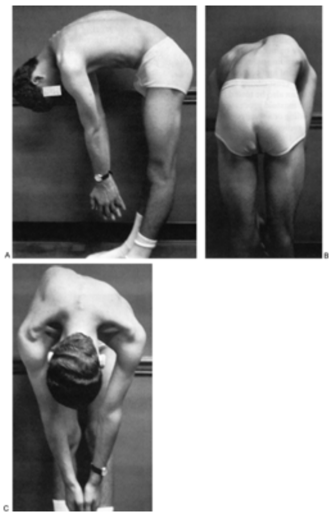

FIGURE 18. A–C: Adams forward-bending test. Asymmetries of the back are best viewed with the Adams forward-bending test as viewed from three positions to best outline the truncal asymmetries.

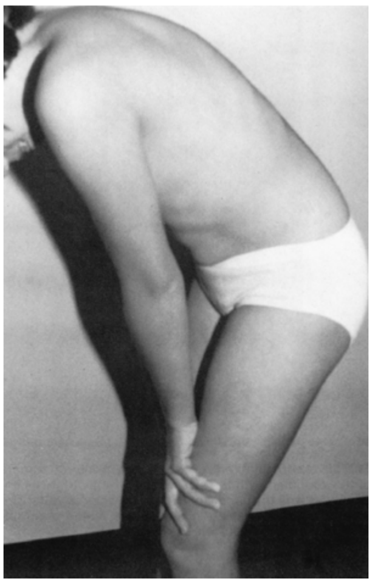

FIGURE 19. Painful scoliosis in a 9-year-old girl unable to perform the forward-bending test because of discitis.

The forward-bending test for small children can be done over the examiner's leg or over the parent's legs while keeping the child's feet on the floor. If there is difficulty in performing the forward-bending test because of tightness of the hamstrings, such as that seen in spondylolisthesis, an equal flexion in the knees allows for increased flexion at the waist and a better examination. Also during the forward-bending test, the spine should be viewed from the side (Fig. 18) to determine whether there are any signs of kyphosis either of a gradual or acute nature, such as might be seen in a congenital deformity secondary to an acute type 1 kyphosis. If there is a rigid lordosis, the spinous processes through the lumbar spine will not reverse on the forward-bending test as they usually do; this can be indicative of an intrathecal mass and warrants a full workup with possible need for a magnetic resonance imaging (MRI) scan.

After the forward-bending test, the patient is asked to stand up and walk across the room so that any abnormalities in gait or balance can be elicited. These may be reflective of problems of a neurologic nature or of lower extremity abnormalities, which may lead to the underlying diagnosis. The abnormalities in the lower extremities associated with spondyloepiphyseal dysplasia may not be identified until the time of the referral for spinal deformities.

The patient is asked to walk toward the examiner, first on the toes and then on the heels to check for muscle functioning. While still in the standing position, a Romberg test can be carried out. An abnormal Romberg test with ataxia during gait may be the initial signs leading to a diagnosis of Friedreich ataxia (9 ,21). Examination of the chest and rib cage, axillary areas, and pubic areas can elicit signs of chest wall deformities, such as pectus carinatum or excavatum, and also supply information for the Tanner rating.

The patient is then asked to sit on the examination table for a neurologic examination of the upper extremities, when indicated, and a full examination of the lower extremities, including reflex testing, sensory testing, and further motor testing. Muscle atrophy can be noted by the measurement of the calf or quadriceps area associated with polio or other neurologic abnormalities (Fig. 20). Straight-leg raising should be carried out in both the sitting and lying positions (29). In the supine position, leg lengths can be evaluated by pulling the legs into full extension and placing one's thumbs beneath the medial malleoli. Unequal leg lengths can be confirmed with a tape measure from the anterosuperior iliac spine to the distal limit of the medial malleolus. An active attempt at situps can give some indication of abdominal musculature and spinal flexibility. Abdominal reflexes should be elicited by stroking the abdomen toward the umbilicus to watch for appropriate deviation of the umbilicus (Fig. 21). In the prone position, palpation of the spinal deformity and any possible areas of tenderness can be examined. An active prone hyperextension test may elicit painful areas in the spine or give some idea of flexibility and muscle strength. The examination of the lower extremities should also include any abnormalities of the feet, remembering that cavus deformities may be indicative of diastematomyelia or neuromuscular disorders. Generalized hyperlaxity (Fig. 22) and flat feet may be consistent with collagen diseases, such as Ehler-Danlos and Down syndromes. Joint contractures of the lower extremities may be noted around the hip, with flexion contractures in achondroplastic and spina bifida patients contributing to excessive lumbar lordotic posturing. Flexion contractures around the knee are consistent with a multiplicity of disorders, including arthrogryposis. Full examination of the child should include a height and weight and placement on a growth chart if there is any indication or suspicion of abnormality in height.

Laboratory *Studies*

Occasionally, the child presenting with spinal deformities requires further laboratory workup to exclude infectious or inflammatory causes. A complete blood count and sedimentation rate may show an elevation in white blood cells, with an elevation in the sedimentation rate indicative of infection. Sedimentation rates can be elevated for many causes, including some spinal tumors, such as Hodgkin disease and histiocytosis X. Older adolescents may show signs of ankylosing spondylitis, necessitating a rheumatologic workup, including an HLA-B27 evaluation.

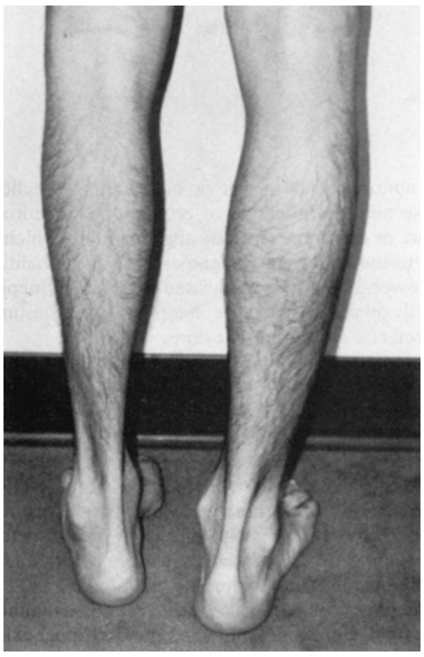

FIGURE 20. Cavus foot and calf atrophy associated with an intrathecal lipoma in a 16-year-old boy.

In patients undergoing surgical correction for spinal deformities, preoperative pulmonary function studies may be indicated. In the presence of severe curvature or neuromuscular diseases, a preoperative workup should also include arterial or capillary blood gases.

Radiographic Studies

On presentation to the orthopaedist's office, any previously done radiographs irrespective of quality or position should be brought with the patient and examined by the orthopaedist. Information from these radiographs may shed light on the type of deformity, the stage of maturity, and the location of the deformity. If the radiographs are recent, no further radiographs may be necessary. The purpose of radiographs is to establish the diagnosis suspected on physical examination. Ideally, radiographs should be taken on 36-inch film. A 17- × 14-inch radiograph can be used but must be positioned so that the entire spine appears on one radiograph with the lower end of the cassette positioned at the level of the anterosuperior iliac spine. This is done to include the top of the iliac apophysis. Some authors are of the opinion that all patients referred for evaluation of spinal deformities warrant a radiograph (32), whereas others believe that adolescents with mild curves do not need radiographic examination provided that the examiner is experienced and the parents understand that clinical follow-up is necessary (16).

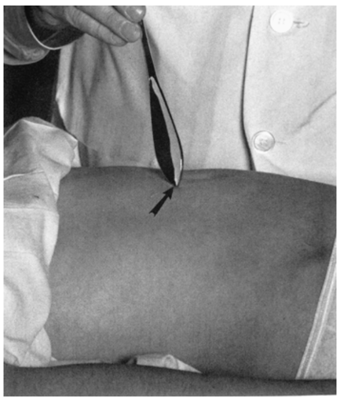

FIGURE 21. Abdominal reflexes are tested in four quadrants of the abdomen, with the skin stroked lightly toward the umbilicus with the handle of a reflex hammer (*arrow*). The lack of umbilical deviation toward the tested quadrant reflects an upper motor neuron lesion.

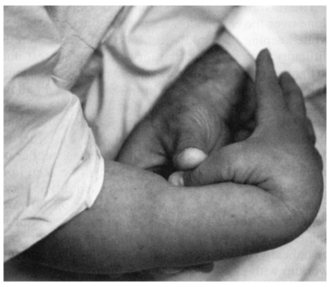

FIGURE 22. Flexibility test for generalized hyperlaxity.

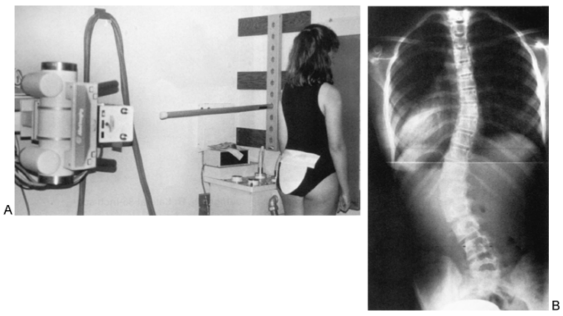

FIGURE 23. A: Positioning for posteroanterior radiographs for scoliosis. **B:** Erect 36-inch anteroposterior spine radiograph with scoliosis placed on illuminator with right side on the right as seen anatomically from the back.

If a radiograph is to be taken, a single upright anteroposterior or posteroanterior view is sufficient for diagnosis and for observational treatment of most patients with curves of less than 20 degrees (Fig. 23). If, however, there is indication of back pain or suspicion of other causes of the scoliosis, a more extensive examination is necessary. Lateral and oblique radiographs of the spine are not indicated for the routine screening referral. Lateral radiographs are indicated for pain or sagittal plane deformities, such as hyperkyphosis or hyperlordosis (Fig. 24). Oblique radiographs of the lower lumbar spine are indicated for the assessment of pars defects associated with spondylolysis (Fig. 25). All these views other than the obliques should be taken in the functional upright position. For wheelchair patients, this is a sitting position. For ambulatory patients, it is a standing positions. For infants, the functional position is supine. Special plane views, such as Stagnara views, bend radiographs, and stretch radiographs, are rarely indicated and are usually taken only before instituting some form of treatment, such as bracing or surgery. Supine radiographs may be indicated for improved definition of bony structures, as in congenital deformities such as scoliosis or kyphosis. Upright radiographs best represent the actual effect on the development of compensatory curves to achieve spinal balance.

Thought must be given to why the radiograph is being taken. “Routine” sets of scoliosis radiographs are unwarranted and unnecessarily expose adolescents to irradiation during a critical stage in their development. Attempts should be made whenever possible to minimize the number of radiographs used to make the diagnosis, and the same effort should be made on subsequent visits. Not uncommonly, surface topography devices, such as the scoliometer, can be used to follow smaller curves as indicators of whether an increase in truncal rotation has occurred, warranting a radiograph. It is well known that increased gonadal radiation increases the mutation rate of reproductive cells, and if pregnancy were to occur within 6 months, the effects of the irradiation might be seen. Certain organs in the body, however, are sensitive in a cumulative fashion to irradiation. The developing breasts, bone marrow, and thyroid gland are vulnerable; therefore radiographic techniques should minimize irradiation to keep organ dosage to a minimum (4 ,15).

Most patients being evaluated by orthopaedists for spinal deformities are girls first seen during early adolescence at a critical time for breast tissue development. The best way to minimize irradiation of these youngsters is to avoid taking a radiograph unless truly indicated. Attempts have been made to decrease the dose of irradiation by improving the quality of the radiograph, using rare earth screens and aluminum screens to filter out a portion of the radiograph beam (15 ,18). Standing radiographs can be taken with a shield over the pelvis to shield the gonads. On anteroposterior view radiographs, some centers have found the use of breast shields useful and unencumbering, whereas others have thought that any device hung around the neck and draped across the chest will cause further spinal deformity. Positioning the patient for a posteroanterior view with the chest positioned against the screen decreases the amount of direct irradiation to the breast tissue without the need for shields. This radiograph can extend from the occiput to the midpelvic region, where a gonadal shield is placed on a free stand in front of the patient or taped to the patient. At least one initial radiograph should be taken with no shielding to look for other possible associated anomalies.

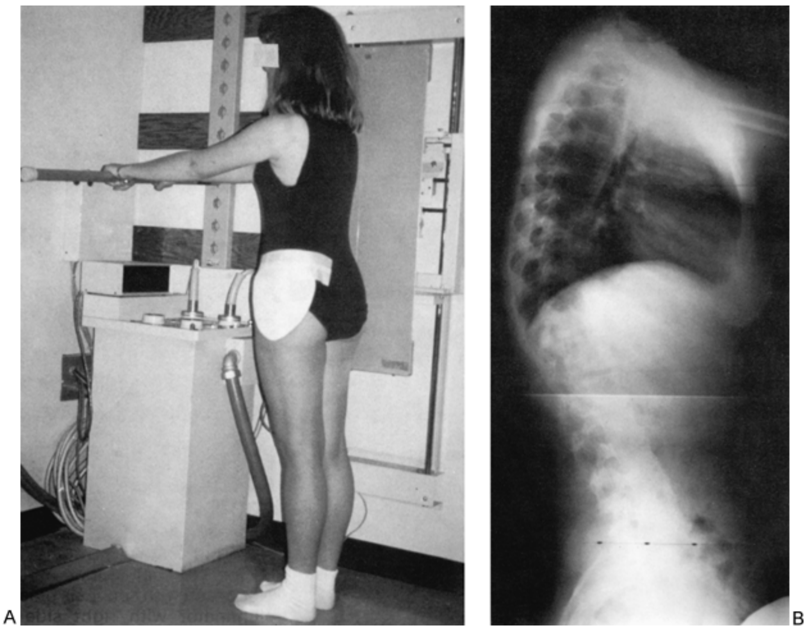

FIGURE 24. A: Positioning for lateral 36-inch scoliosis radiograph. **B:** Lateral 36-inch scoliosis radiograph.

Technique

For erect radiographs, the patient is instructed to stand straight in his functional position (Fig. 23). In the standing position, the feet are together, with arms out to the side and the shoulders pressed against the radiograph plate. For the neuromuscular child, sitting on a stool in front of the plate with an anteroposterior view works adequately. Accessory supports or people may be required to hold the patient upright in an attempt to mimic his usual functional posture. Occasionally, radiographs taken of the patient in the wheelchair may best represent the functional position. For these patients, it is important to visualize the pelvis on the radiograph.

For the lateral projection, most centers have positioned the patient with the right side against the radiograph plate and with the patient looking forward and arms raised at 60 degrees (Fig. 24). It has been pointed out by Stagnara (36) that moving the humeri forward 45 degrees from the vertical line does not modify kyphosis or lordosis. He found that raising the arms straight out in front or above the head considerably changed kyphosis and lordosis. Gonadal shields can be used for this radiograph, but as noted, judgment must be exercised in deciding when to order this radiograph because it does require a higher radiation dose than the standard anteroposterior or posteroanterior views.

Special Views

Evaluation of the patient with low back pain may warrant the use of supine oblique views to better visualize the pars area (Fig. 25). These are generally taken at an angle of 45 degrees off the vertical, visualizing the right and left sides on different radiographs with the beam centered on the L4 to L5 area. Further evaluation of the low lumbar spine for spondylolisthesis frequently requires the use of a standing spot view of the L5 to S1 region to assess the percentage of slip of L5 on S1 (Fig. 26). Occasionally, a Ferguson view taken at a 30-degree angle and tilting the beam cephalad allows for better visualization in patients with low lumbar deformities because this view eliminates the lordosis (Fig. 27). This view has a high irradiation exposure dosage to the gonads. Bending radiographs can be done in the supine or standing position. These are used to assess the flexibility of a particular curve (11). A bending radiograph is generally done with active side bending in the supine position using a 14-

× 17-inch radiograph (Fig. 28). Separate exposures are required for each side bend. Occasionally, forceful bending with a gloved hand is required, especially in assessment of neuromuscular curves (Fig. 28). The traction radiograph, taken on a Risser table with pelvic straps and a cervical halter, can substitute for bend radiographs by supplying similar information especially helpful in the case of neuromuscular patients.

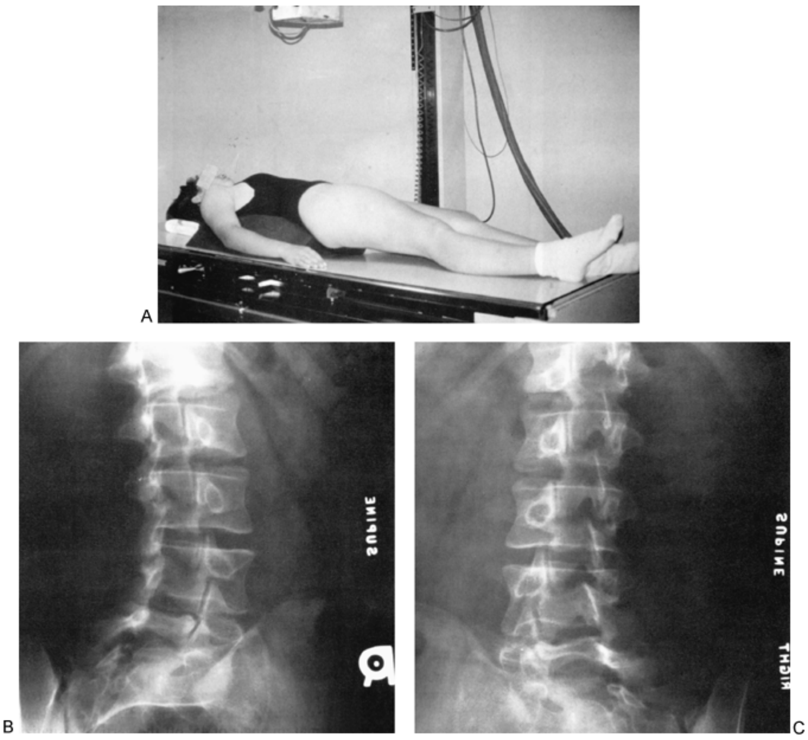

FIGURE 25. A: Positioning for lumbar supine oblique radiograph. **B and C:** Supine oblique radiograph demonstrating bilateral isthmic spondylolysis.

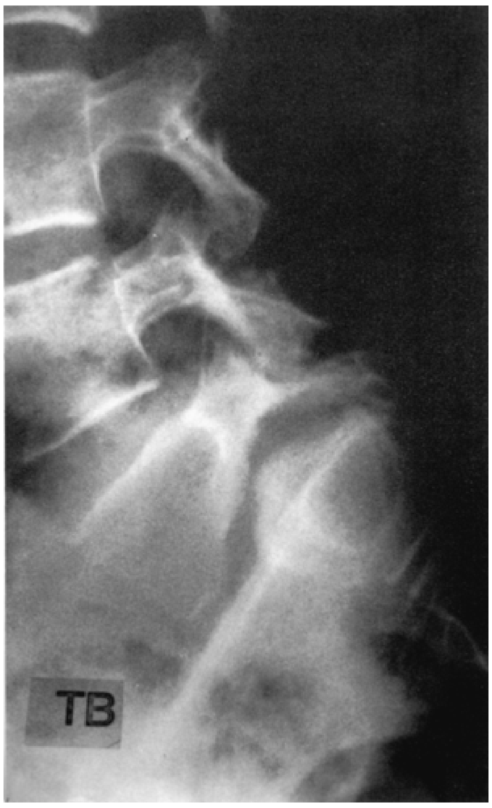

FIGURE 26. Standing lateral radiograph of L5 to S1 demonstrating congenital spondylolisthesis.

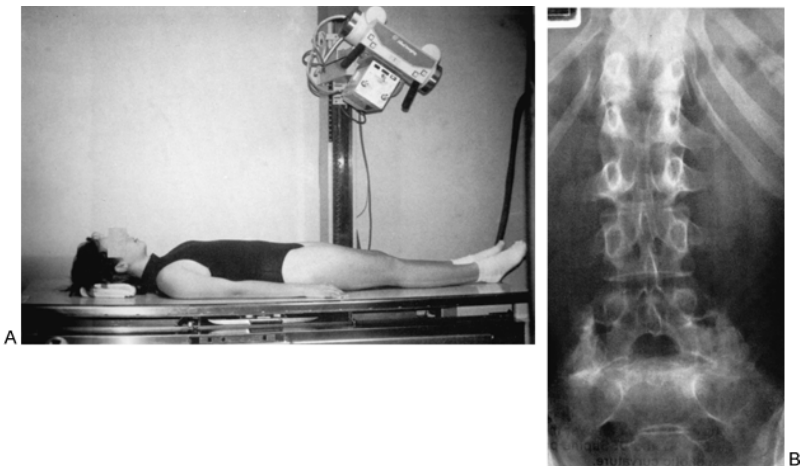

FIGURE 27. A: Positioning for Ferguson view. **B:** This view is most helpful in visualizing low lumbar fusions, such as this posterior intertransverse fusion between L5 and S1.

Hyperextension views over a bolster are frequently helpful in assessing the flexibility of kyphotic curvatures when the patient is laid supine over the foam bolster and a shoot-through lateral radiograph is taken (Fig. 29). The flexibility of lumbar lordosis can be assessed with the patient similarly aligned on the radiograph table without the bolster, drawing the hips into a fully flexed position, clasping the knees across the chest in a knee-chest position (Fig. 30). This can be coupled with thoracic flexion when the patient is placed in a side-lying position for the same view.

In severe curves, the Stagnara view helps to assess the true magnitude of the deformity in extreme positions of rotation (Fig. 31). The radiograph is taken in such a way as to eliminate rotation and look at a true lateral view and the apex of the curve. This is, therefore, actually an oblique radiograph of the apex. An oblique view is taken with the cassette positioned parallel to the medial aspect of the rotational rib prominence, with the x-ray beam positioned at right angle to the cassette. This gives a true coronal view of the apical vertebra.

Curve Assessment

Curves are measured by the Cobb method where the top of the vertebra that best delineates the curve pattern is chosen, and a line perpendicular to the top of that vertebral body is drawn. A similar perpendicular line is drawn across the bottom of the vertebral body that best delineates the maximal curve in its lower aspect. The intersection of these two perpendicular lines is the Cobb angle, which is calibrated with the goniometer on the Cobb ruler (Fig. 32). It is occasionally difficult to determine the location of the bottom of the vertebral body in the immature spine; therefore, the ovoid of the apophysis is outlined, and the limits of the ovoid are marked at their extremes and joined with a line that is then drawn across the bottom of the vertebral body. Occasionally, in the thoracic spine with severe deformities, it is difficult to visualize the top of the vertebral bodies, and in this situation, the top of the corresponding facet joints can be chosen above which to draw the line. In assessment of congenital curves, the best-guess method should be used, but it must be used consistently on subsequent comparison radiographs. For assessment of kyphotic curves, the end vertebra that is T3 and T12 is thought to represent true kyphosis (10). Curve magnitudes are recorded on the radiograph, and subsequent radiographs are measured in a similar manner.

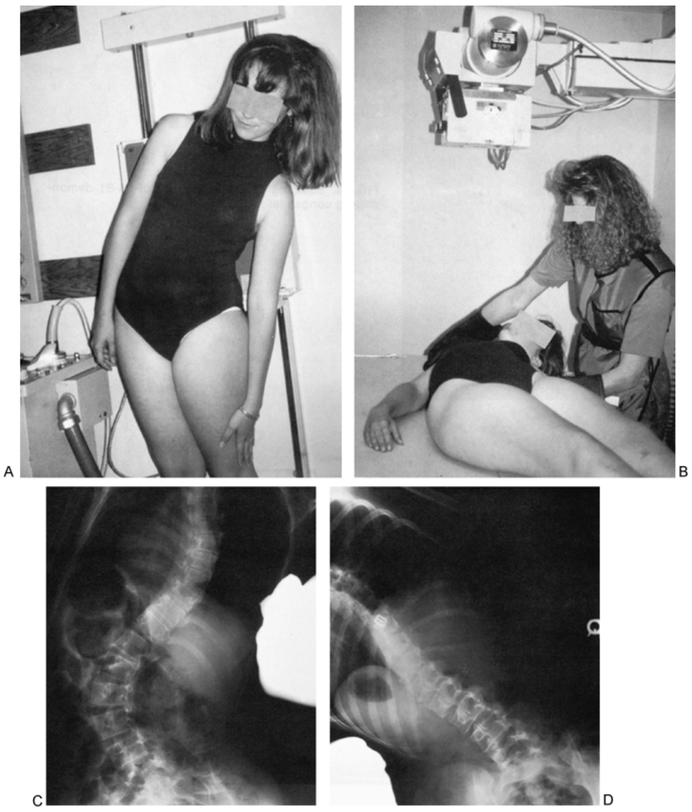

FIGURE 28. Scoliosis bend films can be accomplished actively or passively. **A:** Positioning for standing active-bend radiographs. **B:** Positioning for passive supine radiographs with technologist using a gloved fist over the apex of the spinal curve and pressure exerted with three-point resistance. **C and D:** Supine passive-bend films to determine the maximal degree of flexibility of a scoliotic curvature.

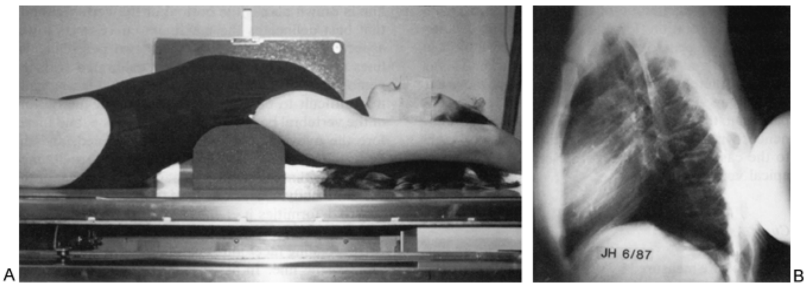

FIGURE 29. A: Positioning for hyperextension lateral thoracic radiograph over a firm bolster positioned at the apex of kyphosis. **B:** Hyperextension cross-table lateral radiograph of a 15-year-old girl with Scheuermann disease demonstrating maximal flexibility of the curvature.

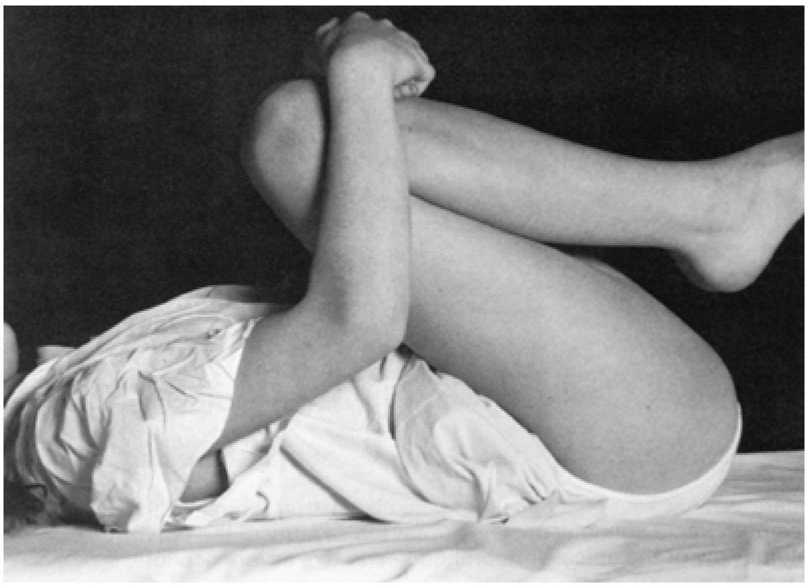

FIGURE 30. Position for lateral shoot-through radiograph of the lumbar spine to assess flexibility.

Vertebral rotation as demonstrated by rotation of the pedicles has been graded using the system of Nash and Moe (30) (Fig. 33). Grades 0 through 4 have designated increased degrees of rotation. Perdriolle and Vidal (31), Coestier and colleagues (12), and Bunnell (6) have also described methods for description of curve rotation. Both erect radiographs and flexibility radiographs can be assessed with the Cobb method to assess the changes in the curve with motion. The vertebral levels are numbered in a standard fashion with 7 cervical levels, 12 thoracic levels, and 5 lumbar levels. Occasionally, extra levels or fewer levels are identified, and judgment must be used to determine whether to number the extra levels as additional or deficient thoracic or lumbar levels. Generally, each thoracic vertebra has ribs attached to it, except in the case of congenital deformities. The Risser sign appears across the top of the iliac crest, progressing from a small area of ossification laterally and growing medially (Fig. 34). When it first appears, it is designated Risser 1; when halfway across, Risser 2; when three quarters way, Risser 3; and when completely to the medial side (capped), Risser 4. Risser 5 describes a fused apophysis and complete maturity. Risser 4 represents completion of spinal growth (33). Additional radiographs may be required for the proper assessment of bone age, with the use of a left wrist and hand radiograph to be compared with the Gruelich and Pyle atlas (17). This atlas has an accuracy of plus or minus 6 months at best. The iliac crest is generally visible on radiographs and readily available for assessment of skeletal maturity in most cases. Occasionally, this fails to appear when expected based on physical maturity, and the wrist for bone age radiograph is helpful. The vertebral apophyses also give some indication of skeletal maturity, and they can appear as a secondary density on both the anteroposterior and lateral views. The lumbar spine apophyses mature before the thoracic levels in a sequential fashion.

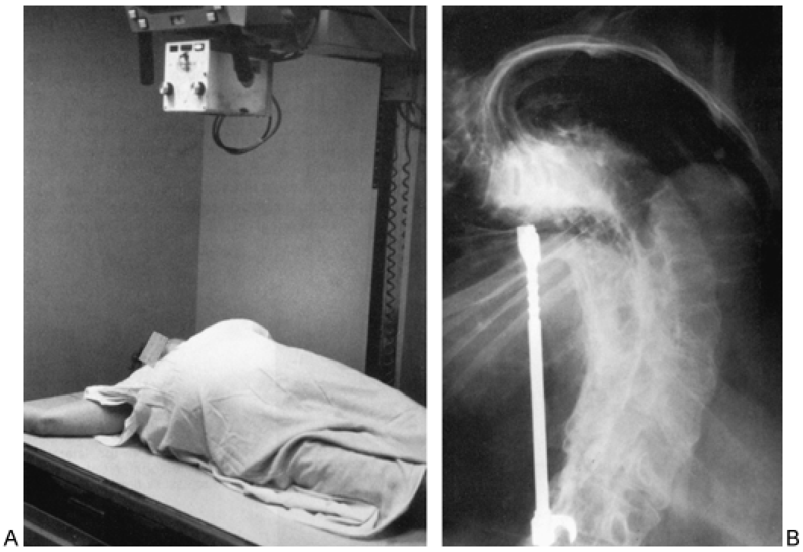

FIGURE 31. A: Positioning for Stagnara view in severe scoliosis to visualize a true lateral of the apical vertebral bodies. The degree of thoracic obliquity depends on the severity of the curve. **B:** Stagnara view showing a lateral view of the apical vertebral bodies in this severe scoliotic treated previously.

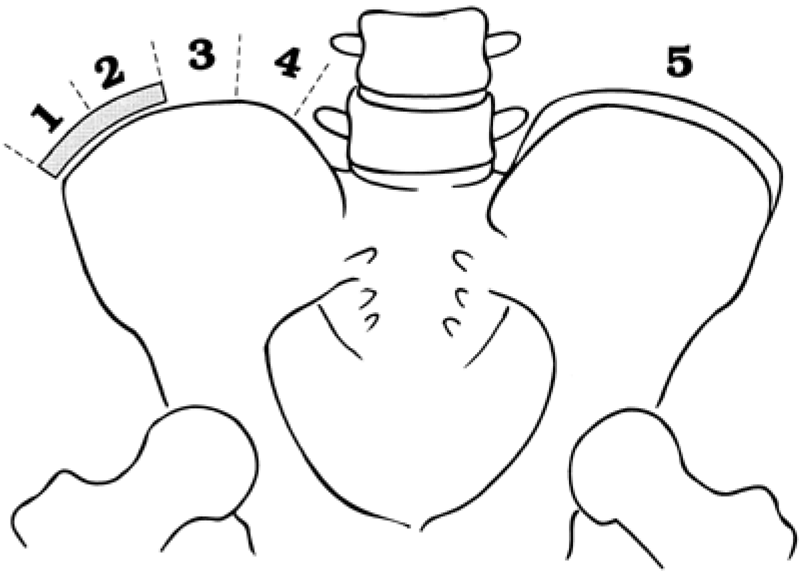

FIGURE 34. Risser sign. The Risser sign is a reflection of skeletal maturity. Risser *1*, initial appearance of lateral ossification of iliac apophysis; Risser *2*, migration halfway across the top of the iliac wing; Risser *3*, migration across three fourths of the distance; Risser *4*, ossification crossing the iliac wing; Risser *5*, complete ossification of the iliac apophysis.

Ancillary Studies

Myelogram

Myelograms are rarely indicated by present-day standards except in cases of gross deformity, in which MRI and computed tomography (CT) scans have too much variability in the planes visualized. In that case, the use of a myelogram with a follow-up CT scan can be most helpful. Water-soluble dye is desirable and adequately visualizes the spinal canal to demonstrate any pathology therein (Fig. 35).

Myelograms have been found useful in situations in which hardware is in place, preventing the use of MRI for intrathecal assessment.

Computed Tomography

CT scanning of the spine has proved to be extremely useful in many spinal anomalies (Fig. 36). CT scanning has allowed for better visualization of the bone, and with improved techniques, the amount of diffraction from adjacent metal rods can be minimized.

Of late, CT scanning has been coupled with three-dimensional reconstruction to better visualize congenital anomalies, especially those that have been poorly understood and are best seen with three-dimensional scanning (Fig. 37). Postmyelography CT scan is extremely useful for visualization of spinal cord or nerve root compression and after discograms to better visualize in a coronal plane extravasation of dye from a torn annulus.

Magnetic Resonance Imaging

MRI has proved to be an extremely valuable tool that has provided a great deal of information in the field of spinal deformities.

Children who had otherwise not been diagnosed as so have been found to have a high incidence of intrathecal anomalies. Lewonowski and associates (22) have identified a high incidence of syringomyelia and other anomalies in a population of juvenile "idiopathic" scoliotic patients (Fig. 38). Numerous youngsters who had previously been watched as they developed severe curvatures have now been identified as having associated intrathecal pathology causing the spinal deformities. The MRI is readily able to identify a thickened filum and other anomalies, such as lipomas, not previously diagnosed easily (Fig. 39). The CT scan remains the best technique for visualization of bony deformities.

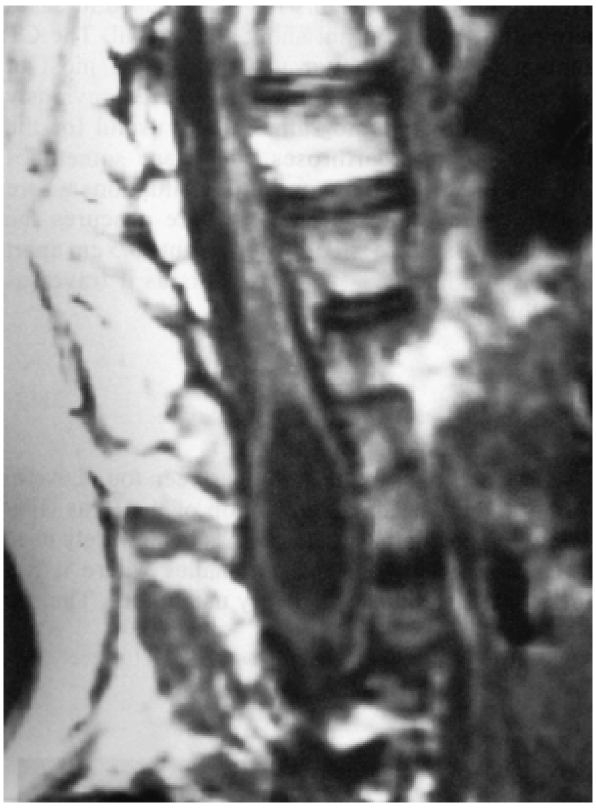

FIGURE 38. Preoperative magnetic resonance imaging in a 12-year-old boy with congenital scoliosis. A large syringomyelia was noted in the cervical canal.

Tomograms

Traditionally, laminagrams have been used in cases in which radiographs did not show good detail. The CT scanning has shown better visualization of most of those cases in which laminagrams were previously used. Tomograms remain useful, however, for the delineation of pseudarthroses, which are sometimes poorly visualized on CT scans and in situations in which the diffraction from adjacent hardware obscures the bony outline. In those situations, fine cuts 0.5 cm apart can show the line of a pseudarthrosis as it traverses across the spine.

Ultrasound

The Doppler ultrasound study has been found useful not only in the prenatal evaluation of the fetus but also in the postnatal situation, in which it has been widely used for the assessment of renal anomalies, where it has gained wide acceptance as a useful tool. The use of intraoperative ultrasound for assessment of the spinal cord is also gaining wider acceptance in the hands of neurosurgeons.

Intravenous Pyelogram

IVPs and retrograde pyelograms have been used for the assessment of the renal deformities seen with congenital scoliosis. In large part, these have been replaced by renograms and ultrasound studies, which better visualize the renal collection system without the potential for allergic reactions to iodine in the IVP dye.

Bone Scan

Bone scans have been useful especially in the assessment of the patient with painful spinal deformity (Fig. 40) or in situations in which the acuteness of a spondylolysis needs assessment. Indium scans can be useful for identification of spinal and paraspinal infections. The use of single photon emission computed tomography (SPECT) bone scanning has also been an adjunct to the localization of tumors and infections in an anteroposterior plane.

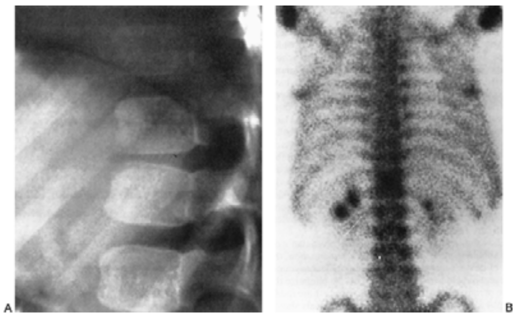

FIGURE 40. A: Lateral radiograph of a 4-year-old with discitis demonstrating disc space narrowing. **B:** A positive bone scan with increased uptake at T11 and T12 confirms inflammatory involvement on both sides of the disc.

Summary

The early diagnosis of the patient with a spinal deformity is dependent on screening examinations that begin from early life extending through the school years into adolescence. School screening programs carried out between the fifth and ninth grades have been carried out in many states to detect truncal asymmetries indicative of spinal deformities. About 2% to 3% of school children have been identified as having spinal deformities and then referred for further evaluation. To minimize inappropriate referrals and maximize on the topographic signs of deformity, certain techniques have been developed to aid in the screening process. Inclinometers have found a place in many screening programs.

The examination of the patient in the physician's office should include a careful physical examination, the use of devices to describe the topographic asymmetry, and judicious use of radiographs. To minimize the dose of radiation to the growing child, only those radiographs necessary for the appropriate diagnosis should be acquired. Further evaluation with special views are often indicated for patients with excessive deformities. Occasionally, ancillary radiographic studies are also indicated, such as MRI and CT of the spine, to exclude soft tissue problems in or around the spinal canal or to better delineate bony deformities. The proper assessment needs to be individualized for each patient and should be appropriate for the specific deformity.

Congenital Scoliosis

Michael J. Mcmaster

M. J. McMaster: Royal Hospital for Sick Children, Edinburgh, Scotland.

Congenital scoliosis is a lateral curvature of the spine caused by developmental vertebral anomalies that produce a lateral longitudinal imbalance in the growth of the spine. The term *congenital scoliosis* is slightly misleading because it implies that the curvature is present at birth, but this is not necessarily so. The vertebral anomalies are present at birth, but the clinical deformity may not become evident until later childhood, when scoliosis develops and the diagnosis is made radiographically. This type of scoliosis must not be confused with *infantile idiopathic scoliosis*, which can also present as a deformity in early childhood. In these patients, however, the spinal radiograph shows that there are no vertebral anomalies.

Congenital scoliosis is relatively uncommon, but the true incidence in the general population remains unknown because some vertebral anomalies produce so little deformity that they remain undetected.

The radiographic appearance of vertebral anomalies varies considerably. As a result, congenital scoliosis was for many years thought to be unpredictable in its behavior, and some thought that it seldom required treatment (2 ,6). In 1952, Kuhns and Hormell (35) reviewed 165 children with congenital scoliosis and concluded that this was usually a relatively benign condition that progressed slowly. It was not until 1968 that Winter and associates (68), in a major study involving 234 children, firmly established the much more serious prognosis for certain types of congenital scoliosis and described a radiographic classification based on the types of vertebral anomalies that cause it.

Ohtsuka and I studied the natural history of 251 patients with congenital scoliosis and found that all degrees of severity of curvature were seen at all ages (44). Some patients presented in their late teens with small curves that did not deteriorate significantly, whereas others presented in the first few years of life with curves that deteriorated rapidly, becoming severe deformities before the child reached the age of 10 years. These severe curves were often rigid, and surgical correction was difficult and dangerous. It is therefore important to be able to anticipate when a congenital scoliosis is at risk for rapid deterioration so that treatment can be initiated when the curve is small, rather than having to attempt dangerous surgical salvage procedures after the curve has become severe. Planning, such prophylactic treatment, requires a thorough knowledge of the pathogenesis and natural history of all types of congenital scoliosis and the various methods of treatment that are available.

Etiology

A family history of congenital scoliosis is unusual. Wynne-Davies (73) found that an isolated single anomaly, such as a hemivertebra, was usually sporadic, and there was no hereditary risk. Multiple vertebral anomalies and spina bifida cystica were etiologically related, however, and there was a 5% to 10% risk of either of these anomalies occurring in siblings or subsequent children. In contrast, Winter (64), found no significant relationship between multiple vertebral anomalies and relatives with spina bifida cystica. In addition, he found that an isolated single vertebral anomaly had about a 1 in 100 chance of occurring in a first-degree relative.

There are two rare hereditary conditions associated with congenital scoliosis in which most of the vertebrae in the thoracic and lumbar regions are malformed (55). In spondylothoracic dysostosis (Jarcho-Levin syndrome) (30), there are, in addition to the vertebral anomalies, also multiple posterior rib fusions that constrict the thorax and result in death from respiratory failure in early infancy. In spondylocostal dysostosis, the ribs are not so severely affected, and there is a normal life expectancy but with marked stunting of the trunk because of the vertebral anomalies.

Reports of congenital scoliosis in monozygotic twins have shown that if one twin has a vertebral anomaly, the other twin usually has a normal spine or less frequently an anomaly at a different level (23 ,51 ,52). Monozygotic twins have the same genetic material, and any difference in their vertebral development is likely to be due to an environmental insult rather than genetic factors. Mice embryos subjected to hypobaric hypoxia or carbon monoxide at an age equivalent to a 6-week-old human embryo also develop vertebral anomalies similar to those seen in congenital scoliosis (38 ,54). It can therefore be postulated that other environmental factors may have a similar effect on the human embryo vertebral column at this stage of its development.

Pathogenesis

To understand the natural history of congenital scoliosis and the great disparity in prognosis, it is necessary to correlate the principles of normal growth of the spine with the pathologic anatomy of the various types of congenital vertebral anomalies that may cause scoliosis. The embryologic development of the vertebral column is a complex and rapid process. The complete anatomic pattern is formed in mesenchyma during the first 6 weeks of intrauterine life (see Chapter 1). Defects of formation or segmentation of the primitive vertebrae occur during this period. After the abnormal mesenchymal mold is established, the cartilaginous and bony stages follow that pattern, and the vertebral anomalies are fully established at birth.

Normal longitudinal growth of the spine is the sum total of growth occurring at the end plates on the upper and lower surfaces of the vertebral bodies (5). This growth occurs symmetrically; as a result, the spine grows in a balanced manner without a pathologic curvature. In the presence of a congenital vertebral anomaly, however, there is an asymmetric deficiency in either the number of growth plates or their rate of growth, resulting in a longitudinal growth imbalance and an increasing spinal deformity as the child grows.

Congenital scoliosis, kyphoscoliosis, and kyphosis are part of a gradually blending spectrum of spinal deformities due to developmental anomalies that produce a localized imbalance in the longitudinal growth of the spine. The type of deformity that develops depends on whether the impaired growth occurs unilaterally producing a pure scoliosis or lies anterior or anterolateral to the transverse axis of vertebral rotation in the sagittal plane, producing kyphosis or kyphoscoliosis. Lordosis, caused by impaired posterior growth of the spine, is uncommon by itself and is usually associated with scoliosis. In a study of 584 consecutive patients with closed congenital spine deformities, I found that 472 patients had pure congenital scoliosis, 76 had kyphoscoliosis, and 36 had a pure kyphosis (48). Care was taken to distinguish between scoliosis with marked rotation, which could mimic kyphosis in the sagittal plane, and true kyphoscoliosis. This chapter deals only with those patients whose major deformity is scoliosis.

The rate of deterioration and final severity of congenital scoliosis are proportional to the degree of growth imbalance produced by the vertebral anomalies. This deterioration continues until skeletal maturity, when the growth plates fuse. However, the rate of spinal growth is not uniform. There are two periods of accelerated growth during which the scoliosis deteriorates more rapidly. The first occurs during the first 2 years of life, and the second occurs later during the adolescent growth spurt, which usually occurs in girls between the ages of 10 and 13 years and in boys about 2 years later. It is during these two periods that congenital scoliosis is most frequently diagnosed. On average, 25% of curves are nonprogressive, 25% progress slowly, and 50% progress more rapidly.

The neural axis and the vertebral column develop at the same time. It is therefore not surprising that neural and vertebral malformations often coexist and are termed *spinal dysraphism.* Abnormalities of the spinal cord are often associated with a failure of development of the posterior vertebral arches and overlying soft tissues, resulting in an “open” spinal defect, such as a myelomeningocele. This type of malformation often presents with major neurologic deficits in the lower limbs and paralysis of the trunk muscles, which contribute to the development of scoliosis. This chapter deals only with “closed” congenital scoliosis in which the skin overlying the spine remains intact, although there may be mild neurologic abnormalities in the lower limbs as a result of occult intraspinal anomalies.

Classification and Natural History

The major advances in the management of congenital scoliosis have been not in devising new methods of correcting severe deformities but rather in achieving a better understanding of the natural history of the condition and knowing when to apply prophylactic surgical treatment to balance the abnormal growth of the spine before there is a significant deformity.

The classification of the developmental vertebral anomalies that produce congenital scoliosis is based on the embryologic development of the spine. There are two basic groups of anomalies: those caused by a defect of formation and those caused by a defect of segmentation of one or more vertebrae (Table 1). About 80% of vertebral anomalies can be classified in this manner (Fig. 1). The remaining 20% are unclassifiable because there is a jumble of anomalies or the anomaly cannot be accurately identified, or because the scoliosis is so severe that it obscures the radiographic characteristics of the anomaly.

Vertebral anomalies may also be present in other areas of the spine outside the scoliotic curve, but these are ignored for the purposes of classification of the scoliosis if they do not contribute to the development of the deformity. Anomalies of the ribs are also common in association with congenital scoliosis, but these are not included in the classification because they do not cause scoliosis by themselves.

Defects of Vertebral Segmentation

Defects of vertebral segmentation may be either unilateral or bilateral and occur most frequently in the thoracic or thoracolumbar region.

Unilateral Failure of Segmentation

A unilateral failure of segmentation of two or more vertebrae results in a unilateral unsegmented bar, which is one of the most common causes of congenital scoliosis (8 ,41 ,44 ,68). This type of anomaly consists of a bar of bone fusing the disc spaces and facet joints on one side of the spine while leaving the other side relatively unaffected. The unsegmented bar does not contain growth plates and therefore does not grow longitudinally. Some degree of growth continues on the opposite side of the spine, resulting in the development of scoliosis (Fig. 2). Rib fusions and other abnormalities of the ribs are often seen adjacent to the unsegmented bar, but they do not by themselves contribute to the development of the scoliosis. The rate of deterioration and the final severity of the scoliosis depend not only on the extent of the unsegmented bar but also on the growth potential on the convexity of the spine opposite the unsegmented bar. If the disc spaces on the convexity are well formed, it is more likely that the growth will be relatively normal, resulting in the development of a severe curvature. However, if the disc spaces are narrow and indistinct, there is likely to be impaired growth, resulting in a lesser curvature. On average, these curves deteriorate at a rate of 5 degrees a year, and most exceed 50 degrees by 10 years of age, resulting in a severe deformity.

TABLE 1. Types of Developmental Vertebral Anomalies Causing Congenital Scoliosis

- Defects of segmentation
  - Unilateral
    - Unsegmented bar
    - Unsegmented bar with contralateral hemivertebrae
  - Bilateral
    - Block vertebra
- Defects of formation
  - Complete unilateral
    - Hemivertebra: fully segmented, semisegmented, nonsegmented, incarcerated
  - Partial unilateral
    - Wedge vertebra
- Mixed or unclassifiable anomalies

FIGURE 1. Congenital scoliosis.

There is also a small but important subgroup of patients who, in addition to the unsegmented bar, have one or more hemivertebrae on the convexity of the curve at the same level as the bar. Radiographically, this type of anomaly is seen most clearly in the first few years of life, but as the curve deteriorates and rotates, the hemivertebrae often become obscured by the deformity (Fig. 3). It is most important to recognize a unilateral unsegmented bar with contralateral hemivertebrae at an early stage because this type of anomaly produces the most severe and rapidly progressive of all types of congenital scoliosis (47 ,50). Although there is no longitudinal growth on the side of the bar, the hemivertebrae produce a greater growth potential on the convexity than in patients with an unsegmented bar alone. On average, these curves deteriorate 6 degrees or more a year, and most exceed 60 degrees by 4 years of age. In addition, there is usually severe vertebral rotation and distortion of the rib cage due to the crankshaft effect produced by continuing growth of the hemivertebrae anterolaterally combined with the tethering effect of the unsegmented bar on the concavity of the curve. If untreated, these children become extremely deformed at an early age, and there is often significant respiratory impairment, which can lead to cor pulmonale.

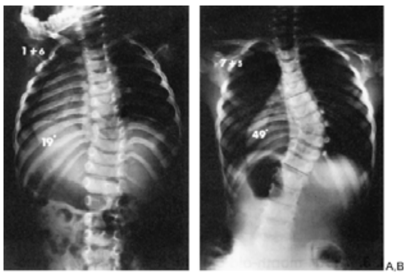

FIGURE 2. A: A boy aged 1 year, 6 months with a unilateral unsegmented bar on the left extending from T8 to T10 and producing a right thoracic scoliosis measuring 19 degrees. The disc spaces on the convexity opposite the bar are clearly seen, indicating a relatively normal growth potential; no growth is occurring in the unsegmented bar. No treatment was given. **B:** By the age of 7 years, 5 months, the thoracic curve had deteriorated to 49 degrees.

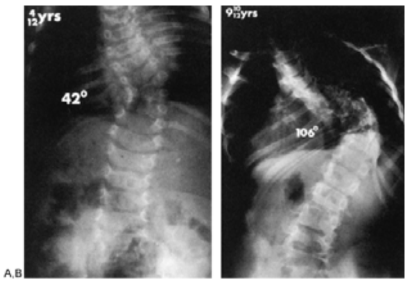

FIGURE 3. A: A 4-month-old girl with a 42-degree right thoracic scoliosis due to a unilateral unsegmented bar on the right extending from T7 to T10, with three adjacent contralateral hemivertebrae at the eighth to the tenth thoracic levels. No treatment was given. **B:** By the age of 9 years, 10 months, the scoliosis had increased to 106 degrees, and the contralateral hemivertebrae were no longer visible. There was marked malalignment of the trunk and distortion of the rib cage, reducing the vital capacity.

In treating patients with an unsegmented bar with or without contralateral hemivertebrae, it is important to remember that it is not possible to create growth on the concave side of the spine where none exists. The only way to stop deterioration of the deformity is to prevent further growth on the convex side of the curve opposite the unsegmented bar, and this can only be accomplished by a spinal fusion.

Bilateral Failure of Segmentation

A bilateral failure of segmentation of a number of adjacent vertebrae results in a block vertebra. The disc spaces between the affected vertebrae are very narrow or fused. As a result, longitudinal growth is impaired on both sides of the spine, producing a shortened segment. When this occurs in the neck, it is part of the Klippel-Feil syndrome (25 ,70) and is usually diagnosed because of the short neck, low hairline, and restricted movement. A block vertebra occurring elsewhere in the spine is diagnosed less frequently because it produces little if any deformity. Occasionally, the longitudinal growth impairment is not symmetric, which can result in the development of lesser scoliosis that rarely exceeds 20 degrees and never requires treatment. Most commonly, the block vertebra is diagnosed as part of a complex of other congenital vertebral anomalies that may produce a more severe deformity.

Defects of Vertebral Formation

A lateral defect of vertebral formation can vary from mild wedging to the complete absence of half of the vertebra (i.e., a hemivertebra). These anomalies may affect one or more vertebrae and can occur in any part of the spine.

Unilateral Complete Failure of Formation

A hemivertebra is one of the most common causes of congenital scoliosis. It is caused by the complete failure of a vertebra to form on one side, resulting in a laterally based wedge of bone consisting of half a vertebral body, a single pedicle, and hemilamina. If the hemivertebra is in the thoracic region, there is usually an attached rib, resulting in an unequal number of ribs.

There are four different types of hemivertebrae, depending on the pathologic anatomy and relationship to the adjacent vertebrae (Fig 1). The hemivertebra may be fully segmented (nonincarcerated), which is most common; semisegmented, which is less common; nonsegmented; or incarcerated, which is the least common. It is important to distinguish among these different types. Each has a different growth potential, and the severity of the resultant scoliosis is related to the degree of segmentation (46).

Fully Segmented Hemivertebra

A fully segmented (nonincarcerated) hemivertebra has a normal disc space above and below and is completely separate from its adjacent vertebrae. Longitudinal growth occurs on the upper and lower surfaces of the hemivertebra, whereas there is an absence of two growth plates on the unformed side. As the hemivertebra grows, it acts as an enlarging wedge, producing scoliosis that usually deteriorates relatively slowly at a rate of 1 to 2 degrees a year.

A single fully segmented hemivertebra lies at the apex of the scoliosis, and as the curve deteriorates, the body of the hemivertebra tends to protrude slightly from the lateral margin of the spine. There may also be slight secondary wedging of the adjacent normal vertebrae (Fig. 4A, B). Lower thoracic and thoracolumbar curves deteriorate most rapidly and can exceed 45 degrees at skeletal maturity. However, there is often only a moderate cosmetic deformity because the hemivertebra does not have the same tethering effect on the concavity of the curve as a unilateral unsegmented bar and there is much less vertebral rotation (Fig. 4C).

A fully segmented hemivertebra at the lumbosacral junction is a particularly pernicious anomaly because it causes the lumbar spine to take off obliquely from the sacrum. This results in the development of long compensatory scoliosis in the thoracolumbar region. The secondary thoracolumbar curve, which does not contain any congenital anomalies, is initially mobile, but it later becomes fixed and rotated, with the upper body listing to the side opposite the hemivertebra (Fig. 5). This can produce a major cosmetic deformity and is best treated by prophylactic surgery at an early stage before the compensatory curve becomes fixed.

Two fully segmented hemivertebrae on the same side of the spine are less common but cause a much greater growth imbalance because there is an absence of four growth plates on the concavity of the curve. These curves deteriorate much more rapidly than those caused by a single hemivertebra. They deteriorate by about 3 degrees a year, and all exceed 50 degrees by 10 years of age (Fig. 6A, B). Without treatment, these curves could reach 70 degrees by skeletal maturity. Therefore, early prophylactic surgical treatment should be given as soon as they are diagnosed.

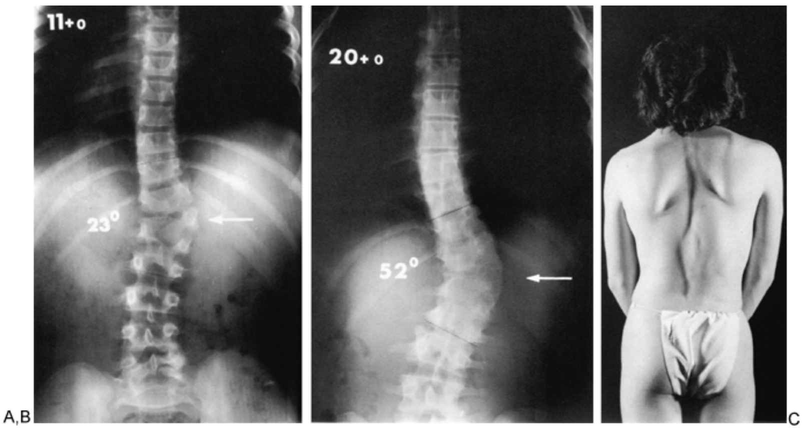

FIGURE 4. A: A boy aged 11 years with a 23-degree right thoracolumbar scoliosis due to a fully segmented (nonincarcerated) hemivertebra at L1. No treatment was given. **B:** By the age of 20 years, the patient was skeletally mature, and the curve had deteriorated to 52 degrees. **C:** Despite the severity of the curve, the cosmetic deformity was relatively mild.

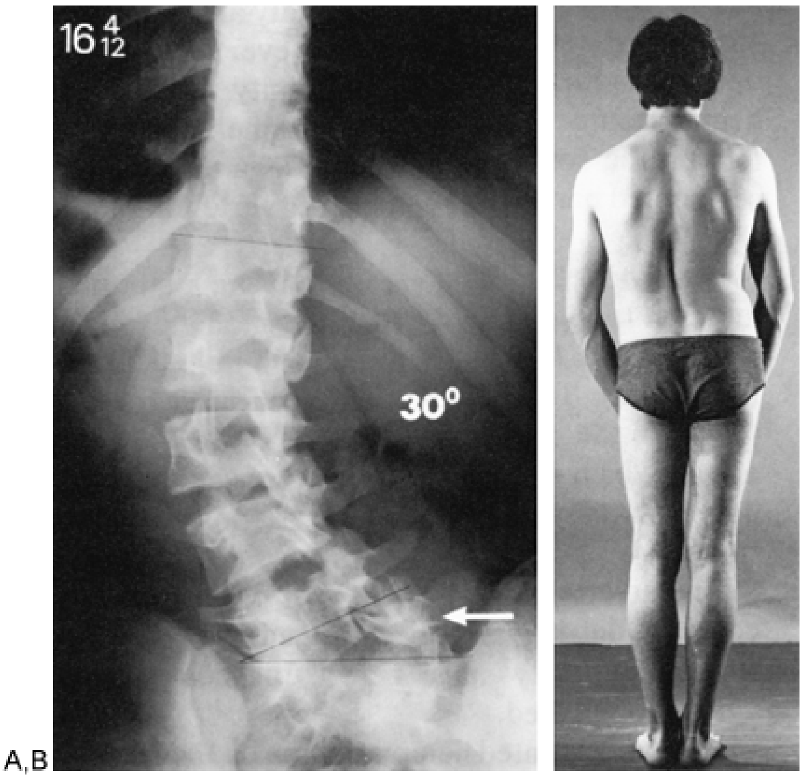

FIGURE 5. A: A boy aged 16 years, 4 months with a single unsegmented (nonincarcerated) hemivertebra at the lumbosacral junction, causing the lumbar spine to take off obliquely from the sacrum. A long secondary lumbar curve has developed, which measures 30 degrees and does not contain any congenital anomalies. **B:** The main cosmetic deformity is caused by the secondary lumbar curve and the tendency of the upper body to list to the left.

Two opposing fully segmented hemivertebrae are thought to be caused by an embryologic hemimetameric shift. The severity of the deformity depends on whether the hemivertebrae are close together or in different regions of the spine. If they are close together, separated by only one or two normal vertebrae, they tend to balance each other, causing only two small kinks in the spine. This produces minimal cosmetic deformity, and no treatment is required. If the hemivertebrae are in different regions of the spine, they produce separate curves that may be unbalanced, causing spinal decompensation and a significant cosmetic deformity (Fig. 7).

Semisegmented Hemivertebra

A semisegmented hemivertebra is synostosed to its neighboring vertebra and has only one disc space either above or below. As a result, two growth plates are obliterated on the convexity of the curve, which tends to balance the absence of the two growth plates on the unformed side of the hemivertebra. Although growth of the spine is theoretically balanced, the hemivertebra causes a tilting of the spine, which can induce slowly progressive scoliosis (Fig. 8). These curves usually do not exceed 40 degrees at skeletal maturity. Treatment is not usually required, except possibly when the semisegmented hemivertebra occurs at the lumbosacral junction.

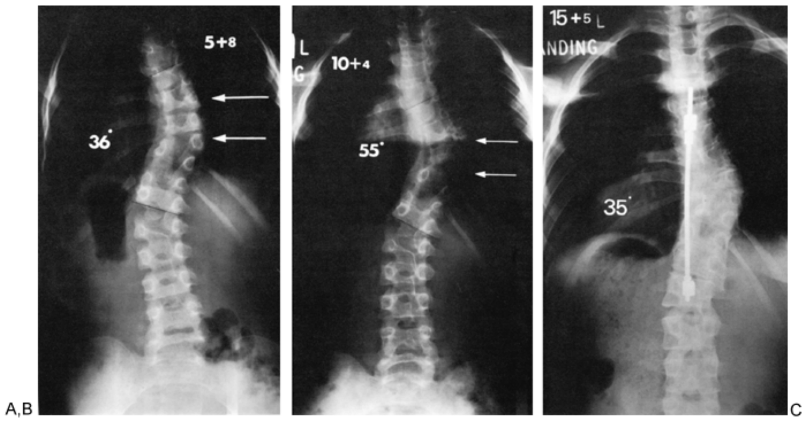

FIGURE 6. A: A girl aged 5 years, 8 months with a 36-degree right thoracic scoliosis due to two unilateral fully segmented (nonincarcerated) hemivertebrae at T7 and T9. No treatment was given. **B:** By the age of 10 years, 4 months, the thoracic curve had deteriorated to 55 degrees. At this time, the patient was treated by means of a posterior spinal fusion with instrumentation, which corrected the curve to 35 degrees. **C:** At 15 years, 5 months, there had been no deterioration.

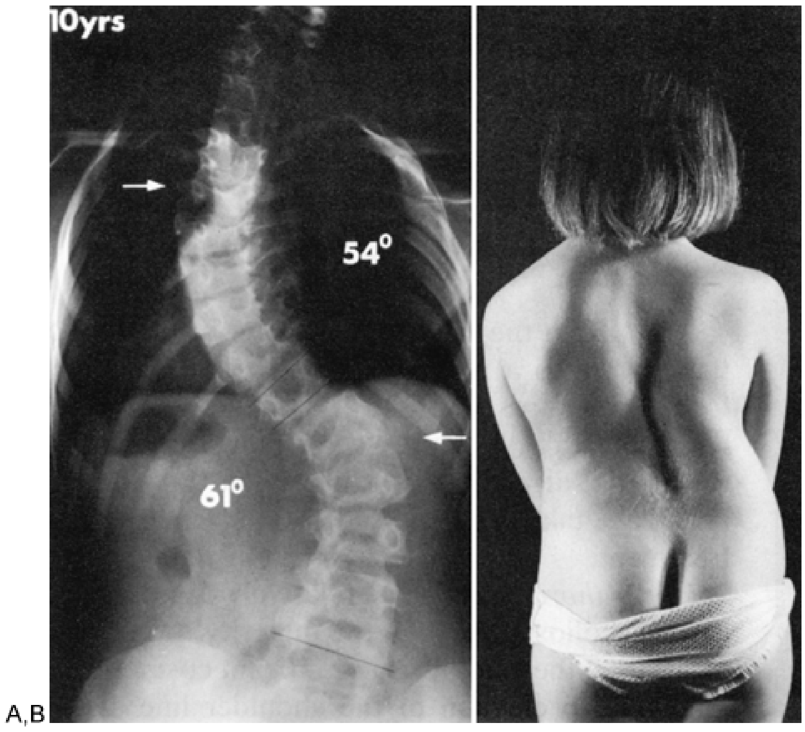

FIGURE 7. A: A girl aged 10 years with two opposing hemivertebrae occurring in different regions of the spine at T5 and L2. These hemivertebrae have produced two curves that are unbalanced. **B:** The patient lists to the left, and there is a significant cosmetic deformity.

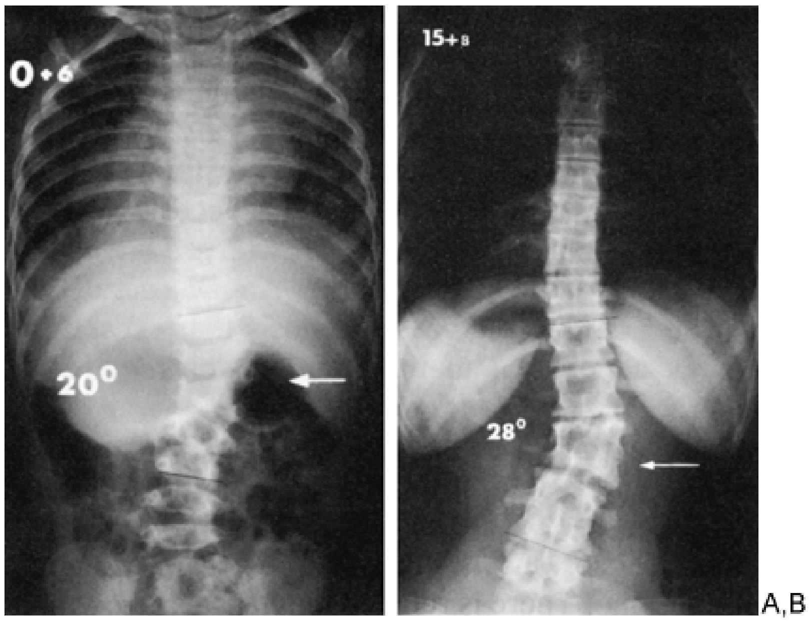

FIGURE 8. A: A girl aged 6 months with a 20-degree right lumbar scoliosis due to a semisegmented hemivertebra at L2. The hemivertebra is synostosed with L3. No treatment was given. **B:** The curve deteriorated very slowly to measure 28 degrees at 15 years, 8 months, when the patient was skeletally mature.

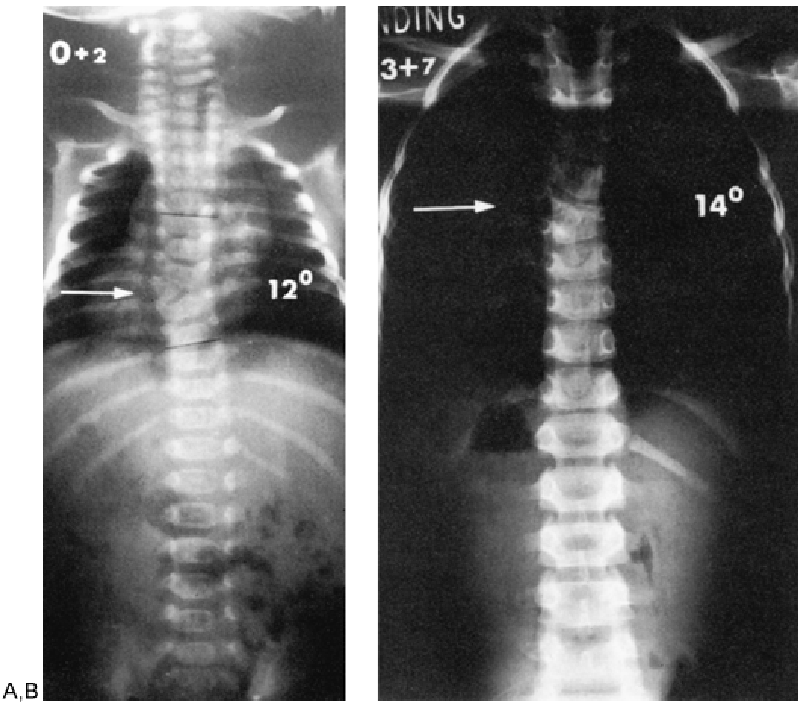

FIGURE 9. A: An infant aged 2 months with a minimal 12-degree left thoracic scoliosis due to an incarcerated hemivertebra at T6. No treatment was given. **B:** There was virtually no deterioration at 13 years, 7 months.

Nonsegmented Hemivertebra

A nonsegmented hemivertebra is synostosed to both of its adjacent vertebrae and has no disc spaces either above or below. This type of hemivertebra, which usually occurs in the thoracic region, has no growth potential and therefore does not cause progressive scoliosis. There is no cosmetic deformity, and no treatment is required.

Incarcerated Hemivertebra

An incarcerated hemivertebra is more ovoid in shape and smaller than a fully segmented (nonincarcerated) hemivertebra. This type of hemivertebra is tucked into the side of the spine and set into a niche scalloped out of the adjacent vertebrae. The vertebrae above and below are shaped in such a way that they tend to compensate for the hemivertebra. As a result, the alignment of the pedicles on that side of the spine remains straight, and there is minimal scoliosis (Fig. 9). The disc spaces above and below the incarcerated hemivertebra are usually narrow and poorly formed, indicating a poor growth potential. The resulting scoliosis deteriorates very slowly if at all. Occasionally, the disc spaces become even narrower with growth and may fuse with the adjacent vertebrae. An incarcerated hemivertebra rarely produces scoliosis exceeding 20 degrees at skeletal maturity and never requires treatment.

Unilateral Partial Failure of Formation

A wedge vertebra is an uncommon cause of congenital scoliosis and is due to partial failure of a vertebra to form on one side. The malformed vertebra contains two pedicles and is slightly wedged toward one side of the spine. There is retarded longitudinal growth on the hypoplastic side, which causes scoliosis that deteriorates relatively slowly. Surgical treatment may occasionally be necessary, especially if there are more than one wedged hemivertebra situated close together on the same side of the spine.

Associated Deforming Features

Apart from the severity of the congenital scoliosis, there are also a number of important secondary deforming features related to the site of the vertebral anomalies. These features contribute significantly to the overall disability and deformity of the patient and must be taken into consideration when planning treatment.

Upper thoracic curves are relatively common in congenital scoliosis. Although most never become very large, they can cause a significant cosmetic deformity because of elevation of the shoulder line and, less frequently, tilting of the head (Fig. 10). The higher the apex of the curve, the more severe the deformity. A 30-degree curve is probably at the upper limit of acceptability, especially in girls.

Midthoracic curves with their apex at T5, T6, or T7, especially those caused by a unilateral unsegmented bar with or without contralateral hemivertebrae, are frequently associated with the development of a long secondary structural curve in the lower thoracic or thoracolumbar region (Fig. 11). As the congenital scoliosis deteriorates, it produces a rotational effect that is transmitted further down the spine into the lower thoracic and thoracolumbar region, resulting in secondary scoliosis on the opposite side. This curve, which does not contain any congenital anomalies, is initially compensatory and correctable. Later, it becomes fixed and may deteriorate even more rapidly than the primary congenital curve. The congenital thoracic curve is often only moderately rotated, but the lower secondary curve is frequently severely rotated, producing the major cosmetic deformity of a large rib hump. In these circumstances, a severe, apparently "idiopathic" curve can develop below a congenital anomaly whose significance may not be fully appreciated.

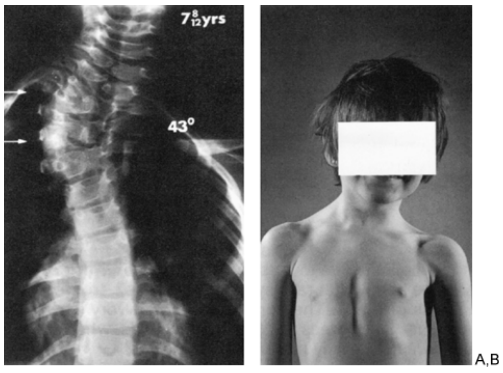

FIGURE 10. A: A girl aged 7 years, 8 months with a 43-degree right upper thoracic scoliosis due to two unilateral fully segmented (nonincarcerated) hemivertebrae at T2 and T4. **B:** Her main cosmetic deformity is the elevation of the right shoulder and slight tilting of the head to the left.

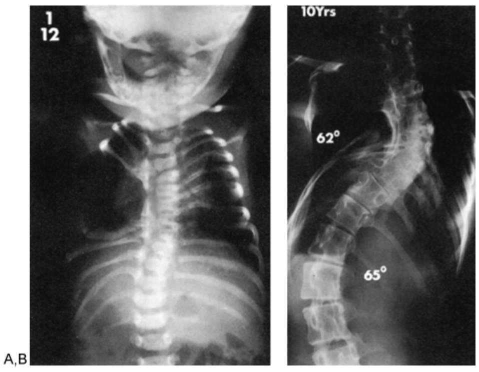

FIGURE 11. A: An infant aged 1 month who had a radiograph because of asymmetry of the thoracic cage. This showed that the spine was relatively straight, but there were absent ribs and a unilateral unsegmented bar extending from T3 to T7 on the left. No treatment was given. **B:** By the age of 10 years, the unilateral unsegmented bar had produced a 62-degree right upper thoracic scoliosis. However, the main deformity was caused by the secondary development of a severe left structural thoracolumbar scoliosis, which contained no congenital anomalies.

Lower thoracic, thoracolumbar, and lumbar curves, especially those caused by a long unilateral unsegmented bar with or without contralateral hemivertebrae, often fail to develop compensatory curves either above or below that are sufficient to balance the congenital curve (Fig. 3). There are too few normal mobile vertebrae between the rigid anomalous segment and either the upper end of the spine or the sacrum. This results in a severe cosmetic deformity because, in addition to the spinal curvature, there is severe malalignment of the body, often associated with pelvic obliquity and an apparent leg length discrepancy.

Severe distortion of the rib cage frequently occurs secondary to the development of significant thoracic scoliosis. When this occurs before the child is 8 years of age, it interfere with the normal development of the lungs (13). Increasing deformity is associated with a steady decrease in vital capacity and may lead to cor pulmonale and possibly death in early adult life. Surgical treatment of the spine is associated with a further reduction in vital capacity, especially in patients with multiple thoracic anomalies (14).

Associated Occult Intraspinal Anomalies

The development of the spinal cord is closely associated with that of the vertebral column. It is therefore not surprising that neural and vertebral malformations often coexist. The spinal deformity may be obvious, but the intraspinal anomaly may not be recognized because the skin overlying the spine is intact and any associated neural deficit in the lower limbs may be mild or absent. It is important to detect these intraspinal anomalies because they may restrict movement of the spinal cord within the spinal canal and attempts to correct the spinal deformity could result in stretching of the neural tissues and serious complications.

A diastematomyelia is found in 5% to 21% of patients with congenital scoliosis (7 ,18 ,27 ,45 ,65). This is a sagittal split in a localized segment of either the spinal cord or cauda equina. Lying within the split is an osseous or fibrocartilaginous spur that projects backward from one or more adjacent vertebral bodies. The term *diastematomyelia* refers to the split in the neural structures and not to the spur or septum. It should not be confused with diplomyelia or true division of the spinal cord. Other types of congenital neural abnormalities—epidermoid cysts, dermoid cysts, neurenteric cysts, lipomas, and teratomas—may be found either alone or in association with diastematomyelia. The spinal cord or cauda equina may also be tethered by fibrous bands, a tight filum terminale, ectopic posterior nerve roots, or arachnoid adhesions to the dura or vertebral column.

In the past, myelography was used to diagnose these intraspinal anomalies. However, magnetic resonance imaging (MRI) is a much better method because it is noninvasive and more sensitive in the visualization of soft tissue abnormalities of the spinal cord. Using MRI, Bradford and coworkers (11) found a 38% prevalence of intraspinal anomalies in 42 patients with congenital spinal deformities; of these, 16 had a tethered cord, 4 had a diastematomyelia, 3 had a diplomyelia, 3 had a low-lying conus, 1 had a teratoma of the sacrum, and, surprisingly, 4 had an unsuspected syringomyelia. Winter and colleagues (72) found a similar prevalence of 41% in 48 patients.

Intraspinal abnormalities may be found in association with all sites and types of congenital scoliosis. However, the most common association (50%) is with a unilateral unsegmented bar with contralateral hemivertebra, producing scoliosis in the lower thoracic or thoracolumbar region (11 ,45).

An intraspinal anomaly may not be immediately obvious, but there are a number of clues to its presence. An abnormality of the skin overlying the spine, such as a dimple, nevus, hairy patch, or lipoma, is present in about 70% of affected patients. These stigmata, however, may also occur without an accompanying intraspinal anomaly (45). Neurologic abnormalities affecting the lower limbs may also be present, but they are often very mild and easily missed. Frequently, only one leg is affected. The leg may be slightly short with a small foot that may have a mild cavus deformity and slight clawing of the toes (29). In addition, the spinal radiograph may show a spina bifida occulta affecting one or more adjacent vertebrae associated with widening of the interpedicular distance and narrowing of the disc spaces. Occasionally, the bony spur associated with a diastematomyelia may be visible on the plain spinal radiograph, but an MRI is necessary to confirm its presence and reveal other possible neural abnormalities.

It is widely accepted that an intraspinal anomaly that tethers the spinal cord should be surgically released if there is a progressive neurologic deficit or before attempting to correct a spinal deformity (49). Excision or release of the intraspinal anomaly will not improve the neurologic status, but it will prevent further deterioration and decrease the risk for complications after correction of the scoliosis. MRI is not necessary for all patients with congenital scoliosis, but it should be used in those with suspicious clinical or radiologic findings and in those who are about to undergo surgery to correct the spinal deformity. If the intraspinal anomaly is diagnosed during the routine assessment of children younger than 5 years of age, it should probably be removed as a prophylactic measure to prevent the possible development of neurologic deterioration. In older children, however, the presence of an intraspinal anomaly is not necessarily an indication for its removal unless there are symptoms or corrective surgery is planned.

Other Congenital Anomalies

Congenital scoliosis is frequently associated with congenital anomalies in other systems, especially those formed from mesenchyma. These anomalies are often asymptomatic and may remain undetected until the patient is fully assessed after diagnosis of a congenital scoliosis. Beals and associates (3) found that up to 60% of patients with vertebral anomalies have one or more associated anomalies in other systems and that many of these are medically important. The prognosis for these patients is excellent if the associated anomalies are detected and, if necessary, treated.

The genitourinary system may be affected in up to 25% of patients. The most common anomalies diagnosed by means of an intravenous pyelogram (IVP) or ultrasound scan are a unilateral kidney, duplication of the kidney, or ureteric obstruction (15 ,43). The Klippel-Feil syndrome may be found in 25% (25 ,70) and congenital heart disease in 10% of patients (53).

Sprengel deformity (congenital elevation of the scapula) is often found in association with congenital scoliosis in the upper thoracic or cervicothoracic region. When it is present on the convexity of the curve, the combination of these two anomalies causes a significant deformity because of elevation of the shoulder line. In these circumstances, the elevated scapula should also be reduced when the scoliosis is treated surgically. If the elevated scapula is on the concavity of the curve, however, it may partially compensate for the scoliotic deformity by leveling the shoulders. In these circumstances, it should not be reduced.

	Type of Congenital Anomaly					
Site of Curvature	Block Vertebra	Wedge Vertebra	Hemivertebra		Unilateral Unsegmented Bar	Unilateral Unsegmented Bar and Contralateral Hemivertebrae
			Single	Double		
Upper thoracic	<1°–1°	★–2°	1°–2°	2°–2.5°	2°–4°	5°–6°
Lower thoracic	<1°–1°	2°–2°	2°–2.5°	2°–3°	5°–6.5°	5°–8°
Thoracolumbar	<1°–1°	1.5°–2°	2°–3.5°	5°–★	6°–9°	7°–14°
Lumbar	<1°–★	<1°–★	<1°–1°	★	>5°–★	★
Lumbosacral	★	★	<1°–1.5°	★	★	★

▣ No treatment required ▨ May require spinal surgery ☐ Requires spinal fusion ★ Too few or no curves

Ranges represent the degree of deterioration before and after 10 years of age.

Modified from McMaster MJ, Ohtsuka K (1982): The natural history of congenital scoliosis: a study of 251 patients. *J Bone Joint Surg Am* 66: 588–601 and McMaster MJ (1998): Congenital scoliosis caused by a unilateral failure of vertebrae segmentation with contralateral hemivertebrae. *Spine* 23: 998–1005.

TABLE 2. Median Yearly Rate of Deterioration (in Degrees) Without Treatment for each Type of Single Congenital Scoliosis in Each region of the Spine

Goldenhar syndrome (oculoauricular vertebral dysplasia) is uncommon (19 ,20). Its main features are unilateral malformation of the ear and facial hypoplasia, and it is associated with congenital scoliosis, usually in the upper thoracic region.

Prognosis

The prognosis for congenital scoliosis with regard to its rate of deterioration and final severity depends on three factors (Table 2):

1. *The type of vertebral anomaly and the degree of growth imbalance it produces.* The type of anomaly that causes the most severe scoliosis is a unilateral unsegmented bar with contralateral hemivertebrae at the same level. Next in severity is a scoliosis caused by a unilateral unsegmented bar alone, followed by two unilateral fully segmented hemivertebrae, a single fully segmented hemivertebra, and a wedge vertebra. The least severe deformity is caused by a block vertebra. Congenital scoliosis caused by a jumble of unclassifiable anomalies can be difficult to predict and requires careful monitoring. The poor prognosis associated with a unilateral unsegmented bar with or without contralateral hemivertebrae is so predictable that these curves should be treated immediately without any period of observation.
2. *The site of the anomaly.* For any type of vertebral anomaly, the rate of deterioration of the resulting scoliosis are most severe in the thoracic and thoracolumbar regions and are usually less severe in the upper thoracic and lumbar regions.

The site of the congenital scoliosis is also an important factor in the degree of cosmetic deformity produced, which can be tilting of the head, elevation of the shoulder line, decompensation of the trunk, and pelvic obliquity.

3. *The age of the patient at the time of diagnosis.* Congenital curves generally stabilize at skeletal maturity. A scoliosis presenting as a clinical deformity in the first few years of life has a particularly bad prognosis because this indicates a marked growth imbalance that will continue throughout the period of growth, resulting in a severe deformity. In addition, the rate of deterioration is not constant; it becomes much more severe after the age of 10 years, during the adolescent growth spurt. Even after skeletal maturity, severe curves may continue to deteriorate slowly as a result of plastic deformation of the spine.

Treatment

The objective of treatment in congenital scoliosis is to produce a spine that will be as straight as possible at the end of growth. It is not possible, however, to create growth on the concavity of the scoliosis, where it is either retarded or nonexistent. For patients with a marked spinal growth imbalance, there is no perfect treatment. The best that can be achieved is to balance spinal growth by retarding the growth on the convexity. In these circumstances, the optimal result is a short, relatively straight spine rather than the severely crooked spine that would have developed without treatment. There are three key factors in achieving an optimal result in patients with congenital scoliosis:

1. *Early diagnosis.* If the diagnosis is made early, while the curvature is still small, there is an opportunity for prophylactic surgery to balance the growth of the spine. Congenital vertebral anomalies are frequently diagnosed in infants on radiographs taken for other reasons, before there is an obvious clinical deformity (Fig. 11A). These radiographic findings should not be ignored. They may provide an opportunity for early prophylactic treatment before a deformity develops (Fig. 11B).
2. *Anticipation.* The prognosis for deterioration of congenital scoliosis can be anticipated based on the amount of spinal growth remaining, the type and site of the vertebral anomaly, and the degree of growth imbalance it produces. This requires careful study of good-quality spinal radiographs and a thorough knowledge of the natural history of the condition. Often, the most helpful radiographs are those taken at an early stage before the vertebral anomalies are obscured by the developing deformity (Fig. 3).
3. *Prevention of deterioration.* It is easier to prevent a severe deformity than to correct one. Some types of congenital scoliosis, such as those caused by a unilateral unsegmented bar with or without contralateral hemivertebrae, have such a bad prognosis that no observation is necessary; they require immediate surgical treatment no matter how young the patient. Other types of congenital scoliosis may be observed, but one of the most common errors is to fail to recognize slow and relentless progression until it is too late for prophylactic treatment. All patients require careful radiologic assessment at 4- to 6-month intervals. After progression is established, immediate treatment is necessary to prevent further deterioration. A simple operation to balance the growth of the spine and prevent increasing curvature is preferable to a hazardous multistage surgical procedure to correct a severe and rigid deformity at a later stage.

Radiographic Assessment

Spinal radiographs are necessary to identify the type of vertebral anomaly that is causing the congenital scoliosis and to monitor any deterioration of the deformity.

Identification of the vertebral anomalies requires good-quality supine anteroposterior and lateral spinal radiographs centered on the abnormal levels. The diagnosis of a congenital scoliosis is made on the anteroposterior spine radiograph. It is also important to examine carefully the lateral radiograph to detect any associated kyphosis because this will affect the treatment. If only the anteroposterior radiograph is viewed, a patient with a posterolateral quadrant vertebra producing kyphoscoliosis may be misdiagnosed as having a lateral hemivertebra producing scoliosis. Treatment by means of a combined anterior and posterior convex epiphysiodesis, which may be appropriate for a lateral hemivertebra, would be contraindicated for kyphoscoliosis because it would increase the deformity in the sagittal plane. A misdiagnosis is also possible in infants with a short unilateral unsegmented bar, which may not appear radiographically until it is fully ossified. A coned-down oblique radiograph of the apex of the curve gives a true anteroposterior view of the more severely rotated spine and may detect hidden vertebral anomalies. An anteroposterior view aligned through the lumbosacral junction shows whether a lumbosacral hemivertebra is fully segmented or semisegmented. An MRI scan may also help define the type of vertebral anomaly.

After the vertebral anomalies have been clearly identified on the anteroposterior radiograph, it should be possible to count the number of vertebral growth plates on both sides of the spine and estimate the potential growth imbalance. Allowance should be made for any disc space that is narrowed or ill defined because this indicates an impaired growth potential. It may be difficult to assess the prognosis in young infants with mixed vertebral anomalies; they require careful radiologic follow-up to detect deterioration of the scoliosis.

Follow-up radiographic assessment of congenital scoliosis does not require detailed visualization of the vertebral anomalies after they have been fully identified. Serial full-length standing anteroposterior spinal radiographs are best for assessing deterioration. The Cobb angle of the scoliosis is always measured at exactly the same vertebral levels with reference to the standing radiograph taken when the patient was first seen (39). These radiographs show any deterioration of the scoliosis as well as any change in shoulder symmetry, decompensation of the trunk, or pelvic obliquity.

Nonoperative Treatment

Certain types of congenital scoliosis can occasionally be managed by the application of an orthosis, but this is never an alternative to appropriate surgical treatment. The problem being treated is one of spinal growth imbalance, and an orthosis should never be applied if there is a severe growth imbalance or a rigid curve such as that produced by a unilateral failure of segmentation.

In young children with congenital scoliosis, the application of a plaster jacket or underarm brace in an attempt to prevent deterioration of the deformity constricts the chest and may have an adverse effect on the developing respiratory system. Winter and colleagues (67) found that the Milwaukee brace does not have the same adverse effects on pulmonary function. It has the advantage of being a nonconstricting device yet is able to apply corrective forces to selected areas of the trunk. This type of brace works best on long flexible thoracic or thoracolumbar curves with a short anomalous segment, such as a hemivertebra at the apex of the curve. A Milwaukee brace is unlikely to be effective if the scoliosis is greater than 40 degrees or if there is less than 50% flexibility assessed on side-bending or distraction radiographs.

If the brace does not control the congenital curve, it is pointless to continue its use. The patient requires immediate surgery. After surgery, a brace may be helpful in controlling spinal alignment and the development of compensatory curves that were not included in the fusion. These secondary structural curves are easier to control than primary congenital curves because they occur in areas of the spine where the vertebrae are relatively normal and therefore much more mobile than the anomalous segment, which is often rigid. Tilting of the head may be controlled in a Milwaukee brace with a head extension. An underarm brace may be sufficient for an adolescent with a secondary thoracolumbar or lumbar curve.

Surgical Treatment

Surgical treatment is frequently necessary for congenital scoliosis and is indicated at any age if the deformity is severe or the curve is increasing and cannot be controlled. There is no one operative procedure that can be applied to all types of deformities. The method of surgery selected depends on the age of the patient, the site and type of vertebral anomaly, and the size of the curvature. Successful surgical treatment depends on selecting the right procedure and applying it at the right time.

Prophylactic surgical procedures are applied to young patients presenting with small curves that have a bad prognosis. The objective of treatment is to prevent further deterioration by balancing the growth of the spine. After prophylactic surgery, these curves must be carefully followed to skeletal maturity because further surgical treatment may be required later.

Salvage surgical procedures are necessary for patients who present at a later stage with larger deformities that require correction. The primary objective is still to prevent further deterioration, and correction is attempted only if it can be safely achieved.

Prophylactic Convex Growth Arrest (Hemiepiphysiodesis)

A convex growth arrest procedure (combined anterior and posterior convex hemiepiphysiodesis) is the optimum form of early prophylactic surgical treatment for patients with a small progressive scoliosis due to a unilateral failure of vertebral formation in which there is some growth potential on the concavity at the site of the vertebral anomaly. This procedure is best applied to patients younger than 5 years of age with a short curve caused by a fully segmented hemivertebra that corrects to less than 40 degrees, with the patient supine (1 ,9 ,59 ,61 ,63 ,71) (Fig. 12). The objective of the surgery is to balance the growth of the spine by preventing further unbalanced growth on the convexity at the site of the hemivertebra. Theoretically, this should allow the scoliosis to correct slowly by means of the continuing growth on the concavity. This is a relatively safe procedure; the only disadvantage is the slow and often uncertain correction because of the unpredictable growth potential on the concavity of the curve. Even if there is no correction of the deformity, however, a convex growth arrest is often sufficient to stabilize the deformity.

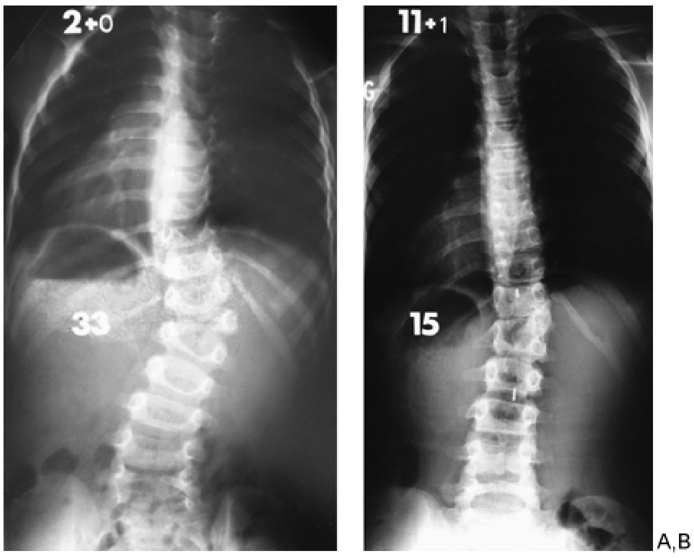

FIGURE 12. A: An infant aged 2 years with a 33-degree right thoracolumbar scoliosis due to a single fully segmented (nonincarcerated) hemivertebra at L1. A combined anterior and posterior convex growth arrest procedure was performed. **B:** By the age of 11 years, 1 month, the curve had improved to 15 degrees.

This procedure does not result in correction of the scoliosis in patients with a unilateral failure of vertebral segmentation because there is no potential for growth on the concavity of the curve. The presence of any degree of kyphosis is also a contraindication to the procedure because the anterior convex growth arrest aggravates the deformity.

The surgery is performed in two stages that are usually carried out under the same anesthetic. The spine is first approached anteriorly on the convexity of the scoliosis through a thoracotomy, a thoracoabdominal retroperitoneal exposure, or a purely retroperitoneal approach beneath the diaphragm, depending on the site of the hemivertebra. The lateral half of the discs and their adjacent end plates are removed not only at the site of the hemivertebra but also at one intervertebral level above and below. This removes the anterior growth plates at the site of the anomaly, which are the main cause of the increasing scoliosis. To create an anterior convex fusion, the excised disc spaces are packed with chips of bone taken from an excised rib. The second stage of the procedure is performed through a separate posterior exposure of the convexity of the curve at the site of the hemivertebra. Care is taken not to strip the paraspinal muscles on the concavity of the curve and possibly interfere with the growth potential on this side of the spine. A posterior convex fusion is performed by excising the facet joints and decorticating the posterior elements not only at the site of the hemivertebra but also to one intervertebral level above and below. Strips of excised rib are applied to the fusion area. Several days after surgery, partial correction may be attempted by means of manual traction and the application of a plaster jacket, which is maintained for 6 months until the convex growth arrest has soundly healed.

A transpedicular anterior convex epiphysiodesis, which can be performed at the same time as the posterior convex epiphysiodesis, has been described as an alternative that obviates the need for a separate anterior approach (31 ,34). The pedicle of the hemivertebra and the pedicles of the vertebrae above and below are entered on the convexity. Using a curette, the hemivertebra is decancellated along with the convex half of the vertebrae above and below. Curved curettes are used to perforate the end plates of the vertebrae to be included in the hemiepiphysiodesis. Strips of autogenous iliac crest bone graft are then placed through the pedicles and into the decancellated portion of the vertebral bodies and packed across the disc spaces. This technique has the potential advantage of reducing the morbidity associated with a separate thoracotomy or thoracoabdominal retroperitoneal approach. There are as yet no long-term follow-up reports of this procedure, however, and the results can only be fully assessed at skeletal maturity.

Minimally invasive thoracoscopic and laparoscopic procedures have recently gained considerable clinical interest and can also be used to perform an anterior convex epiphysiodesis or arthrodesis as well as excise the body of a hemivertebra. These procedures have the potential to reduce postoperative pain and recovery time, and they produce a more cosmetically pleasing result because of small incisional scars. There is a considerable learning curve associated with these techniques, however, and as yet, there are no long-term results.

Excision of a Hemivertebra

Excision of a fully segmented hemivertebra is theoretically attractive as a prophylactic procedure because it removes the primary cause of the scoliosis, which is the enlarging wedge on the convexity at the apex of the curve (12 ,56 ,62). This also creates a wedge osteotomy of the spine, which, when closed, produces correction.

The major advantage of resecting a hemivertebra is that it allows maximal correction of the deformity and realignment of the spine. Most single hemivertebrae, however, do not cause significant spinal imbalance when seen at an early stage. Most surgeons, therefore, use the simpler combined anterior and posterior convex growth arrest procedure, which is a less risky operation, but it has the relative disadvantage of less predictable correction that depends on continuing growth on the concavity of the curve. If there is a more severe deformity, excision of the hemivertebra and realignment of the spine can be a more beneficial, although more hazardous, procedure.

The hemivertebra is excised in two stages. The spine is approached both anteriorly and posteriorly in a manner similar to that for a convex growth arrest procedure. In the first stage, the body of the hemivertebra and the anterior part of the pedicle are removed along with the adjacent discs and vertebral end plates, and the dura is visualized. In the second stage of the procedure, the spine is exposed posteriorly, and the posterior elements of the hemivertebra are removed, along with the transverse process and posterior part of the pedicle. This is a technically demanding procedure with a risk for direct injury to the spinal cord and bleeding from the epidural veins (26). It has also been suggested that the dissection necessary to resect the hemivertebra may interfere with the segmental blood supply to the spinal cord (32). To prevent possible ischemic neurologic complications, some surgeons have advocated that the two stages be separated by 10 days to allow time for the vasculature to recover (33 ,36 ,64). However, it has now been established that successful results can be achieved when both procedures are performed under the same anesthetic (4 ,10).

After the hemivertebra has been excised, the scoliosis can be corrected by closing the wedge osteotomy. During this procedure, the spine remains relatively stable because the ligaments have been maintained on the concavity and act as a stabilizing hinge as the wedge is closed. However, correction may be difficult to obtain in the thoracic region because of the supporting rib cage. Correction is easier and safer in the more mobile lumbar spine, where the cauda equina is also more resilient. Spinal compression instrumentation applied to the convexity of the curve above and below the excised hemivertebra may be used posteriorly to close the wedge osteotomy (4 ,26). This requires strong bone to seat the hooks. Care must be taken not to compress the emerging nerve root as the osteotomy is closed, especially at the lumbosacral junction. It may be difficult or dangerous to apply this type of instrumentation to very small children. In these situations, correction may be easier and safer to obtain by the postoperative application of a double-pantaloon spica cast; this may be wedged at a later stage to obtain further correction (10). Regardless of the method of correction, the patient must wear a spica cast for 3 months after the surgery. This should be followed by 3 months in a brace until the osteotomy is soundly healed.

The objective of excising the hemivertebra is to achieve a balanced spine and prevent curve progression. The operation should be performed early while the scoliosis is still relatively mobile and before the development of secondary structural changes in the curve. The best long-term results after resection of a hemivertebra are achieved if the scoliosis can be nearly completely corrected. It is usually possible to obtain up to 30 degrees of correction of lumbar curves. Larger curves, especially those that have already developed secondary structural changes or fixed compensatory curves, do not fully correct and often continue to deteriorate. This may be partially prevented by extending the surgery to include an anterior and posterior convex growth arrest of the disc spaces one level above and below the excised hemivertebra. Failure to fuse the whole length of the scoliosis often leads to a slow progressive loss of correction, which necessitates further posterior surgery to extend the fusion when the child is older.

In my opinion, the best indication for hemivertebra excision is its occurrence at the lumbosacral junction, where it causes an oblique take-off of the lumbar spine and a major spinal imbalance. The only way of realigning the trunk is by excising the hemivertebra and closing the osteotomy (57). This is successful only at a relatively early stage before the secondary thoracolumbar compensatory curve becomes fixed.

Prophylactic Early Spine Arthrodesis in Situ

Arthrodesis in situ is the optimal form of early prophylactic surgical treatment for a congenital scoliosis caused by a unilateral failure of vertebral segmentation when seen at an early stage before there is significant deformity. A convex growth arrest procedure would not correct this type of deformity because there is no growth potential in the unsegmented bar on the concavity of the curve. These anomalies produce very rigid deformities with a known potential for severe progression. After significant scoliosis has developed, it can be corrected only by a spinal osteotomy, which can be a difficult and hazardous procedure. The object of an early spine arthrodesis is to stabilize the curve at an early stage by creating a solid thick fusion that will stop the unbalanced growth of the spine. The arthrodesis should be performed as soon as the anomaly is recognized, and the best results are achieved when this is carried out before the age of 2 years (47 ,66). The argument that an early spine fusion will stunt the growth of the spine is of no relevance with this type of congenital scoliosis. The abnormal segment is not contributing to vertical height, and it is only making the spine more crooked. It is much better to achieve a short, relatively straight spine that is balanced than a spine that is even shorter because of the severe curvature.

The congenital scoliosis contains not only the unilateral unsegmented segment but also a number of relatively normal vertebrae at the upper and lower ends that are also tilted into the curve. Failure to include all of these vertebrae in the fusion results in continued progression of the deformity (47). With this type of congenital scoliosis, the surgeon is unlikely to regret operating too early or fusing too many vertebrae but will always regret delaying surgery or having fused too few vertebrae.

Loss of correction after an early posterior spinal fusion in infantile and juvenile idiopathic scoliosis has been attributed to either a weak fusion mass or increasing rotation of the spine resulting from the crankshaft effect produced by continuing unbalanced anterior growth of the spine in the presence of the posterior tether caused by the fusion (16 ,24). This phenomenon, however, does not usually occur to a great extent in congenital scoliosis because the anterior growth plates in the anomalous segment are also frequently abnormal. A posterior arthrodesis alone can produce an acceptable result in congenital scoliosis, provided it results in a strong, thick fusion capable of overcoming the anterior growth of the spine (58). The crankshaft effect is seen only in those patients who already have marked vertebral rotation as part of the deformity (40).

In my experience, it is usually advisable to perform a single-stage combined anterior and posterior spine arthrodesis if there is a severe growth imbalance, such as that produced by a unilateral unsegmented bar with contralateral hemivertebra (47). This procedure has the advantage of directly overcoming any possible crankshaft effect and producing a more solid stable fusion. The rib excised at the time of the thoracotomy provides a good source of autogenous bone graft, which may not be available from the iliac crest in these very young children. Postoperatively, a spinal jacket is applied for 6 months to allow the fusion to heal.

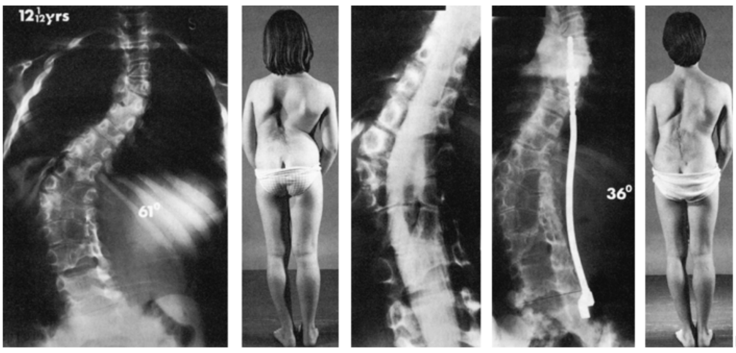
The secondary structural thoracolumbar scoliosis, which can develop below congenital thoracic scoliosis with its apex at T5, T6, or T7, also requires prophylactic treatment. This secondary deformity is not controlled by an early fusion of the primary congenital scoliosis. Bracing may control the secondary curve and postpone extending the fusion to the lower lumbar region, especially if many years of further growth are anticipated. Alternatively, it is possible at the time of the posterior arthrodesis of the congenital curve to apply pediatric spine instrumentation across both curves without fusing the secondary curve. Subsequent serial extension of the instrumentation allows additional longitudinal growth in the unfused thoracolumbar curve before extending the fusion when the child is older.

Correction and Posterior Spinal Arthrodesis

Attempted correction of the deformity and posterior spinal arthrodesis is the usual surgical procedure for an older child with a moderately severe congenital curve that is still relatively flexible (Fig. 13). The object of surgery is to achieve overall balance of the spine rather than excessive correction of the congenital curve. The posterior arthrodesis is performed over the whole length of the deformity from the upper to the lower neutral vertebrae and not just at the anomalous segment. Although it is not usually possible to obtain correction at the site of the anomalous vertebrae, moderate correction may be achieved at the relatively normal vertebral levels that lie above and below this area and are still within the scoliosis. Correction may be attempted either intraoperatively by the insertion of instrumentation at the time of the posterior spinal arthrodesis or postoperatively by the application of a spinal jacket.

An MRI scan is essential in all patients before intraoperative correction of the deformity is attempted. This may reveal the presence of an intraspinal anomaly, such as a diastematomyelia, that could be tethering the cord. If this is not removed, the patient could develop serious neurologic complications if a distraction force is applied to the spine to correct the deformity (Fig. 13C). Because of the complexity of the two operative procedures, it is best to have the intraspinal anomaly removed during a separate neurosurgical procedure performed several weeks before the attempted correction of the spinal deformity and posterior arthrodesis.

The safest method of correcting the deformity is to apply a spinal jacket 5 days after the posterior spinal arthrodesis. The patient is awake during this procedure, and the jacket is applied on a traction frame. With this technique, there is negligible risk for neurologic complications. The disadvantages are that it produces relatively little correction, and the patient has to wear a cumbersome spinal jacket extending from the neck to the pelvis for 6 months until the fusion is solid. This method is best applied to young children whose bones are too soft or underdeveloped to allow the effective application of internal fixation.



A,B,C D,E

FIGURE 13. A: A girl aged 12 years, 1 month with a 61-degree thoracolumbar scoliosis due to complex multiple vertebral anomalies. The spinal radiograph also shows a spina bifida occulta affecting a number of adjacent vertebrae in the thoracolumbar region, associated with widening of the interpedicular distance and narrowing of the disc spaces. **B:** The patient had a hairy patch at the thoracolumbar junction, and there was slight shortening and hypoplasia of the left leg. **C:** A myelogram shows a diastematomyelia at the thoracolumbar junction. **D:** The diastematomyelia was excised, and the scoliosis was corrected to 36 degrees with Harrington instrumentation. **E:** At the age of 15 years, there is a solid fusion with no loss in correction and a good cosmetic result.

The use of posterior spinal instrumentation to correct a congenital scoliosis at the time of the spinal arthrodesis has several advantages: It achieves moderately better correction and reduces the incidence of pseudarthrosis when compared with a posterior spinal fusion in a spinal jacket alone (21 ,69). Spinal instrumentation does, however, carry a greater risk for neurologic complications because of the effect of distraction on the spinal cord while the patient is anesthetized. Of the various types of scoliosis, the congenital variety carries the highest risk for neurologic complications after intraoperative correction. Arthrodesis and instrumentation without correction, other than that achieved passively while the patient is lying on the operating table, should be used if there is any suspicion of an intraspinal anomaly, even if it has been removed before the surgery. The instrumentation should be used only as an internal strut to support the spine and aid the development of a solid fusion (42).

Despite the risks, spinal instrumentation is frequently used to obtain moderate correction in patients with congenital scoliosis, but specific measures must be taken during the surgery to detect the possible development of neurologic complications. Spinal cord monitoring using evoked potentials is essential, but unfortunately it is not completely reliable (17). The wake-up test (60) or the ankle clonus test (28) should be performed immediately after correction of the deformity. These tests, however, monitor only the current neurologic status, and it is possible for neurologic abnormalities to develop at a later stage in the operative procedure (22 ,37).

In the past, Harrington instrumentation has been used most frequently in the treatment of congenital scoliosis (21 ,69). Newer forms of segmental spinal instrumentation using multiple hooks, pedicle screws, or sublaminar wires are more controversial in their application. Congenital abnormalities of the laminae may make it difficult to apply these types of instrumentation. It may also be dangerous to pass wires or hooks into the spinal canal at the site of the anomalous segment, which could be congenitally narrowed or contain an abnormal spinal cord. Regardless of the method of instrumentation, it is important to remember that the main objective is to achieve trunk balance rather than excessive correction of the scoliosis, which may be dangerous. If there is any suspicion that a neurologic deficit may have developed during the surgery, the spinal instrumentation should be removed immediately and the patient treated postoperatively in a plaster jacket.

Anterior and Posterior Spinal Osteotomy, Vertebrectomy, Correction, and Arthrodesis

A spinal osteotomy is a major salvage procedure that theoretically should never be necessary in congenital scoliosis. Its use is indicative of a failure to apply the basic principles of early diagnosis, anticipation, and prevention of increasing deformity. Patients who require a spinal osteotomy would have been much better treated at an earlier stage by simpler surgical procedures.

The indication for a spinal osteotomy is a severe rigid deformity with either fixed pelvic obliquity or marked decompensation of the upper trunk relative to the pelvis (Fig. 14). These severe spinal deformities are usually caused by a unilateral unsegmented bar with or without contralateral hemivertebrae.

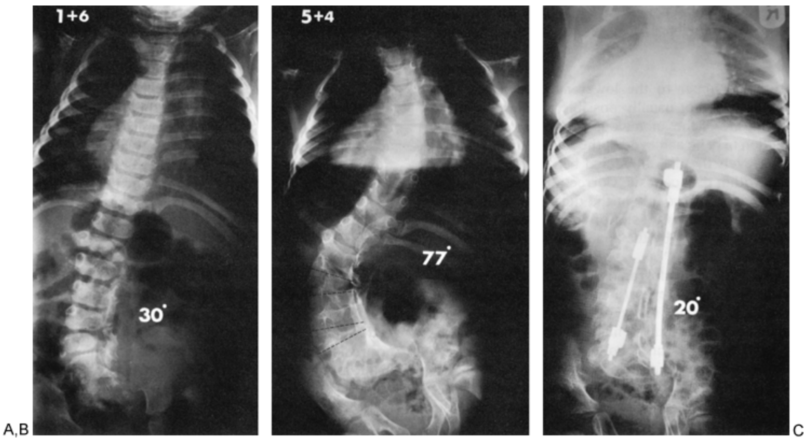


FIGURE 14. A: An infant girl who was radiographed at 1 year, 6 months and found to have 30-degree left lumbar scoliosis due to a unilateral unsegmented bar on the right extending from L4 to the sacrum, with a contralateral hemivertebra at L6. No treatment was given. **B:** By the age of 5 years, 4 months, the scoliosis had increased to 77 degrees, resulting in a severe rigid deformity with translocation of the trunk and marked pelvic obliquity. **C:** Two-stage anterior and posterior spinal osteotomies were performed at two levels in the lumbar region, and the scoliosis was corrected to 20 degrees with posterior spinal instrumentation.

The object of the surgery is to osteotomize the spine both anteriorly and posteriorly to create mobility, which will allow correction and enable the head and upper trunk to be balanced over a level pelvis. This is a technically demanding procedure with a significant neurologic risk and should be performed only by an experienced spinal surgeon after full consultation with the patient or parents and only if there are no alternatives.

The surgery can be performed as a single combined procedure or in two stages separated by 5 to 7 days. In the first stage, the spine is exposed anteriorly through a thoracotomy or a thoracoabdominal retroperitoneal approach, depending on the site of the vertebral anomalies. The intervertebral discs and their associated end plates are excised over the whole length of the deformity. The unsegmented bar on the concavity is then osteotomized through the sites of the excised discs. Simply osteotomizing the unsegmented bar will not allow the spine to grow straight because there is no growth potential on that side of the curve. To obtain significant correction, it may also be necessary to perform a wedge resection of a vertebral body at the apex of the curve, with the base of the wedge on the convexity and tapered toward the concavity. This is a difficult and dangerous procedure that is often associated with significant blood loss from the raw bony surfaces and epidural veins.

In the second stage of the procedure, the whole length of the congenital scoliosis is exposed posteriorly. The sites of the anterior osteotomies are identified, and posterior osteotomies are performed at the same levels by removing part of the lamina and facet joints on the convexity and dividing the unsegmented bar on the concavity. If an anterior vertebrectomy has been performed at the apex of the curve, it will be necessary to carry out a posterior wedge osteotomy at the same level by excising the lamina and removing the pedicle and transverse process on the convexity. The safest and best site for a vertebrectomy is in the lumbar region, where it is easier to close the wedge because there is no interference from the rib cage and the cauda equina is more resilient than the spinal cord.

After the anterior and posterior osteotomies have been performed, correction is obtained by applying posterior compression instrumentation to the convexity to close the wedge osteotomies. This shortens the spinal column and relaxes the neural structures, decreasing the risk for complications as well as straightening the scoliosis and balancing the spine (36). Only after this has been achieved is it safe to apply instrumentation to the concavity—not to achieve further correction but to act as a supporting strut and to maintain correction over the whole length of the deformity. A posterior spinal arthrodesis is performed over the entire length of the scoliosis extending from the upper to the lower neutral vertebrae and not just at the site of the osteotomy. Postoperatively, a plaster jacket or spica is applied to help stabilize the spine until the fusion is solid.

Summary

Congenital scoliosis is a potentially serious condition that can result in an extreme deformity with malalignment of the body. Ideally, this type of scoliosis should be diagnosed at an early stage when it is possible to anticipate the prognosis based on the amount of spinal growth remaining, the type and site of the vertebral anomalies, and the degree of growth imbalance they produce. Deterioration of the deformity must always be prevented. Scoliosis that is at risk for progression requires immediate prophylactic surgical treatment, no matter how young the patient. It is much better to carry out a relatively simple operation to balance the growth of the spine at an early stage than to wait and perform a dangerous surgical salvage procedure when the deformity is severe.

Congenital Kyphosis and Lordosis

Jean Dubousset

J. Dubousset: Hôpital Saint Vincent de Paul, Université René Descartes, Paris, France.

Congenital deformities in the sagittal plane result from congenital vertebral anomalies, leading to immediate deformities (e.g., when one element is missing) or progressive deformities (e.g., when the normal balance of growth potential of the various segments of the spine is more or less altered depending on the nature of congenital defect).

A sagittal plane abnormality means that the major deformity will be either an increase of the normal sagittal alignment of the affected segment of the spine or a decrease. Most of the time the deformity is not purely sagittal but also involves the coronal plane to some degree; thus, in kyphoscoliosis or lordoscoliosis the major deformity is in the sagittal plane. The deformity must be viewed in a spacial fashion for pure congenital kyphosis or lordosis as well as for the scoliosis group (kyphoscoliosis or lordoscoliosis). This is logical from the anatomical, mechanical, clinical, and surgical viewpoints because all treatment will be directed to the prevention and alleviation of any spinal cord and spinal canal compromise.

Pathologic Anatomy, Mechanism, and Spontaneous Evolution

The embryologic (9 ,10 ,11) and anatomical relationships for congenital anomalies of the spine indicate that there is a permanent association between osteoarticular elements that are more or less abnormal at the various levels of the vertebra (e.g., disc, pedicles, ligaments, bodies) and the nervous elements (e.g., spinal cord, meninges). The nervous system may be absolutely normal or congenitally disordered (e.g., dysraphism, lipoma).

Cartilaginous, Bony, Joint, and Ligament Anomalies

Bone and joint anomalies result from an embryologic defect at the time of vertebral formation or segmentation or both. Tondury (10), Rivard et al. (9), and Watanabe (11) demonstrated (either in experimental work or correlation with human embryonic studies) that vertebral malformations are acquired at the mesenchymal phase of development between the twentieth and thirtieth day of embryonic life, most of the time secondary to dysfunction of notochord cells. Most nervous system malformation also develops during this time frame of embryonic life, in addition to other anomalies, such as cardiac or urinary. After birth, the analysis of these bone and joint defects can be done in conjunction with an analysis of the central nervous system anomalies (2).

Computed tomography (CT) and magnetic resonance imaging (MRI), in addition to the clinical examination and plain frontal and sagittal radiography, allow one to study the deformity in three dimensions, establishing the balance for stability, spinal growth potential, and potential danger to the nervous structures so well seen on MRI.

However, even today (Fig. 1) we cannot predict the growth potential of an area based on the clear space (on radiograph) or dark space (on MRI sequences). In fact, we may be viewing stable or unstable fibrous tissue without the potential to form bone, or ossifying fibrocartilage without growth potential, or growing cartilage. Most of the time it is necessary to observe and follow the patient over time to determine if an anomaly is getting worse.

Congenital Kyphosis

Congenital kyphosis may be attributed to three causes: failure of formation, failure of segmentation, and rotatory dislocation of the spine.

Failure of Formation

Failure of formation leads to a total or partial absence of one or more vertebral bodies, and the abnormalities of the posterior arch determine the degree of stability of the spine (Fig. 2).

The analysis must consider two mains points:

1. *Location of the malformation.* Bodies, pedicles, and posterior arch may each be absent, totally or partially and symmetrically or asymmetrically.
2. *Alignment of the canal*, particularly at the level of the posterior

wall of the bodies in the sagittal plane. A well-aligned canal may exist with an acute kyphosis or a dislocated canal may exist when the alignment of vertebral bodies results in an offset or sudden loss of continuity.

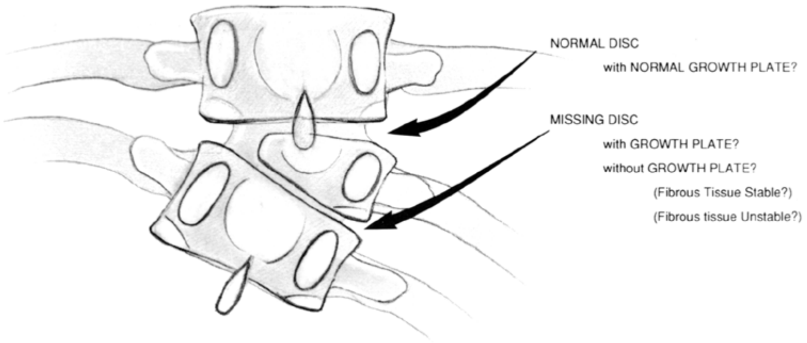

FIGURE 1. Congenital kyphosis or kyphoscoliosis factor for progression. Prognostic value of the "clear space."

Three types of failure of formation can be found:

1. *Partial failure of formation with a well-aligned canal.* Pure anterior and symmetrical failure is rare and results in an angular kyphosis. The posterior arch is strong, and normal kyphosis in such a condition progresses slowly. It is difficult to determine the exact value and histologic nature of this anterior "empty space." Is it cartilaginous, nuclear, or fibrous tissue?

   The differential growth potential results in a progressive kyphosis and spinal cord tethering. This type of deformity may also be seen in the case of binuclear or butterfly symmetrical bodies. These cases may progress 5 degrees to 7 degrees per year.

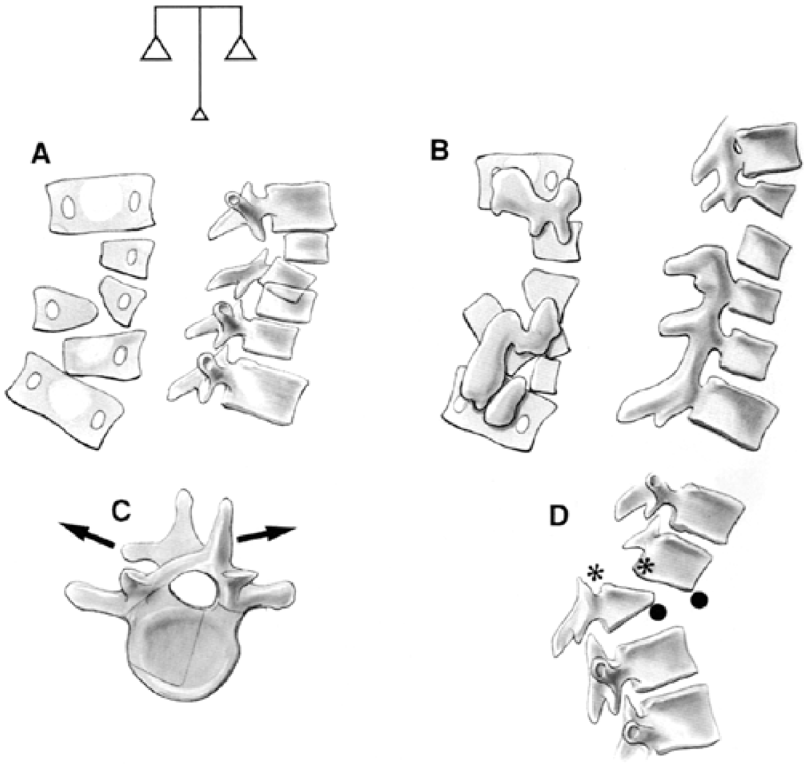

FIGURE 2. Congenital vertebral anomalies: stability analysis of the three-dimensional studies in the coronal, sagittal, and horizontal planes. *A*, Anterior column disc space and bodies. *B*, Posterior bolt elements—pedicles; joints; lamina; transverse and spinous processes; ligaments. *C*, Instability on the horizontal plane. *D*, An example of a congenitally dislocated spine.

   If the failure of formation is anterolateral, as in the posterolateral hemivertebra, the bending of the canal occurs at only one level. This leads to kyphoscoliosis, with a more or less normal posterior arch. The more acute the kyphosis, the greater the risk to the spinal cord even if the cord is always located on the concave side. If there is a fused hemivertebra, there is little or no progression of the kyphoscoliosis; but if the hemivertebra is "free," meaning movement of the half vertebral plateau on each side above and below the normal half disc space, a progression of 3 degrees to 5 degrees per year is anticipated in the sagittal as well as the coronal plane (1).

   This abnormality progresses at an increased rate once the pubertal growth spurt starts. If the defect is an asymmetrical binuclear vertebra, the pedicles may be absent, and more than 10 degrees progression may occur in a year. This condition exists mostly in the thoracic or thoracolumbar region and frequently leads to a progressively increasing neurologic deficit.

2. *Partial failure of formation with a dislocated canal* (Fig. 3B). This condition was described in 1973 using the term "congenital

dislocation of the spine” (5). Here the offset is clear, and the neurologic risk for the spinal cord is greater. It is also more dramatic because the condition (neurologic injury) can occur suddenly (e.g., as the result of a minor trauma). If the offset is clear on the sagittal radiograph, it can also frequently be seen in the coronal plane and almost always has a bayonet-type appearance. Frequently there is a narrowing of the right and left pedicles and some coronal and horizontal stenosis of the spinal canal.

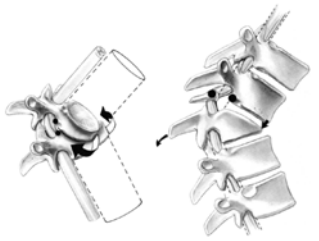

FIGURE 3. Congenital kyphosis. Note the difference between rotatory dislocation of the spine with a continuous canal **(A)** and congenital dislocated spine **(B)**.

With this malformation there is always a defect of the posterior arch, which explains the often considerable instability, but the defect is not always demonstrated by the dynamic radiographs. This is why we call the instability “potential,” that is, because the defect is revealed only as the result of a minor or major trauma. Progression of such an unstable kyphotic spine is always observed (e.g., 45 degrees at age 1 year to 135 degrees at age 15 years). During anterior surgery we have sometimes seen “neojoints” with fluid between the anterior part of the two adjacent bodies, demonstrating real mobility. The normal or dysplastic spinal cord often escapes from the normal spinal canal above and courses directly under the skin to enter the spinal canal below the offset. The cord can be severed accidentally by too vigorous a posterior approach because the skin covering it may be completely normal or may have a mild “angioma aspect,” which might be indicative of dysraphism or a mild lipoma.

But the big danger is instability where a minor trauma to a normal spinal cord can lead to a nonreversible, acute paraplegia, in contrast to those cases in which the spinal cord is progressively stretched.

Frequently, in this condition of “dislocated congenital spine” there is an associated dysraphic cord. Therefore, it is important to know the neurologic status at birth. We have seen completely normal patients as well as a patient in whom the only manifestation of a dysraphic condition was a paralytic club foot and a neurogenic bladder. We also have a patient manifesting complete congenital paraplegia, as is seen in some cases of lumbar agenesis. Generally, the location of the dislocated spine is thoracolumbar. That is why we describe this type of congenital kyphosis as a partial form of suspended lumbar agenesis.

The prenatal diagnosis can be made with ultrasonography, but the prognosis for normal or automatic motion of the lower limbs is guarded.

3. *Total failure of formation of the vertebral bodies* (1) results in the agenesis of one, two, three, or more vertebral bodies, with or without agenesis of their posterior arches. This occurs more frequently at the lumbar spine level. In such patients, there is almost always a congenital paraplegia and very often an increased motion at the kyphosis between the two parts of the spine. The hips may be normal, or subluxated, or dislocated and stiff in extension, in such cases, all mobility of the trunk and flexion-extension of the lower limbs occurs at the site of agenesis.

   There is often a complete motor spastic or flaccid paraplegia, with urinary problems and generally with normal sensation of the skin at the level of the lower limbs. We have observed a wide variety of findings, from dislocated spine, to spinal canal stenosis, to partial or total lumbar agenesis with sacrum, to partial or total agenesis of the sacrum and caudal regression syndrome.

Failure of Segmentation

Anterior or Anterolateral Typical Bar

The defect of anterior or anterolateral typical bar involves one or multiple levels (Fig. 4). When strictly anteriorly located, a pure kyphosis results. When anterolaterally located, a kyphoscoliosis results from the posterior elements that continue to grow in the face of the anterior elements having no growth potential. The resulting kyphosis generally has a smooth contour with no sharp angles and thus imposes minimal neurologic risk.

Delayed Fusion Anterior Bar

There is a special type of defect of segmentation that may not be evident at first glance but in which a progressive ossification of a part of or of a complete disc space develops slowly (7). It is often necessary to distinguish this type of defect from Scheuermann kyphosis, which has a similar appearance clinically and radiographically; however, with growth and maturation the spontaneous anterior fusion becomes evident. The fusion generally begins at age 8 to 10 years, but it is unpredictable and sometimes ossification is completed only when growth is completed. A histologic specimen of such a defect looks like bipolar cartilage progressively ossifying without any nucleus pulposus disc material in between. The angulation may be considerable, and we have one patient progressing from 20 degrees at age 3 years to 135 degrees at the end of puberty. The hereditary factor in these cases is evident because among the 10 cases of this progressive defect that we have reported, 7 cases involved only two families (one family in four generations and one family with three cases in two generations).

Rotatory Dislocation of the Spine

Rotatory dislocation of the spine (6) (Fig. 3A) is a mechanical deformity caused by the sudden presence of a kyphotic zone between two areas of scoliosis, each of them often in lordosis and rotating in opposite directions. In the first report (1973) of this deformity, we described three patients (one with neurofibromatosis, one with chondrodystrophy, and one with congenital vertebral anomalies). The deformity may be anywhere in the spine but generally is located in the upper thoracic or thoracolumbar region. The sudden kyphosis is angular, with a scissoring effect at the apex with often considerable collapse of the spine. Because this apex is abrupt and because of the twist of the spinal cord inside the spine, neurologic complications are common. The progression of this type of kyphosis is variable and depends on the progression of each scoliotic curve above and below. When an early diagnosis of neurologic impairment is made, traction may be beneficial and often allows complete neurologic recovery. This is followed by anterior and posterior fusion, which can stabilize the spine without the need for neurologic decompression.

Congenital Lordosis

Congenital lordosis or lordosciolosis is the result of three factors (Fig. 4):

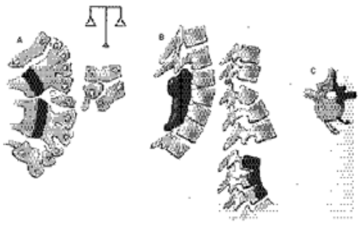

FIGURE 4. Congenital vertebral anomalies: analysis of the three-dimensional local growth potential asymmetry. *A*, Right–left coronal view showing scoliosis. *B*, Front–back sagittal view showing lordosis. *C*, Horizontal view showing rotation.

1. The most important factor is *posterior defects of segmentation* associated with a normal anterior growth. A symmetrical posterior bar leads to pure lordosis. If asymmetrical this lead to lordoscoliosis, which is sometimes very severe, especially when it involves almost the entire thoracic area. The consequence is a severe impairment of pulmonary function; the worse the lordosis, the worse the pulmonary function. In some cases, the resulting intrathoracic vertebral protrusion gives compression of the main bronchi with temporary or permanent atelectasia, leading to frequent pulmonary infection and sometimes lung abscess (Fig. 9). Sometimes several ribs are missing, which makes surgical treatment very difficult. In a few cases, the lordosis involves the cervical area with secondary esophageal compression. When it occurs in the thoracolumbar area there is usually only postural impairment (12).
2. The second factor is *posterior failure of formation* or absence of the posterior elements in the face of normal anterior elements. This occurs in patients with myelomeningocele as well as in those with dysraphism. The lordosis is more or less pure according to the mixture with partial posterolateral congenital bars.
3. The third factor that must be taken into consideration is the *postural factor* whereby lordosis can be increased by the evolution or progression of a congenital kyphosis below.

Prognosis

Because of associated anomalies, mainly skeletal (ribs fusion), nervous (dysraphism), cardiopulmonary, and urinary, the prognosis (Fig. 5) of congenital sagittal anomalies must be studied from three major perspectives: mechanical, neurologic, and respiratory.

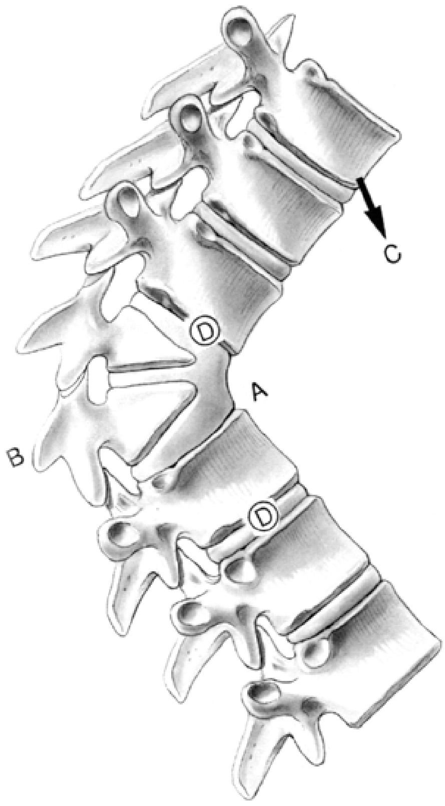

FIGURE 5. Prognosis, mechanical factors. *A*, Anterior empty space (fibrous and soft, fibrous and strong, or cartilaginous?). *B*, Quality and stability of the posterior bold. *C*, Effect of gravity (angular deformity, value of the angulation). *D*, Growth factors—growth imbalance at the level of the malformation and bad orientation of the growth plates on normal elements.

Mechanical

From the mechanical perspective, two factors must be analyzed:

1. *Stability and instability* (4). Particularly for a kyphotic deformity, when an anterior empty space is filled with nonosseous tissue, a potential instability exists, where even with good posterior “bolts” created by normal posterior elements the progression of deformity is inevitable.

   From time to time, where posterior anomalies exist, there is great risk for sudden neural injury even by minor trauma.

   Evidently, when there is a congenital absence of anterior and posterior elements, maximum instability is apparent. Very often this is associated with congenital spinal cord defects detected not only by skin anomalies on the back but by problems such as a unilateral paralytic foot, or urinary or bladder dysfunction. For all these congenital anomalies, MRI is mandatory from skull to coccyx.

   Once an existing instability (on dynamic imaging) or a potential instability is detected, it is necessary to stabilize and fuse the spine both anteriorly and posteriorly. Lordotic deformities are much less prone to produce such instability.

2. *Growth imbalance.* Regardless of the defect (hemivertebra, asymmetrical binuclear vertebra, unsegmented bar, or a mixture of all these basic defects), growth imbalance must be studied in three dimensions. The spatial location of the defect of segmentation, for example, will determine the orientation of the deformity: defects of the bodies cause pure kyphosis, whereas defects solely of the posterior elements that develop in a symmetrical fashion induce pure lordosis. However, if the defect is slightly lateralized, it will induce the scoliotic component, with either a lordotic or kyphotic deformity depending on whether there is an posterolateral or anterolateral congenital bar. The bar's extent will determine the degree of deformity. Finally, the importance of the pubertal growth spurt must be stressed because it is at this time when suddenly an previously undetected deformity may quickly progress. Once such progression is documented, the best treatment is epiphysiodesis of the opposite side to balance the entire spine, if there is growth remaining.

Neurological Aspect

Instability or a progressive deformity will lead to neurologic complications, suddenly or gradually. However, as previously noted, often the neural structures are also congenitally abnormal. This is best documented with MRI. In specific patients, the existing dysraphism requires neurosurgical treatment (e.g., lipoma removal or release of an attached filum, or removal of a dermoid cyst). This treatment is often combined with definitive orthopedic treatment. The prognosis for the neurologic deficits occurring with such anomalies depends on three factors: clinical, pathoanatomical, and the “rest test.”

1. *Clinical factor.* The longer the neurologic deficit has been present and the more severe the neurologic deficit from cord compression is, the less chance of recovery one can expect. Some deficits may have been present before birth; some are secondary to malformation of the cord; and some are secondary to the evolution of the spinal deformity itself. Only the last type can be expected to recover following treatment; the first two cannot. The prognosis is better if the neurologic compromise occurs progressively rather than suddenly, as in trauma to the cord. Complete paraplegia has a worse prognosis than incomplete but progressive paraplegia with persistent sensation on the skin below the level of the lesion or if some small voluntary motion persists. Recovery from a progressive neurologic deficit is better for younger patients (infants and children) than it is for older patients. Cord compression in the upper thoracic spine has a worse prognosis than other areas of the spine because of the precarious cord blood supply at this level.
2. *Pathoanatomy of the deformity.* If the apex of the deformity is acutely kyphotic and stiff during a hyperextension test, there is danger in applying traction for reduction. On the other hand, if the apex is flexible, traction is often recommended and generally leads to recovery, especially in a “rotatory dislocation” pattern.
3. *Rest test.* Very often it is sufficient to place the recently compromised spinal cord at rest—for example, with a cast or halo cast—to see if improvement occurs; sometimes complete recovery occurs. If recovery occurs, then surgical stabilization both anteriorly and posteriorly without opening the canal can prevent any further problems. If recovery does not occur, then direct surgical decompression is mandatory.

Respiratory Aspect

Progressive lordosis or lordoscoliosis, as in an unsegmented thoracic posterior or posterolateral bar, can have associated severe respiratory compromise. The increased transverse rib orientation decreases the rib excursion and motion. Often multiple rib fusions increase chest rigidity. The diaphragm may not function normally. The bronchi may be stretched on the vertebral “billot” and create atelectasia and lung collapse. The respiratory compromise in such a cases may be dramatic. These problems must be detected early and treatment by appropriate epiphysiodesis implemented promptly.

Multiple absent ribs on one side in the absence of lung and cardiac anomalies is a less dangerous anomaly than multiple fused ribs.

Sometimes kyphosis and kyphoscoliosis may also induce respiratory compromise, but much less so than lordotic deformities.

Treatment: General Principles

The treatment of congenital kyphosis and lordosis is exclusively surgical. Nonoperative treatment alone has no value in halting the progression of these congenital anomalies; however, it may have some role in controlling compensatory deformities above or below the congenital defect, but only when the level of the congenital anomaly is stabilized or stopped from progressing.

Before any surgical treatment is undertaken, it is necessary to make some general and specific assessments, with emphasis on cardiopulmonary anomalies, associated visceral or urinary anomalies, and neurologic problems (e.g., filum terminal, lipoma, Arnold-Chiari syndrome, various dysraphism considerations). These findings will sometimes change the timing of and the approach to treatment. The limits of the fusion both posteriorly and anteriorly must be established prior to surgery. For the very young patient, a fusion should be as short as possible to allow the normal spine to balance as best it can naturally, but it should be sufficiently long to achieve some correction using the growth potential of the normal levels involved in the fusion area to balance the defect. For the older patient close to puberty or at adolescence, the entire deformity must sometimes be fused front and back, as is done for an adult patient. The fusion must be as close as possible to the gravity line. This can be determined preoperatively by the sagittal bending radiographs either in flexion for lordotics or hyperextension for kyphotics to achieve good balance and to keep one or two disc levels free below the fusion.

Emergency Situations Needing Treatment to Protect Life Itself and its Quality

1. *When instability is diagnosed*, there is the risk of sudden damage to the spinal cord. For the very young child (a few weeks to a few months old) with an unstable congenital kyphosis, external immobilization by a cast with posterior and anterior fusion of the unstable levels as early as a few weeks of age is the recommended treatment. In the author's experience, the youngest patient to receive this treatment for a dislocated spine with normal nervous function was 3 weeks old. The child was successfully casted and a posterior fusion was performed leaving intact the midline structures extending the fusion to the laminae and the transverse process. The facets were left intact (their destruction would increase the instability). The fusion extended two levels above and below the pathologic one, with a second reinforcement fusion 4 months after the initial fusion. In a similar case, a pseudarthrosis was found at the second reinforcement fusion; in this case, an anterior interbody fusion was also done at the same time.

   Of course, when such an emergency situation is encountered in an older patient, one has to adapt the techniques (with or without instrumentation). In general, anterior fusion is done in conjunction with a protein fusion as soon as the child is older than 3 or 4 years.

2. *When progressive neural deficits are demonstrated*, the condition must be considered an emergency and treated immediately. This would apply whatever the age of the patient, with the same basic principle that we will use for the older child. These include, for example, the rotatory dislocation phenomena, or where growth increases the neural deficit of a spinal dysraphism, or when progressive deformity stretches the spinal cord and causes neural impairment.
3. *When respiratory function is clearly involved* and worsened by a spinal deformity (mainly congenital lordoscoliosis) and/or lung abnormalities, this must be considered an emergency that requires immediate treatment in conjunction with the cardiopulmonary team. For the orthopedic team in such a case, the immediate partial correction of the lordosis can be attempted, as can airway decompression if necessary, but generally the correction is achieved progressively by epiphysiodesis and in some cases by thoracic rib distraction.

Progressive Deformities During Infancy and Childhood as Best Indications for Epiphysiodesis or Hemivertebra Excision

Preoperative Planning

The preoperative planning of an epiphysiodesis (Fig. 6) of the spine, with or without hemivertebra excision, requires knowledge of the normal growth of a vertebral unit and its growing cartilages in three dimensions. Consider the entire vertebra to be a cube divided into four quadrants, with all vertebrae growing equally around the spinal canal.

FIGURE 6. Planning for epiphysiodesis of the spine. *A*, Schematic division of the vertebral element into four quadrants in the horizontal plane. *B*, Symmetrical posterior bar and the required area of the epiphysiodesis. *C*, Symmetrical absence or failure of formation of the body—posterior symmetrical epiphysiodesis required. *D*, Pure anterior hemivertebra. An increase in the relative anterior length results in lordosis. Epiphysiodesis is required along with anterior fusion. *E*, Posterolateral congenital bar. An anterior convex hemiepiphysiodesis is required. *F*, Anterolateral hemivertebra requires simultaneous anterior and posterior homolateral hemiepiphysiodesis.

When an imbalance in the growth potential exists, it is necessary to plan preoperatively the exact zones to be fused to reestablish good balance. We use a schematic axial drawing divided into four quadrants and a schematic sagittal drawing where all of the vertebrae belonging to the lesion are included. This gives a mental three-dimensional reconstruction and plan of exactly what has to be done (Fig. 7). By doing this we can treat any kind of deformity by adapting the three-dimensional defect to the three-dimensional area of epiphysiodesis.

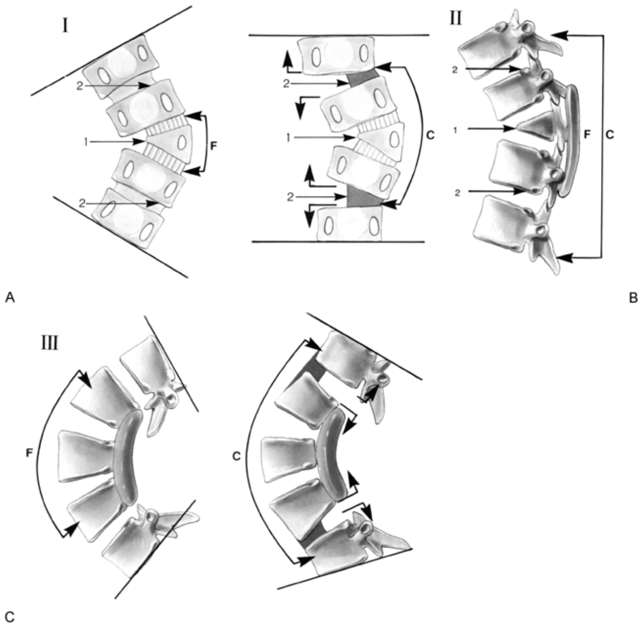

FIGURE 7. Planning for epiphysiodesis. **I:** Coronal plane, lateral hemivertebra. **II:** Sagittal plane, posterior hemivertebra. **III:** Sagittal plane, posterior bar. (1) If hemifusion is done only at the level of the anomaly, there will be a fusion effect *F*. (2) If hemifusion is done one level above and below the anomaly, there will be a correcting effect *C*.

When a single posterolateral hemivertebra leads to a kyphoscoliosis at the lower thoracic, thoracolumbar, or lumbar area, the author favors hemivertebra excision and short fusion.

Technique of Epiphysiodesis (3)

Outcomes are classified according in three ways: *improvement effect*, when clinical and radiologic improvement can be measured

by more than a 5-degree Cobb angle; *fusion effect*, when even with a considerable cosmetic improvement there is no change above or below 5 degrees from the angle from the postoperative cast; and *worsening effect*, where the curve has been exacerbated by more than 5 degrees.

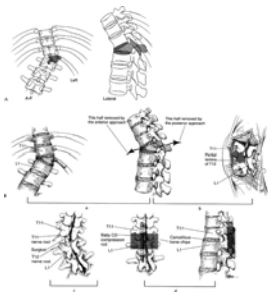

FIGURE 8. Kyphosing hemivertebra of the thoracolumbar junction (T12), posterolateral hemivertebra excision. **A:** What we see on a regular radiograph anteroposteriorly and laterally. Anteroposterior: it is important to know where the hemiposterior arch is located. Lateral: Note that the posterior hemivertebral body shadow overlaps the upper and lower adjacent bodies. **B:** Technique:

(a) What has to be removed on the front?

- The hemibody of T12, including more than half the length of the pedicle inside the canal.
- The adjacent growth plates of T11 and L1.

We always start with the anterior approach. After removal, we secure the canal lateral to the dura with a piece of Surgicel tape and place between the two vertebral plateaux T11 and L1 mashed cancellous bone.

(b) What has to be removed on the back, the hemilamina, facets, and remaining pedicle?

What do we see on the back and the hemilamina to be removed? Note: Do not strip the periosteum of vertebrae T10 and L2 because of risk of extending the fusion.

(c) After removing the hemiarch, we see the dura, the root, and the piece of Surgicel tape placed in front.

(d) Compression is done posteriorly by any device between T11 and L1 (we use Baby CD) to close the gap unilaterally until both posterior arches of T11 and L1 have been approximated.

Posterior fusion is achieved with cancellous bone coming from the body excised and chips of the rib used for the approach.

The postoperative cast is realized 3 or 4 days after with general anesthesia.

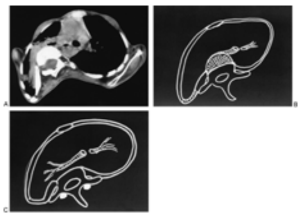

FIGURE 9. Decompression of the airway. **A:** Congenital lordoscoliosis with CT scan atelectasia of the inferior main bronchi of the right lung. **B:** Drawing of the planned resection of vertebral body "billot." **C:** After anterior resection and proper kyphosing posterior instrumentation, the airway is free.

For example, for *kyphosis* secondary to pure symmetrical posterior hemivertebra, symmetrical posterior epiphysiodesis on both sides is required.

For *kyphoscoliosis* caused by a posterolateral hemivertebra, an anterior and posterior convex hemiepiphysiodesis on the same side as the hemivertebra is required. In fact, if we start first with a posterior convex hemiepiphysiodesis, we achieve correction of the kyphotic component but not for the coronal plane component, and we observe a crankshaft phenomenon that is avoided by the simultaneous anterior fusion. For this reason, particularly in the thoracolumbar or lumbar spine, we prefer to perform a *unilateral hemivertebra excision* with closure of the posterior elements with a small compressive device, correcting at the same time the anteroposterior and sagittal plane and simultaneous fusion and postoperative cast (Fig. 8).

For *lordoscoliosis* caused by posterolateral bar, we need to perform an anterior and posterior convex hemiepiphysiodesis, which is located at the opposite side of the bar. Sometimes compression of the airway exists due to protrusion of the vertebral bodies at the same time that epiphysiodesis anterior hemivertebral body resection is being performed (Fig. 9).

Finally, in some patients with lordoscoliosis associated with asymmetrical defect of segmentation and absence of ribs, the use of a progressive rib distractor (see Chapter 7 on congenital scoliosis), in young children gives surprising good results both pulmonary and spinal without any direct vertebral epiphysiodesis.

Established Deformities in Older, Adolescent, or End-of-Growth Children

Patients Without Neurologic Deficits

1. *For kyphosis and kyphoscoliosis*, the plan of treatment will depend on the stiffness or flexibility of the curve, particularly the mobility at the apex. For a *flexible apex*, preoperative traction with hyperextension with careful close neurologic evaluation is useful. This should be followed by anterior and posterior fusion. It is recommended that one start with the anterior approach and release of fibrous tissue, with the disc spaces remaining. This improves the reduction either with a temporary anterior distractor

or, more often, with posteroanterior pressure directly on the apex to open the anterior gap, where struts of tibial graft are inserted in a palisade fashion from the bottom of the apex as symmetrically as possible above and below this apex until the gravity line is approached (Fig. 10 for palisade graft example). This results in segmental anterior multilevel bridges. We favor the concave approach when we treat a kyphoscoliosis in order to be well aligned in the gravity line. We do not like to start with the posterior approach because it can increase a previously unrecognized instability that may result in neurological compromise.

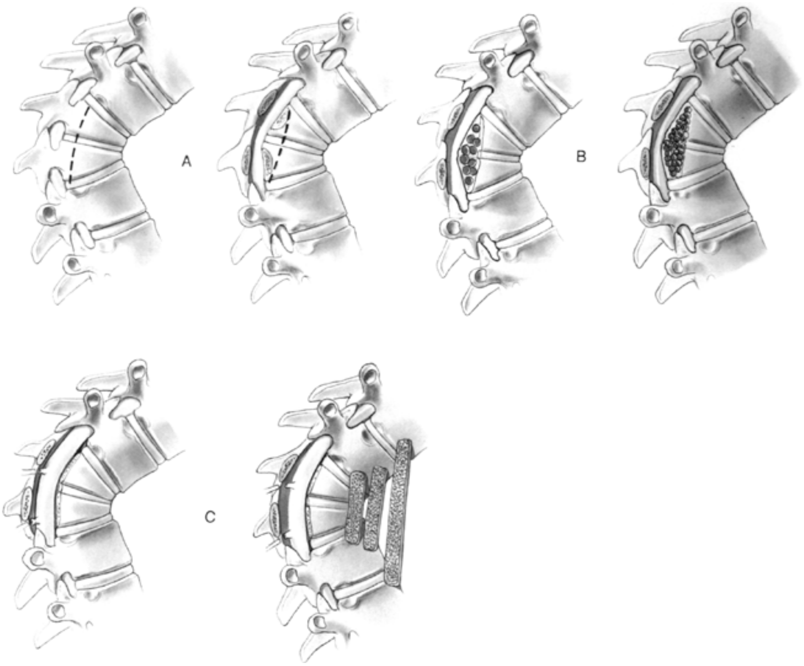

FIGURE 10. Congenital kyphosis with a stiff apex: anterior decompression and fusion. *A*, The bone to be removed. *B*, Holes are made with a power drill without touching the dural sac and by breaking the bridge. This allows the cord to move anteriorly. *C*, From time to time, it is necessary to divide a root by suspending the dural sac and the cord at the ceiling of the spinal canal. The anterior palisade strut graft must be completed at the same time.

One can do the posterior fusion first only if there is certainty regarding stability and if the hyperextension test demonstrates mobility.

With time this palisade graft consolidates. Only in very few cases have we used vascularized rib because generally this type of anterior material does not give immediate stability. We never use it alone, only in association with rigid struts.

For a *rigid apex*, in the case of a congenital cause, we do not favor osteotomy, cord decompression, and fusion because these may result in only partial improvement of the cosmetic aspect and from time to time may cause a neurologic deficit. We prefer to do the anterior approach first to keep the apex intact and to have partial correction through the disc spaces above and below, followed by a posterior fusion. This approach, while not giving cosmetic correction, does preserve spinal cord function.

2. *For lordosis*, flexibility of the congenital lordosis deformity is very uncommon, existing mainly in cases where the absence of the posterior elements explains the reducibility. In such cases, the best treatment is anterior release with shortening and anterior instrumentation with any compressive system (if located in a safe area for the great vessels), followed by posterior instrumentation and fusion, with a kyphosing distraction effect on the mobile levels.

   More often, the lordotic curve is rigid. Correction is generally achieved with the anterior approach first and sometimes anterior body resection when airway compromise exists, followed by posterior osteotomies with posterior instrumentation and fusion, or in a reverse order, with posterior osteotomies first, followed by anterior multiple wedging and anterior compressive instrumentation when possible. For younger children, in the thoracolumbar area, we have used this technique without instrumentation.

The closure of the anterior wedge was achieved with 4 weeks of traction with the hips and knees flexed 90 degrees and vertical suspension of the inferior part of the body. Then a body cast extending down to the hips and knees for another 2 months is used.

The advantage of not using metallic implants is that safe neurologic control can be achieved afterward with CT or MRI. Generally, for lordoscoliosis, it is always better to shorten the anterior convexity without lengthening the posterior concavity.

Patients with Neurologic Deficits

A clear difference must be established between neurologic signs that are secondary to the progressive deformity and those existing from birth because of malformation of nervous tissues (8).

Congenital kyphosis and kyphoscoliosis are the most common cause of neurologic complication secondary to an angular kyphosis, sometimes occurring in young children but usually appearing only at puberty, especially when the congenital defect is in the upper thoracic spine (T3-5) and thoracolumbar junction (T12-L1). If *the apex is flexible* the deformity can be partially reduced, especially if the patient has previous radiographs that show a less pronounced deformity—either angular or of the rotatory dislocation type. If the neurologic signs were definitely acquired recently, the deformity may be progressively reduced using a distraction cast, very often combined with halo traction independent of the cast. The patient must be monitored very closely for the evolution of neurologic signs. The author prefers the distraction cast to the direct halo traction because the cast adds spatial stabilization to the spine, which is not the case with a simple halo traction in the bed.

Once recovery occurs, the same strategy can be used as described for patients without neurologic deficit. Both anterior and posterior fusion must be accomplished to ensure a good outcome.

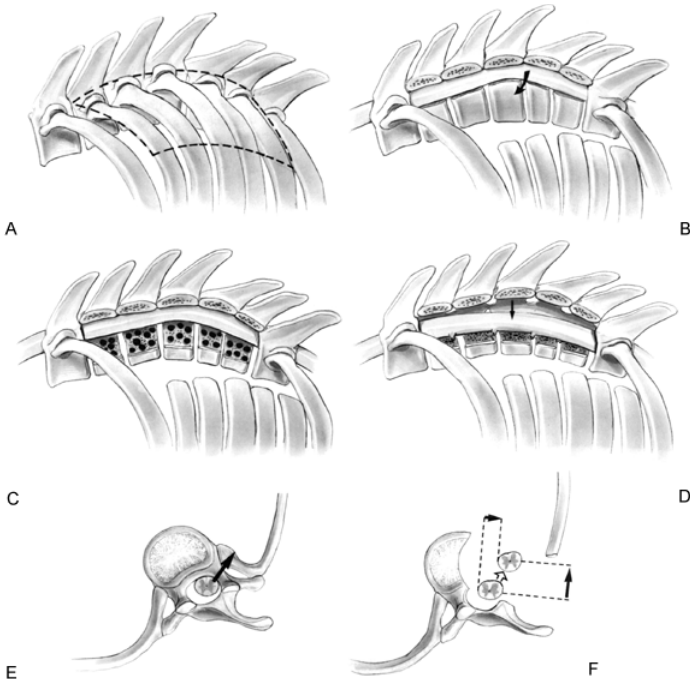

FIGURE 11. Anterolateral decompression for kyphoscoliosis using the Guiot-Capener approach. **A:** Approach is done on the concave side from the spinous processes to the ribs. The route of the canal follows one root through a foramen that is distant from the apex with a costal transversectomy. **B, C:** Once the canal and bodies are exposed, a power drill is used to create a bridge under the cord. One must break the bridge in the direction from the cord to the hole (and not the reverse) to avoid touching the cord at the apex. **D:** The cord is transposed more or less on the heads and strump of the ribs. **E, F:** Horizontal view of the surgery showing anterior and lateral transposition of the dural and cord elements.

If *the apex is stiff and not reducible*, then rest and immobilization are the first line of therapy. If improvement occurs, one can wait 1 or 2 months or more; in some cases there is complete recovery, and an in situ anterior and posterior fusion is performed. If there is no change in neurologic status or progression, decompression of the spinal cord must be accomplished. However, in patients with long-term neurologic deficit (over 3 years or from birth, i.e., congenital), decompression of the cord in our experience gives no improvement and runs the risk of loss of one or two additional roots.

In all other cases (major neurologic compromise relatively recent—3 years or less—or worsening seen during the short rest period), decompression of the cord is combined with an anterior and posterior fusion.

If the anatomy demonstrates pure kyphosis (Fig. 10), decompression is achieved with the anterior approach. This involves removing the bony apex but never starting at the apex, instead creating a big hole from one or more levels above and below the apex, in the bodies, and creating a bridge. The bridge is then removed without touching the dural sac at any time. Anterior strut interbody fusion is done under direct visualization of the sac. Posterior fusion is performed the same day or a few days later, with internal fixation done whenever possible. Of course, in young children, external immobilization by halo cast is recommended and the surgery is performed inside the cast on a relatively stable spine. With *kyphoscoliosis*, decompression is done through the costal transversectomy approach on the concave side using the technique described by Guiot. The dural sac and the cord are moved gently outside the canal and are often close to the rib heads or stumps (Fig. 11).

It is mandatory to perform the anterior fusion at the same time. Not doing this renders it dangerous to approach the spine with a dural sac “inside” the chest but outside the canal!

In the French experience with approximately 40 patients having congenital anomalies with acquired progressive neurologic signs, we used the preoperative traction strategy. Improvement occurred in about 60% of the cases, and this without having to perform decompression but only anterior and posterior fusion. We have never seen recurrence of neurologic signs after this circumferential fusion in such patients. In patients on whom we performed decompression and circumferential fusion, significant improvement or recovery of the neurologic signs was observed only in 50%, while 20% showed a worsening of signs.

So far, we have not seen any patient with congenital spinal anomaly without neurologic signs who was appropriately treated by fusion (circumferential if necessary) during infancy and childhood who later developed neurologic impairment.

Conclusion

Persons with sagittal plane congenital anomalies require the earliest possible diagnosis and proper evaluation of the pathoanatomy, including stability, growth potential imbalance, associated anomalies, and consequences on the vital functions (primarily cardiopulmonary and neurologic). Early treatment should be provided to correct the deformity—if possible. But treatment should mainly be directed at *preventing* any worsening of the deformity and any onset of progression of the consequences of the deformity on vital functions.

Sacral Agenesis

William A. Phillips

W. A. Phillips: Texas Children's Hospital and Baylor College of Medicine, Houston, Texas 77030.

Sacral agenesis is the term commonly applied to a group of disorders characterized by absence of a variable portion of the caudal portion of the spine. Individuals with sacral agenesis lack motor function below the level of the remaining normal spine, similar to those with myelomeningocele. In myelomeningocele, however, sensory nerve function is impaired below the level of affected vertebrae. In sacral agenesis, sensation tends to be present at much more caudal levels. In more severe cases of sacral agenesis, part or all of the lumbar spine and even the lower thoracic spine may be absent. By convention, even these severely affected individuals are referred to as having sacral agenesis, despite attempts by some to use the more descriptive term *lumbosacral agenesis* (14 ,25 ,27 ,35 ,38 ,42).

Individuals with sacral agenesis frequently have other abnormalities of the musculoskeletal system. Of greatest interest to the spinal surgeon is the abnormal articulation between the pelvis and the remaining normal spine that characterizes children with agenesis of the lumbar spine. With increasing severity of vertebral agenesis (i.e., more proximal involvement), the articulation between the spine and pelvis becomes more abnormal and the lower extremities present with more severe deformities. Abnormalities of the renal system are commonly reported, and other viscera can also be affected.

In this chapter, management of the lower-extremity deformities and of the articulation of the spine and pelvis unique to this condition are discussed. This approach is necessary because these problems and their management are often interdependent.

Nomenclature

Sacral agenesis has been referred to by a variety of terms, including congenital absence of the sacrum (15 ,22 ,51), congenital anomaly of the sacrum (6), sacrococcygeal agenesis (18), vertebral agenesis (10), caudal regression (5 ,23 ,38 ,39), caudal dysplasia (29 ,56), and sacral aplasia. Williams and Nixon (57) in 1957 appear to have been the first to use the term sacral agenesis. As the absence of the coccyx is not known to cause any problems (22), mention of its absence seems unnecessary.

The level of involvement in sacral agenesis is best described by the most caudal normal vertebral body (42 ,47). Although there may be a more caudal nubbin of malformed bone, the last vertebral body usually corresponds well to the degree of motor impairment seen in affected children.

Renshaw (47) classified patients by the amount of sacrum remaining and the characteristics of the articulation between the spine and the pelvis (Fig. 1):

Type I has either total or partial unilateral agenesis of the sacrum.

Type II has partial sacral agenesis with a bilaterally symmetrical defect, a normal or hypoplastic first sacral vertebra, and a stable articulation between the ilia and the first sacral vertebra.

Type III has variable lumbar and total sacral agenesis, with the ilia articulating with the sides of the lowest vertebra present.

Type IV has variable lumbar and total sacral agenesis, with the caudal end plate of the lowest vertebra resting above either fused ilia or an iliac amphiarthrosis.

Sacral agenesis is considered by some to be a form of caudal regression or caudal dysplasia syndrome (16 ,23 ,39).

Epidemiology Factors

Sacral agenesis is an uncommon congenital affliction of the spine occurring in approximately 1 of 25,000 live births (50). The actual incidence may be higher because minor defects of the sacrum without other external manifestations may not be obvious at birth. The first reported case of sacral agenesis is attributed to Hohl (27) in 1852.

The majority of reported cases involve absence of the sacrum and perhaps some lumbar vertebrae. Complete absence of the lumbar spine is uncommon. Based on a cumulative review of the literature (more than 500 cases of sacral agenesis), there appears to be little difference in the incidence of sacral agenesis between males and females.

Etiologic Factors

The exact cause of sacral agenesis is unknown. In 1959, Blumel et al. (6) first called attention to the increased incidence of diabetes in mothers of affected children. The incidence of maternal diabetes is about 16% (29). Rusnak and Driscoll (50) reviewed the cases of 1,150 infants born to diabetic mothers. Three had sacral agenesis, making the incidence 1 of every 350 births to diabetic mothers. Passarge (39) estimated that no more than 1% of infants born to diabetic mothers have sacral anomalies. The degree of sacral agenesis does not appear to be related to the severity of the maternal diabetes, and severe defects have been noted in children whose mothers had no evidence of diabetes or were in a prediabetic state (42). Kalter (30) suggested the association of maternal diabetes and specific malformations cannot be established from case reports due to selection bias. He notes that the incidence of these malformations is too low for the incidence of diabetes in women of childbearing age.

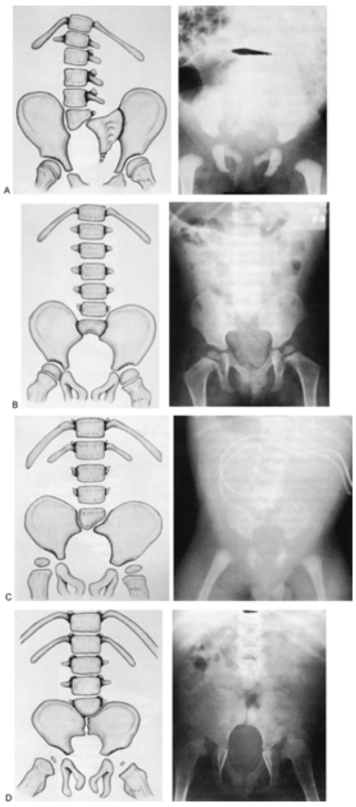

FIGURE 1. Renshaw classification of sacral agenesis. **A:** Type I sacral agenesis—unilateral agenesis of the sacrum. **B:** Type II sacral agenesis—partial sacral agenesis with a bilaterally symmetrical defect, a normal or hypoplastic first sacral vertebra, and a stable articulation between the ilia and the first sacral vertebra. **C:** Type III sacral agenesis—variable lumbar and total sacral agenesis with the ilia articulating with the sides of the lowest vertebra present. **D:** Type IV sacral agenesis—variable lumbar and total sacral agenesis with the caudal end plate of the lowest vertebra resting above either fused ilia or an iliac amphiarthrosis. (From Renshaw TS (1978): Sacral agenesis: a classification and review of twenty-three cases. *J Bone Joint Surg Am* 60:373–383, with permission.)

Several kindreds have been described in which a sacral defect is inherited and there is no association with maternal diabetes (43). Welch and Aterman (56) described three forms of familial sacral dysgenesis: familial hemisacrum type I (Cohn-Bay-Nielsen syndrome), familial hemisacrum type II (Ashcraft syndrome), and familial partial sacral agenesis. Chromosomal studies have been normal (4 ,8 ,40), with a few exceptions (5 ,53).

Clinical Features

Just as the degree of agenesis of the spine can vary greatly in children with sacral agenesis, so can the number and severity of associated problems. Renshaw (47) and others (42) have noted that higher levels of agenesis seem to be associated with more anomalies of greater severity (Fig. 2). Certain problems are associated with specific patterns of agenesis.

The Renshaw type I pattern of unilateral sacral agenesis (the so-called scimitar sacrum) is often inherited in either an autosomal or a sex-linked dominant pattern (7 ,59). In familial hemisacrum type I (Cohn-Bay-Nielsen syndrome), anterior meningocele is often seen (13). In familial hemisacrum type II (Ashcraft syndrome), there is a high incidence of presacral teratoma (31).

Musculoskeletal Problems

Musculoskeletal problems related to sacral agenesis can be divided into those that are dependent on the level of agenesis of the spine and neural elements and those that are independent of the level. Orthopedic problems not related to the level of agenesis include foot deformities, such as clubfoot, and other anomalies of the spine, such as congenital scoliosis, myelomeningocele, and Klippel-Feil syndrome. Problems dependent on the level of involvement include spinal-pelvic instability, dislocation of the hips, and knee flexion contractures, sometimes with popliteal webbing. These tend to be seen most frequently in children with Renshaw III or IV sacral agenesis. Involvement of the upper extremities is rare (6 ,47).

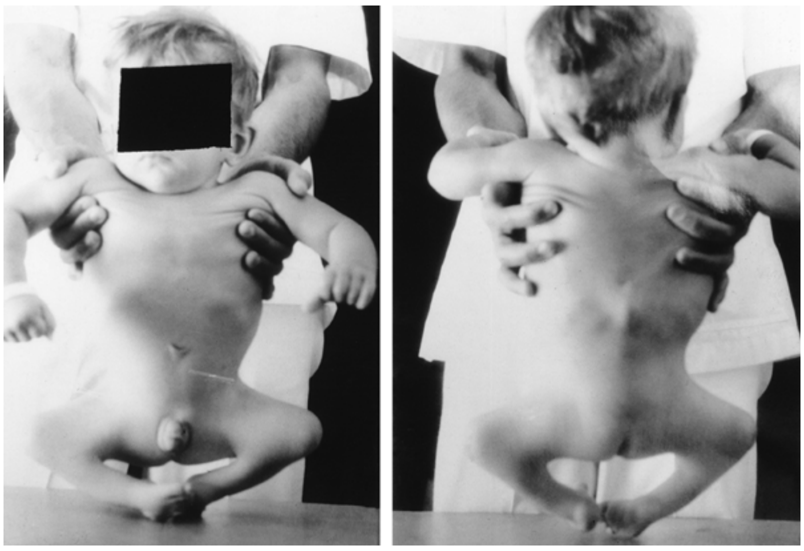

FIGURE 2. A child with agenesis of the spine below T12. Note the small pelvis, the flexed webbed knees, and clubfeet in the posterior view. Note the prominent nubbin at the end of the thoracic spine, which represents the end of the spine in this child. (From Phillips WA, Cooperman DR, Lindquist TC, et al. (1982): Orthopaedic management of lumbosacral agenesis. *J Bone Joint Surg Am* 64:1282–1294, with permission.)

Spine

In the more severe forms of sacral agenesis (Renshaw types III and IV), the articulation between the spine and pelvis is rudimentary (type III) or nonexistent (type IV). This results in a kyphosis at the end of the spine as well as an abnormal amount of motion between spine and pelvis. Affected individuals sit in the so-called Buddha position with knees flexed and legs crossed, leaning forward because of their kyphosis (51). This motion has been commonly referred to as spinal-pelvic instability (3 ,14 ,41 ,42 ,58) (Fig. 3).

A variety of other spinal abnormalities have been reported in children with sacral agenesis. In several series, few of the children had normal spines above the level of agenesis (4 ,47). Congenital scoliosis due to hemivertebra and duplicated or fused ribs has been reported (26). Developmental scoliosis (i.e., with no obvious bony defect in the spine above the level of agenesis) is also common (42). Klippel-Feil syndrome has also been reported occasionally in children with sacral agenesis (4 ,21 ,42 ,44 ,47).

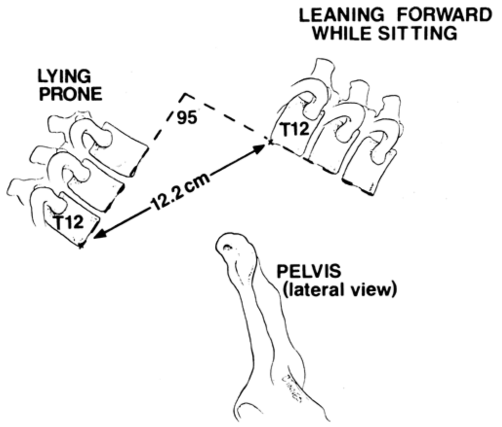

FIGURE 3. Spinal pelvic instability. This composite drawing of lateral radiographs of the spinal-pelvic junction of a 35-year-old woman with lumbosacral agenesis at the twelfth thoracic level was made while she was lying prone and while she was sitting leaning forward. The iliac wings appear flattened due to absence of the sacrum. Note the large translation as well as rotation possible. This patient was asymptomatic. (From Phillips WA, Cooperman DR, Lindquist TC, et al. (1982): Orthopaedic management of lumbosacral agenesis. *J Bone Joint Surg Am* 64:1282–1294 , with permission.)

Hips

The possible inclusion of children with myelomeningocele in some reports makes it difficult to determine the exact incidence of hip problems occurring in sacral agenesis. Hip dislocation in sacral agenesis usually occurs in cases of relatively severe involvement. Hip dislocation in higher level sacral agenesis appears to be a consequence of muscle imbalance (42). The situation is similar to myelomeningocele, in which preservation of hip flexor and adductor power with loss of hip abduction and extension is associated with a high incidence of hip problems.

Knees

One of the most striking features in children with high-level sacral agenesis (L1 and above) is the presence of severe knee flexion contractures, often with popliteal webbing. The contractures, which can be greater than 120 degrees, preclude the use of a brace and attempts at ambulation (14). Lack of active quadriceps power appears to correlate with the severity of the knee flexion contracture. Children with L1 and above sacral agenesis tend to have the most severe contractures. Children with sacral agenesis below the L1 level tend to have less severe contractures that rarely need intervention.

Feet

Foot deformities in sacral agenesis tend to be stiff and similar to those seen in arthrogryposis. Clubfoot, vertical talus, and cavus foot deformities have been reported (1 ,4 ,22 ,23).

Neurologic Involvement

The degree of neurologic involvement varies and is usually related to the amount of spine remaining. In most individuals, the level of motor function is usually within one level of the last normal-appearing vertebral body. Because the absence of the sacral vertebrae suggests absence of the corresponding sacral motor nerves, virtually all individuals with sacral agenesis above S2 (i.e., missing two or more sacral segments) will have a neurogenic bladder (24 ,57). Sensation tends to be spared more distally, and even high-level children tend to have at least protective sensation in their feet. Most also have at least some sensation in the perianal region. Pressure sores have been reported only rarely, and it is unclear whether these children had sacral agenesis alone or myelomeningocele as well (4). Pathologic fractures appear to be uncommon and are not mentioned in most reports.

In most cases of sacral agenesis, the neurologic level does not change. There have been occasional reports of children with sacral agenesis who developed progressive neurologic deficits that improved with surgical intervention. Tethered cord (11 ,37), lipomas (25), and dural sac stenosis (12) have been described. In most cases, the child presented with a progressive neurologic deficit. Several recent reports in the neurosurgical literature have suggested taking a more aggressive approach to asymptomatic anomalies. Muthukumar (34) reported improved urinary continence after tethered-cord releases in several patients with stable deficits.

Myelomeningocele is often associated with sacral agenesis. In these individuals, the neurologic deficits correspond to the level of involvement, with both motor and sensory loss. Spinal lipomas and tethering of the spinal cord have been noted in conjunction with myelomeningocele, and a child may occasionally present with a progressive neurologic deficit due to one of these conditions. Intelligence seems normal in individuals with sacral agenesis who do not have the hydrocephalus associated with myelomeningocele (10 ,42).

Imaging and Functional Studies

The pathognomonic finding on radiographs is the absence of part or all of the sacrum and possibly the lumbar spine. In more severe cases, the ilia tend to be rotated back almost parallel to each other in the coronal plane rather than forming the typical 90-degree angle. This is a result of the absence of the sacrum.
Imaging studies beyond plain radiography that are helpful in evaluating patients with sacral agenesis include myelography, computed tomography (CT), magnetic resonance imaging (MRI), ultrasonography, and intravenous pyelography. Both CT and MRI have been used to delineate the spinal cord pathology and to detect the occasional tethered spinal cord (5 ,9 ,25 ,38 ,55 .36). Ultrasonography has been used to detect anterior meningocele and presacral teratomata in individuals with the hereditary forms of sacral agenesis as well as to screen for renal and collecting system abnormalities.

Pathoanatomy

Observations on sacral agenesis have been based on autopsy studies, surgical dissections, and amputation specimens. The extremities tend to have muscle replaced with fibrofatty tissue with irregular nerve structures, similar to that seen in arthrogryposis (21 ,50). In severely involved individuals with popliteal webbing, the neurovascular bundle tends to take the shortest course and is often just below the skin at the apex of the webbing. This can hinder attempts at correcting the severe knee flexion contractures.

Examination of the spine at autopsy or during attempts at spinal-pelvic fusion has found irregular threads of nerves coming from the end of the vertebral column and extending down through the pelvis (21 ,82). In some cases, no distal extension of the spinal cord was found, even in patients who had distal sensation (41 ,58). The spinal cord and dural sac often terminate at the same level as the vertebral column (2 ,21 ,25 ,28 ,50 ,55 ,56 ,57).

Natural History

Most reported cases of sacral agenesis are in children. Reported causes of death in infancy have included cardiac anomalies (2 ,10) and other severe congenital anomalies. Deaths in childhood have been due to sepsis or renal failure (42). The highest known level of spinal agenesis in which the patient is known to have survived is at the T7 level (54). Information on adults with sacral agenesis is sparse, with no longitudinal studies (4 ,13 ,20 ,22 ,32 ,35 ,42 ,45 ,49 ,59).

Most higher level patients become wheelchair users as adults despite attempts at orthotic or prosthetic management of their lower extremity deformities. Virtually all the adults reported in the literature received no special treatment for their spinal-pelvic instability, and few had problems that could be attributed to spinal-pelvic instability. Many were dependent on others for assistance with activities of daily living. Urinary and fecal incontinence seems to become less of a problem for adults with sacral agenesis. Satisfactory sexual function is possible. The lack of education and society's indifference to the handicapped appear to have contributed to these individuals' dependent states.

Orthopedic Management

High-level sacral agenesis presents the orthopedic surgeon with two unique problems—spinal-pelvic instability and severe knee flexion contractures with popliteal webbing—whose solutions are often interrelated. Before planning a surgical procedure on a child for one of these two problems, one must plan for the other. Otherwise, the options for management may be unnecessarily restricted.

Spine

Several problems have been attributed to spinal-pelvic instability and have been offered as justification for attempts to fuse the shortened spine to the abnormal pelvis. Perry et al. (41) were the first to report in English on results of spinal-pelvic fusion in children with sacral agenesis. Their justification for performing spinal-pelvic fusion was threefold:

1. To free the upper extremities from the necessity of supporting an unstable collapsing back
2. To protect the viscera from unphysiologic compression and angulation
3. To establish a stable vertebral-pelvic complex about which lower-extremity contractures can be stretched or surgically released.

Few reports have been published on the technique and results of fusions for spinal-pelvic instability (33 ,41 ,52 ,58 ,46 ,17).

Winter (58) reported a case of T10 level agenesis that he successfully fused when the patient was 5 years 11 months old. He used Harrington compression rods in a claw configuration on the top and bottom of the pelvis linked to the upper thoracic spine (Fig. 4). Simultaneous knee disarticulation provided bone graft. When the patient was aged 10 years 6 months and 12 years 6 months, Winter osteotomized the fusion mass and lengthened it each time by an inch in an attempt to prevent crowding of the patient's internal organs.

Satisfactory results of spinal-pelvic fusion have been reported. No neurologic complications (e.g., loss of sensation) and few pseudarthroses have been reported, although several authors reported exploring the fusion mass in the first 6 months and adding more bone. Hand-free sitting and gastrointestinal function have been reported to be improved after surgery.

Although the reported attempts at spinal-pelvic fusion have generally been successful, a solid fusion may not solve all problems. Phillips et al. (42) reported an 18-year-old who was fused at age 5 but had daily back pain despite a solid fusion. Andrish et al. (3) noted that “multiple problems have been related to spinal-pelvic stabilization, primarily related to the hips. Several patients had minimal hip motion discovered postoperatively. In some, resection of the proximal femur was necessary to improve sitting balance, but made them non-ambulating.”

The three reasons advanced to justify spinal-pelvic fusion—to allow hand-free sitting, to prevent visceral compression, and to stretch hip flexion contractures—are at best relative indications. The natural history of untreated spinal-pelvic instability should also be considered.

Andrish et al. (3) noted that as patients get older, the degree of instability (i.e., the excessive motion of the spinal-pelvic junction) decreases. In another series (42), 17 of 19 patients with unfused spines (both children and adults) could sit with their hands free.

The risk of visceral compression due to spinal-pelvic instability is difficult to assess. Instances of documented problems are uncommon (19).

Given the risk of obstructive uropathy resulting from anomalous urinary tracts and an abnormally innervated bladder and sphincter mechanism, it may be difficult to determine the cause of an obstructive uropathy in patients with sacral agenesis. In reports of adults with sacral agenesis, problems with visceral compression have seldom been noted. Further investigation of this problem is needed. Adults with severe sacral agenesis tend to be barrel-chested, suggesting that they compensate for lack of trunk height by increased trunk width (42 ,49).

Stabilization of the spinal-pelvic junction may allow stretching of severe hip flexion contractures (41). The children with the most severe spinal-pelvic instability have the least functioning musculature in the lower extremities and will probably become wheelchair users as adults. The necessity of correcting hip flexion contractures in such patients has not been established.

Currently, spinal-pelvic fusion does not seem justified for asymptomatic spinal-pelvic instability. The risk of visceral compression remains largely unsubstantiated, and the functional benefits seem few. If spinal-pelvic fusion is to be performed, the technique of Dumont et al. (17) of segmental instrumentation with claws on the pelvis and spine is recommended. If amputation of the legs is not performed, large segments of allograft bone can be used to maintain a more normal trunk height, although the long-term results of this are unknown. A limited amount of autocraft can be obtained by harvesting the lower ribs. Use of allograft cortical bone would require prolonged postoperative immobilization to protect the graft during its slow incorporation. Regardless of the type of graft used, prolonged postoperative immobilization in the recumbent position is often necessary. Subsequent lengthening of the fusion mass to gain trunk height may be possible, but the impact on the child and family of repeated operations with prolonged recovery times should be carefully weighed against the potential benefits.

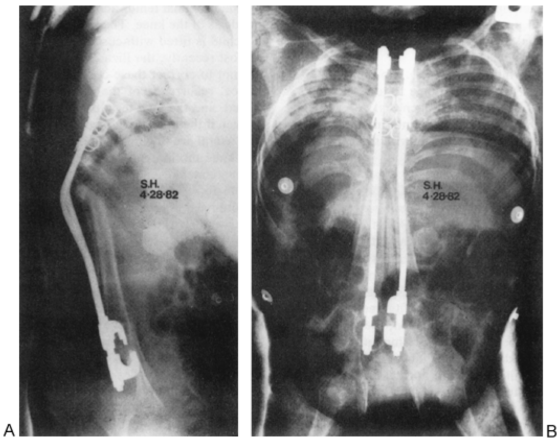

FIGURE 4. Postoperative radiographs of a child with T10 level lumbosacral agenesis who underwent posterior spinal pelvic stabilization using amputated tibiae for bone graft and large Harrington compression rods, sublaminar wires, and Harrington hooks for internal fixation. (From Winter RB (1991): Congenital absence of the lumbar spine and sacrum: one-stage reconstruction with subsequent two-stage spine lengthening. *J Pediatr Orthop* 11:666–670, with permission.)

Knees

To assist these children in standing with braces, attempts have been made to straighten knee flexion contractures, with mixed success.

Most recently, the Ilizarov device has been used to correct these contractures. Even with this device, the contractures can recur and the long-term outcome is unknown.

Even if the knee flexion contracture is straightened, how useful are the limbs? It is unclear how much passive knee motion can be obtained.

Faced with severe hip and knee flexion contractures in paralyzed limbs (frequently accompanied by foot deformities), some surgeons have elected amputation and prosthetic fitting for these children.

There is general agreement that the severe knee flexion contractures seen in some children with sacral agenesis can interfere not only with brace wear and standing but also with sitting and hand walking (14). Such severely affected children will probably not be functional ambulators as adults. The parents must be informed that the alternative to amputation is a *series* of procedures to maintain correction as the child grows. The aesthetics of preserving limbs of limited function should be weighed against the physical and emotional costs of repeated hospitalization and surgery. The “best” treatment may depend on the degree of deformity, the presence of other anomalies, the parents' concerns, and the medical resources available.

A combination of soft-tissue releases, supracondylar extension osteotomies, and serial casting will probably result in satisfactory correction of some knee contractures. Prolonged nighttime splinting is also needed (4). Recurrence with growth should be anticipated. If amputation is chosen, disarticulation at the knee is the recommended level of amputation. There is little need for subtrochanteric amputation as long as any hip flexion contracture is compensated for by increased motion at the spinal-pelvic junction. As the tibiae are a commonly used source of bone graft for spinal-pelvic fusion, arrangements to preserve the bones for later use should be considered.

Feet

The feet in children with sacral agenesis are often deformed. Clubfeet have been reported in up to 50% (22). Both equinovarus and calcaneocavus foot deformities have been reported.

The decision to correct foot deformities depends on what other lower-extremity anomalies are present and the ambulatory potential of the child. Conventional methods of managing paralytic foot deformities seem satisfactory. The presence of protective sensation makes both serial casting and orthotics less of a problem than in a similarly deformed child with myelomeningocele.

Hips

The decision to treat hip dislocation in sacral agenesis depends on the type of dislocation and the ambulatory potential of the child. Bilateral, paralytic hip dislocations in children with high-level sacral agenesis (Renshaw III and IV) probably do not need reduction. The occasional unilateral dislocation seen in lower level (Renshaw I and II) sacral agenesis can be managed much like a developmental dislocation in normal children. Richards's (48) caution about the Salter osteotomy and the potential for excessive motion at an abnormal sacroiliac joint should be kept in mind.

Other Problems

Occasionally, a child with sacral agenesis may present with a progressive neurologic deficit. In some but not all cases, the deficit has improved following surgical exploration and correction of an anatomical problem. Despite sporadic reports of neurologic improvement following surgical exploration of the spinal cord in sacral agenesis, routine exploration is probably not indicated. Most of these patients had developed symptoms of a progressive neurologic deficit, such as a limp, weakness, incontinence, or pain. Pang and Hoffman (37) recommended serial neurologic examinations with imaging of the spinal cord at the first sign of deterioration.

Summary

Orthopedic management of a child with sacral agenesis will never be routine. The clinical picture can vary tremendously. Although intervention will alter the child, will it allow him or her to be a more functional person? Given what is currently known about the natural history of untreated adults with sacral agenesis, it is important to set realistic goals for each child, allowing him or her to lead as normal a life as possible.

Congenital and Developmental Spinal Stenosis

Mark B. Kabins

M. B. Kabins: Department of Orthopedics, University of Nevada Medical Center, Las Vegas, Nevada 89106.

Stenosis is defined as “the narrowing or stricture of a passage, duct or opening” (90). The effects of stenosis on any inner contents are caused by compression by two or more directly opposed forces (47). The term *spinal stenosis* has been elegantly demonstrated by Verbiest (164) to be ambiguous in that it does not identify the location, nature, or cause of the process. For general purposes, this chapter uses the definition of spinal stenosis established by Arnoldi et al. (4): any type of narrowing of the spinal canal, nerve root canals, or intervertebral foramina.

Spinal stenosis may occur locally or segmentally, or it may be generalized. It may be caused by bone or soft tissue, and the narrowing may involve the bony canal, the dural sac, or both. Furthermore, spinal stenosis may be absolute or relative, static or dynamic. Verbiest (162,163,164,165,166,167) stated that those with absolute stenosis may be symptomatic in the absence of additional stimuli or compressive forces. In other words, there is no remaining reserve capacity, which implies a noninterfered, physiologic space between the thecal sac and the surrounding bone and soft tissue (172). With relative stenosis, the reserve capacity is so small that minor additional compressive forces, such as a herniated disc, spondylosis, or disc space narrowing, may produce symptomatic stenosis. In fact, it has been suggested that individuals with reduced functional spinal reserve capacities may be potential occupational hazards (171). Clinically significant stenosis does not always occur as a static phenomenon but frequently occurs as part of a dynamic process (80).

Congenital stenosis, which occurs as a result of a congenital malformation, constitutes only a small subset of patients with spinal stenosis. Sarpyener (133,134) was one of the first to recognize and describe this entity in the thoracolumbar spine. He identified a “congenital stricture of the spinal canal” in patients with spina bifida occulta, spastic diplegia, clubfeet, enuresis, and/or spastic or flaccid paralysis. He stated: “The narrowing of the bony canal compresses the cord, and, by the law of Delpech, prevents it from normal development.” Our understanding of congenital stenosis has grown since then, but it remains limited.

Developmental stenosis, as described by Verbiest (159,160,161,164,166), is caused by a growth disturbance of the bony walls of the vertebral canal during the pre- and postnatal periods. Vertebral stenosis in patients with achondroplasia is an example of developmental stenosis.

Classification and Definitions

In the past, the distinction between congenital and developmental stenosis was vague. In fact, some authors considered the terms to be synonymous. In 1976, Verbiest (164) limited the term *congenital stenosis* to cases of abnormally narrow spinal canals resulting from congenital malformation. Congenital stenosis of the thoracolumbar spine typically is identified in young children and infants, although it can be first identified in adults. It is often associated with spina bifida, failure of vertebral segmentation, congenital tumors in the lumbosacral region (most commonly, lipoma), diastematomyelia, gait abnormalities, enuresis, and developmental abnormalities of the hips, knees, and feet.

Developmental stenosis refers to a genetic disturbance of both fetal and postnatal development that usually continues until maturity. Periosteal apposition of bone that may occur after maturity is also included in the category of developmental stenosis.

Developmental stenosis may be idiopathic or part of a generalized growth disturbance, which is most frequently found in achondroplasia. *Idiopathic* implies that the cause of the condition is not known. Generalized growth disturbances typically occur as a result of an inherited chromosomal abnormality or a mutation.

Nightingale (99) has identified an association between cervical spine developmental canal stenosis and somatotype. Specifically, those with developmentally narrow cervical canals are more likely to have relatively shorter long-bones (particularly in the upper arms) and longer trunks.

Idiopathic developmental stenosis of the lumbar spine is typically identified later in life than congenital stenosis. Verbiest (164) reported that his youngest patient with idiopathic developmental stenosis was 22 years old, and that the average age at onset of symptoms was between 45 and 50 years. Associated musculoskeletal anomalies are rare, with the exception of coinciding idiopathic cervical stenosis.

Acquired spinal stenosis implies a process that occurs following birth that is caused by degenerative changes, trauma, or bone diseases or is iatrogenic in nature. Most cases of clinically significant stenosis that involve an acquired process likely have underlying idiopathic developmental stenosis. Verbiest (164,167,168) and Schatzker and Pennal (135) suggested that spondylotic, traumatic, and iatrogenic stenoses likely represent processes occurring within a developmentally ("relative") stenotic canal, and that acquired processes alone seldom lead to clinically significant stenosis.

Porter et al. (121,124), Heliovaara et al. (55), and others (41,128,173) demonstrated that patients who present with symptomatic herniated discs generally have significantly smaller than normal spinal canals. Porter et al. (121,124), Ramani (128), and Winston et al. (173) reported significant differences in the midsagittal diameters in this group of patients. Surgical failures of patients with herniated discs frequently occur because of the presence of underlying developmental stenosis that has not been recognized. These patients frequently require a more extensive decompression rather than a nucleotomy or disc excision alone.

Porter et al. (118,121) stated that the risk of developing disabling symptoms from disc protrusion is inversely related to the size of the spinal canal, and that prophylactic measures in childhood may ultimately reduce morbidity in adulthood.

Development of the Vertebral Canal

Vertebral bodies enlarge circumferentially through perichondral and periosteal apposition and grow vertically through endochondral ossification (103,104,109,174). The spine consists of anterior primary centers of ossification located within the vertebral body and posterior primary centers of ossification located within the posterior elements. The anterior ossification centers enlarge toward the posterior ossification centers, creating two obliquely oriented cartilaginous gaps, which are referred to as *neurocentral junctions.* Upon closure of the neurocentral junctions, canal expansion for the most part ceases. Thus, canal diameters tend to approximate adult size by 3 to 6 years of age, which is when the neurocentral junctions close.

Ogden (103,104) noted that some remodeling of the canal may occur later through the periosteum on the inner and outer surfaces of the posterior elements. Spinal stenosis may result from premature fusion of the synchondroses or from premature osseous fusion anteriorly or posteriorly. Disorders of endochondral ossification, such as that seen in achondroplasia and other forms of dwarfism, affect canal diameter and may ultimately lead to stenosis.

After studying 155 pediatric and 839 adult vertebrae, Porter (118) reported that individuals younger than 4 years had mean midsagittal diameters in the lumbar spine that were approximately 10% greater than those found in adults. This reduction in size with age is likely a reflection of the remodeling witnessed within the posterior portion of the vertebral body. The mean interpedicular diameter in pediatric vertebrae was reported to be approximately 85% of the adult size. This additional increase in interpedicular distance from early childhood to adulthood occurs through membranous bone formation with internal resorption and external deposition. Vertebrae located in the cephalad portion of the lumbar spine were found to mature earlier than the more caudal vertebrae. Radiographic studies (79,81) have independently shown similar findings: interpedicular diameters increase until puberty, and growth in the lower lumbar spine continues after cessation of growth in the upper lumbar spine.

The shape of the lumbar spinal canal has also been shown to change with age. Porter et al. (118,120,123) demonstrated that the anterior vertebral borders of the lumbar canal—in particular those of L4 and L5—were generally concave in infancy and convex in adulthood. When convexity of the vertebral body occurred with continued widening of the interpedicular distance, the canal was molded into a trefoil configuration. Eisenstein (31,32) identified 15% of negroid and caucasoid skeletons as being trefoil in shape at L5. None of these changes was seen before puberty. However, the canal at L2 was shown to become dome-shaped with maturity.

The association between smaller vertebral canals and impairment of health and certain intellectual abilities has been demonstrated (122). Individuals with smaller vertebral canals have been found by association to have more cardiovascular and gastrointestinal symptoms along with fewer post-school qualifications. This may arise, in part, from adverse environmental factors that affect several growing systems prior to the age of 4 years. The smaller canal can be considered a marker of a more generalized developmental disturbance.

Porter et al. (121) also demonstrated that the lumbar canal in women was larger than that of men in age-matched individuals in a South Yorkshire population. They speculated that a larger canal would be advantageous during pregnancy, when the spine is subjected to altered mechanical forces and increased ligamentous laxity. They also showed that the canals of women contained more extradural fat than those of men.

Interpedicular distance typically widens as one proceeds down the lumbar spine. An unusual relative increase in interpedicular distance at a particular level should be considered a warning sign and may reflect the presence of an underlying neoplasm, dural ectasia, or dysraphism (60,109). In the cervical or thoracic spine, an unusually enlarged area of the canal may occur as a result of syringomyelia, hydromyelia, or Arnold-Chiari malformation (62).

In utero, the spinal canal develops partially in response to the underlying spinal cord. The spinal cord spans the length of the spinal canal in neonates. During childhood, particularly during the adolescent growth spurt, the vertebral bodies and their accompanying discs elongate at a faster rate than the spinal cord (103). The cord ultimately terminates in adults at the T12–L1 level. Unlike the midsagittal diameter of the spinal canal, the midsagittal diameter of the spinal cord varies little among individuals (20,33,100), depending on sex (15) and age, and is not dependent on body habitus.

Radiographic Analysis

Determination of spinal canal size to identify stenosis can be accomplished through various imaging techniques.

Plain radiography is used most frequently to screen for spinal abnormalities and stenosis. Interpretation of plain films is highly dependent on the radiographic and measurement techniques.

Plain radiographic measurements are affected by gantry-to-patient distance, patient-to-grid distance, angulation, and patient position. Standardization of technique and knowledge of the technique used when interpreting such films are critical in maximizing the reliability and validity of measurements. In the cervical spine, the most commonly used focus-grid distance measures 183 cm (72 in.) (17,33,112,177); in the lumbar spine, the standard focus-grid distance measures 101.6 cm (40 in) (61,83).

When assessing for stenosis by plain radiography, it is important to first recognize the normal values (means and ranges) of various measurements. Many authors have studied and published their findings (Table 1) (53,54,57,60,61,62,88,96,138). This information is helpful as a reference when screening patients, but only when using radiographic measuring techniques and focus-grid distances identical to those used for comparison.

Many techniques for measuring canal size and determining the presence of stenosis through the use of lateral radiographs have been described. Kessler (72) believes that the lateral view of the cervical spine is the most critical for measurement and identification of stenosis. In the cervical spine, canal size is usually measured from the posterior aspect of the vertebral body at the midpoint between the superior and inferior end plates to the nearest point of the radiopaque line marking the inner aspect of the lamina directly under the spinous process (developmental segmental sagittal diameter) (28,29,62,88). The spondylotic segmental sagittal diameter is also directly measured from the lateral radiograph (Fig. 1A). The adult developmental sagittal canal diameter between C2 and C7, with a target distance of 183 cm, has been shown to average 17 ± 5 mm. Using the same target distance and measuring techniques, Epstein et al. (36,37) and Countee and Vijayanathan (17) reported severe spinal stenosis at less than 13 and 14 mm, respectively. According to Kessler (72), subaxial values under 14 mm were below the standard deviation for any cervical segment and were associated with myelopathy and neurapraxic symptoms. The cervical spinal cord is widest at the midcervical level (C4–C5), with a maximum sagittal diameter in the adult of 10 mm (10,20,130,177). Unfortunately, the spinal canal is narrowest at C4, followed by C5 (67).

TABLE 1. Sagittal Diameter of the Bony Cervical Spinal Canal in 120 Normal Children: Relation to Age

	3–6 years			7–10 years			11–14 years		
Age group Sex n	**Boys 20 Mean mm**	**Girls 20 Mean mm**	**Total 40 Mean/SD mm**	**Boys 20 Mean mm**	**Girls 20 Mean mm**	**Total 40 Mean/SD mm**	**Boys 20 Mean mm**	**Girls 20 Mean mm**	**Total 40 Mean/SD mm**
C1	20.2	19.6	19.9 ± 1.3	20.5	20.6	20.6 ± 1.3	21.2	21.4	21.3 ± 1.4
C2	18.2	17.6	17.9 ± 1.3	18.8	18.9	18.8 ± 1.0	19.3	19.5	19.4 ± 1.1
C3	16.3	15.8	16.0 ± 1.3	17.3	17.2	17.2 ± 1.0	17.8	17.7	17.8 ± 1.0
C4	16.0	15.6	15.8 ± 1.3	17.0	16.9	16.9 ± 0.9	17.3	17.2	17.3 ± 0.9
C5	15.9	15.5	15.7 ± 1.3	16.7	16.6	16.7 ± 0.9	17.1	16.9	17.0 ± 0.9
C6	15.8	15.3	15.6 ± 1.2	16.5	16.3	16.4 ± 0.9	16.8	16.6	16.7 ± 0.9
C7	15.6	15.0	15.3 ± 1.1	16.1	15.9	16.0 ± 0.9	16.3	16.2	16.2 ± 0.9

These data are based on studies of lateral radiographs of the cervical spine measured from the middle of the posterior surface of the vertebral body to the nearest point on the ventral line of the cortex seen at the junction of the spinous process and lamina. The radiographs were taken with patients standing erect and their necks in the neutral position. The focus-film distance was 150 cm (59.05 in.). (Data from Hensinger RN, ed. *Standards in pediatric orthopedics. Tables, charts, and graphs illustrating growth*. New York: Raven Press, 1986; and Markuske H, ed. Sagittal diameter measurement of the bony cervical spinal canal in children. *Pediatr Radiol* 1927;6:129–131.)

Pavlov's ratio (111,148,149,150) (Fig. 1B) compensates for variations in radiographic technique because the sagittal diameters of the canal and the vertebral body are similarly affected by magnification. Generally, this ratio is a more reliable indicator of cervical stenosis than absolute measurements made by plain lateral radiographs. There is normally a 1:1 relationship between the sagittal diameter of the spinal canal and that of the vertebral body. Using a cutoff ratio of 0.82, Pavlov et al. (111) showed that this method was more than 2.5 times more sensitive than direct measuring techniques and that the ratio method was a more specific indicator of spinal stenosis. A Pavlov ratio of 0.80 or less has been shown to have a high sensitivity (93%) for transient neurapraxia (151). However, the low positive predictive value of the ratio (0.2%) precludes its use as a screening mechanism for determining the suitability of an athlete for participation in contact sports.

Odor et al. (102) found contrast-enhanced computed tomography (CT) to be more accurate in the detection of cervical stenosis than the Pavlov ratio method. They evaluated 34 adult cervical spines (139 levels) from symptomatic patients using both methods. At all levels where the ratio method was less than or equal to 0.80, contrast-enhanced CT measured midsagittal diameters to be 10 mm or less. Although the ratio method proved highly specific, it demonstrated a 19% false-negative rate in detecting cervical spinal stenosis.

Using myelography, Nurick (101) and others have studied the measurements of intrathecal contrast in the cervical spine and have defined critical stenosis as a measurement equal to or less than 10 to 12 mm. Nakstad (97) reported that a quotient of less than 0.9 between the sagittal diameter of the spinal canal, as determined through myelography, and the midsagittal diameter of the vertebral body was indicative of stenosis in the cervical spine.

Plain lateral radiographs are not as helpful in the lumbar spine in the screening for stenosis (108). Myelography is the radiologist's gold standard in the diagnosis of spinal stenosis. Bolender et al. (9) reported better accuracy in the diagnosis of lumbar stenosis with myelography, in comparison to CT without intrathecal contrast. They reported that the dimensions of the canal derived from CT provided a correct diagnosis in 20% of patients, and myelography was accurate 83% of the time.

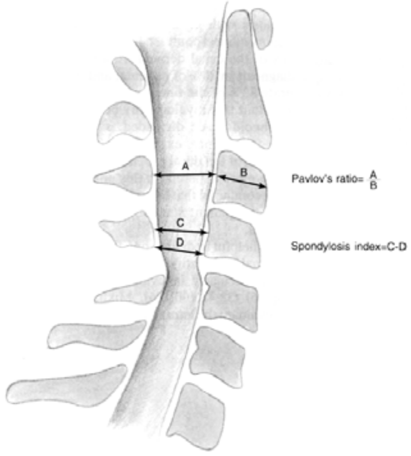

FIGURE 1. (a) The cervical developmental segmental sagittal diameter (DSSD) *C*, and the spondylotic segmental sagittal diameter (SSSD) *D*, are illustrated. Using standard lateral radiographic techniques and a focal-grid distance of 72 in., perpendicular lines are drawn to the posterior margin of the spinal canal at the level of the pedicular-vertebral body junction and at the level of the disc space. The difference between the two measurements is the spondylosis index and represents stenosis due to degenerative disease. (From Epstein JA, Carras R, Hyman RA (1979): Cervical myelopathy caused by developmental stenosis of the spinal canal. *J Neurosurg* 15:489–496;

Epstein JA, Carras R, Rerrar J, et al. (1982): Conjoined lumbosacral nerve roots. Management of herniated discs and lateral recess stenosis in patients with this anomaly. *J Neurosurg* 55:585–589.

Redrawn with permission.) **(b)** The ratio of the spinal canal *A*, to the vertebral body *B*, equals Pavlov's ratio. The vertebral body is measured from the midpoint of the anterior and posterior vertebral body, and the canal is measured from the midpoint of the posterior aspect of the vertebral body to the nearest point on the spinolaminar line. A ratio of less than 0.80 is indicative of stenosis. (From

Torg JS, Pavlov H, Warren R, et al. (1991): The relationship of cervical spinal canal narrowing (stenosis) to permanent neurological injury to the athlete: an epidemiological survey. *Proceedings of the sixth annual meeting of the Federation of Spine Association*.

Redrawn with permission.)

It is important that myelography be performed with the subarachnoid space distended, such as with the patient standing. Since extension of the spine decreases the size of the dural sac, milder degrees of stenosis may be more apparent in this position (142).

CT is most helpful in delineating the bony shape and size of the canal (24,33,82,166) (Fig. 2). Mikhael et al. (91) used CT to evaluate the lateral recesses in symptomatic and asymptomatic patients. They reported that normal lateral recesses decreased in size from L2 to S1. Symptomatic lateral recess stenosis occurred most often at the L5–S1 level. Lateral recess depth of 3 mm or less was likely to be associated with symptoms.

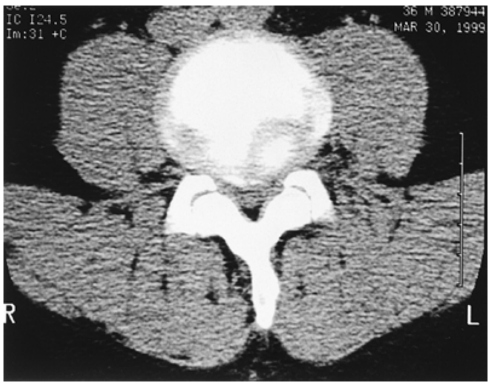

FIGURE 2. Axial lumbar CT scan of a symptomatic 36-year-old man with underlying developmental stenosis and small disc protrusion.

Magnetic resonance imaging (MRI) (52,132) is helpful in identifying thecal sac and nerve root impingement, cord abnormalities (e.g., hydromyelia, Arnold-Chiari malformation, syringomyelia, tethered cord), degenerative changes, and disc herniations, but it does not demonstrate the surrounding bony structures as well as CT does.

Ultrasonography is a noninvasive, safe, and relatively inexpensive and accurate way for evaluating canal dimensions (34). Intraoperative sonography can be valuable in assessing the degree of neural compression in up to 90% of patients. (112) Intraoperative sonography may be used to diagnose calcified posterior longitudinal ligaments, spinal cord atrophy, myelomalacia, herniated discs, and osteophytes at all levels in the spine.

Congenital and Developmental Stenosis by Location and Type

Cervicomedullary Junction and Rostral Cervical Spine

Brain stem and upper cord stenosis can occur as a result of congenital abnormalities. This may occur due to static forces, such as basilar impression, narrowing of the foramen magnum, elevation of the dens, shortening of the clivus, invagination of the occipital condyles, and elevation of the petrous pyramids, or dynamic forces, such as instability associated with os odontoideum and absence of the dens. Developmental atlantoaxial instability may also be found in patients with Down syndrome, spinal epiphyseal dysplasia, Larson syndrome, Morquio syndrome, osteogenesis imperfecta, and neurofibromatosis.

Congenital basilar impression occurs as a result of the failure of formation (or fusion) of the occipital somites. It is often associated with other vertebral defects, including unilateral or bilateral atlantooccipital fusion (181), hypoplasia of the atlas, bifid posterior arch of the atlas, odontoid abnormalities, and Klippel-Feil syndrome (58). Occipital hypoplasia is frequently associated with other congenital malformations of the base of the skull, cervical spine, and brain stem. Narrowing of the foramen magnum is also associated with the presence of accessory occipital vertebrae, which have been found to occur unilaterally and bilaterally.

Bony anomalies of the cervicomedullary junction are not necessarily associated with anomalies of the nervous system. However, Arnold-Chiari malformation, syringomyelia, and hydromyelia are often associated with these bony anomalies (181).

Developmental stenosis of the foramen magnum has been shown to occur in patients with achondroplasia. The foramen magnum is narrowed through hypertrophy of its bony rim. This is frequently accompanied by hypoplasia of the clivus and basilar impression and occasionally by stenosis of the remaining cervical spine. Together these findings produce kinking at the junction of the brain stem and the cord. Although patients with achondroplasia and thoracolumbar stenosis typically present in adulthood, those with significant stenosis of the foramen magnum usually present in infancy. Yamada et al. (179) reported respiratory insufficiency, quadriparesis, and a high rate of mortality in patients with achondroplasia and stenosis of the foramen magnum. Patients typically respond to foramen magnum decompression.

Hypoplasia of the completed posterior arch of C1 (114) has been identified in Asians. It creates congenital stenosis that becomes increasingly symptomatic with age and advancement of degenerative disease. Effective surgical intervention consists of removal of the shortened posterior C1 arch and surrounding degenerative ligaments.

Prakash et al. (126) first identified localized spinal stenosis as a cause of myelopathy due to developmental hypertrophy of the posterior neural arch of C2. The cause was likely premature fusion of the posterior cartilaginous neurocentral synchondrosis. Decompression with laminectomy alleviated symptoms.

Congenital malformations of the dens may also lead to stenosis (140). Duplication of the dens occurs secondary to an abnormality in segmentation and frequently presents with torticollis. Condylicus tertius syndrome may be diagnosed when a large abnormal dens is found to articulate with the third occipital condyle on the anterior rim of the foramen magnum. Cord compression occurs at the level of the narrowed foramen magnum.

Idiopathic Developmental Cervical Stenosis

Heightened awareness of idiopathic developmental cervical stenosis, particularly among adolescents and young adults, arose in the mid-1980s following the historic publications of Torg et al. (152) and Ladd and Scranton (78), in which they described the presence of neurapraxia of the spinal cord with transient quadriplegia in football players with developmental cervical stenosis.

Prior to this, Payne and Spillane (112) reported the association of myelopathy in patients with developmental cervical stenosis and recognized that spondylosis and degenerative disc disease were confounding factors. Symptomatic idiopathic stenosis was recognized to occur primarily in older boys. In 1970, Moiel et al. (92) reported a case of an 18-year-old individual with developmental stenosis (without spondylosis) who developed a central cord syndrome following a hyperextension injury. Grant and Puffer (49) subsequently reported a case of quadriparesis in an 18-year-old with developmental stenosis. This patient's canal reportedly measured 13 mm from C4 to C6. In 1979, Countee and Vijayanathan (17) described an association between quadriplegia following traumatic events and underlying idiopathic developmental stenosis. This was found to occur primarily in black males with cervical canal diameters of 14 mm or less. The association of developmental cervical stenosis with an increased risk of spinal cord injury was also reported by Epstein et al. (42) in 1980 and Eismont et al. (33) in 1984.

In a retrospective review, Epstein et al. (42) reported 23 patients with cervical spinal stenosis and traumatic myelopathy without evidence of fracture or dislocation. Plain radiographs and myelography demonstrated 7 patients to have “absolute” developmental stenosis without evidence of degenerative changes. The remaining 16 patients had degenerative changes along with “relative” stenosis. Absolute stenosis was defined as a canal diameter of less than 10 mm, measured on lateral films from the posterior aspect of the vertebral body to the posterior laminar line. Relative stenosis measured less than 13 mm, using the prominent vertebral osteophytes as the anterior landmark. Patients with narrower canals presented with more severe myelopathies. When stenosis is severe, any additional pressure, swelling, and/or edema from trauma may cause neurologic catastrophe (46). The neurologic level of injury most frequently occurs between C4 and C6.

Eismont et al. (33) examined 98 patients with fracture dislocations of the cervical spine. Forty-five patients demonstrated no neurologic deficit, 39 had incomplete quadriplegia, and 14 had complete quadriplegia. The greatest percentage of neurologic deficits occurred between C4 and C6. Patients with small sagittal diameters, as evaluated by plain lateral radiographs, were significantly more likely to have neurologic deficits (Fig. 3); patients with larger canals were more likely to be spared neurologic injury. This finding was not surprising because the midsagittal diameter of the canal varies between individuals (15,33,112,177), unlike that of the spinal cord, which does not vary significantly (20,100).

Later, Torg et al. (152) and Ladd and Scranton (78) described 19 (17 and 2, respectively) patients with developmental cervical stenosis who sustained spinal cord neurapraxia and transient quadriplegia. Torg also reported similar presentations in patients with failure of segmentation of the cervical spine, diffuse idiopathic skeletal hyperostosis, instability, and intervertebral disc disease. They theorized that spinal cord neurapraxia occurred because of narrowing of the anteroposterior diameter of the spinal canal with or without concomitant degenerative changes, herniated discs, posttraumatic instability, or congenital anomalies. All but three of the patients sustained their injuries while playing football. All patients were male and ranged in age from

15 to 32 years. The mechanism of injury was thought to be hyperextension in eight cases, hyperflexion in six cases, and axial loading in five cases.

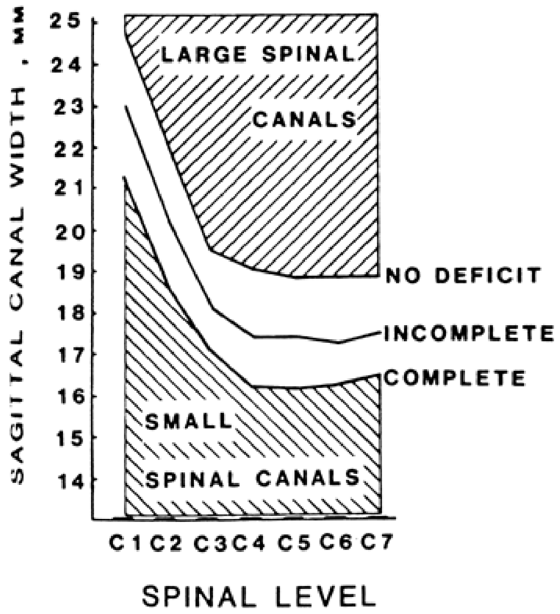

FIGURE 3. Ninety-eight patients suffered cervical spine fracture-dislocations. The area labeled "large spinal canals" represents patients with midsagittal canal diameters larger than the mean and without neurologic injury. The area labeled "small cervical canals" represents patients with midsagittal diameters less than the mean and with complete neurologic deficit. (From Eismont FJ, Clifford S, Goldberg M, et al. (1984): Cervical sagittal canal size in spine injury. *Spine* 9:663–666, with permission.)

It has been shown that patients with cervical stenosis are particularly at risk during hyperextension (113,152). Hyperextension leads to infolding and thickening of the ligamentum flavum and posterior longitudinal ligament, resulting in further canal compromise (1,14,147). Hyperextension in addition to hyperflexion may lead to further canal compromise by as a result of "pinching" of the cord between the vertebral body and the lamina of the adjacent level. Penning (113) demonstrated this through measurement of plain lateral radiographs in varying degrees of flexion and extension. He described the "pincer mechanism," whereby the cord is pinched between the inferior portion of the superior vertebral body and the closest point on the spinolaminar line of the inferior vertebra in hyperextension, and between the superior portion of the inferior vertebral body and the closest point on the spinolaminar line of the superior vertebra in hyperflexion. He stated that pinching was dependent on underlying (developmental) stenosis, the extent of flexion and extension, and the size of underlying degenerative osteophytes. Sagittal diameters of less than 11 mm in extreme ranges of motion represented an increased risk for spinal cord compression. The cord in the spondylitic spine has also been shown to move in the rostral and caudal direction by as much as 3 mm at the C7 level during flexion and extension, thus angulating the nerve roots at their foramina (14).

Patients with neurapraxia of the spinal cord can experience burning pain, paresthesias, numbness, anesthesia, motor weakness, or even complete quadriplegia (78,148,152). Symptoms may be present in the upper extremities, lower extremities, or all four extremities. Except for burning paresthesias, pain in the neck is not usually present at the time of injury. These episodes are temporary, and recovery usually occurs in 10 to 15 minutes; sometimes there may be gradual resolution of symptoms over 36 to 48 hours. Motor function returns completely, and full, pain-free motion of the cervical spine usually ensues. Motor and sensory function at times returns in a cephalad to caudad direction. Routine radiographs usually show no evidence of fracture or dislocation.

The incidence of transient paresthesias in all four extremities with quadriplegia has been reported to be 1.3 per 10,000 athletes in a survey of 503 schools (39–377 participants) in the National Collegiate Athletic Association. Six per 10,000 reported transient paresthesias in all four extremities (152).

Because of anthropomorphic differences, asymptomatic football players demonstrate somewhat smaller Pavlov ratios, and players who experience cervical cord neurapraxia demonstrate significantly ($P < .001$) smaller Pavlov ratios than their asymptomatic controls (153).

Individuals with cervical canal narrowing, defined as a Pavlov ratio of less than 0.8, are no more susceptible to permanent neurologic injury than individuals in the general population and should not be precluded from participating in contact sports if symptoms of spinal cord neurapraxia are absent (152). According to Torg et al. (148,149,150), even neurapraxia of the spinal cord does not predispose individuals to permanent neurologic injury, and patients with developmental stenosis or failure of segmentation should be managed on an individual basis. None of the original 17 patients with transient quadriplegia and developmental stenosis later developed permanent neurologic injury. Nine abandoned football after one episode; three resumed playing temporarily and later gave it up after experiencing a second episode. One patient returned to football and, despite a second episode, went on to play for 3 years without additional difficulties; three returned without any problems at 2 years follow-up. A professional boxer received a laminectomy following two episodes of transient quadriplegia and continued to box without problems at 5 years follow-up.

One hundred seventeen football players with permanent quadriplegia were studied separately to determine the occurrence of antecedent cord symptoms (153). None had experienced a previous motor event, and only one had experienced a previous sensory event before the catastrophic injury.

Torg et al. (150) recently reviewed 110 cases of transient cervical cord neurapraxia. They concluded that in uncomplicated cases, patients may return to their previous activities without increased risk of permanent neurologic injury; congenital or developmental narrowing of the sagittal diameter was a causative factor; the recurrence rate after return to play was 56%; and the risk of recurrence was strongly and inversely correlated with sagittal canal diameter and was predictive of future episodes of cervical cord neurapraxia.

Torg et al. (148,152,149,154) specifically recommend that patients with developmental stenosis and concomitant instability, intervertebral disc disease with cord compression, MRI evidence of cord defect or swelling, symptoms of positive neurologic findings lasting more than 36 hours, more than one recurrence, and/or acute or chronic degenerative changes not be allowed to participate in contact sports. He later described a clinical entity called the “spear tacklers spine” (155). This constituted an absolute contraindication to participation in football. These individuals had developmental cervical stenosis, persistent straightening or curve reversal of the cervical spine, preexisting posttraumatic radiographic abnormalities, and employment of the spear tackler's technique.

In contrast, Ladd and Scranton (78) believe that a potentially dangerous situation may arise if any individual with developmental cervical stenosis is permitted to participate in contact sports. They found that stenosis was present in a large percentage of athletes with neck injuries that resulted in permanent neurologic deficit, including quadriplegia and death (personal communication).

Edwards and LaRocca (28,29) demonstrated that clinical symptoms in patients with degenerative spondylosis of the cervical spine were related to the underlying (developmental) size of the canal. They measured the cervical developmental sagittal diameter and the spondylotic segmental sagittal diameter from C4 to C7 in 63 symptomatic patients and calculated the spondylosis index (Fig. 1A). Patients were labeled as having narrow (C5 < 17 mm) or wide (C5 ≥ 17 mm) cervical canals. Symptomatic patients with narrow canals had a spondylosis index averaging 2.08 mm per segment, and those with wide canals had a spondylosis index averaging 3.29 mm. Myelopathic patients presented with average midcervical (developmental) canal diameters of 11.7 mm per segment, with 2.43 mm of additional degenerative (spondylosis index) narrowing per segment. Premyelopathic patients had developmental midcervical canal diameters from 10 to 13 mm, with a spondylosis index of 2 to 4 mm. Patients with canals measuring 13 to 17 mm were reported to be less likely to present with myelopathy but may be prone to symptomatic cervical spondylosis. Patients with canal (developmental) diameters greater than 17 mm were believed to be less likely to develop symptomatic cervical spondylosis. They concluded that larger midcervical (developmental) diameters may enable a patient to better tolerate degenerative disease with fewer or no symptoms.

Ogino et al. (105) studied spinal cord destruction in nine cadaveric specimens with cervical spondylotic myelopathy. The degree of spinal cord destruction correlated well with the ratio of anteroposterior diameter to transverse diameter. Of the factors responsible for a decrease in the ratio, developmental narrowing of the spinal canal was the most significant; multiplicity of spondylotic protrusion was less so. Developmental narrowing resulted in extensive demyelination of the posterolateral funiculus and infarction of the gray matter. Recurrent trauma also caused distinct manifestations and cord pathology.

Combined Developmental Cervicolumbar Stenosis

Combined cervical and lumbar developmental stenosis (without spondylosis or disc injury) has been reported (156) in young, symptomatic patients. Clinical manifestations include back pain, intermittent claudication, polyradiculopathy, and myelopathy. The additive effects of irritation to both the spinothalamic tract at the cervical level and the nerve roots at the lumbar level probably lead to the early onset of symptoms. Cervical cord compression alone has been reported to cause symptoms in the lumbar region (18,43). Surgical decompression for symptomatic combined cervical and lumbar stenosis can be performed under a single anesthetic (156) or staged.

Klippel-Feil Syndrome

Although most patients with Klippel-Feil syndrome have normal or enlarged canals, several authors have described patients with Klippel-Feil syndrome and congenitally narrow canals (35,37,42,112,116,127,132) (Fig. 4). Patients with congenital cervical fusions are also at increased risk of developing spondylosis and hypermobility at adjacent segments (50,58,115,127,132). These conditions alone or in combination may lead to the development of radiculopathy, myelopathy, or sudden quadriplegia.

Patients may not reveal their symptoms until directly questioned (50,132). They may experience episodic weakness, paresthesias, pain in the upper or lower extremities, or bowel or bladder dysfunction. Case reports of sudden quadriplegia after minor trauma have also been described. For example, Strax and Baran

(146) described a 13-year-old boy with Klippel-Feil syndrome who fell out of bed attempting to silence an alarm clock and became quadriplegic. A male with Klippel-Feil syndrome who became quadriplegic following a whiplash injury in an automobile accident was also described. Elster (35) described a patient with Klippel-Feil syndrome who became quadriplegic following a fall onto the back of his head. The coexistence of congenital stenosis with hypermobility (instability) in patients with Klippel-Feil syndrome is potentially hazardous and may predispose them to quadriplegia following minor trauma (127).

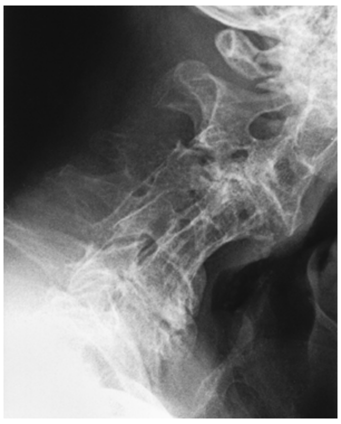

FIGURE 4. Lateral cervical spine radiograph of a middle-aged man with Klippel-Feil syndrome. The second cervical vertebra is dysplastic and C3–C4–C5 are nonsegmented. Note the instability at the C2–3 level and the spondylosis adjacent to the fused segments. This patient presented with radiculopathy and myelopathy due to underlying congenital and developmental stenosis.

Congenital stenosis may occur at one or more segments. It may occur at, above, or, more typically, below the level of the congenital fusion (132). Patients may have "absolute" (midsagittal diameter ≤ 10 mm) or "relative" (midsagittal diameter between 10 and 13 mm) stenosis (42,127). The unlikely coexistence of spinal cord neoplasms [e.g., multiple intradural meningiomas (65)] should also be considered when evaluating symptomatic patients with Klippel-Feil syndrome.

Pizzutillo et al. (116) examined lateral cervical spine radiographs of 81 patients between 3 and 14 years of age with Klippel-Feil syndrome. Sagittal diameters were measured and compared with both control groups and previously published norms. Significant narrowing was detected at unfused levels, which included C1, C3, and C4.

Prusick et al. (127) described a 23-year-old patient with Klippel-Feil syndrome and failure of segmentation at C2–C3. This patient demonstrated an elliptically shaped and eccentrically positioned stenotic canal from C3 to the upper thoracic spine on myelography and CT. Following laminoplasty from C4 to C7, the patient's neck and back pain improved, and her radiculopathy resolved.

Dynamic MRI studies in flexion and extension may also be helpful in delineating the site of pathology and identifying the mechanism by which neurologic compression occurs. Ritterbusch et al. (132) examined 20 pediatric Klippel-Feil patients ranging in age from 3 to 20 using MRI. They identified five (25%) with instability and five (25%) with stenosis (canal diameter of 9 mm or less below C1). Three (12%) cord abnormalities were identified, including hydromyelia with Arnold-Chiari malformation in one and diplomyelia in two.

The above reports clearly document that stenosis occurs in pediatric patients with Klippel-Feil syndrome. Previous notions that the diameters of the spinal canal were normal, and that stenosis and subluxation were events of adult life secondary to degenerative changes and hypermobility, are incorrect (35).

It is the author's opinion that patients with Klippel-Feil syndrome should be screened for underlying stenosis and instability through plain radiographic examinations that include lateral flexion and extension views. Disastrous complications can occur if these findings go unrecognized. Patients with congenital scoliosis and kyphosis are at increased risk (25%) of having associated segmentation defects of the cervical spine (58,115,174). They should also be screened with lateral radiographs of the cervical spine.

Segmental Spinal Dysgenesis

Segmental spinal dysgenesis is a localized congenital defect in which severe stenosis occurs with malalignment and focal agenesis or dysgenesis in the thoracolumbar or lumbar spine (139,175,176). Patients may be neurologically intact or they may have complete paraplegia. Generally, neurologic deficits occur at the cord or root level and are usually present at birth. Patients may have congenital absence of roots or segments of the spinal cord. However, patients with associated instability due to progressive kyphosis and/or scoliosis can develop additional neurologic deficits in childhood and adulthood. Lower limb deformities, such as congenital talipes equinovarus, occasionally accompany this syndrome. The canal above and below the involved segment is usually normal. The sacrum is also well formed, differentiating this syndrome from sacral agenesis. Additional congenital deformities, including heart disease, may be present.

Several authors have described patients with this syndrome using various names, including "congenital stricture of the spinal canal" (133,134), "congenital kyphosis" (26,94), "congenital kyphosis and subluxation" (84), and "congenital duplication of the spinal canal" (89).

Sarpyener (133,134) was one of the first to describe patients with this syndrome. Strictures occurred with and without concomitant spina bifida. He classified patients in four categories. The first group consisted of patients with "ring constriction" of the cord at one or more levels. These patients typically had neurogenic bladders (enuresis). Laminectomy readily improved symptoms within a few hours after surgery. The second group consisted of patients with more extensive regional strictures, which were usually associated with spastic paralysis. The third group consisted of those with localized strictures causing paralysis of certain groups of muscles. This was associated with and thought to be responsible for clubfoot formation. The fourth group consisted of atypical cases with clefts in the cord and occasionally in the dura.

Initially, Winter et al. (175) referred to this syndrome as "congenital spinal stenosis," because nine patients presented with focal narrowing of the spinal canal in both the sagittal and frontal diameters. This localized area of canal stenosis occurred at the lower thoracic and upper lumbar spine. It was commonly, but not always, part of a congenital scoliosis or kyphosis. Congenital absence of one or more vertebral segments was typical. They reported that CT scans and myelography were helpful in diagnosis.

In 1988, Scott et al. (139) named this entity "segmental spinal dysgenesis." They described three children with this syndrome, all of whom demonstrated failure of formation, spinal dysraphism, and spinal cord tethering. In neonatal cases, ultrasonography was extremely helpful in demonstrating the absence of the dorsal bony elements, the anatomy of the thecal sac at and adjacent to the area of maximal involvement, and the presence of a low-lying conus.

Winter et al. (175) later described 20 additional patients with this syndrome. Localized spinal stenosis was a universal finding, thus explaining their original name for this syndrome. The stenotic area typically extended three vertebral segments but could be as long as six. Patients presented from birth to 19 years of age, with the majority between 1 and 4 years old. Most deformities were at the thoracolumbar junction, but two patients had deformities in the upper thoracic spine, and one had a deformity that extended as far caudad as L4. Kyphosis at the level of stenosis was seen in 12 patients (60%) and ranged from 10 degrees to 87 degrees. Five (25%) had concomitant sagittal plane subluxation, and three (15%) had frontal plane subluxation. Scoliosis ranging from 10 degrees to 71 degrees was identified in eight patients (40%). Three patients were reported to have ribs at the level of the lesion that crossed in front of the vertebral bodies from one hemithorax to the other. The neurologic status was normal in four patients, neurogenic bladders were present in two, and the remainder had varying degrees of motor weakness. The spinal cord itself was usually much smaller than normal, especially in those with neurologic deficits.

The cause of this process is unknown. No genetic explanations, history of exposure to toxic agents, or maternal illnesses (such as diabetes) have been identified. Scott et al. (139) stated that the cause of these anomalies appears to be "embryological segmental maldevelopment."

Surgical decompression may be helpful in patients with partially functioning nerve roots and spinal cords. According to Scott et al. (139), surgical decompression may be indicated in children when neurologic function is preserved below the level of the anomaly and when significant compression of the spinal cord can be demonstrated by myelography. However, stability would be further compromised with decompression alone, and fusion and bracing would also be required.

Clearly, patient management must be individualized. Fusion should be performed whenever conservative measures, such as bracing, fail to prevent progression of instability at the dysgenic site. Progressive neurologic deficit caused by tethering of the spinal cord or instability requires immediate attention. An appropriately performed release, decompression, and/or combined anterior and posterior fusion is advised.

Winter et al. (176) reported that they could not bring about improvement in children born with neurologic deficit by decompression of the canal. They were, however, able to reverse worsening paraparesis in an adolescent with progressive spinal deformity through a posterolateral spinal cord transposition as well as an anterior and posterior spinal fusion.

Other Forms of Congenital Stenosis of the Lumbar Spine

Congenital stenosis of the lumbar spine without accompanying malformations is rare (19). Symptoms may present at any time. Verbiest (164,165) described four patients whose first symptoms appeared between ages 45 and 50. Two patients had block vertebrae (failure of segmentation) with hypoplastic articulations, and the remainder had occult dysraphism with upward-directed lamina, paramedial clefts, and narrowed interpedicular diameters.

Verbiest (168) also described an unusual form of congenital intermittent stenosis in which the S1 lamina is absent and the posterior spinous process of L5 is enlarged, hooked downward, and possibly connected to a rudimentary spinous process of S1. Patients were symptomatic in the upright standing position as lordosis increased and the spinous process of L5 and the rudimentary process of S1 compressed the canal through the sacral cleft at S1. Symptoms were relieved with flexion of the lumbar spine. Symptoms resolved following resection of the spinous process.

Borkow and Kleiger (11) reported a case of spondylolisthesis at the L4–L5 level in a newborn. This patient likely had congenital stenosis, as the vertebral body and canal at L5 were smaller than the vertebrae cephalad to L4. This neurologically intact patient developed a lumbar kyphotic deformity. Fusion was performed posteriorly from L3 to S1, and the patient did well postoperatively without a decompression.

Conjoined nerve roots have been reported to occur in 1% to 2% of the population (38). These patients are predisposed to symptoms of stenosis and suffer a greater risk of becoming symptomatic due to small disc protrusions, subarticular narrowing, and disc space narrowing (38,56).

Idiopathic Developmental Lumbar Stenosis

Developmental stenosis is usually uniform and involves the entire lumbar spine. However, it also may be isolated, involving the L2–L3 or L4–L5 segments (12), or it may be associated with developmental stenosis of the cervical spine (29,43). The sagittal canal diameter is frequently narrowed, yet the interpedicular diameter is usually not significantly affected (12,22,31,32,119,123,135,161,163,166,167).

Verbiest (168) reported similarities between patients with idiopathic developmental stenosis and those with stenosis associated with achondroplasia, in that scalloping (posterior lipping) of the vertebral bodies occurs above the L4 level, disc herniations are common, and hypertrophy of the vertebral arches can occur. Hypertrophy is usually limited to the posterior bony column of the spine (163,166). Prior to the onset of degenerative changes, the ligamentum flavum does not typically increase in thickness or hypertrophy (161). The laminae may be enlarged, which results in a decrease of the interlaminar space. In fact, the laminae may become so large that they begin to overlap. Bowen et al. (12) termed this "shingling of the laminae." This usually occurs at L4–L5 and/or L5–S1 and can also be seen with spondylolisthesis. The facets are also frequently hypertrophied. Verbiest (163,166) showed that the medial borders of the inferior articular processes may extend close to midline and can encroach upon the canal.

Porter and Pavitt (123) reported that stenosis resulted not only from narrowing of the midsagittal diameter but also from the trefoiled shape of the canal seen in individuals following puberty. This was most prominent at L5, but it also occurred at L4. They reported that trefoiling was associated with smaller midsagittal diameters. With continued interpedicular growth, the canal was hypothesized to become trefoiled in shape.

Verbiest (168) used a stenosimeter to examine 195 patients with developmental stenosis. Intraoperative measurements demonstrated that midsagittal diameters of 10 mm or less appeared to produce symptomatic stenosis. He defined "absolute," "relative," and "mixed" stenosis through measurement of the midsagittal diameter (162). Absolute stenosis was defined as a midsagittal diameter of 10 mm or less. Midsagittal diameters between 10 and 13 mm were termed relative stenosis. Mixed stenosis represented patients with midsagittal diameters less than or equal to 10 mm in some locations and between 10 and 13 mm in other locations. Most patients had absolute stenosis (42%), as compared with mixed (30%) or relative (28%) stenosis.

Overall, men present more often than women with signs, symptoms, and radiographic features of developmental stenosis (110,121,160,161,168). Newman (98) reported that the normal spinal canal varied in volume at different levels and according to sex. It was characteristic for males to have narrow canals at the L3–L4 and L4–L5 levels, whereas females had narrow canals at the lumbosacral level. He related this narrowing at the midlumbar region in males with the greater incidence and prevalence of developmental stenosis in men.

Verbiest (162,168) reported that in absolute and mixed stenoses, males were afflicted more frequently than females. However, females and males had an equal incidence of relative stenosis. This substantiated Verbiest's belief that relative stenosis was a variant of an otherwise normal vertebral canal and did not represent a pathologic condition.

Patients with absolute stenosis were generally symptomatic due to compression of the cauda equina and/or nerve roots. Patients with relative stenosis alone were not symptomatic but were predisposed to developing symptoms later in life due to trauma, disc pathology, and/or osteophyte formation.

The cause of developmental lumbar stenosis is unknown. Familial cases have been described in the literature (125,158,162), lending credence to the notion that the dimensions of the canal may be regulated by genetic factors. In further support of genetic regulation, Eisenstein (31,32) showed that the shape of the vertebral canal is markedly consistent across race and sex. The trefoil configuration of the canal, which almost invariably occurs at the L5 level, was considered by Eisenstein to be a variation of normal anatomy. The low average age (46 years) and the low incidence of associated degenerative changes support a developmental etiologic process over a degenerative process. Eisenstein also showed that the negroid canal was marginally smaller than the caucasoid canal in skeletons of both sexes. However, caucasoids predominated in symptoms, which was theorized to be due to “soft-tissue structures bordering the canal.”

Eisenstein (32) reported that developmental lumbar stenosis was found in 27 of 433 (6.3%) adult negroid and caucasoid skeletons—4.3% in the midsagittal plane and 2% in the frontal (interpedicular) plane. He stated that this incidence of stenosis was high for any population and that a large number of these patients were “very slightly subnormal.” The shortest midsagittal diameter was 11 mm; he had defined the low limit of normal to be 13 mm. The narrowest interpedicular distance was reported to be 16 mm; his low-normal limit was 18 mm. Eisenstein reported that bony degenerative changes were more likely to cause neurologic compression in the nerve root tunnel than in the spinal canal.

Adverse environmental factors in the first years of life have also been shown to be associated with developmental stenosis. Porter and Pavitt (121) theorized that a narrow canal in an adult may be a marker of impaired development in early life. Narrowing of the midsagittal diameter—the primary marker of developmental stenosis—was believed to be highly influenced by the environment, both prenatally and postnatally (first 4 years of life). They examined the lumbar canals in adult spines from two archaeological populations and demonstrated an association between small midsagittal diameters, small interpedicular diameters, and trefoiling of the canal at L4 and L5 and physiologic indicators of stress (cribra orbitalia, porotic hyperostosis, dental hypoplasia, Harris lines).

Porter et al. (119) retrospectively and prospectively demonstrated a crude association between canal size, as measured ultrasonographically, and health and academic status during childhood. Patients with smaller canals tended to have a greater incidence ($P < .1$) of childhood illnesses and infections.

Clark et al. (16) presented evidence to suggest that infant malnutrition may be related to developmental vertebral stenosis. Lumbar and thoracic vertebrae were measured from a prehistoric Native American population. Over time (950 to 1300 AD), their diet reportedly changed from a hunting-gathering, protein-rich diet to a maize agriculture, protein-deficient diet. Multivariate analysis was used to control for age, sex, and culture. Canal size was shown to be significantly smaller in the population that consumed the protein-deficient diet. The sagittal diameters and the lumbar segments were shown to be more affected by growth disruption than the frontal (interpedicular) diameters and the thoracic segments, respectively. Canal size was shown to be independent of stature and was ultimately determined to be the most powerful index for the assessment of infant malnutrition. Platt and Stewart's (117) laboratory findings in neonatal pig malnutrition substantiate these findings. They found that the vertebral canal was approximately 20% smaller in malnourished pigs than in their well-fed littermates.

Patients with developmental stenosis may be continuously or intermittently symptomatic (110). Bowen et al. (12) stated that patients with developmental stenosis usually become symptomatic when their condition is complicated by a herniated nucleus pulposus, degenerative stenosis, or both. Young adults usually present because of a herniation in the lower lumbar spine. Patients aged 30 through 50 years frequently relate a history of many years of low back pain, often following a traumatic episode. These patients present with low back pain and pain in one or both legs. Symptoms in this age group are produced by mild to moderate degenerative changes and/or disc herniations superimposed on an already developmentally stenotic canal. Older individuals between 40 and 70 present with a clinical picture of degenerative stenosis.

Achondroplasia

Spinal deformities are most common among those with achondroplastic dwarfism. Stenosis arises from two processes: kyphosis at the thoracolumbar junction and concentric narrowing of the vertebral canal (5,23,24,27,40,168). Thoracolumbar kyphosis is most common and occurs in almost all patients prior to walking (59). It resolves spontaneously in most patients (5,75,178), but approximately 15% to 20% have clinically significant kyphosis in adulthood (5,69,178). Narrowing of the canal and foramina continues through childhood and adulthood, in part through excessive periosteal bone formation, which causes the bone to thicken (40,168). All regions of the spinal canal may be affected. Stenosis may occur at the level of the foramen magnum, and potentially devastating consequences can arise should this go unrecognized or untreated (87,95,145,179).

One hallmark of stenosis in persons with achondroplasia is progressive narrowing of the interpedicular distance in the caudal direction of the midthoracic and lumbar spine (69,86,178). This is not found in every patient, however, and is not always a reliable indicator of the extent of stenosis (23,85). Stenosis occurs at the canal and foramina level by means of narrowing of the interpedicular and midsagittal diameters, shortening and thickening of the pedicles, thickening of the lamina and inferior facets, concomitant disc pathology (e.g., bulging, protrusion, herniation), spondylosis (e.g., scalloping of the vertebral body and osteophyte formation), excessive lordosis (in part due to hip flexion contractures), and thoracolumbar kyphosis (69,86,168,178). Stenosis may increase in severity from the midthoracic level toward the lower lumbar spine, or it may be localized at the thoracolumbar junction or upper lumbar spine.

Symptoms of stenosis in persons with achondroplasia include back pain (present in over 50%), leg pain, neurogenic claudication, neurogenic bowel and bladder, paresthesias, anesthesia, weakness, and paraplegia (3,5,69,75,85,95,137,178). Stenosis in the lower thoracic spine may lead to bowel and bladder difficulties, spasticity, and weakness. Intermittent neurogenic claudication may result from compression at the thoracic or lumbar spine. When neurogenic claudication occurs as a result of cord compression, the patient may complain of weakness, loss of sensation, or incontinence that occurs during or shortly after activity and dissipates with rest. Generally, symptoms are slowly progressive. They may tentatively improve with changes of position, including forward bending or squatting. Onset of symptoms typically occurs from 20 to 40 years of age but may occur in childhood (5,40,85,178).

Wynne-Davies et al. (178) reported that neurologic complications (e.g., severe back or leg pain with weakness, paralysis) are rare in patients with simple narrowing of the spinal canal or persistence of a thoracolumbar kyphosis. However, when these two are combined, the risk of neurologic complications is high. Specifically, when the ratio of the interpedicular distance at L1 to that at L4 is greater than 1.3 and there is persistent thoracolumbar kyphosis, serious neurologic sequelae are likely. Kahanovitz et al. (69) reported similar findings. They also reported that interpedicular distances less than 20 mm at L1 or less than 16 mm at L5 were associated with symptoms of stenosis.

Neurogenic claudication without accompanying neurologic deficit has been reported to improve with rest alone (85). Conservative treatment may be worthwhile in the absence of progressive neurologic deficit (85).

Patients with symptoms unamenable to conservative treatment and those with progressive neurologic deficit or cauda equina syndrome require surgical decompression. Decompressions may extend from the lower aspect of the thoracic spine throughout the lumbar spine. In fact, Grabias (48) stated that decompressions in achondroplastic patients should include laminectomies and partial facetectomies from the first sacral vertebra through at least the tenth thoracic vertebra, as either a single or a staged procedure.

Disc herniations are a common cause of radiculopathy and tension signs in persons with achondroplasia (27,85,95,144). Appropriate treatment in this case entails discectomy along with a generous posterior decompression.

Results following decompression for thoracolumbar and lumbar stenosis have varied (40,85,95,137). The earlier surgical intervention is performed in the symptomatic adult, the better the outlook for improvement (48). For example, Bethem et al. (8) reported that six patients with paraparesis lasting from 6 weeks to 2 years who were treated by laminectomy did not improve neurologically. Verbiest (168) stated that neural complications are often not detected during early stages of this developmental process, which may contribute to the mixed results following decompression. In a considerable number of patients, operative treatment does not result in noticeable improvement and may fail to arrest progressive neurologic deficits, even in cases of symptomatic stenosis thought to be limited to the lumbar spine. Verbiest emphasized the importance of early detection. He suggested that profile radiographs of the cervicooccipital region be taken soon after birth to identify potential life-threatening malformations. Frequent histories and examinations must be performed because neural disturbances, including neurogenic claudication, may not be recognized by the patient or family.

Surgical failures can occur because of the surgeon's failure to perform a complete decompression or to recognize additional pathology (69,85,95).

Postlaminectomy instability may also arise following a wide multilevel decompression. For this reason, Bethem et al. (8) recommend fusion following decompression. However, Kopits (75) believes that this is not necessary, provided the facets are not significantly damaged following decompression. The transverse processes are frequently small, which sometimes makes posterolateral fusion more difficult. Under these conditions, an anterior interbody fusion should be considered to maximize the possibility of obtaining a solid fusion.

If thoracolumbar kyphosis is associated with stenosis and neurologic deficit, an anterior decompression and strut grafting should be performed (8,59), along with a posterior decompression and fusion. Posterior decompression alone produces poor results.

Hypochondroplasia

Hypochondroplasia was first described in the English literature in 1969 by Beals (6). As reported by Wynne-Davies et al. (178) and others (5,168), its features are similar to those of achondroplasia but are less severe and usually do not involve the skull. Hands and feet also tend to exhibit more normal proportions. Hypochondroplasia in its most severe form is indistinguishable from achondroplasia. Like achondroplasia, this disorder is inherited as autosomal dominant, though most patients in the community present as new mutations. The foramen magnum and spinal canal are concentrically reduced in size, but usually not of the magnitude seen in achondroplasia. Symptoms, diagnosis, prognosis, and treatment are similar to those of achondroplasia.

Miscellaneous Forms of Developmental Stenosis

Developmental stenosis is seen in other forms of dwarfism, including diastrophic dwarfism (7,8), thanatophoric dwarfism, and Morquio syndrome (7,13). In Morquio syndrome, bony stenosis can occur at any level but is most common in the lumbar spine (168). Developmental stenosis can occur in association with many congenital anomalies, including, but not limited to, brachydactyly, syndactyly, and hyperopia (66).

Adults with Down syndrome (106) appear to have an increased prevalence of spondylosis with associated stenosis in the lower cervical spine. This seems to occur at an earlier age than in the normal population, predisposing these individuals to myelopathy.

Patients with hereditary multiple exostoses (68,168) are also at risk for developmental stenosis. This occurs through bony exostoses that can extend from any location into the canal.

Wackenheim (169,170) described a developmental entity called cheirolumbar dysostosis (168) in which patients presented with lumbar spinal stenosis along with acromelic disturbances, such as brachyphalangia. Approximately 25% demonstrated a circular, symmetrical type of stenosis, with the remaining patients showing shortening of the midsagittal diameter as typically seen in idiopathic developmental stenosis.

Diffuse developmental stenosis has been identified in patients with acrodysostosis (52). Findings associated with this rare skeletal dysplasia include peripheral dysostosis, nasal hypoplasia, and mental retardation. Loss of normal caudad widening of the coronal and sagittal diameters is frequently observed.

Narrowing of the spinal canal has been reported in patients with acromegaly (24,30,44) and is related to generalized bony overgrowth. Pseudogout (24,71) (calcium pyrophosphate dihydrate deposition) may also cause stenosis through crystal deposition and accumulation in the ligamentum flavum. Degenerative disc disease and facet joint disease can also occur in these patients. Spinal stenosis in patients with Paget disease (24,25,45,136) most commonly results from bony overgrowth at a single lumbar vertebra and paraspinal masses of incompletely ossified osteoid. Neurologic complications are unusual, and partial or complete relief following medical therapy has been described.

Developmental stenosis is rare, but it does occur in patients with ankylosing spondylitis (21,24,76,141). Outpouching of the dural sac (arachnoid diverticula) most commonly occurs dorsally, which can cause back and leg pain. Symptoms may occur as long as 10 to 40 years after the primary disease has become quiescent. Destructive lesion of the disc spaces (inflammatory and noninflammatory) and vertebral bodies can also cause stenosis.

Other diseases in which developmental stenosis can occur include calcification and ossification of the posterior longitudinal ligament (24,39,63,64,73,74,131,157,180), diffuse idiopathic skeletal hyperostosis (2,131), and calcification and ossification of the ligamenta flavum (70,77,107).

Treatment

Treatment of patients with congenital and developmental stenosis of the spine should be determined on an individual basis. A general knowledge of the pathophysiologic factors, natural history, and prognosis of a given disease is helpful for making appropriate treatment recommendations.

In general, surgical decompressions are recommended for patients who have progressive functional and/or neurologic deficits without sustained remission (48,129,144,165). Once severe symptoms of spinal stenosis develop, it is unlikely that improvement will occur without surgical treatment (48). (This is in contrast to younger patients with disc herniations, who frequently improve over time.) Fusions and reconstructive surgery are also recommended for patients with instability or progressive deformity (e.g., kyphotic gibbus) with natural or iatrogenic causes. The goals of treatment are the relief of pain and the preservation or restoration of neurologic function and spinal stability.

Craniovertebral Junction Abnormalities in the Pediatric Spine

Arnold H. Menezes

Timothy C. Ryken

A. H. Menezes and T. C. Ryken: University of Iowa Hospitals and Clinics; Division of Neurosurgery, University of Iowa College of Medicine, Iowa City, Iowa 52242.

Embryology and Development of the Craniovertebral Junction

The cranial aspect of the craniovertebral junction (CVJ) is composed of the squamous occipital bones posteriorly, the exoccipital bones laterally, and the basioccipital bones anteriorly (9). They coalesce to form the foramen magnum in their center. The atlas vertebra acts as a washer between the cranium and the axis (32). The funnel-shaped bony enclosure encompasses the medulla oblongata and the cervical spinal cord. Bony abnormalities affecting this complex result in dysfunction of the neural structures by compression along the entire circumference, by alteration in the arterial supply as well as the venous drainage, and by alteration in the cerebrospinal fluid dynamics (34,52,57,65). Thus, a vast array of congenital, developmental, and acquired lesions that arise or are located at the CVJ produce changes that ultimately affect the neural structures.

Their clinical significance was appreciated only after the classic radiographic studies on basilar invagination by Chamberlain in 1939 (15) and the recognition of the neurologic syndromes by List in 1941 (52). Early classification of the limited atlantoaxial abnormalities was attempted by Greenberg (34). Until then, the treatment of bony lesions at the CVJ consisted of posterior decompression with enlargement of the foramen magnum and removal of the posterior arch of the atlas (6,102). Greenberg recognized that anteriorly placed lesions at the foramen magnum that were treated in such a manner had a very high mortality and morbidity, especially when an irreducible ventral lesion of the CVJ caused cervicomedullary compression (34).

In 1977, we proposed a physiologic approach to treatment of abnormalities of the CVJ based on an understanding of the stability of the craniovertebral region, the dynamics, the associated neural abnormalities, and the site of encroachment (65). Since then, 3,500 patients with neurologic symptoms and signs secondary to an abnormality of the craniovertebral region have been evaluated. Advances in imaging and instrumentation have led to treatment of such lesions. Although these abnormalities may appear complex, they are easily understood, and their treatment is simplified with knowledge of the bony anatomy, biomechanics, and embryology (64,99,100).

Anomalies of the CVJ appear to be the result of faulty development of the cartilaginous neural cranium and adjacent vertebral skeleton during the early embryonic weeks. Congenital anomalies at the base of the skull in the atlantooccipital region involve both the osseous structures and the nervous system (30,54,79,99). The frequent occurrence of patterns with various combinations suggests an interrelationship if not a common cause of the origin and development (43,47,86).

Lymphatic Drainage of the Craniovertebral Junction

The lymphatics of the synovial bursa that line the occipitoatlantoaxial joint complex drain primarily into the retropharyngeal lymph nodes and up the cervical chain (9,71,72). This set of nodes also receives drainage from the paranasal sinuses, the nasopharynx, and the retropharyngeal areas. It is important to keep in mind that a retrograde infection from any of these areas may affect the synovial lining of the craniovertebral joint complex, resulting in effusion and instability as an inflammatory response (64,71). This may result in neurologic deficit and is what contributes to Grisel syndrome (36).

Biomechanics of the Occipitoatlantoaxial Complex

The occipitoatlantoaxial complex serves as a transition between the skull and the completely different vertebral joint structures (99,100,106). This functions as a single unit and is the most mobile part of the axial skeleton (32).

Cadaveric studies of infants have shown that during hyperflexion at the CVJ, the odontoid process invaginates into the foramen magnum in 25% of individuals (99). Likewise, extreme hyperextension may cause the posterior arch of the atlas to intrude into the spinal canal and into the foramen magnum, causing compromise of the cervicomedullary junction. Extreme hyperflexion or hyperextension may occur as a result of the positions in which infants are extracted during breech delivery. A similar situation may arise during general anesthesia (64).

Injury to the craniovertebral region is more common in infants and young children than in the older pediatric population due to the large infantile head and small body, resulting in high torques being applied to the neck with acceleration and deceleration (50,64). The cervical musculature does not become supportive until puberty (43,46,48). In addition, the ligaments and joint capsules are lax in small children, allowing for mobility at the cost of stability (99,105). The facets in the first three cervical vertebrae have a horizontal orientation to the articular surfaces, permitting increased translation motion. These facets never become as oblique as the lower cervical spine. There is an incomplete development and flattening of the uncinate processes in children younger than 10 years, making them ineffective in withstanding flexion-rotation forces. Finally, the fulcrum of cervical motion may be higher in young children than in adolescents and adults (99).

Both the occipitoatlantal and the atlantoaxial articulations are involved with flexion-extension (99,105). In a child, the amount of anterior-posterior translation that occurs between the dens and the anterior ring of the atlas can be up to 5 mm (25,53,64). When the transverse component of the cruciate ligament has been disrupted, the alar ligaments are still intact; hence, the amount of displacement stays between 5 and 6 mm until the alar ligaments become incompetent (25,48,78).

The anatomical design of the occipitoatlantal articulation precludes rotation (85,86). The largest degree of rotation occurs at the atlantoaxial joint and is explained by the geometry of the articular surfaces, which is meant to allow maximum mobility. When rotation exceeds 40 to 45 degrees, an interlocking of the facets takes place (64,85,105,106). More importantly, rotation of more than 35 degrees produces an angulation of the contralateral vertebral artery. With greater rotation, there is stretching of the vertebral artery, and at 45 degrees the ipsilateral artery may demonstrate angulation or occlusion. This phenomenon has implications in sudden rotation of the head as may occur with general anesthesia, chiropractic manipulations, and wrestling and football injuries (64). Usually, a large part of the rotation that takes place in the neck is shared by the atlantoaxial joint as well as the remainder of the cervical spine (32).

It has been recognized that muscular action is principally responsible for holding the head firmly to the neck and preventing abnormal excursions. When the protective muscles are relaxed or inadequately developed, as in the case of a child under general anesthesia, the CVJ becomes inherently less stable than in an adult.

Between 1977 and 1999, 3,500 symptomatic patients with abnormalities of the CVJ were evaluated. A wide variety of congenital, developmental, and acquired abnormalities of the CVJ exists and may occur as single or multiple anomalies in the same individual. These entities have been categorized as congenital, developmental, and acquired disorders for the purposes of understanding and discussing CVJ abnormalities (Table 1).

TABLE 1. Classification of Craniocervical Junction Abnormalities

I. Congenital malformations
    A. Malformations of occipital bone (e.g., bifid clivus, remnants around foramen magnum, dens anomalies, atlas anomalies, assimilation of atlas, condylar hypoplasia, basilar invagination)
    B. Malformations of atlas (e.g., assimilation of atlas, atlantoaxial fusion, hypoplasia of arches)
    C. Malformations of axis [e.g., segmentation defects of C1-2, C2-3); dens dysplasia (os terminale, os odontoideum, hypoplasia)]
II. Developmental abnormalities
    A. Abnormalities at the foramen magnum
        1. Foraminal stenosis (e.g., achondroplasia, rickets)
        2. Secondary basilar invagination (e.g., Paget disease, Hajdu-Cheney disease, osteogenesis imperfecta)
    B. Atlantoaxial instability
        1. Errors of metabolism (e.g., mucopolysaccharidosis, types II and IV)
        2. Bone dysplasia (e.g., spondyloepiphyseal dysplasia)
        3. Miscellaneous (e.g., Conradi syndrome, fetal warfarin syndrome, Scott syndrome, Goldenhar syndrome)

Clinical Presentation of Craniovertebral Junction Abnormalities

The most interesting feature of the region's pathology is the diverse presentation. Frequently, there is an antecedent history of minor trauma, which sets off a pattern of symptoms and signs that may progress at a rapid pace. Alternatively, neurologic progression may be insidious and gradual but may suddenly precipitate death (18,22,43,57,60,66,86,91).

The symptoms of craniovertebral dysfunction may be insidious; at times, it may present with false localizing signs (64,85,105,106). A constellation of symptoms and signs may occur as a result of compromise of the brain stem, cervicomedullary junction, cranial nerves, cervical roots, and their vascular supply as well as alterations in cerebrospinal fluid dynamics. Varied pictures exist with hindbrain herniation syndromes, hydromyelia, foramen magnum constriction, and hydrocephalus. This list of pathologic states that affect the CVJ is extensive (64). Each of these abnormalities may vary in the magnitude of neurologic dysfunction and abnormal findings, exclusive of involvement of the central nervous system.

Congenital abnormalities of the CVJ are often associated with an abnormal general physical appearance (2,5,7,18,33,50,88,101). This may involve a short stature and an abnormally short neck; at times, the head may be cocked to one side or the other, as with patients with rotary luxation of the atlas on the axis vertebra. An abnormally low hairline may be present posteriorly, with limitation of neck motion—part of the classical triad of Klippel-Feil syndrome (49). In addition, there may be facial asymmetry and webbing of the neck. Scoliosis is present in a significant number of these individuals. Sprengel shoulder deformity and abnormal stature also fall within the spectrum of Klippel-Feil syndrome. It is not uncommon to see children with a small dysmorphic stature. There is an increased incidence of associated defects involving the genitourinary and cardiopulmonary systems, as well as defects of the skeletal and nervous systems in Klippel-Feil syndrome (4,37,55,69).

The skeletal dysplasias have a peculiar propensity for developmental abnormalities involving the CVJ. Disease states, such as achondroplasia, spondyloepiphyseal dysplasia, and the related diseases of dwarfism, are well represented in this region (2,3,7,10,21,33,38,50,77,80,88,90,108).

The most common deficit in the author's series of children with abnormalities of the CVJ is myelopathy. The most common symptom is neck pain, present in 85% (64). This originates in the suboccipital area with radiation to the cranial vertex. False localizing signs associated with abnormalities of the foramen magnum are usually motor and may present with hemiparesis, monoparesis, paraparesis, and quadriplegia. The “central cord syndrome” was often seen in children with basilar invagination in whom the myelopathy mimicked a lower cervical disturbance (64,66). In 1974, in a classical experimental study, Taylor and Byrnes (96) investigated this phenomenon and proved that the venous drainage of the central gray matter in the lower portion of the cervical cord occurs in an upward direction. A separate venous drainage exists for the white and gray matter of the spinal cord. Thus, in compressive lesions of the cervicomedullary junction, there is venous stagnation in the lower cervical spinal cord, leading to hypoxia and dysfunction in the anterior horn cells. This may present as a lower cervical myelopathy between the C6 and C8 levels.

The sensory abnormalities are related to posterior column dysfunction. Brain stem and cranial nerve deficits were exhibited by abnormalities such as sleep apnea, dysphagia, and aspiration pneumonia. Not uncommonly, internuclear ophthalmoplegia was present and led to a misdiagnosis of upper brain stem dysfunction. Downbeat nystagmus was present in compressive lesions of the craniovertebral border, whether they were associated with Chiari malformations or not.

The most common cranial nerve dysfunction was hearing loss in 25% of children (64). This had an increased incidence in Klippel-Feil syndrome. A bilateral or unilateral paralysis of the soft palate and pharynx led to repeated bouts of aspiration pneumonia as well as poor feeding and inability to gain weight. Vascular symptoms, such as intermittent attacks of altered consciousness, confusion, and transient loss of visual fields, as well as vertigo occurred in 15% to 20% of children. At times, this was provoked by extension of the head or rotation, as with manipulation of the head and neck.

The syndrome of “basilar migraine” was frequently encountered in children with basilar invagination with atlas assimilation and compression of the medulla as well as the vertebrobasilar tree (22,35). In these individuals, the symptoms completely regressed upon surgical decompression of the area. The excessive mobility of an unstable occipitoatlantoaxial joint may cause repeated trauma to the anterior spinal artery and the perforating vessels of the medulla and upper cervical cord, leading to occlusion or spasm and the attendant neurologic deficits.

Children with nasopharyngeal infections and neck spasm or torticollis must be suspected of harboring CVJ abnormalities, which may be caused by an osseous abnormality secondary to effusion into the CVJ joints or rotary luxation.

Neuroradiologic Investigations

The diagnosis of CVJ abnormalities should be suspected when symptoms and signs referable to the brain stem, high cervical cord, and cerebellum are present. The factors that influence treatment are as follows (62):

1. Reducibility
2. Mechanics of compression
3. Cause of the associated neurologic abnormalities, such as Chiari malformation, syringohydromyelia, or associated vascular abnormalities
4. Presence of abnormal ossification centers and epiphyseal growth plates with anomalous development

The primary treatment for reducible craniovertebral lesions is stabilization. Surgical decompression is performed in patients with irreducible pathology. When irreducible lesions are encountered, the decompression is performed in the manner in which encroachment occurs (60). If a ventral encroachment is present, a transpalatopharyngeal decompression or LeForte I drop-down maxillotomy is made; alternatively, a lateral extrapharyngeal approach may be performed if decompression is possible by this route. When dorsal compression is present, a posterior decompression is mandated. In either circumstance, if instability follows, posterior fixation is required.

The above factors regarding treatment are determined by plain radiographs and dynamic studies that include the flexed and extended positions (Fig. 1A, B), computed tomography (CT) of the craniovertebral area, and magnetic resonance imaging (MRI). The effects of cervical traction must be documented. Magnetic resonance angiography and CT angiography is supplemented by direct visualization with selective vertebral angiography, when necessary. Each of these techniques has important features and provides complementary information about the CVJ and the presence of any incidental and pathologic changes in normal as well as abnormal relationships (19,35,47,57,68).

There has been a gradual trend toward the use of MRI as the only neurodiagnostic procedure other than plain radiography of the craniovertebral border. MRI cannot completely visualize the osseous pathology and cannot delineate the true extent of congenital and developmental lesions in this region. The authors rely on three-dimensional CT for identifying the osseous pathology (Fig. 1C, D). Dynamic imaging is performed in the flexed and extended positions and, subsequently, with cervical traction. This defines the bony pathology and acts as a preoperative assessment of the stability in both the anterior-posterior and vertical dimensions. Cervical traction with an MRI-compatible halo is used to determine the stability and reducibility of the lesion.

The predental space, also called the atlas-dens interval, is the space seen on the lateral radiograph between the anterior aspect of the dens and the posterior aspect of the anterior arch of the atlas vertebra. Locke et al. (53), in a radiographic study performed at the University of Iowa in 1966, reviewed 160 patients and observed the lateral radiographs in normal individuals. The maximum amount of flexion-permitted motion is between 3 and 4 mm; in very rare instances, there was up to 5 mm of predental space. The upper limit of normal in adults is 3 mm (26,48), and in children below age 8 years it is 5 mm. The atlantodental interval is of limited value in evaluating chronic atlantoaxial instability resulting from congenital anomalies. In these situations, the odontoid process may be small and hypermobile. List (52) and subsequently McRae (56) called attention to the relationship between neurologic symptoms and the effective sagittal diameter of the spinal canal at the foramen magnum. They noted that when the effective diameter of the spinal canal at the foramen magnum (the space available for the cervicomedullary junction) was less than 19 mm, neurologic deficits ensued. In our own series this held true. However, with the availability of MRI, this measurement can be more specifically defined.

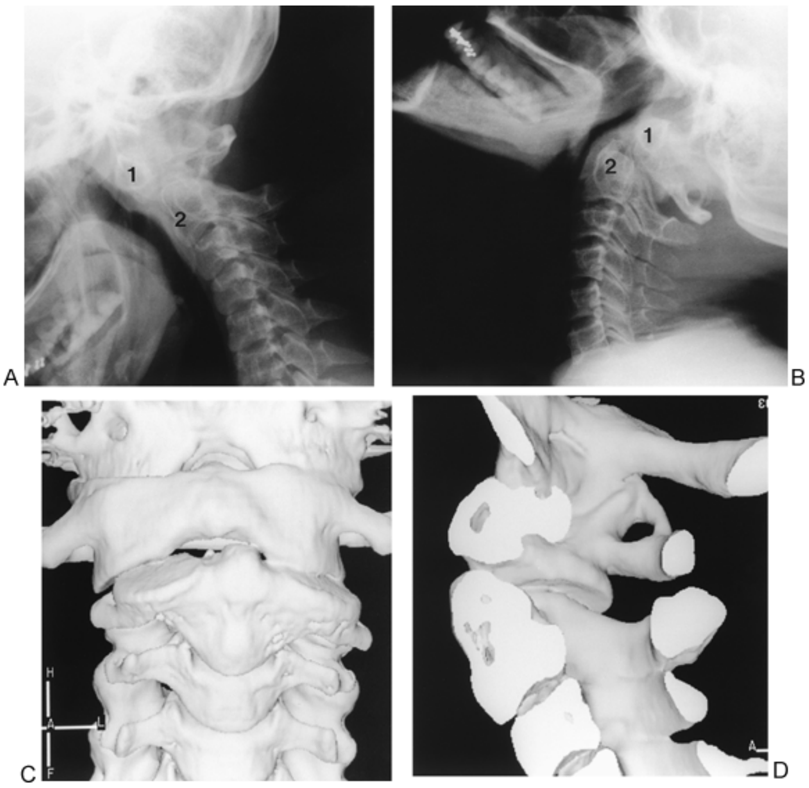

FIGURE 1. A: Lateral craniocervical junction plain radiograph in a 14-year-old boy with severe spastic quadriparesis in the flexed position. Note the os odontoideum, the anterior position of the anterior atlantal arch, and the marked widening of the interspinous distance between the atlas and the axis vertebrae. **B:** Lateral craniocervical radiograph of patient in **A** in the extended position. There is significant dorsal displacement of the anterior atlantal arch together with the dystopic os odontoideum. **C:** Three-dimensional computed tomographic construction of the craniocervical junction and upper cervical spine. Note the lateral atlantoaxial displacement and the hypoplastic dens. **D:** Midsagittal view of the craniocervical junction from within the spinal canal. There is a dystopic os odontoideum with an offset of the lateral atlantal mass on the superior articular facet of the axis vertebra.

TABLE 2. Craniometric Relationship of the Craniovertebral Junction as Seen on Plain Lateral Radiographs

Synonym	Definition	Normal Measurements	Implications
Chamberlains palatooccipital line	Joins posterior tip of hard palate to posterior tip of foramen magnum	Tip of dens below this line ± 4 mm	In basilar invagination, the odontoid process bisects the line
McRae's foramen magnum line	Joins anterior and posterior edges of foramen magnum	Tip of odontoid is below foramen magnum	When effective sagittal diameter of canal is less than 20 mm, neurologic symptoms occur
Wackenheims clivus-canal line	Line drawn along clivus into cervical spinal canal	Odontoid is ventral to this line	Odontoid transects the line in basilar invagination
Bulls angle	Angle between Chamberlains line and central plane of atlas	13 degrees or less	If the angle is more than 13 degrees, basilar impression is present due to either hypoplastic clivus or occipital condyles

A general consensus is that the space behind the anterior arch of the atlas and the spinous interlaminar line is divided into thirds. The first third is occupied by the odontoid process and the second third by the spinal cord; the last third is a free safe “space” that is roughly equal to the transverse diameter of the odontoid process. The craniometric lines of reference are enumerated in Table 2 and illustrated in Figure 2 (15,16,47,64,86,95).

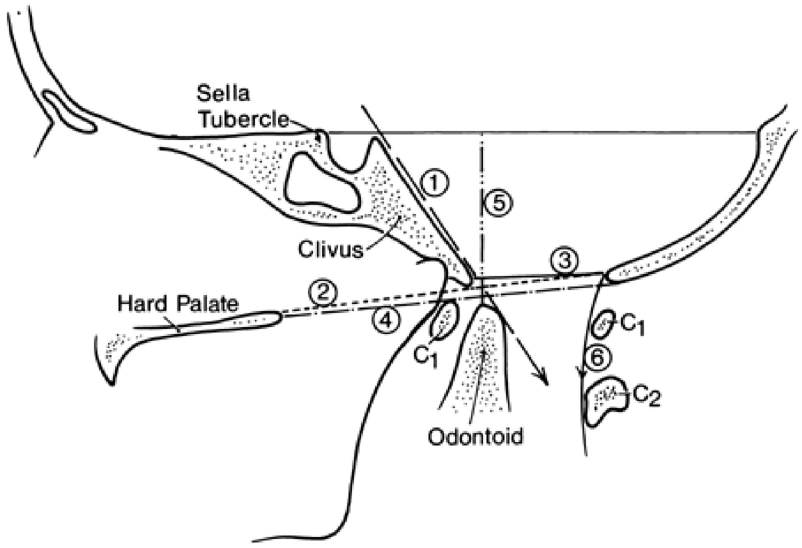

FIGURE 2. Lateral craniometry of the craniocervical junction with points of reference. *1*, Wackenheim clivus-canal line; *2*, Chamberlain line; *3*, McRae line; *4*, McGregor line; *5*, Height index of Klaus; *6*, Spinous interlaminar line (posterior canal line).

Specific Conditions

Griesel Syndrome

Griesel syndrome is defined as a spontaneous subluxation of the atlantoaxial joint following parapharyngeal infection (36). This inflammatory subluxation has been ascribed to metastatic inflammation causing ligamentous stretching, subluxation, muscle spasm, and regional hyperemia with decalcification of the ligamentous attachments (64). These children present with a stiff neck with neck pain, torticollis, and neurologic deficit. This may occur with tonsillitis, mastoiditis, retropharyngeal abscess, and otitis media. Most children affected are younger than 12 years. This may be explained by the greater ligamentous laxity and vascularity of the region in the pediatric population (72).

In 1987, Wilson et al. reviewed 62 cases of nontraumatic subluxation of the atlantoaxial articulation that fulfilled the otolaryngologic criteria of Griesel syndrome (107). In 14 children this occurred following surgical procedures for tonsillectomy, adenoid removal, mastoiditis, and resection of a pharyngeal rhabdomyosarcoma. Twelve children had symptoms of pharyngitis or cervical adenitis, several had tonsillitis, and seven harbored a cervical abscess. There were five children who had acute rheumatic fever and four with acute mastoiditis. Several patients were assigned the diagnosis of non-specific parapharyngeal infection. In children with Grisel syndrome, the neurologic deficit may range from paresthesias to quadriparesis, suggesting compression of the cervicomedullary junction or arterial compromise. In our own experience with 29 children, the causes were similar. Unilateral or bilateral rotary subluxation of the atlantoaxial complex was evident (64).

Treatment of such lesions consists of precise visualization of the region by means of MRI and CT. It is paramount that the source of infection be eliminated. Stabilization is achieved with a sterno-occipitomandibular immobilizing brace or a halo vest. In the acute phase, a Philadelphia collar may be applied to allow careful monitoring of the respiratory function. Once the infection is under control it is important that further diagnostic procedures be obtained to define the instability and possible rotational abnormalities. These are corrected by traction, derotation, and immobilization for 10 to 12 weeks. It is rare that a fusion procedure is necessary. We have not had to do this in any of our 29 children.

Malformations of Occipital Vertebrae

Anomalies and malformations of the most caudal of the occipital sclerotomes are collectively called manifestations of occipital vertebrae (31,51,57,86,88). An occipital vertebra occurs when there is failure of the third occipital sclerotome to be incorporated into the more rostral two occipital sclerotomes (64,100). The occipital condyles are then attached to the vertebra, and if the occipital vertebra has a transverse process, it does not have a foramen for the vertebral artery (100). In contrast, in occipitoatlantal fusion or assimilation of the atlas, the transverse process of the atlas maintains the bony foramina of the vertebral arteries. This latter condition is the most commonly recognized anomaly of the craniovertebral joint. It is frequently associated with Klippel-Feil syndrome.

A significant abnormality representing malformation of the occipital vertebra is a pseudojoint formed by an abnormal articulation between the clivus, anterior arch of the atlas, and apical segment of the dens (50,54,86). Even though the bony abnormality is situated extracranially at the anterior margin of the foramen magnum, an abnormal angulation of the CVJ occurs, with ventral compression of the cervicomedullary junction. The normal clivus canal angle should not be less than 130 degrees in flexion (99). This particular abnormality is often associated with Chiari malformation and syringohydromyelia (23,35,61,67). When the hypochordal bow assumes a large knobby configuration, it has been called the third condyle and may in itself form an abnormal articulation.

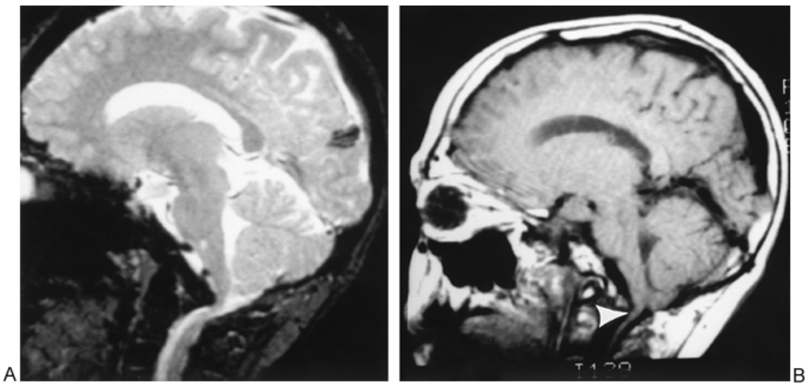

FIGURE 3. A: Midsagittal T1-weighted magnetic resonance image of head and upper cervical region in a 12-year-old boy. The proatlas component of the odontoid is attached to the clivus and projects into the spinal canal with severe ventral compression of the lower medulla oblongata. **B:** T2-weighted magnetic resonance image of head and craniocervical region. Note the extension of the clivus into the ventral spinal canal with severe compression of the cervicomedullary junction.

Abnormal segmentation of the clivus is not uncommon and should not be mistaken for the sphenooccipital suture line (61,99).

There are many anomalies that involve the proatlas. For example, in a 12-year-old boy with severe spastic quadriparesis, the proatlas component of the dens failed to separate from the portion that forms the basiocciput of the clivus (Fig. 3). The anterior arch of the atlas thus rests above the axis body, and the neurocentral synchondrosis of the axis itself is well visualized. The abnormality moves in unison with the clivus, grossly distorting the cervicomedullary junction ventrally, especially in flexion. This anomaly is similar to the reptilian spine in lower vertebrates. An anterior decompression is essential. In the author's experience with such individuals, a dorsal occipitocervical fusion is mandatory following anterior decompression.

Assimilation of the Atlas

Occipitalization, or assimilation, of the atlas implies bony union between the skull and first cervical vertebra. This anomaly occurs in 0.25% of the population (56,64,100). It is defined as failure of segmentation between the fourth occipital sclerotome and the first spinal sclerotome. It involves the skull and the anterior arch of the atlas, or the lateral atlantal masses, causing a disappearance of the joint space (14). This anomaly may be bilateral, unilateral, segmental, or focal (64). In most instances, it occurs in conjunction with other abnormalities, such as basilar invagination and Klippel-Feil syndrome (5,12,42,69). Fusion between the second and third cervical vertebrae was present in 18 of 25 patients with occipitalization of the atlas reported by McRae and Barnum (56). In the senior author's own series reviewed in 1988 (64), 96 such patients were detected among 890 patients with CVJ abnormalities. There were 32 segmentation failures between the second and third cervical vertebrae (Fig. 4). In all of these patients a Chiari malformation existed. In addition, Chiari malformation was seen in 42 of 96 patients with assimilation of the atlas. Paramesial invagination was present in 12 of 42 individuals with Chiari malformation (Fig. 5). Reducible atlantoaxial instability, or reducible basilar invagination, was detected in 15 of 18 children younger than 14 years (61). As age progressed, the lesion became irreducible. In partially reducible lesions there was prolific granulation tissue around the dislocation. In those individuals in whom an irreducible lesion was present, the granulation tissue was tough and fibrotic. An irreducible basilar invagination was more often than not associated with a horizontally oriented clivus and abnormal grooving behind the occipital condyles, articulating with the lateral masses of the axis vertebra (61). There is an inability to move in a rostral-caudal dimension or in a sagittal plane.

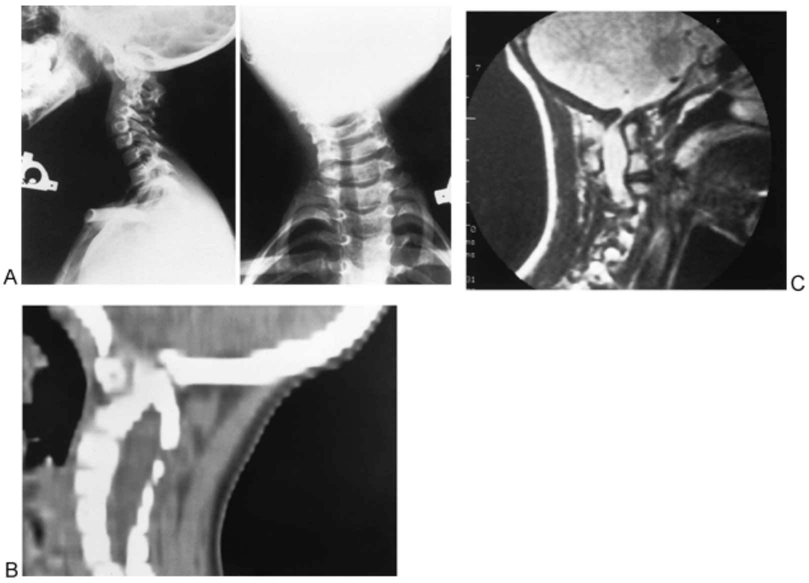

FIGURE 4. A: Composite of lateral and frontal cervical spine radiographs in a 5-year-old girl. She had torticollis and was unable to walk. There is segmentation failure of C2–3 and atlantoaxial dislocation. **B:** Reformatted computed tomogram of the craniovertebral junction in the midsagittal plane. There is atlas assimilation with marked odontoid invagination and dorsal displacement of the odontoid process. **C:** Midsagittal T2-weighted magnetic resonance image of the craniovertebral junction. The subarachnoid sac of the cervicomedullary junction is grossly deformed and compressed by the abnormal odontoid process.

In keeping with these findings, the authors believe that the combination of assimilation of the atlas and segmentation failures between the second and third cervical vertebrae results in progressive laxity of the atlantodental joint, with development of luxation between the dens and the atlas in childhood (64). As a result of this instability, progressive proliferation of granulation tissue occurs. During this time, there is remodeling of the inferior surfaces of the foramen magnum, involving the occipital condyles as well as the unsegmented atlas vertebra. This then leads to an irreducible state, with the newly formed “socket” attended to by the ball-like configuration of the superior facet of the axis vertebra placed in an abnormal position behind the occipital condyle and within the socket formed by the structures of the assimilated atlas. The odontoid invagination then combines with the abnormal clivus, leading to progressive neural compromise. These children become symptomatic during adolescence.

Acute trauma and infections of the upper respiratory tract have been implicated in precipitating symptoms of atlantoaxial instability. In developing countries, the carrying of heavy loads on the head constitutes a chronic trauma that results in flexion-extension injuries and further instability. Unfortunately, this has been termed congenital atlantoaxial subluxation; however, the phenomenon should be considered developmental rather than congenital (6). Irregular segmentation of the atlas and the axis may be associated with assimilation and unilateral fusion between the axis and the atlas vertebra. These fusions are not common and may be associated with other anomalies.

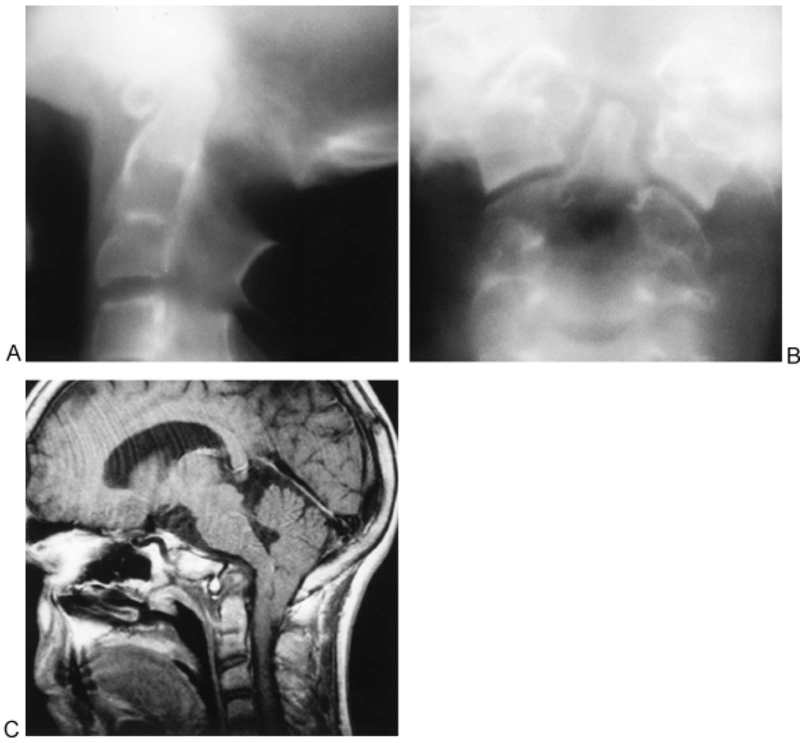

FIGURE 5. A: Midline lateral pluridirectional tomogram of the craniovertebral junction. Note the atlas assimilation and odontoid invagination. **B:** Frontal tomogram through the plane of the odontoid process. There is assimilation of the atlas lateral masses (C1) with an abnormally angulated and elongated odontoid process. The skull base is elevated. **C:** Midsagittal T1-weighted magnetic resonance image of the head and cervical spine. There is near-horizontal position of the clivus (platybasia) and a 100-degree clivus-odontoid angle. This indents into the ventral pontomedullary junction. There is a hindbrain herniation into the cervical canal. The vertical height of the posterior fossa has been markedly reduced.

The initial treatment is traction. If reduction is not adequate, as documented by MRI, a ventral decompression of the clivus-odontoid complex with the associated granulation tissue is essential, and subsequent stabilization is needed.

Basilar Invagination and Basilar Impression

The terms *basilar invagination, basilar impression*, and *platybasia* are often used erroneously (15). Basilar invagination applies to the primary form of basilar impression consisting of a distinct developmental defect of the chondrocranium, which is often associated with anomalies in the region of the CVJ, such as occipitalization of the atlas and Klippel-Feil syndrome (Fig. 5B, C) (64). It is also associated with anomalies of development in the epichordal neural axis, such as Chiari malformation, syringobulbia, and syringomyelia (5,22,55,59,65,79).

Basilar impression refers to the secondary, acquired form of basilar invagination that is caused by softening of the bone (100). This is characterized by invagination at the base of the skull as a consequence of such abnormalities as osteomalacia, hyperparathyroidism, osteogenesis imperfecta, Paget disease, Hurler syndrome, rickets, tumors or infections with local bone destruction, and ligamentous injury (Fig. 6) (7,10,38,39,73,74,75,92,104).

Platybasia, on the other hand, refers only to an abnormally obtuse basal angle formed when the plane of the clivus joins with the plane of the anterior fossa of the skull. This angle is of anthropologic significance only (100). There are no symptoms or signs that can be attributed to platybasia. It is not a measure of basilar invagination, although it may be associated with invagination. Confusion between platybasia and basilar impression dates to Chamberlain's 1939 paper (15). Although the title of Chamberlain's paper implies that the terms platybasia and basilar impression are synonymous, they do not refer to the same anomaly.

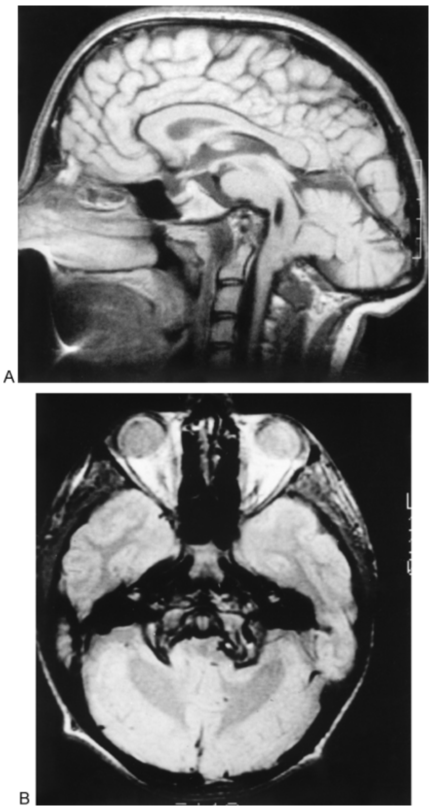

FIGURE 6. A: Midsagittal T1-weighted magnetic resonance image of the head and upper cervical spine. This 16-year-old with Paget disease presented with headaches, arm weakness, and lower cranial nerve palsies. Note the horizontal clivus. There is severe secondary skull base upward invagination, and compression of the cerebellum and brain stem. There is a 90-degree angle at the pontomedullary junction. **B:** Axial T2-weighted magnetic resonance image through the plane of the clivus. Note the invaginated atlas and odontoid process.

In basilar invagination, all three parts of the occipital bone are deformed. Two types are distinguished: anterior and paramedian (64,100). In anterior basilar invagination, there is shortening of the basiocciput and an associated platybasia, which raises the plane of the foramen magnum. In paramedian basilar invagination, hypoplasia of the exoccipital bone is present. There is a medial elevation of this portion of the occipital bone; on anteroposterior skull views, this can be seen as the rise of the skull base toward the foramen magnum. The distinction between these two forms is not important clinically, and an admixture does occur (Fig. 7).

The radiographic diagnosis of basilar invagination is based on a pathologic alteration in craniometric relationships made visible by plain radiographs, pleuridirectional tomography, CT, and MRI (19,64,99). Basilar invagination should be suspected when the lateral atlantoaxial articulations cannot be clearly visualized in the open-mouth anteroposterior view of the upper cervical spine (100). The tip of the dens should normally not exceed the bimastoid line by more than 10 mm. The digastric or biventral line is approximately 10 mm rostral to the bimastoid line. This should not be crossed by the normal dens. There are multiple reference lines to identify basilar invagination on the lateral projection. The tip of the odontoid process should usually lie below Chamberlain's line and not more than 2.5 mm above it (99). McRae's line represents the plane of the foramen magnum and should not be encroached on by the dens under normal circumstances (57). When the sagittal diameter at the foramen magnum is less than 19 mm, neurologic deficits have been recognized.

In basilar invagination, there is elevation of the floor of the posterior fossa (35,99,100). This may be simulated by an abnormally short clivus, resulting in upward elevation of the anterior aspect of the foramen magnum. The elevation of the floor of the posterior fossa is most prominent around the foramen magnum, so the margins may curve upward; the lateral portions of the posterior fossa may curve downward. Thus, the space within the posterior fossa is compromised (35,38,64,79).

When chronic instability is present, as with occipitalization of the atlas, an excess of granulation tissue may build up around the odontoid process. This in itself acts as a space-occupying mass in the anterior portion of the foramen magnum. In addition, fibrous bands and dural adhesions are common in the posterior cervicomedullary junction and around the cerebellar tonsils in both primary and secondary basilar invagination.

A severe form of secondary basilar invagination may occur following childhood diseases of bone, such as renal rickets. Although the patient shows no manifestations of the problem at a later age, the invagination has occurred and persists. In this situation, it is very difficult to differentiate this form of invagination from the other varieties.

Condylar hypoplasia is often a feature of malformations of the CVJ and leads to the paramedian type of basilar invagination (99,100). The occipital condyles are flattened, leading to an elevated position of the atlas and the axis. There are transitional stages between condylar hypoplasia and basilar invagination. Condylar hypoplasia limits movement of the atlantooccipital joint and at times may lead to vertebral artery compression as a result of the backward glide of the occiput. An asymmetrical flattening of the occipital condyle may produce scoliotic changes in the cervical spine. In some instances, medial placement of the occipital condyles causes a marked reduction in the transverse diameter of the foramen magnum, resulting in lateral medullary compression that is compounded by an existing Chiari malformation. A secondary form of this is seen in children with osteogenesis imperfecta, where there is paramesial invagination due to the side-to-side intrusion of the occipital condyles into the foramen magnum (2,3,7,39,73,75,77).

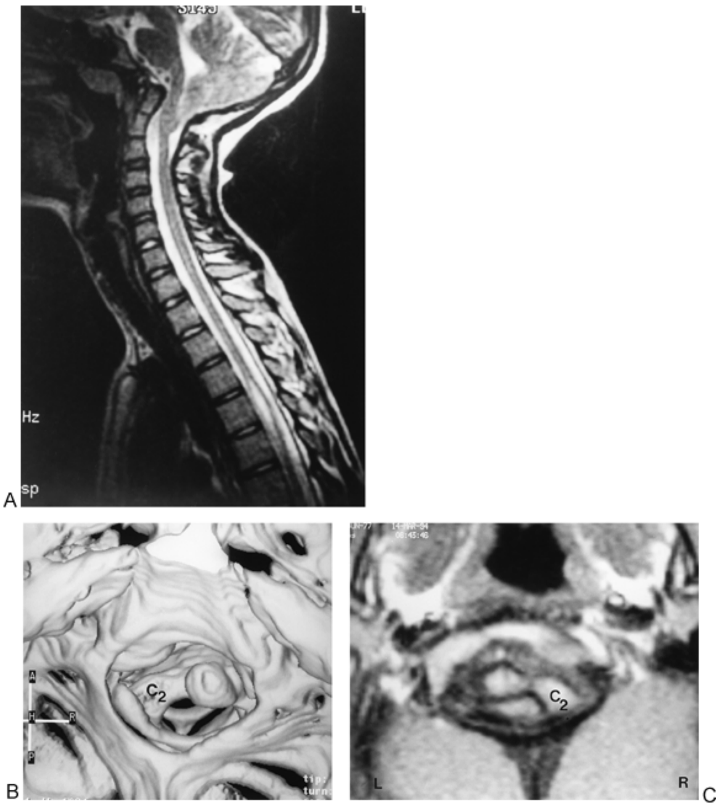

FIGURE 7. A: Midsagittal T2-weighted midsagittal magnetic resonance image of posterior fossa, cervical and upper thoracic spine. There is atlas assimilation with foreshortened clivus and a 90-degree angle between the clivus and odontoid process. This invaginates into the pontomedullary junction. A hindbrain herniation is also present with upper thoracic syringohydromyelia. This 13-year-old boy presented with difficulty swallowing, basilar migraines, and spastic quadriparesis with thoracic scoliosis. **B:** Three-dimensional computed tomogram of craniocervical junction viewed from within the cranium and posterior fossa. Note the orientation such that the odontoid process is to the right. Thus, there is atlas assimilation seen better on the left. There is gross atlantoaxial dislocation with severe canal compromise at foramen magnum. **C:** Axial T2-weighted magnetic resonance image through the plane of the atlas vertebra. The odontoid process is now visible to the left of the midline, and atlantoaxial dislocation is evident with significant compression of the medulla.

Symptomatic patients with basilar invagination require cervical traction using an MRI-compatible halo ring. Basilar invagination associated with Chiari malformations is not uncommon (22,61). When this is the case and there is ventral compression of the cervicomedullary junction by a bony abnormality, a ventral decompression must be performed before the posterior surgical procedure. The ability to reduce the invagination is age-related. The presence of a syringohydromyelia does not mean that a posterior operative procedure is indicated (Fig. 7A). The majority of the syringohydromyelia will disappear once the ventral abnormality has been corrected (59). This occurs because of an equalization of the abnormal cerebrospinal fluid dynamics such that the cerebrospinal fluid flow is restored to its normal values. In addition, the bony compression is reduced, leading to an improved neurologic state. If a posterior decompression is performed first, a significant number of patients will show no improvement or experience a progressive deterioration of brain stem and high cervical cord function (6,34,64,99,102). Posterior decompression and rerouting of the cerebrospinal fluid pathway should be performed before a cervical fusion, after the ventral pathology has been corrected. The secondary basilar invagination that is seen with osteogenesis imperfecta and the Hajdu-Cheney syndrome with acroosteolysis requires bracing as early as possible (17,38,45,81), preferably with a Minerva brace or a custom-fitted one. The youngest child seen by the authors was fitted with a brace shortly after birth.

Anomalies of the Odontoid Process

Aplasia-Hypoplasia of the Dens

Aplasia-hypoplasia of the dens may be expressed in several degrees; a rudimentary dens may be present or it may be completely absent (13). In this entity, the cruciate ligament is incompetent, leading to atlantoaxial instability. Extensive hypoplasia may be combined with developmental forms of os odontoideum (28,29,34,43,62). A significant vascular compromise—the result of stretching and distortion of the vertebral arteries—has been seen in such lesions. Chronic atlantoaxial dislocation in this situation may result in the formation of granulation tissue at the site of the luxation, with compression of the cervicomedullary junction.

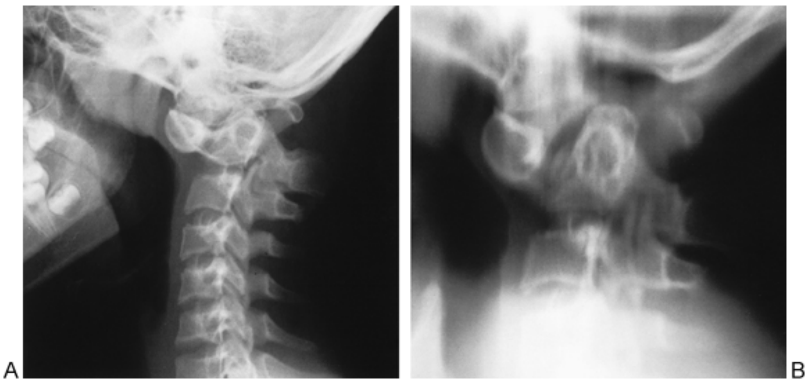

FIGURE 8. A: Lateral cervical radiograph of a 12-year-old girl who presented with hemiparesis after gymnastics. There is gross atlantoaxial instability, with the anterior atlas arch descending toward the C2–3 interspace. **B:** Midline polytomograms of the craniovertebral junction reveal a large dystopic os attached to the inferior clivus, with sclerotic borders. The anterior C1 arch is enlarged. The hypoplastic odontoid process and the axis body have ascended and moved dorsally.

Os Odontoideum

The term *os odontoideum* was first coined by Giacomini in 1886 (62). It refers to an independent bone seen cranial to the axis, in the place of the dens. It is not an isolated dens but exists apart from a small hypoplastic dens. Radiographically, the os odontoideum has rounded, smooth cortical borders that are separated by a variable gap from a small odontoid process (100). It is usually located in the position of the normal odontoid tip or near the basiocciput in the area of the foramen magnum, where it may fuse with the clivus. The gap between the free ossicle and the axis usually extends above the level of the axis superior facets. This leads to incompetence of the cruciate ligament and subsequent atlantoaxial instability.

Fielding has described two types of os odontoideum: the orthotopic variety wherein the ossicle lies in the position of the normal dens and moves in unison with the atlas and the axis vertebrae, and the dystropic variety wherein the ossicle lies near the inferior end of the clivus and fuses with the occipital bone and moves in unison with the clivus (27) (Fig. 8).

Radiographically it may be difficult to differentiate an os odontoideum from an old odontoid fracture. In the traumatic nonunion, the gap between the fracture fragments is characteristically irregular and narrow and extends into the body of the axis below the level of the superior facets of the axis vertebra (62). The bone fragments appear to have no cortical margin or rounded appearance, and the fragments "match."

Evidence favors an unrecognized fracture in the region of the base of the odontoid as the most common cause of os odontoideum (27). It has been seen in patients who have had a recognized complete odontoid process in early childhood and subsequently progressed to have an os odontoideum in one of identical twins who had cervical trauma and in patients with gross ligamentous laxity, such as that associated with Down syndrome and Morquio syndrome (3,28,40,44,62,78,92). Following fracture of the odontoid in early childhood or acute ligamentous injury, a separation may take place. With time and contracture of the alar ligaments, a distraction force pulls the odontoid fragments away from the centrum of the axis toward the occipital bone. The blood supply of the odontoid is easily traumatized and may contribute to poor healing or callus formation that would now retard closure of the gap (1,27,64,71,83,91). The ossicle is then supplied through the proximal arterial arcade, accounting for the hypertrophy of the anterior atlantal arch that shares the same blood supply. There is now increasing evidence that os odontoideum is more commonly associated with trauma, upper respiratory infections, bony abnormalities such as spondyloepiphyseal dysplasia, and previously mentioned Morquio syndrome and Down syndrome (28,62,91) (Fig. 9).

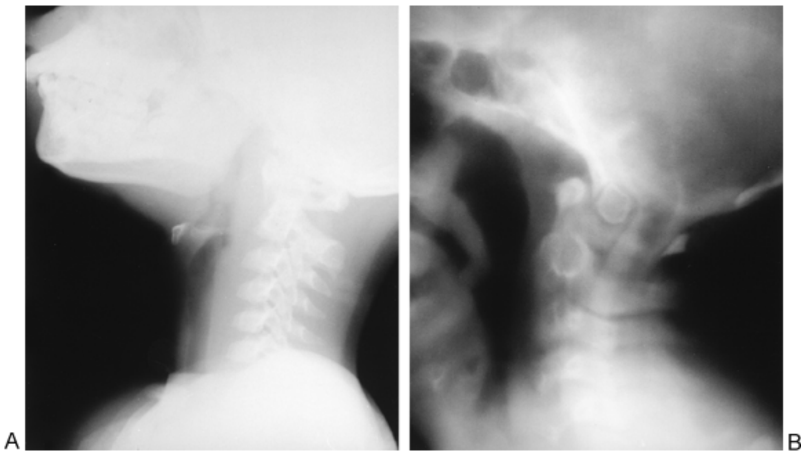

FIGURE 9. A: Lateral cervical radiograph made in a 4-year-old with traumatic atlantoaxial dislocation. She was treated with cervical traction and a pediatric Minerva cast (1967). **B:** Midline pluridirectional myelotomogram of craniocervical junction. Iohexol outlines the cerebrospinal fluid spaces. This study was made in 1980, when the patient was 17 years old. The patient had acute quadriparesis following a minor accident. Note the dystopic os odontoideum with ventral compression of the cervicomedullary junction. The odontoid process was intact at age 4, as seen in **A**.

The biomechanics of os odontoideum must be carefully studied because it is varied. The movement of os odontoideum is individual with each patient and cannot be extrapolated to another. In the dystropic variety, a dorsal compromise of the spinal cord may occur by the forward position of the posterior arch of the atlas in the flexed position, as well as ventral compromise by the odontoid ossicles. At times the axis may be displaced dorsally in extension and increase the ventral compromise (Fig. 10A–C). Thus, each patient should be carefully assessed by dynamic studies in the flexed and extended and the lateral positions. Lateral displacement of the atlantoaxial complex is a common finding at the time of operative fixation in such individuals (27,62) (Fig. 1).

Direct pathologic examination of the area at the time of ventral decompressive surgery has shown that an irreducible state may be caused by slippage of the transverse portion of the cruciate ligament beneath the ossicle and at times even in front of it (58). In addition, intense granulation proliferation may occur ventral to the bone defect owing to repeated luxations. In severe chronic dislocation, this may become fixed over several years, accompanied by severe basilar invagination. At its worst, os odontoideum has significant implications concerning the compression of the cervicomedullary junction. There is no argument that in unstable situations, as well as in cases involving neurologic deficits, therapy is mandated. However, the most difficult question to answer is whether an asymptomatic child, recognized as having an os odontoideum on a routine cervical spine radiographic after head trauma, should undergo treatment. It is not uncommon for children who are asymptomatic with os odontoideum to have severe neurologic deficits following minor trauma, as with dental work, sports activities, and gymnastics. We believe that all patients with recognizable instability at the craniocervical junction and associated os odontoideum should undergo stabilization. If a fixed irreducible abnormality exists, decompression should be done first.

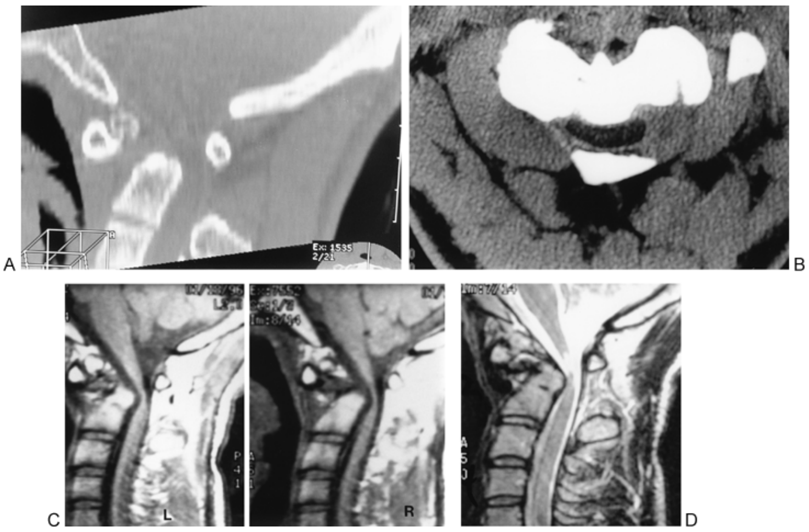

FIGURE 10. A: Midsagittal two-dimensional computed tomographic reconstruction of craniocervical region. This 15-year-old presented with spastic quadriparesis and ninth and tenth nerve cranial palsies. There is a dystopic os odontoideum with a dorsal and upward migration of the axis body, causing severe canal compromise. **B:** Axial computed tomogram through the plane of the superior axis body. Note the dorsally displaced axis with marked compromise of the cervicomedullary junction between the axis body and the posterior atlantal arch. **C:** Composite of T1-weighted magnetic resonance image of craniocervical junction in the sagittal and parasagittal location. There is significant ventral compression of the cervicomedullary junction by the displaced axis body. **D:** T2-weighted midsagittal magnetic resonance image through the craniocervical region. There is atlantoaxial dislocation with a dystopic os odontoideum. The compression of the ventral cervicomedullary junction is caused by the dorsal aspect of the superior axis body. Note the contusion within the cervicomedullary junction at the level of the axis compression.

Down Syndrome (Fig. 11)

The incidence of craniovertebral anomalies related to Down syndrome warrants special comment. The treatment of instability at the CVJ in patients with Down syndrome has become somewhat controversial because some authors have reported high fusion-related complication rates and suggested that the incidence of neurologic abnormality associated with this abnormal motion may be low. This has led to neurologic disasters with minor neck manipulations, as with tonsillectomy under general anesthesia. The authors have reported on the clinical and radiographic findings in 33 patients treated at their institution (63,94). Common presenting symptoms included neck pain (14 patients), torticollis (12 patients), myelopathy manifesting as hyperreflexia (21 patients), or varying degrees of quadriparesis (11 patients). Four patients suffered acute neurologic insults, two after receiving routine general anesthetics for minor surgical procedures and two other patients following minor falls. Atlantoaxial instability was the most common abnormality documented on radiography (22 patients). Atlantooccipital instability (15 patients) was also frequently observed and was coexistent with the presence of atlantoaxial luxations in 14 patients. A rotary component of the atlantoaxial luxation was present in 13 cases. In 17 patients, bony anomalies were present, the most frequent of which was os odontoideum (10 patients). Twenty-four patients underwent operative intervention, and successful fusion was achieved in 23. In 6 of 9 patients with basilar invagination, reduction was achieved with preoperative traction, avoiding the need for ventral decompressive procedures. There were no incidents of postoperative deterioration, and 22 patients made excellent or good recoveries. The results of this series highlight the clinicopathologic phenomena of craniovertebral instability in patients with Down syndrome and suggest that satisfactory outcomes can be achieved with a low rate of surgical morbidity.

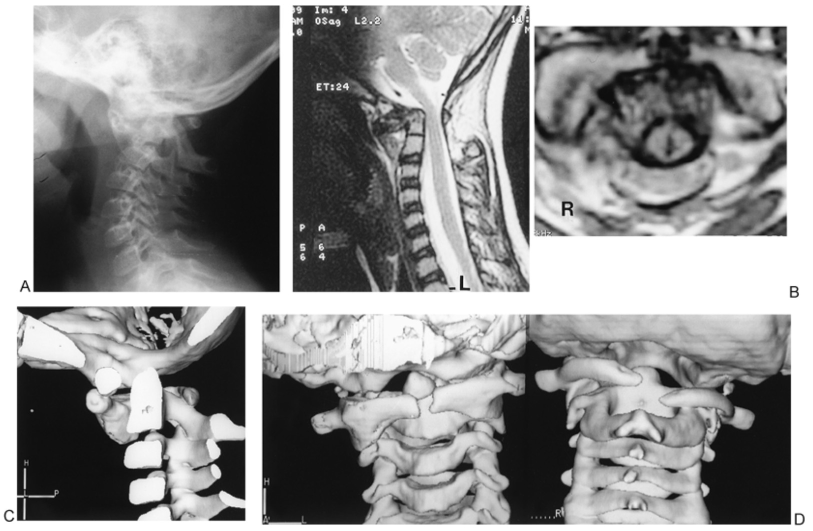

FIGURE 11. A: Lateral cervical radiograph in a 9-year-old girl with Down syndrome. She presented with head tilt, arm weakness, and inability to walk. Note the gross atlantoaxial dislocation. **B:** Composite of T2-weighted midsagittal magnetic resonance image of craniocervical junction on the left and axial view through the plane of the axis body. A dystopic os odontoideum is seen. However, the cervicomedullary compression is caused ventrally by the superior aspect of the axis body and dorsally by the posterior arch of C1. **C:** Midsagittal view of three-dimensional computed tomogram of craniocervical junction viewed from within. Note the os odontoideum, the bifid posterior and anterior arch of C1, the atlantoaxial dislocation, and the upward migration of the axis body. **D:** Composite of three-dimensional craniocervical images viewed from in front *(left)* and behind *(right)*. The atlas is bifid anteriorly and posteriorly in the midline. There is a lateral displacement of the lateral atlantal masses with a rotary luxation of the right lateral mass being displaced forward and downward. This is a grossly unstable craniocervical junction.

The most common chromosomal abnormality in humans, trisomy 21, occurs approximately once in every 700 births. The clinical syndrome associated with this genetic aberration was originally described in 1866 by John Langdon Down and subsequently bore his name (76,89,96). Down syndrome is well recognized by its phenotypic features, which include characteristic facies, hypotonia, ligamentous laxity, mental retardation, and transverse palmar creases. This disorder can variably affect nearly every organ system, resulting in numerous potential complications. Manifestations of the disease affecting the CVJ were first described in 1961 by Spitzer et al., who reported on 9 of 29 patients with atlantooccipital dislocations (89).

The generalized ligamentous laxity associated with Down syndrome, as well as incidence of bony anomalies, predisposes the CVJ to instability because of the complex interaction of ligamentous and bony anatomy required to maintain stability. In 7% to 40% of patients with Down syndrome there is radiographic evidence of atlantoaxial instability, although the incidence of symptomatic instability may be less than 1%. Atlantooccipital instability and rotary luxation of the atlas are well described in patients with Down syndrome and should not be overlooked. Parfenchuck et al. have suggested that the incidence of posterior atlantooccipital hypermobility in Down syndrome is 8.5% (70). Bony anomalies, such as os odontoideum and hypoplasia of various craniovertebral elements, including the atlantal ring and condyles, likely increase the risk for instability at the CVJ. This evidence in part prompted the American Academy of Pediatrics Committee on Sports Medicine and Fitness to mandate that participants with Down syndrome undergo physical examination and radiographic screening of the cervical spine prior to competition in the Special Olympics (63).

Evidence regarding the natural history of atlantoaxial instability suggests that it may be a progressive disease. In follow-up of 33 patients over a 13-year period, 7 were found to have developed instability (predental space of more than 5 mm), as compared with only one patient in whom this instability was present at the start of the study (13). Two patients underwent arthrodesis and one died of the pathologic process. Pueschel et al. evaluated 95 patients over a 3- to 10-year period and found that in 7 a predental space greater than 5 mm had developed (77). These authors claimed that no patient became symptomatic. Ferguson et al. recently called into question the relationship of neurologic abnormality and atlantoaxial instability (25). Eighty-four patients with Down syndrome were evaluated for a predental space of 4 mm or greater or 2 mm of translation in flexion and extension. In 20% (17 patients), instability at the atlantoaxial joint was demonstrated. In a comparison of results of neurologic examinations with patients in whom subluxation was present with those in whom it was not, no significant difference could be found relative to incidence (29% and 27%, respectively) or type of positive neurologic finding. Results of our series demonstrate not only that children with this phenomenon are predisposed to neural compromise but also that a high rate of neurologic recovery can be expected (94).

Atlantooccipital and occipitoatlantoaxial instability are expected findings in the Down syndrome population (97). Clinical correlations were not made in the first description of atlantooccipital luxation by Spitzer et al. (89). Neurologic abnormalities have been found in up to 66% of patients with atlantooccipital instability. In a prospective review of 64 patients with atlantooccipital instability, 61% of the patients were shown to have a posterior occipital subluxation greater than 4 mm and 21% to have a predental space greater than 5 mm. Uno et al. reviewed flexion and extension cervical radiographs obtained in 75 patients with Down syndrome. Comparing their findings with those of 30 age-matched controls, they found a significant number of patients in whom atlantooccipital hypermobility was demonstrated (98). Furthermore, they found occipitoaxial instability coexistent with atlantoaxial instability in all cases. In 11 of the 14 patients in our series, atlantoaxial instability along with atlantooccipital instability was found, which supports their finding, although correlation is not absolute. In this light, both Brooke et al. and El-Khoury et al. have reported two patients with Down syndrome in whom atlantooccipital instability was present without atlantoaxial abnormality (11,24).

Rotary luxations of the atlantooccipital and atlantoaxial joint were initially described in a Down syndrome patient in 1969 by Sherk and Nicholson (87). Surgical intervention was not undertaken, and 9 years after the diagnosis was made this female patient developed acute quadriplegia and died of respiratory failure. Other investigators have recognized a rotary component of instability in some patients with Down syndrome (20). In more than one third of the patients in our series a component of rotary luxation at C1-2 was found, and in one patient rotary luxation at *occiput -C-C2* was demonstrated. It is important to recognize this phenomenon because the ipsilateral vertebral artery can kink and the contralateral vessel put on stretch as the rotation at C1 exceeds 35 degrees (85). Subsequently, the facets may lock, resulting in a fixed luxation, and can only be disengaged if traction and derotation are performed. One must recognize that this rotary component can worsen the canal compromise and increase the stress placed on the cruciate ligament; thus, it can worsen the stability of an already compromised CVJ in a patient with Down syndrome.

The bony anomalies associated with Down syndrome, particularly os odontoideum, deserve emphasis. Unsuspected fractures of the odontoid, with secondary pull of the alar and apical ligaments, may result from repeated minor traumatic events in these patients. Over time, the cruciate ligament becomes incompetent, resulting in atlantoaxial dislocation and possibly allowing for decompression at the ventral cervicomedullary junction because the odontoid ascends into the foramen magnum. In 1985, Burke described 20 patients in whom myelopathy had developed secondary to atlantoaxial instability; in nine of these patients, either an os odontoideum or odontoid hypoplasia was present (8). Pueschel and Scola have provided evidence that a higher rate of cervical bony anomalies exists in the subgroup of Down syndrome patients in whom atlantoaxial instability is present (31 of 39) (76). In this report, the authors also reviewed the bony anomalies in Down syndrome patients, and os odontoideum and ossiculum terminale were shown to be common. This evidence supports the findings in our series that in nearly half of patients with bony anomalies, the particular anomaly was os odontoideum, followed by posterior atlantal arch hypoplasia (Fig. 11).

In the clinical setting, achieving consistent, successful outcomes in this patient population is challenging. Incomplete evaluation or understanding of the complex interactions at the CVJ has resulted in poor pre- and perioperative planning and treatment, including failure to recognize simultaneous instability at the different segments of the CVJ, failure to obtain proper reduction prior to the decompression and fusion procedure, and performance of intraoperative reduction without application of traction. In our own clinical experience, we have seen fusion failure as a result of inappropriate postoperative immobilization, failure to recognize and appropriately treat ventral pathologic processes, and inadequate bone grafting. Segal et al. have reported successful initial fusion in only 2 of 10 patients and bone graft absorption in 6 patients (84). More recently, in 7 of 15 patients with

Down syndrome, a nonunion occurred after attempted posterior arthrodesis (20). In this series, reported by Doyle et al. (20), 4 of the 7 patients achieved solid bony fusion after reoperation; in 3 of these 4 patients, fusion was preceded by loss of reduction and neurologic deterioration, and successful fusion was achieved only after the occiput was incorporated on the second attempt.

Abnormal physiologic processes in the Down patient may also contribute to poor outcome (8). The T-cell-dependent processes of the immune system in patients with Down syndrome are deficient as measured both quantitatively and qualitatively. The overall number of T lymphocytes is decreased as is the synthesis of lymphokines and the secretory products of these cells. These products may affect the initial inflammatory stages of bone graft incorporation. Other authors have implicated a collagen defect intrinsic to Down syndrome patients as responsible for bone graft resorption and poor graft maturation (84). The sequential forms of collagen required for successful graft incorporation may be deficient and thus contribute to nonunion or graft absorption.

Based on our own series and our interpretation of the literature, we find that occipitocervical fusion is required to address cranial settling, reducible basilar invagination, and anterior, posterior or lateral cranial dislocation within the CVJ. This is performed in as far lateral an interlaminar fashion as possible between the axis and atlas. Although iliac crest may be harvested, we favor the use of autologous full-thickness rib as the donor bone. Sawin et al. have shown that posterior rib harvesting was not associated with significant pulmonary morbidity when compared with autologous iliac crest harvesting in patients undergoing cervical fusion procedures (82). Furthermore, rib grafting was associated with an excellent fusion rate in their series. Titanium cable is used to purchase the exoccipital bone to improve the stiffness of the construct. Generally, patients are immobilized in a halo vest for 3 to 4 months for atlantoaxial fusion and up to 6 months for atlantooccipital fusion. Inadequate immobilization invites nonunion, resorption of the graft, and progressive instability.

Skeletal Dysplasias

The practical approach to skeletal dysplasias in infancy was formulated by Dutton based on the international nomenclature of constitutional disease of the bone (21). Many authors have attempted to clarify the older well-known titles of dysplasias, which now fall into the category of skeletal dysplasias. Skeletal dysplasias are divided into five large categories: (a) osteochondral dysplasia; (b) dysostosis; (c) idiopathic osteolysis; (d) chromosomal aberrations; and (e) primary metabolic abnormalities.

Osteochondral dysplasias and dysostosis account for the largest and most complex entities. Each category is further subdivided into numerous subcategories and individual diagnoses. Osteochondral dysplasias are defined as abnormalities of cartilage or bone growth in development. This category includes achondrogenesis, thanatophoric dysplasia, chondrodysplasia punctata (Conradi-Hünermann syndrome), achondroplasia, dystrophic dysplasia, metatrophic dysplasia, spondyloepiphyseal dysplasia, Kniest dysplasia, cleidocranial dysplasia, and multiple epiphyseal dysplasias (33,41,43,77,81,90,94,108,109).

The dysostoses are defined as malformations of individual bones manifested singly or in combination. The category may include Crouzon, Apert, and Carpenter syndromes with vertebral defects. This category also includes Sprengel deformity and Klippel-Feil syndrome.

The subcategory of idiopathic osteolysis includes the diagnosis of spondyloepiphyseal dysplasia tarda, fibrous dysplasia, neurofibromatosis, osteogenesis imperfecta, and multicentric forms such as the Hajdu-Cheney form (17,38,90).

The primary metabolic and chromosomal abnormalities are numerous. The metabolic abnormalities include problems with calcium or phosphorus metabolism, such as rickets and pseudohypoparathyroidism. Abnormalities of calcium and phosphorous metabolism will lead to bone softening and a secondary form of invagination. This may be paramesial, which is common with achondroplasia, in which case the sagittal diameter of the foramen magnum is preserved whereas the transverse diameter is markedly reduced. In addition, an inward bending of the exoccipital bone results in further invagination and creation of a dural shelf, which compresses the dorsal cervicomedullary junction (80) (Fig. 12). Thus, in these syndromes, posterior decompression is necessary with a duraplasty. Upper cervical and spinal stenosis is a well-known entity with such syndromes as achondroplasia and Morquio syndrome (50,93,103).

Atlantoaxial instability occurs with increasing incidence in the skeletal dysplasias. In patients with achondroplasia, we have noted cervicomedullary compromise most frequently in those younger than 3 years (80). Sleep apnea has been a major symptom, as has progressive spastic quadriparesis. In this situation, CT myelography with iohexol has permitted visualization of the compression at the foramen magnum as well as at C1 and C2. There is an inward bending of the posterior arch of the atlas, further compromising the stenosis. Prior to embarking on therapy, one must confirm that prior attention has been given to hydrocephalus, if present.

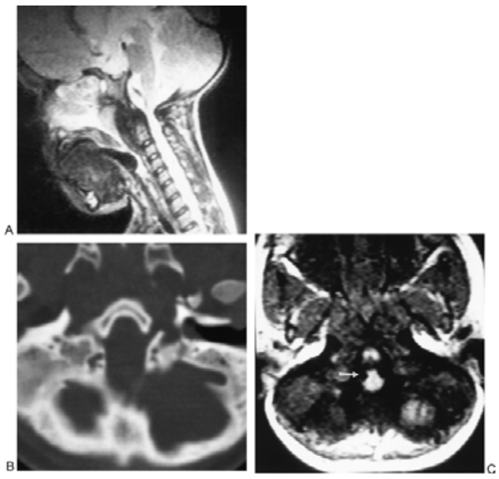

FIGURE 12. A: Midsagittal T2-weighted magnetic resonance image of craniocervical region in a 4-year-old girl with achondroplasia. She presented with weakness in the arms and gait difficulty. Note the constriction of the subarachnoid sac at the foramen magnum and C1 level. The brain stem is abnormally “vertical,” with the pons above the sella turcica. **B:** Axial computed tomogram through plane of foramen magnum. The bone formatted windows demonstrate a narrowing of the transverse diameter of the foramen magnum with paramesial invagination. **C:** T1-weighted magnetic resonance image at foramen magnum illustrates a paramesial invagination with compromise of the cervicomedullary junction.

Spondyloepiphyseal dysplasia is a complex disorder with atlantoaxial instability seen in infancy. Our approach has been to brace the infant with a custom-built orthosis until definitive surgical treatment can be performed between ages 2 and 4 years (59). In individuals in whom this occurs at a later age, the treatment would be as previously outlined.

Congenital Abnormalities of the Cervical Spine

Frederick Dietz

F. Dietz: Department of Orthopaedic Surgery, University of Iowa, Iowa City, Iowa 52242.

Development of the cervical vertebral column begins with the process of gastrulation, during which the embryonic mesoderm and the notochordal plate are formed. This process is completed by the third week of embryonic life. The notochord induces formation of the neural groove, which gradually closes from cranial to caudad to form the neural tube. By the twenty-third day of fetal life, the neural groove is closed except for the most cranial and caudal ends, which are called the neuropores. These usually close by the end of the fourth week.

With the formation of the neural tube, the mesoderm on each side of the notochord develops lateral, intermediate, and paraxial proliferations. The lateral plate mesoderm gives rise to the pleural pericardium, peritoneum, and mesentery, blood vessels, and limb-bud mesoderm. The intermediate mesoderm gives rise to the urogenital system. The paraxial mesoderm becomes the vertebrae and ribs as well as the dermis and musculature. At the end of the third week of development, the paraxial mesoderm segments into paired masses, called somites. The somites are formed craniad and extend caudally, with each somite differentiating into three portions: the dermatome laterally, the sclerotome ventromedially, and the myotome in between. The dermatome differentiates into the dermis of the skin; the myotome into muscles, tendons, and fascia; and the sclerotome into the vertebral discs and ligaments of the vertebral column and ribs.

At the fourth week, the sclerotomic cells from each pair of somites migrate medially, meeting around the notochord and separating it from the dorsal neural tube and the ventral gut. Between adjacent somitic segments is a transverse intersegmental artery. The segmental spinal nerves originally lie at the midportion of the somitic sclerotomal mass. A process of resegmentation of sclerotomic tissues occurs at about 4½ weeks. Each somitic sclerotome thins out cranially and condenses caudally by variable-rate mitosis. Part of the condensed portion migrates cranially to the center of the sclerotome, and this central condensed portion differentiates into the intervertebral disc. The rest of the dense caudal portion of each sclerotome unites with the less condensed cranial part of the next sclerotome to form the primordium of the vertebra. Thus, the skeletal portions of the somites no longer correspond to the original segmentation. The segmental spinal nerves, which were originally in midsomite, now lie at the level of the disc. The intersegmental artery, initially located between somites, comes to lie at the midportion of the vertebral bodies, and the myotomes now bridge the vertebrae. Although somites form from craniad to caudad, the resegmentation process with intervertebral disc formation progresses caudally to cranially in the cervical spine. Cartilage appears in the primordia of the bodies of the cervical vertebrae during the fifth week and in the posterior arches slightly later. Ossification, like segmentation, begins in the thoracic region and progresses both cranially and caudally. Segmentation of the cartilaginous anlagen of the vertebrae occurs in the sixth to eighth weeks and is generally completed by the end of the eighth week.

A physical and temporal proximity of the developing urogenital ridge to the developing spinal column explains the high association of anomalies in these two systems. Furthermore, the physical proximity of the brachial arches, which arise from the intermediate mesoderm, helps explain the high incidence of malformations of the ear and facial bones associated with congenital cervical spine fusions.

Klippel-Feil Syndrome

The appellation *Klippel-Feil syndrome* has been used in two different ways. Some authors use Klippel-Feil syndrome to denote only those patients with the clinical triad of a short neck, a low posterior hairline, and marked limitations of neck range of motion. This usage stems from Maurice Klippel and André Feil's 1912 description of a single patient who manifested these signs as a result of massive fusion of the cervical spine (52).

Feil reported additional cases and developed a classification system in 1919. The common element in the patients he described was a congenital fusion of at least two vertebrae, resulting in use of the term Klippel-Feil syndrome to denote any congenital cervical spinal fusion. Feil described three patterns of congenital cervical fusions that are still used for classification today. Type I lesions consist of a massive fusion of the cervical vertebrae, sometimes extending to the upper thoracic spine. Type II lesions consist of only one or two fused vertebral segments. Type III lesions are type I or II lesions with distant anomalies in the thoracic or lumbar spine.

Klippel-Feil syndrome refers to any congenital fusion of the cervical spine, with or without the originally described clinical triad. Therefore, Klippel-Feil syndrome can denote a wider range of disorders representing different etiologic processes with varying associated anomalies and differing clinical implications. Nonetheless, the implications for the mechanics of the spine and the occurrence of embryologically related anomalies are sufficiently similar to warrant considering all cervical vertebral fusions as a single group, at least for clinical convenience. Often, it is more important to treat the associated anomalies of the central nervous system, genitourinary system, cardiovascular system, gastrointestinal system, and musculoskeletal system than it is to diagnose and treat the cervical spine anomaly.

Incidence

The incidence and prevalence of Klippel-Feil syndrome are unknown. No population screening studies have been done. Only sketchy information about prevalence can be obtained from cases that have come to medical attention in reasonably closed populations. The best of these studies is that of Gjorup and Gjorup (38). They reviewed the radiographic files of all of the hospitals in Copenhagen and determined the incidence of congenital spine fusions by comparing the number of spine fusions found to the population of Copenhagen. This is a minimal estimate of the incidence because asymptomatic cases could not be ascertained and some of the hospitals had not maintained radiographs from the entire study period. They found a prevalence of 0.2 symptomatic congenital fusion per 1,000 in their population.

A little more illumination is gained from a study by Brown et al. (14), who reviewed 1,400 skeletal specimens in a collection at Washington University School of Medicine in St. Louis. They found that 0.71% of the skeletons had congenital fusions. The selection criteria for inclusion in the collection are not stated, and this number may be artificially high if pathologic specimens were selectively preserved. However, if one assumes that many single-level fusions are asymptomatic throughout life, this prevalence seems reasonable when compared with the 0.2 clinically evident congenital fusion per 1,000 found in the Copenhagen study. In a related investigation, Brown et al. (14) reviewed all of the radiographic examinations of the cervical spine made for 1 year at their institution and found 7 congenital cervical fusions among 1,158 patients, yielding an incidence of 0.6% congenital fusion in patients radiographed for symptoms of cervical spine problems.

Because the incidence and prevalence of Klippel-Feil syndrome are not known, counseling patients is difficult. For those who are found to have a congenital fusion after minor trauma or after a radiograph is taken for unrelated reasons, the chance of their developing problems is unknown (Fig. 1).

Etiologic Factors

The cause of Klippel-Feil syndrome is unknown. Conflicting hypotheses include those proposing a primary vascular disruption, a global fetal insult, a primary neural tube abnormality, a primary genetic causation, or failure of facet joint segmentation. Congenital cervical fusion also occurs occasionally in other well-recognized syndromes.

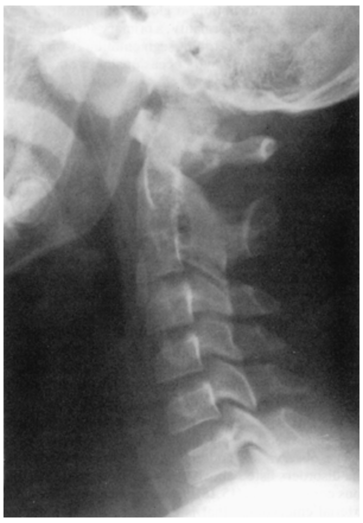

FIGURE 1. This 12-year-old boy was found to have a C2–3 block vertebra during evaluation for a depressed skull fracture. Flexion and extension radiographs revealed no instability. He was entirely asymptomatic and neurologically intact. Appropriate couseling of this patient about the natural history of this lesion is difficult because of the uncertainties about its prevalence.

Primary Vascular Disruption

A prominent hypothesis to explain the causes not only of Klippel-Feil syndrome but also of Poland anomaly, Möbus syndrome, absence of the pectoralis major, isolated terminal transverse limb defects, and Sprengel deformity is the subclavian artery disruption sequence (10). Disruption occurs when a normal embryo suffers a destructive process with cascading consequences. As all the tissues affected in these various disorders receive their major blood supply from the subclavian artery, it is hypothesized that a defect of arterial formation or an injury to existing arteries causes these various congenital defects. The location and extent of tissue abnormality is determined by the extent, location, and timing of the interruption of normal blood supply.

The observation underlying this hypothesis is that the disorders listed above often occur together in various combinations

(10,12). According to this scheme, Klippel-Feil syndrome results from an interruption of flow in the vertebral arteries or their branches, causing arrest of the normal segmentation process if it occurs at the appropriate embryologic time (about 6 to 7 weeks). Ischemia at this time might interrupt the normal vertebral segmentation process, resulting in the congenital fusions.

If a single longitudinal anastomosis between two intersegmental arteries is blocked, fails to develop, or is delayed in forming past the critical developmental stage, then a single level of fusion occurs. If many longitudinal anastomoses are blocked or fail to form, a more extensive fusion occurs. A disruption of the vertebral artery near its origin or a disruption of the subclavian artery proximal to the vertebral artery takeoff, resulting in reversal of flow in the vertebral artery, would result in a massive fusion, often with associated anomalies. Because the vertebral artery gives rise to the basilar and labyrinthine arteries supplying the cochlea and vestibular structures, disruption of this vessel could explain the sensorineural hearing defects often found in patients with Klippel-Feil syndrome.

The hypothesis of vascular disruption is attractive because it can explain the varying severity of cervical anomalies seen in Klippel-Feil syndrome as well as many of the associated anomalies. Furthermore, this hypothesis easily explains the generally sporadic occurrence of this disorder. There are limitations to this hypothesis, however. It fails to explain the many anomalies unrelated to the subclavian artery that are often associated with Klippel-Feil syndrome. It does not easily account for the hereditary occurrence of Klippel-Feil syndrome, although a genetic propensity toward vascular disruption or abnormal vessel formation can certainly be hypothesized. The major difficulty with the hypothesis, however, is whether the vascular anomalies cause the embryologic abnormalities, or the vascular abnormalities are the effect of a more primary cause or a reflection of the distorted tissues supplied.

Global Fetal Insult

Beals and Rolfe (9) pointed out that, in addition to the major components of the VATER association (i.e., vertebral defects, imperforate anus, tracheoesophageal fistula, and radial and renal dysplasia), another group of anomalies, including Klippel-Feil syndrome, was associated in a nonrandom fashion. They argued that these anomalies are not embryologically related either spatially or temporally and that no single insult could reasonably explain the wide range of associated anomalies. They suggested that a global insult with variable effects on different tissues or multiple separate insults might best explain the associated anomalies. That 34% of rabbits whose mothers were subjected to decreased oxygen between the ninth and eleventh days of gestation developed vertebral anomalies, including fusion, supports the concept of global insult causing vertebral anomalies (25).

Genetic Causation

Evidence for a genetic cause of Klippel-Feil syndrome comes from the work of Gunderson et al. (43). Eleven probands with Klippel-Feil syndrome were identified. All were symptomatic, most because of neck pain. Of these 11 probands, seven had type II lesions with only one or two interspaces fused; four had type I with a more massive fusion. Eleven of 52 radiographs of type II patients' relatives showed a type II fusion. In six of the seven families of probands with type II lesions, multiple family members were radiographed; in four of these six families, the affected family members had the same vertebral fusion at either C2–3 or C5–6, as did the probands. In two of these six families, relatives and probands had different vertebrae fused. Gunderson's interpretation was that congenital C2–3 fusion is an autosomal dominant condition with variable expressivity and penetrance; congenital C5–6 fusion is an autosomal recessive condition. These conclusions are weakened by incomplete ascertainment of relatives of probands and by simple segregation analysis. Nonetheless, this study strongly suggests a hereditary component in isolated fusions of C2–3. The four patients with type I fusions (massive fusions) had no affected family members with similar fusions.

Clark et al. studied a family with four generations of vocal impairment and two generations in which cervical vertebral fusions were associated with vocal impairment and inherited in an autosomal dominant manner. In affected individuals C2–3 were always fused, with C4–5 or C6–7 fusions occurring as well in some individuals. A gene locus on chromosome 8 has been identified based on an incision in 8q that segregates with the anomaly (17).

In Gray's (41) review of 418 cases of Klippel-Feil syndrome reported in the literature, there were 168 family histories, 136 of which were negative. Of the 32 positive family histories, 15 came from 10 families; the other 17 were cases in which another family member was believed to be affected. This suggests a much lower incidence of inheritance than that reported by Gunderson.

Syndromic Associations

Klippel-Feil syndrome is associated with other well-identified syndromes. One of these, fetal alcohol syndrome, has a known cause, although the mechanism remains obscure (57,101). Fetal alcohol syndrome results from heavy maternal alcohol use and is characterized by developmental delay, poor growth, and characteristic facies. Tredwell et al. (101) radiographed the cervical spines of 38 patients with fetal alcohol syndrome and found that 19 (50%) had congenital fusion. Ten of these 19 patients had fusion of C2–3 alone, six more had a C2–3 fusion plus one or more other levels, and three had more than two levels that did not include C2–3. Only two patients were found to have clinically abnormal necks on physical examination. The result causing fetal alcohol syndrome is believed to occur between the twenty-fourth and twenty-eighth day of fetal life, which is a little earlier than most hypotheses place the timing of failure of segmentation of the cervical spine. Reports of multiple-level fusions in siblings affected with fetal alcohol syndrome support maternal alcohol abuse and a hereditary predisposition as etiologic factors (57).

Congenital cervical fusion is also seen in Goldenhar syndrome slightly less than 10% of the time (7). This is a sporadic disorder of unknown cause characterized by hemifacial microsomia with ocular dermoid cysts, ear appendages, and fistulae. It is associated with other musculoskeletal anomalies, including clubfoot, Sprengel deformity, developmental dysplasia of the hip, and radial limb defects.

Clinical Features

The best available data on the clinical features of Klippel-Feil syndrome come from several medical centers' experience with this disorder (38,47,58,103). Articles that review the available literature are obviously biased by the unusual findings that warranted case reports (41,46,90). Surveys of Klippel-Feil patients seen at single medical institutions are uniform in showing a gender predominance of females over males of 1.5:1 (38,47,58,103). The age at presentation is extremely variable, extending throughout the entire life span. Massive fusions are often noted in infancy or early childhood because of the cosmetic deformity. Less extensive fusions may come to light because of associated anomalies detected in infancy or childhood. Neurologic problems in infancy are usually related to craniovertebral junction abnormalities, although cervical-vertebral fusions may also be present in this age group. In general, higher fusions near the craniovertebral junction present earlier; C1–2 fusions often present in childhood, usually with pain (28). Lower cervical fusions, if not massive, often do not present until the third decade or even later in life, when degenerative changes or instability of adjacent segments develops (41,55). Overall, about 20% of the patients destined to develop neural symptoms do so in the first 5 years. Sixty-five percent of patients who eventually develop neurologic symptoms will do so before age 30 (41). One clue to finding a congenital cervical vertebral anomaly in the newborn is asymmetrical crying facies due to a partial seventh nerve palsy (75). Many of these children will have a hemivertebra; occasionally, a congenital fusion will also be found. This clinical finding should prompt a radiographic search for vertebral anomalies.

The clinical triad of short neck, decreased range of motion, and low posterior hairline is seen in 40% to 50% of patients. In single-institution surveys, decreased range of motion is the most common finding, occurring in 50% to 76% of patients (47,58,103). The decrease in motion is most commonly in lateral bending and rotation; flexion and extension are relatively well preserved, except in the most massive fusions. In general, if fewer than two motion segments are fused or if the fusion is confined to the lower cervical spine, minimal or no detectable diminution in range of motion may be evident clinically. A normal range of motion due to excessive motion at motion segments adjacent to the fused vertebra is common. Definite shortening of the neck is evident in less than half of patients, and a low posterior hairline seems to reflect this shortening of the neck rather than being a separate entity (Fig. 2).

Patients with Klippel-Feil syndrome present with a wide range of chief complaints, including cosmesis (either of the neck or due to associated anomalies such as Sprengel deformity), neck pain alone, radicular pain with or without weakness, slowly progressive or acute paraparesis or quadriparesis, and complications caused by associated anomalies of the genitourinary, cardiovascular, or gastrointestinal systems.

Radiographic Features

One-level fusions are the most common pattern. Gjorup and Gjorup (38), in a review of 76 patients with Klippel-Feil syndrome, found 44 patients with one-level fusions, 19 patients with two to five fused vertebrae, and 13 patients with six or more levels fused. Similarly, in a review of skeletal specimens, Brown et al. (14) found 69 with one-level fusions and three with two separate one-level fusions. Van Kerckhoven and Fabry (103), in their population in Copenhagen, found 14 patients with one- or two-level fusions, 1 with a massive fusion, and 3 with either a limited or a massive fusion and associated lower spine anomalies. In a review of reported cases by Gray et al. (41), 20% of patients had one joint affected and 50% had three or fewer joints affected. Variable patterns of fusion may be seen, with anterior, lateral, and posterior fusion occurring in about half of patients. Anterior fusion alone occurs in about 20% of patients. Isolated posterior or lateral fusions make up the remainder. Generally, the involved vertebrae have flat wide bodies (32). The disc spaces are absent or hypoplastic (28,47,103). Spinal stenosis at the level of the segmentation defect has been reported (67,79), but this is not uniform, and a decrease in canal size is not thought to be common in children (28,47). Two brief reports suggest a higher incidence of stenosis in children than generally accepted (77,78). Pizzutillo et al. (77) reported a high incidence of decreased spinal canal width at unfused C1, C3, and C4 segments in children and adolescents with Klippel-Feil syndrome as compared with controls. Spinal stenosis often develops with aging due to degenerative changes from adjacent segment hypermobility (55). The C1–2 articulation is generally spared, as is the C7–T1 motion segment. Massive fusions beginning at the C4–5 level often extend into the upper thoracic spine and include the cervicothoracic segment.

The diagnosis of congenital cervical fusion in infants and young children can be difficult because the lack of vertebral ossification makes the hypoplastic or absent disc spaces difficult to appreciate. Flexion and extension radiographs can demonstrate a lack of motion between fused segments, and flexion and extension laminograms may be needed to confirm the diagnosis. In massive fusions, overlap of the mandible often makes the upper cervical spine anatomy difficult to appreciate on plain radiographs. Laminograms are most helpful in defining the bony architecture, but computed tomography (CT) can also be used. Care must be taken in the radiographic diagnosis to assess the craniovertebral junction, as anomalies are common and an abnormal cranial-cervical junction coupled with a lower cervical fusion may increase the risk of neurologic injury (67,68). Occipitalization of the atlas, basilar impression, os terminale, os odontoideum, hypoplastic dens, and other less common anomalies of the craniovertebral junction may be found (60,67,68,93,103).

Clinically unapparent vertebral abnormalities of the thoracic, lumbar, and sacral spines are associated with Klippel-Feil syndrome (47,82). Radiographic evaluation of the entire spine is appropriate. Conversely, 15% to 25% of children presenting with congenital scoliosis will be found to have Klippel-Feil syndrome, suggesting a need for routine cervical spine films in any child with a congenital scoliosis (109). If plain radiographs, flexion-extension laminograms, or CT scans are suggestive of instability, magnetic resonance imaging (MRI) is indicated to assess the space available for the spinal cord. Obviously, in patients with neurologic symptoms, a combination of CT, laminography, and MRI may be necessary to define the pathoanatomy and guide appropriate treatment.

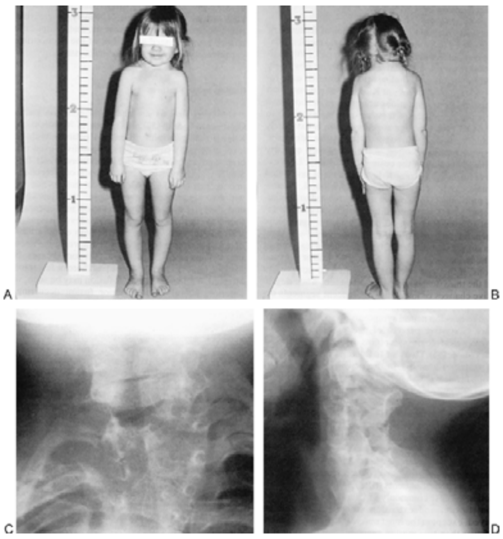

FIGURE 2. Photographs **(A, B)** and radiographs **(C, D)** of a 4-year-old girl with multiple segmentation defects of the cervical spine, congenital scoliosis, and Sprengel deformity. She also had a moderate sensorineural hearing loss in the right ear and a cleft palate.

The majority of patients with massive cervical fusion have spina bifida occulta, and somewhat less than half have cleft vertebral bodies and cervical hemivertebra in addition to the congenital fusions (6,38,41,58,109).

Associated Anomalies

Multiple anomalies associated with Klippel-Feil syndrome have been reported. Some of these are common, whereas others have been reported in so few case reports that their occurrence may be coincidental. Nonetheless, the search for associated anomalies is warranted with the finding of Klippel-Feil syndrome, as these anomalies may threaten the patient's life, health, or development. Therapeutic interventions may be necessary.

Musculoskeletal Anomalies

The most common associated musculoskeletal anomaly is scoliosis (usually congenital), occurring in up to 60% of patients with Klippel-Feil syndrome (38,41,47,99,103). Compensatory curves containing apparently normal vertebrae below primary congenital curves have a strong propensity to progress and may create significant deformities (46,47). These should be carefully monitored and appropriate treatment of bracing or fusion undertaken. The high incidence of congenital scoliosis reflects the high associated occurrence of hemivertebra (58,103). Unilateral bars may occur, and reports of combined failures of formation and segmentation in the cervical spine and in other areas of the spine are common in this syndrome (88).

Sprengel deformity is commonly reported in 20% to 30% of patients but was found in 50% of patients in one series (38,41,47,58,103). Therefore, screening of the cervical spine for congenital fusions is appropriate in patients with Sprengel deformity. An omovertebral bone may be associated with Sprengel deformity; this has been reported to contribute to cord compression in association with instability resulting from a congenital C4–C5 fusion (93).

Cervical ribs occur in 12% to 15% of patients with Klippel-Feil syndrome, which is much higher than the 1% prevalence in the general population (38,41,90). When evaluating the cause of neurologic symptoms in patients with Klippel-Feil syndrome, the possibility of thoracic outlet syndrome should be kept in mind, even though there are no reported cases associated with Klippel-Feil syndrome. The known association of cervical ribs with thoracic outlet syndrome suggests that this may occur (2,18,23,24,89). If degenerative changes and/or instability have resulted from congenital fusion, the possibility of a thoracic outlet syndrome based on a cervical rib might be overlooked.

Rib anomalies are common and occur in about one third of patients with Klippel-Feil syndrome (41,58,103). Absence of ribs occurs with appropriately equal frequency. Less common associated musculoskeletal anomalies include hypoplastic pectoralis major, radial clubhand, syndactyly of the fingers, hypoplastic thumb, supernumerary digits, clubfoot, and sacral agenesis (41,47,103).

Torticollis, neck webbing, and facial symmetry are often combined in reviews, and one or more of these findings occur in 21% to 50% of the patients (41,47,103). Torticollis stems largely from congenital spinal anomalies, but muscular torticollis does occur (13). Neck webbing may be severe, and other joints webbings are occasionally seen. Treatment of the associated musculoskeletal anomalies is generally standard for the individual deformity. Treatment of Sprengel deformity in patients with Klippel-Feil syndrome is the same as and produces similar results to treatment of patients without congenital fusions of the cervical spine (46,58). If muscular torticollis is present, release is appropriate (13). Severe pterygium colli may be treated with Z-plasty of the soft tissues, which occasionally improves cosmesis with or without resection of underlying muscle (41,58,90). Resection of cervical ribs may be indicated for symptoms or cosmesis. Bonola (11) reported that resection of the cervical ribs plus the posterior portions of the first, second, and third thoracic ribs increased the apparent length of the neck. He reports no complications and good cosmetic results from this procedure.

Craniofacial Anomalies

Hearing loss is one of the most common anomalies associated with Klippel-Feil syndrome. Institutional surveys report a 15% to 36% incidence of hearing loss or congenital deafness (47,58,103). The majority of the hearing loss is sensorineural due to abnormalities of the inner ear. However, at least one third appears to be conductive hearing loss associated with abnormalities of the ossicular chain, particularly fixation of the stapes foot plate (50,59,74,85). Mixed conductive and sensorineural hearing loss also occurs in some patients (71,95,96). Early recognition of an auditory defect is important so that patients can be rehabilitated for deafness and not miss crucial developmental milestones in language skills and speech. Audiologic tests should be performed on all children with Klippel-Feil syndrome (62,74). Malformations of the middle and external ear are also reported, including absence of the external auditory meatus (71).

Klippel-Feil syndrome and congenital hearing loss have been associated with a third finding, called Duane syndrome. Duane syndrome, or retraction bulbi, results from an abducens nerve palsy in which the adducting eye becomes retracted, causing narrowing of the palpebral fissure and enophthalmus (20,56). This combination of anomalies was called cervicooculoacoustic syndrome by Wildervanck, who initially described the association in 1960 (19,22,91,98,105). It is now more commonly referred to as Wildervanck syndrome. There is a marked female predominance of this syndrome of about 10:1, and the family history is almost always negative for similar defects. A review of 126 patients with Duane syndrome showed that 5 had Klippel-Feil syndrome and 12 had congenital hearing loss (51). Of the 3 patients who had all three components in this series, 2 also had pseudopapilledema.

Approximately 10% of patients with maxillonasal dysplasia, also called Binder syndrome, have congenital fusions of the cervical spine (73,81). Other anomalies of the cervical spine, especially defects at the craniovertebral junction and scoliosis, are even more common with Binder syndrome (73,81). Binder syndrome is characterized by premaxillary agenesis.

Although cleft lip and palate are not commonly associated with Klippel-Feil syndrome, Klippel-Feil syndrome is disproportionately represented among those with cleft lip and palate, occurring in about 4% of patients (94). Less common oral facial abnormalities reported with Klippel-Feil syndrome include frontal nasal dysplasia, mandibular duplication, and velopharyngeal insufficiency (26,37,54).

Central Nervous System Anomalies

The most commonly associated central nervous system anomaly is the occurrence of mirror movements (synkinesia), which are involuntary paired movements of the hands and arms. Fifteen to twenty percent of patients with Klippel-Feil syndrome show clinically evident mirror movements (46,103). Mirror movements are not always abnormal; they are common in preschool children and may occur as a familial trait. If mirror movements are persistent or severe, occupational therapy can often help a child disassociate the movements and improve upper extremity function.

Other congenital central nervous system anomalies have been reported less commonly. Syringomyelia, neuroschisis (failure of closure of the neural tube), fibrous diastematomyelia with cervical spinal cord duplication, posterior fossa dermoid cysts, and an isolated aberrant bony fragment embedded in the cord have all been reported (27,41,66,107). These unusual problems can give rise to confusing neurologic symptoms. One must consider underlying central nervous system pathology as a possible cause of a patient's neurologic problems in addition to possible neurologic injury from instability or stenosis due to the congenital cervical fusions.

Genital and Urinary Anomalies

Significant renal abnormalities are present in 25% to 35% of patients with Klippel-Feil syndrome (47,58,63,80,103). The most common renal anomaly is unilateral renal agenesis, with other structural abnormalities, such as malrotation, ectopic kidney, horseshoe kidney, and pelvic and ureteral duplication, occurring less often (63). Ultrasonography is an effective noninvasive screening tool without the small risk associated with intravenous pyelography (29). If a structural anomaly is found by ultrasonography, intravenous pyelography should be done to identify other problems, such as ureteral vesicular reflux, which, if untreated, could result in permanent damage to an abnormal or singular kidney. All patients with Klippel-Feil syndrome should have a renal ultrasonography as a screening precaution.

Genital anomalies have been infrequently reported. Ten to twenty percent of patients with Mayer-Rokitansky-Küster-Hauser syndrome, consisting of congenital absence of the uterus and upper vagina, have congenital skeletal abnormalities, including congenital cervical fusion (108). Gonadal dysplasia has also been reported with congenital cervical fusion, as well as hypospadias and cryptorchidism (44).

Cardiovascular Anomalies

The incidence of cardiac anomalies in patients with Klippel-Feil syndrome is difficult to define. From a review of the literature, Morrison et al. (64) believed that a minimum of 4.2% of those with Klippel-Feil syndrome had cardiovascular anomalies. Nora et al. (70) reported that five of eight patients admitted to their hospital with Klippel-Feil syndrome had significant cardiac disease. All of these patients had a ventricular septal defect as a component of their anomalies. Two surveys of patients seen at single institutions where cardiovascular anomalies were sought found an incidence of 14% and 29%, respectively (47,103). The anomalies noted were ventricular septal defect, atrial septal defect, bicuspid aortic valve, mitral insufficiency, pulmonary stenosis, and patent ductus arteriosus. Most of the cardiac conditions that are commonly associated with Klippel-Feil syndrome involve a murmur. Forney et al. (36) reported on three members of a family, all of whom had congenital cervical spine fusions, conductive deafness due to a malformed stapes, and mitral insufficiency.

Gastrointestinal Anomalies

Rarely, anomalies of the gastrointestinal tract are associated with Klippel-Feil syndrome (41). These include intrathoracic gastrogenic cysts and mediastinal cysts of foregut origin (1,35,104). These may result from a failure of the notochord to separate completely from the primitive gut. There have been several reports of recurrent meningitis in patients with Klippel-Feil syndrome, usually due to defects of or fistulae from the inner ear.

Pulmonary Problems

Pulmonary disease associated with Klippel-Feil syndrome is generally related to scoliosis or chest wall deformities (47). Restrictive lung disease has been reported from multiple rib fusions. Deformity and shortening of the thoracic spine have also been associated with restrictive lung disease and should be sought in the appropriate setting (8).

Miscellaneous Associations

Case reports of Klippel-Feil syndrome associated with meningiomas, dural hemangiolipomas, and lipomas of the spinal cord have been published (16,49,110). The presence of craniocervical dermoid cysts presenting as aseptic meningitis in a patient with Klippel-Feil syndrome has been reported (27).

Natural History and Treatment

Congenital cervical fusions can cause serious neurologic compromise. The lesions can cause anything from persistent pain with radiculopathy to sudden death from minor traumas (31,34,41,60,65,67,68,79,82,92,97,106). The risk of significant disability or injury from these lesions is not known. If the incidence figures quoted at the beginning of this chapter are within an order of magnitude of being correct, the risk of death or serious disability is small. However, because the accuracy of these figures is unknown, the physician's task of counseling families and patients is difficult.

Pain can result from stress on motion segments above or below fused segments, and the articulations above and below fixed segments often are not entirely normal (61,65,76). Instability can develop, resulting in pain and spinal cord injury, including complete quadriplegia. The excess stress on motion segments adjacent to fused areas can cause degenerative changes with osteophyte formation, resulting in acquired spinal stenosis that can cause cord compromise or foraminal stenosis with radiculopathy. Both instability and the lever arm of a congenital fusion can put an individual at risk for spinal cord injury from relatively minor trauma. The combination of fusion and spinal stenosis puts the cord at risk as well.

If a neurologic lesion is present, significant pain persists despite conservative measures, or instability is documented, then spinal fusion must be considered. Similarly, if neurologic injury is present and stenosis is documented, decompression with or without fusion is indicated. One must be cautious, especially with congenital fusions associated with craniovertebral anomalies, to rule out intrinsic cord anomalies, such as syringomyelia and diastematomyelia (65,82). In an asymptomatic patient, it is difficult to decide whether prophylactic treatment is appropriate because the natural history of Klippel-Feil syndrome is not known. For this reason, attempts to identify high-risk patients are warranted.

Gray et al. (41), in their review of all reported cases up to 1964, found that 34% of patients exhibited spasticity or hyperreflexia. Pain was present in 38%. Flaccid paralysis, weakness, anesthesia, or paresthesia was found in 10% to 15% of the reported cases. This is obviously a highly selected group; neurologic injury in association with the bony abnormality would tend to warrant a case report, whereas less dramatic sequelae would not.

Nagib et al. (67,68) attempted to identify high-risk patients with Klippel-Feil syndrome and described three patterns of deformity that they believe put patients at particular risk for neurologic injury. Pattern 1 consists of two sets of block vertebrae with open intervening disc spaces. This puts the patient at risk for gradual subluxation or acute subluxation with minor trauma at the open disc space. The second pattern consists of craniocervical anomalies (most commonly occipitalization of the atlas and basilar invagination) with a congenital fusion below C2. This lesion may cause increased mobility at the craniocervical junction and risks foramen magnum encroachment. An Arnold-Chiari malformation, syringobulbia, or syringomyelia may occur with this pattern. Pattern 3 consists of fusion at one or more levels associated with spinal canal stenosis. Stenosis may occur above, below, or at the level of the fusion. This classification scheme was based on only 21 patients with Klippel-Feil syndrome seen over a 20-year period. Of this group, 12 had no neurologic symptoms; nine of these asymptomatic patients had only two vertebrae fused, and two more had a single massive fusion. Of the nine patients with neurologic symptoms, three had the unstable fusion pattern (pattern 1), four had craniovertebral abnormalities and a lower fusion (pattern 2), and two had congenital fusion with associated spinal stenosis (pattern 3). Support for the potential problems of these three patterns is present in the literature. Two sets of fused vertebrae separated by an open interspace have caused quadriplegia, according to several authors reporting single cases (31,61,65). The association of craniovertebral anomalies with cervical fusions is the most commonly reported cause of cord injury (48,60,61,65,84,92) (Fig. 3). Spinal cord damage in patients with spinal stenosis and congenital fusions has also been reported by other authors (34,45,79). In a study of 25 cases of occipitalization of the atlas by McRae and Barnum (60), there was significant cord involvement with long-tract signs of spasticity or weakness in 16 patients. Eleven of these had a congenital fusion of C2–3 in addition to the craniovertebral anomaly (Fig. 4). Klippel-Feil syndrome associated with spinal stenosis is not commonly reported in the literature, but the combination certainly does predispose the patient to significant cord injury with minor trauma. Of 32 patients described by Torg et al. (100) with neurapraxia of the cervical cord causing transient quadriplegia, four had Klippel-Feil syndrome in addition to congenital stenosis. Other reports of transient or permanent quadriplegia after trauma with this combination of anomalies exist (31,34).

Fusions that do not fit Nagib's at-risk groups have also been reported to cause neurologic damage ranging from radiculopathy to quadriplegia to death from minor trauma (33,55). Graaff (40) evaluated 145 patients with cervical myelopathy and purposely excluded those with craniocervical abnormalities and severe Klippel-Feil syndrome. Nonetheless, eight of these 145 patients had an isolated C2–3 fusion, and one also had a C5–6 fusion. These patients all had quadriparesis and upper extremity dysfunction.

Pizzutillo et al. (76) reviewed 111 patients with Klippel-Feil syndrome and found five patients with neurologic deficits, four of whom had instability of the upper cervical spine. Twelve other patients had degenerative changes or instability of the lower cervical spine that generally resulted in pain but not neurologic deficit.

It may be that Gray's (41) 1964 assessment of patients at risk for neurologic injury remains correct: “The level of fusion does not greatly affect the incidence of neurologic symptoms. The most frequent defect—occiput to first cervical vertebra and second and third cervical vertebra—also produced the most symptoms. Lesions beginning below the third and fourth cervical vertebra were slightly less likely to be accompanied by symptoms as lesions starting higher.”

All patients with congenital cervical fusion should be treated as being at increased risk of pain, instability, or neurologic injury. Some evidence and common sense suggest that certain patterns, such as occipitalization of the atlas with C2–3 fusion, would stress the C1–2 articulation and cause a high incidence of instability and potential cord injury. One should be especially cautious about the potential for damage in these patients.

Certain principles are apparent. If a congenital fusion is identified, stability must be assessed. Flexion and extension radiographs may be sufficient if the patient is asymptomatic, but flexion and extension laminography or CT may be needed if the anatomy is obscured. Plain radiographs must be scrutinized for evidence of either congenital or acquired spinal stenosis and for evidence of degenerative changes that would compromise the neural foramina. If none of these abnormalities is present in an asymptomatic patient, it is unwise to recommend prophylactic fusion or decompression. In cases in which the anomalies are such that there is concern about the space available for the cord, MRI in flexion and extension should be performed. If it

demonstrates a significantly small space available for the spinal cord, prophylactic decompression and/or fusion might be considered. It instability is demonstrated prior to the onset of significant symptoms, it is difficult to decide when prophylactic fusion should be done. Koop et al. (53) reported several asymptomatic patients who developed cervical instability of 6 to 18 mm who underwent posterior fusion with excellent results.

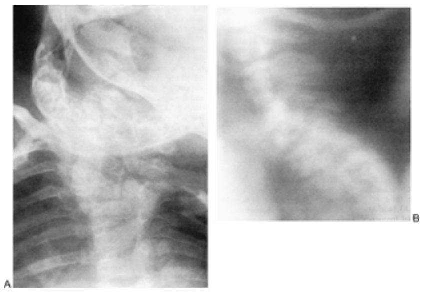

FIGURE 3. This 3-month-old girl had multiple segmentation defects as well as a unilateral bar on the left, resulting in congenital scoliosis. She had a bifid thumb but no other congenital anomalies. She eventually underwent posterior in situ fusion on the left from T2 to T5 and on the right from T1 to T7 for progressive deformity. **A:** Anteroposterior radiograph. **B:** Midline lateral tomogram.

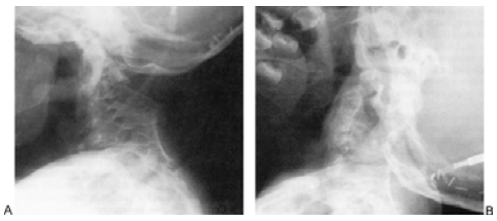

FIGURE 4. This 3-year-old boy with massive fusion but no instability had an associated posterior fossa dermoid cyst that was resected. With occipitalization of C1 and fusion of C2–3 and C4–5, this cervical spine would seem to be at risk for developing instability. Flexion **(A)** and extension **(B)** tomograms in early childhood did not reveal any instability, but continued follow-up would be appropriate.

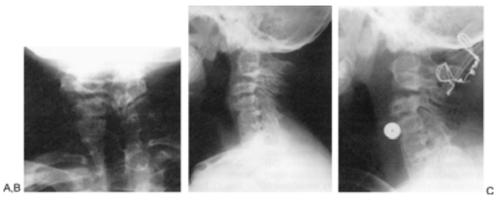

FIGURE 5. This 10-year-old boy with chronic severe neck pain was recognized as having Klippel-Feil syndrome at age 6 years. Over the years, he developed progressively increasing neck pain that was unresponsive to conservative therapy. He had occipitalization of C1 with basilar invagination and segmentation defect from C2 to C7, sparing only the C3-4 articulation **(A,B)**. Magnetic resonance imaging (MRI) revealed impingement of the ventral cervicomedullary junction by an abnormal odontoid process in an invaginated position from the foramen magnum. In spite of halo ring traction, he had persistent compression of the cervicomedullary junction as revealed by MRI. The patient underwent a transoral transphalangeal decompression of the cervicomedullary junction followed by a posterior occipital cervical fusion with rib graft **(C)**.

It is prudent to obtain flexion and extension radiographs periodically to seek developing instability in patients with Klippel-Feil syndrome. Patients may become symptomatic at any time, and it is a matter of philosophy whether lifelong assessments are made or the patient is simply counseled about the warning signs of neurologic compromise so that these can be detected and treated soon after the onset of symptoms (Fig. 5). All patients with congenital cervical fusion should avoid contact sports as well as occupations and recreational activities that put them at risk for head trauma. Patients who do develop symptoms of nerve root injury, irritation, or cord injury need a careful workup to identify the source of the neurologic symptoms because more than one anomaly with the potential to cause symptoms might be present. This is especially critical with anomalies of the craniovertebral junction. Therapy must be tailored to the pathology and often involves the combined services of a neurosurgeon and an orthopaedic surgeon.

Summary

Klippel-Feil syndrome encompasses a wide range of cervical anomalies, all characterized by a failure of segmentation of at least one motion segment. Several causes of this disorder may exist. A high index of suspicion for Klippel-Feil syndrome should be maintained in the presence of other congenital anomalies; conversely, if congenital cervical fusions are found, a diligent search for associated anomalies should be done. Management of this disorder requires recognition of the limitation of our knowledge concerning its general incidence so that overtreatment is avoided. However, the potential for catastrophic outcomes with this lesion must be kept in mind. Long-term follow-up and careful counseling of patients and families should be undertaken.

Cervical Ribs

Cervical ribs are a common anatomical variation that is rarely symptomatic in childhood. The prevalence of cervical ribs in the general population is estimated at between 0.5% and 1% (21). More than 90% of these apparently cause no problems. The remaining 10% are most commonly associated with thoracic outlet syndrome, which usually develops in the third to fifth decade (21). Cervical ribs are generally considered to be of two types: complete or incomplete. The complete cervical rib arises from the transverse process and is continuous with the first thoracic rib. The incomplete cervical rib does not have bony continuity with the first thoracic rib, although it usually does have a fibrous connection; the remaining cervical ribs end in the soft tissues without a fibrous or bony connection to the thoracic cage. A nonrib bony connection between the cervical spine and rib cage has been reported (39). The diagnosis of a cervical rib is generally made on plain radiographs and is an incidental finding, although unsuspected cervical ribs have been found with other imaging techniques (69). If the transverse process of the cervical vertebra is larger than the transverse process of the first thoracic vertebra, a rudimentary cervical rib is felt to be present. Although cervical ribs are most common at the seventh cervical level, they do occur at the sixth level and rarely at the fifth level.

Cervical ribs seem to be inherited in an autosomal dominant fashion, although extensive population studies have not been done to confirm this. A carefully pedigreed family showed a high degree of dominance and complete penetrance (86). There was variable expressivity, with some affected members showing bilateral complete cervical ribs and others showing only rudimentary unilateral cervical ribs. Cervical ribs occur approximately twice as commonly in females as males, and they are bilateral twice as often as unilateral.

The most common problem with cervical ribs is irritation of the brachial plexus, causing the neural symptoms of thoracic outlet syndrome. There is an extensive literature addressing the appropriate treatment, and disagreement still exists whether anterior scalenotomy is sufficient or cervical rib resection is necessary for relief of symptoms (15). This is largely a problem of adults, although thoracic outlet-like symptoms relieved by cervical rib resection in a child as young as 6 years have been reported (3). Vascular compromise from cervical ribs can cause vague symptoms of the thoracic outlet syndrome type, but it may also cause arterial stenosis with aneurysm development, thrombosis, and embolism (87). If a cervical rib causes direct compression resulting in stenosis or aneurysm, resection of the rib is obviously indicated, along with all other soft tissues compressing the vessel (87). A subclavian artery aneurysm due to a cervical rib was reported in a 9-year-old child (102). This presented as a mass with a bruit that had probably been present since infancy. Cervical ribs have also been implicated in axillary vein thrombosis occurring in young athletes without other risk factors or with risk factors such as the taking of oral contraceptives (5). In this setting, the decision of whether to excise the cervical ribs largely depends on whether a return to the activities that precipitated the thrombosis is desired and anticipated. A rare complication of cervical ribs was reported by Grimer et al. (42) in which a brachial plexus injury occurred after correction of a right thoracic scoliosis in a patient with cervical ribs. Isolated cervical rib fracture after blunt trauma has been reported (30).

Miscellaneous Disorders

Cervical meningocele is an uncommon disorder (26). Meningoceles are distinctly less common than myelomeningoceles; only 4% to 20% of spinal bifida cysticas have no neural elements and qualify as meningoceles. Less than 10% of these meningoceles are in the cervical spine. Meningocele is far more common in the lumbosacral spine. Cervical meningoceles warrant special attention because of the high incidence of associated central nervous system anomalies. Hydrocephalus, Arnold-Chiari malformations, hydromyelia, lipomyelocele, tethered cord, Klippel-Feil syndrome, and diastematomyelia have all been found in association with cervical meningocele (26). Therefore, in spite of the generally benign nature of this lesion, a careful evaluation and probably MRI of the entire spinal cord should be done when this condition is found.

Cervical diastematomyelia is also quite rare (4,72). Thoracic and lumbar diastematomyelia are far more common. Vertebral abnormalities occur in 85% to 90% of patients with cervical diastematomyelia and provide a clue to the presence of this disorder. Cervical diastematomyelia may present with primary upper extremity signs and symptoms. Although this condition usually manifests itself in childhood, adult presentation has rarely been reported (72).

Spinal dysraphism encompasses several spinal malformations. All have in common a disorder of dorsal midline development that involves any or all of the dorsal midline structures—skin, dorsal muscles, vertebrae, and the neural tube and its coverings. Dysraphic malformations can be conveniently classified according to type of skin covering into open malformations (spina bifida aperta) and closed malformations (spina bifida occulta). Open dysraphic malformations lack an intact skin covering over the neural malformation, and the neural lesion is readily visible on the back of the infant. Occult dysraphic malformations are covered by an intact, although often abnormally formed, skin covering. Myelomeningocele is the most common open malformation. The frequency is approximately 1 in 1,400 live births (16,69,134). Other, less common open dysraphic malformations include meningocele and combined anterior and posterior spina bifida (12,22,25,27,31,135). The most commonly encountered occult dysraphic lesions is lipomyelomeningocele (spinal lipoma). Other occult dysraphic lesions include split-cord malformation (diastematomyelia), dermal sinus tract and dermoid tumor, thickened filum terminale, and myelocystocele. More complex malformations may have combinations of the foregoing anomalies and are not as readily classified (23). A working knowledge of normal and abnormal neuroembryology helps in understanding the anatomy, presentation, and management of these lesions.

Normal Neural Development

The human embryo at the end of the first week is composed of two layers—the epiblast adjacent to the amnionic cavity and the hypoblast adjacent to the yolk sac (Fig. 1A). During the second week, a midline structure, the primitive streak, forms in the midline in the caudal half of the embryo; the cranial end of the primitive streak is called *Hensen's node* (Fig. 1B). Cells of the epiblast migrate toward the primitive streak and enter between the epiblast and hypoblast in a process known as *gastrulation.* This gives the embryo three layers—ectoderm, mesoderm, and endoderm. The ectodermal cells give rise to the surface ectoderm and neuroepithelium; the mesodermal cells give rise to the somites and mesenchyme of the embryo; and the endodermal cells give rise to the gut.

During gastrulation, the primitive streak first elongates toward the cranial end of the embryo then regresses back toward the caudal end of the embryo. During regression, cells within Hensen's node are laid down to form the midline notochordal process between the overlying neuroepithelium and the underlying endoderm. These prospective notochordal cells enter through the primitive pit within the center of Hensen's node and enter between the ectoderm and endoderm rostral to the retreating Hensen's node (Fig. 1C). The notochordal process initially is rod shaped and has a central lumen, the notochordal canal, which is contiguous with the amnionic cavity through the primitive pit (Fig. 2A). Later, the notochordal process fuses, or intercalates, with the underlying endoderm to form the notochordal plate (Fig. 2B). The fusion of the notochordal process with the endoderm places the amnionic cavity and yolk sacs in direct communication through the primitive neurenteric canal. This canal lasts approximately 3 days, after which the notochordal plate detaches, or excalates, from the endoderm (Fig. 2C), and the primitive neurenteric canal is closed. With regression of the primitive streak and Hensen's node during gastrulation, the primitive pit ultimately occupies a caudal position at the coccyx; benign coccygeal dimples are thought by many to represent a remnant of the primitive pit. Abnormal development of the notochord during gastrulation has been implicated as a cause of split-cord malformations and other complex dysraphic malformations (25).

The nervous system and the skin are both derived from ectoderm. The development of the neuroectoderm to form the neural tube is called *primary neurulation.* By gestational day 16, the neuroectoderm is visible as pseudostratified columnar epithelium in the midline of the dorsal surface of the embryo. It overlies the notochord and is contiguous laterally with the cutaneous ectoderm. By day 18, the neural groove (median hinge point) forms in the midline of the neuroectoderm, and the two adjacent neural folds begin to elevate (Fig. 3A). This is the beginning of primary neurulation, the process whereby the neural plate undergoes several morphogenetic movements to form the neural tube (129).

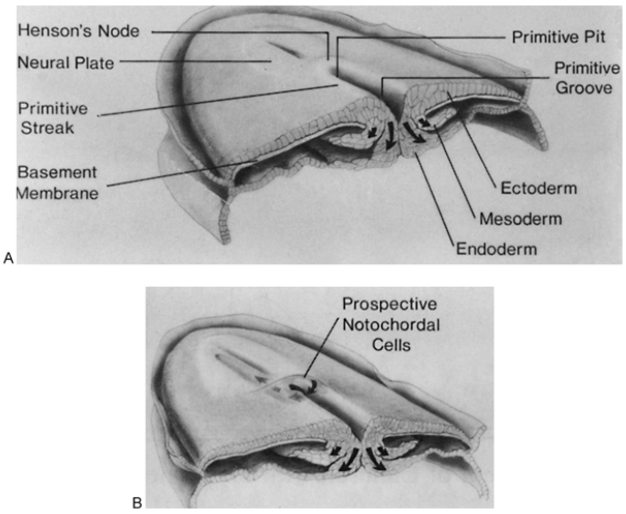

FIGURE 1. Illustrations show early human development. **A:** Human embryo at the time of gastrulation is composed of two layers—the epiblast adjacent to the amnionic cavity and the hypoblast adjacent to the yolk sac. During gastrulation, cells of the epiblast migrate toward and enter the primitive streak to form the endoderm and mesoderm. **B:** Presumptive notochordal cells in Hensen's node enter the primitive pit during the latter half of gastrulation (during regression of the primitive streak) to form the notochordal process.

As primary neurulation continues, the neural groove deepens, and the adjacent neural folds continue to elevate dorsally (Fig. 3B). Later, two dorsolateral hinge points form on both sides of the developing neural tube, bringing the neural folds together in the midline (Fig. 3C). The apposition and fusion of the neural folds completes the neural tube; simultaneously, the cutaneous ectoderm separates from the neural folds to form the skin of the back. Mesenchymal tissues intercalating between the newly formed neural tube and the overlying cutaneous ectoderm form the paraspinous muscles and dorsal vertebral arch.

Closure of the neural tube in human embryos usually begins in the midcervical region and proceeds both cranially and caudally from this point. Whereas neurulation was previously thought to occur in a simple linear manner, as the closing of a zipper, from the point of initial closure, it is now known that there are multiple points of closure (42,43,95). The last areas to close are the cranial neuropore, located near the optic chiasm at the lamina terminalis, and the caudal neuropore, located at the second sacral level of the spinal cord. The cranial neuropore closes at about gestational day 24, and the caudal neuropore at about day 26 (96,97). More caudal regions of the neural tube (the spinal cord caudal to the S2 segment and the filum terminale) are formed thereafter through a process known as *secondary neurulation.* This secondary neural tube develops from the caudal cell mass, a pluripotent group of cells that additionally gives rise to the caudal vertebrae and mesenchyme through a process of canalization and fusion of adjacent tubules (Fig. 4). The secondary neural tube eventually becomes contiguous with the neural tube formed by means of primary neurulation (71,97,126,127,128).

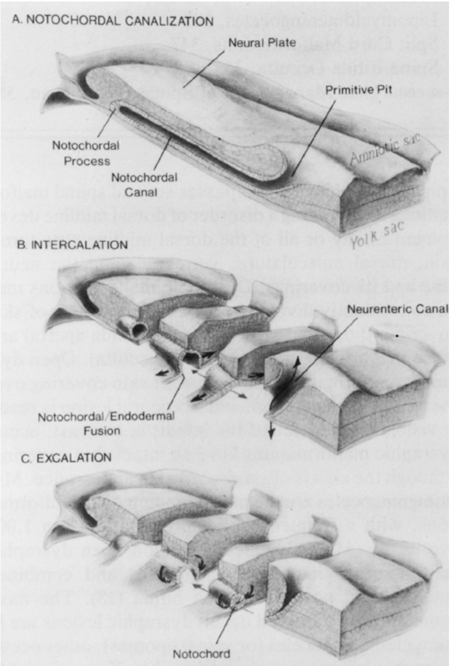

FIGURE 2. Formation of the notochord. *A*, The notochordal process contains a central lumen (the notochordal canal), which is continuous with the amnionic cavity through the primitive pit. *B*, During intercalation, the canalized notochordal process fuses with the underlying endoderm. The communication of the amnion with the yolk sac forms the primitive neurenteric canal. *C*, During excalation, the notochord rolls up and separates from the endoderm to become the definitive notochord. The primitive neurenteric canal is obliterated.

Beginning during the sixth embryonic week and continuing into postnatal life, the neural tube undergoes several morphogenetic changes collectively called the *ascent of the conus medullaris.* Before embryonic day 54, the caudal neural tube undergoes morphogenetic changes known as *retrogressive differentiation.* The result is formation of the filum terminale and an apparent ascent of the conus medullaris. After day 54, differential growth of the vertebral column relative to the neural tube causes a progressive length discrepancy so that the conus medullaris undergoes a true ascent (Fig. 5). The conus by 1 to 2 months after birth normally lies opposite or craniad to the L1–2 disc space (4,26,149,151). A more caudally positioned conus suggests spinal cord tethering (see later).

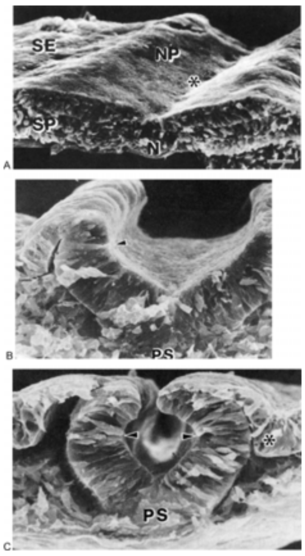

FIGURE 3. Scanning electron micrographs show neurulation in the chick embryo. **A:** Midline bending of the neural plate (*NP*) over the notochord (*N*) to form the neural groove, or median hinge point (*asterisk*). *SE*, Surface epithelium; *SP*, segmental plate mesoderm. **B:** Further elevation of the neural folds about paired dorsolateral hinge points (*arrowhead*). *PS*, Primitive streak. **C:** Apposition of neural folds in preparation for fusion to form the neural tube. *Asterisk*, Surface epithelium; *arrowheads*, dorsolateral hinge points; *PS*, primitive streak. (From Shoenwolf GC (1986): On the morphogenesis of the early rudiments of the developing central nervous system. In: Schoenwolf GC. ed. *Scanning electron microscopy studies of embryogenesis.* O'Hare, IL: SEM, Inc., pp. 289–308, with permission.)

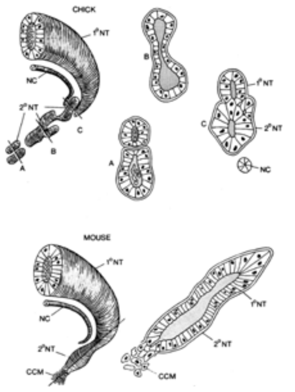

FIGURE 4. Secondary neurulation in chick and mouse. *A*, In the chick (*top*), cells of the caudal cell mass located caudal to the primary neural tube (*1° NT*) form multiple independent vesicles. *B*, These vesicles fuse to form a secondary neural tube (*2° NT*). *C*, The secondary neural tube then fuses with the primary neural tube. *NC*, Notochord. In the mouse (*bottom*), cells of the caudal cell mass (*CCM*) fuse directly with the caudal end of the primary neural tube to form the secondary neural tube. Among humans, it is unclear whether secondary neurulation more closely resembles that of the chick or the mouse.

Philadelphia: WB Saunders, p. 383, with permission.) **E**, Level of the conus medullaris in humans during gestation and postnatal development (From Barson AJ (1970): The vertebral level of termination of the spinal cord during normal and abnormal development. *J Anat* 106:489–497, with permission.)

Embryogenesis of Spinal Dysraphism

Dysraphic spinal cord malformations are the result of abnormalities of early neural development during the first 4 through 6 weeks of embryogenesis. Myelomeningocele involves either primarily or secondarily a failure of the neural tube to close properly over a portion of its length. Occult dysraphic lesions are thought to arise through a variety of mechanisms involving several key processes in early neural development. The embryogenesis of all of these malformations is beyond the scope of this chapter, and the interested reader is referred to more extensive discussions of this topic (24,25,84). This chapter concentrates on four disorders of the spinal neural tube: (a) myelomeningocele, (b) meningocele, (c) lipomyelomeningocele, and (d) split-cord malformations. Also included is a review of the embryogenesis of spina bifida occulta.

Myelomeningocele

Myelomeningocele arises through a localized failure of neural tube closure. The nonclosure theory (146) suggests that these malformations arise through a primary failure of neural tube closure, whereas the reopening or overdistention theory (37,38,39,40,93) suggests that the neural tube reopens after an initial period of normal closure. In most cases, myelomeningocele arises by means of the former mechanism. Myelomeningocele is likely the end product of a variety of environmental, teratogenic, and genetic abnormalities and has a heterogeneous and multifactorial origin. Neither the contributing etiologic factors nor the molecular events that underlie human neural tube defects are known with certainty (15).

Use of the terms *myelomeningocele* and *myeloschisis* is confusing, in part because various authors have used these terms to refer to what they have considered to be two distinct disorders. *Myeloschisis* has traditionally referred to a malformation in which the neural tube has failed to close over a large portion of its length. The involved neural tissue is flat, lies open on the back, and has no investing meninges (59). In contrast, the term *myelomeningocele* refers to an open neural tube that sits atop a spinal-fluid-containing sac (Fig. 6). These terms are confusing and misleading. In both disorders, a portion of the neural tube has failed to close, the neural folds remain attached to the adjacent cutaneous ectoderm, and a portion of the neural plate—the placode—is therefore exposed on the dorsal embryonic surface. Because the exposed placode remains attached to the cutaneous ectoderm, cerebrospinal fluid (CSF) can form only in the subarachnoid space beneath the placode. The extent to which the underlying CSF elevates the placode determines the type of malformation. If CSF accumulates beneath the placode and displaces it to the top of a fluid-filled sac, a myelomeningocele results (Fig. 6). If CSF is vented, perhaps through the central canal or through a tear in the attenuated surrounding tissues, it does not accumulate, the placode lies flat on the dorsal surface, and myeloschisis results. These two malformations therefore differ not in origin but in subsequent development. The term *myeloschisis* should be discarded, and all such lesions called myelomeningocele.

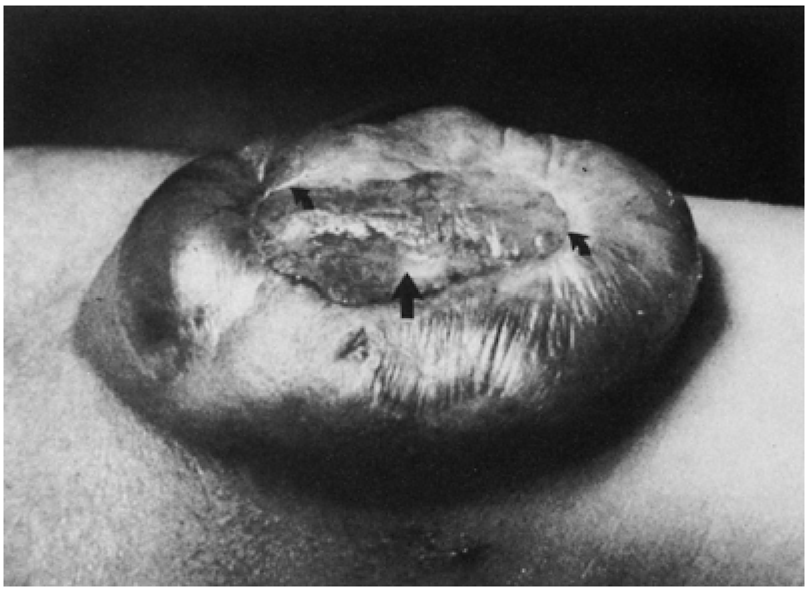

FIGURE 6. Myelomeningocele in a newborn infant. *Straight arrow* points to the neural placode on the dorsal aspect in the center of the sac. *Curved arrows* denote the junction of the neural placode with the surrounding skin (cutaneous ectoderm).

Another point of confusion is the use of the term *closed myelomeningocele* to refer to a fluid-filled lumbosacral mass covered with full-thickness skin. When neurulation fails to occur, the neuroectoderm remains attached to the skin laterally, and myelomeningocele is by definition an open lesion. “Closed myelomeningocele” is not a myelomeningocele at all. Most often it is a myelocystocele, a terminal dilation of the spinal cord contained within a dilated, fluid-filled, thecal sac (88,106).

Meningocele

Meningocele is a skin- or membrane-covered sac, usually in the lumbar region, that contains no demonstrable neural tissue. The sac, which contains CSF, comprises the spinal dura mater and underlying arachnoid, which balloon dorsally from the spinal thecal sac. The spinal cord is normal and within the spinal canal. True meningocele, which has no element of neural tissue, is extraordinarily rare. In many cases, the sac contains strands of mesenchymal or central or peripheral neural tissue that connects with the dorsal surface of a low-lying (tethered) spinal cord (Fig. 7). The neural-tissue-containing lesions probably are a form of myelomeningocele. Meningocele likely is caused by either a postneurulation disorder of cutaneous ectodermal or dorsal mesenchymal development or by abnormal separation of cutaneous ectoderm from neuroectoderm. Despite the presence of small amounts of neural tissue in some of the malformations, these patients usually have normal neurologic findings, and their prognosis is excellent if the spinal cord is properly untethered. Hydrocephalus and Chiari malformation are unusual.

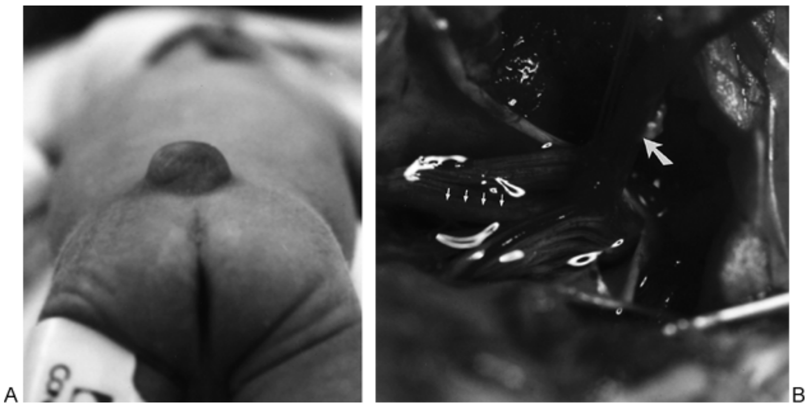

FIGURE 7. Meningocele in a newborn infant. **A:** The malformation consists of a fully skin-covered lesion with no spinal fluid leakage. **B:** Operative photograph shows the distal spinal cord terminating in a filum terminale (*small arrows*). A track of mesenchymal tissue (*large arrow*) is attached to the dorsal portion of the distal spinal cord just cranial to the tip of the conus and separate from the filum terminale. This projects into and ends within the skin-covered sac.

Lipomyelomeningocele

Lipomyelomeningocele (spinal lipoma) is a malformation that contains an element of fat (lipoma) contiguous with a low lying, or tethered, spinal cord. Lipoma usually is an isolated malformation, although it can occur in combination with myelomeningocele and other dysraphic malformations. Most lipomyelomeningoceles involve the lumbosacral spinal cord, filum terminale, or both. Cervical or thoracic lesions are rare. Two general types of lipomyelomeningocele have been described. In the first and more frequent type, a subcutaneous fatty mass of variable size is contiguous with the spinal cord through a dorsal vertebral and dural defect (Fig. 8A). In the second type, the dura and posterior vertebral elements are intact, and the fat is located solely within the thecal sac (Fig. 8B). In both cases, the spinal cord has failed to close properly at the level of the lipomyelomeningocele, and the fat arises from the dorsal spinal cord through the defect (Fig. 9). The dorsal nerve roots, which are derived from neural crest and normally arise from the neural folds just lateral to the site of dorsal midline fusion, are located immediately lateral to the junction between the fat and the dorsal cord. Lipomyelomeningocele is thought to arise from disordered neural tube closure in which the cutaneous ectoderm separates prematurely from the approximating neural folds before neural tube closure is complete (Fig. 9). The surrounding mesenchyme enters the central lumen of the neural tube and is induced to form fat (78).

Split-Cord Malformations (Diastematomyelia)

Split-cord malformation is an anomaly whereby the spinal cord is clefted over a portion of its length to form a double neural tube. The two hemicords both may be contained within a single dural sheath, or each may be contained within its own, separate dural sheath. Split-cord malformations can occur in isolation or in association with myelomeningocele or other closed dysraphic malformations. Early classification schemes were confusing and misleading. The term *diastematomyelia* (from the Greek “diastema” meaning *cleft* and “melos” meaning *medulla*) was used to describe malformations in which the spinal cord was “split” into two half-cords, each with a single, lateral set of dorsal and

ventral nerve roots. The term *diplomyelia* was used to describe complete duplication of the spinal cord, each cord containing both medial and lateral sets of ventral and dorsal nerve roots (20,52,53,64,98).

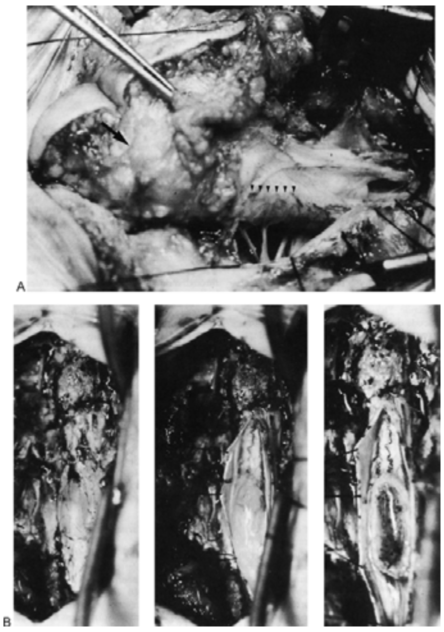

FIGURE 8. Lipomyelomeningocele. **A:** Lipoma with subcutaneous extension (*arrow*). The subcutaneous mass enters the spinal cord through a dorsal dural defect and infiltrates the central canal of the cord. The nerve roots exit immediately lateral to the lateral edge of the lipoma (*arrowheads*). **B:** Intradural lipoma. The lipoma is located entirely within the dural sac. *Left*, Before dural opening, the lipoma is visible through the thinned dura. *Center*, After dural opening but before resection. *Right*, After resection.

FIGURE 9. A, B, C, D: Embryogenesis of lipomyelomeningocele. *A,B*, Premature dysjunction of the cutaneous ectoderm (*CE*) from the neuroepithelium allows mesenchymal cells (*Me*) to gain access to the central canal of the neural tube. *C,D,* These cells form a fibrofatty subcutaneous lipoma (*SL*) beneath the surface ectoderm and extending into the central canal. The dorsal roots (*DR*) arise immediately lateral to the lipoma. *NC*, Neural crest; *LF*, lumbodorsal fascia; *DREZ*, dorsal root entry zone; *D*, dura; *P-A*, pia and arachnoid; *IL*, intracanalicular lipoma. (From Pang D: Tethered cord syndrome. In: Hoffman HJ, ed (1986): *Advances in Pediatric Neurosurgery. Neurosurgery: State of the Art Reviews*, vol. 1, no. 1: Philadelphia, Hanley and Belfus, with permission.) **E:** Anatomic features of lipomyelomeningocele. The subcutaneous mass extends through the dorsal aspect of the spinal cord to end within the central canal. The dorsal roots arise immediately lateral to the lipoma at the dorsal root entry zone (From Oakes WJ (1991): Management of spinal cord lipomas and lipomyelomeningoceles. In Wilkins RH, Rengachary SS, eds. *Neurosurgery Update II.* New York: McGraw-Hill, pp. 345–352 with permission.)

The confusion has been compounded by classification of these malformations according to the composition of their dural coverings or by the presence or absence of tethering midline structures. In diastematomyelia, each of the hemicords lies within its own dural sheath, whereas in diplomyelia, both duplicated cords lie within a common dural sheath. In diastematomyelia, midline bony, cartilaginous, or fibrous tethering bands are present between the two hemicords. In diplomyelia, no such midline structures are thought to be present. Thus the widespread belief has been that diastematomyelia involves a splitting of the spinal cord into two half-cords lying within two separate dural sheaths and separated by an osseous or fibrocartilaginous tethering spur. Diplomyelia, however, is thought to be a true spinal cord duplication within a common dural tube with no interposed tethering elements (20,52).

Several more recent observations suggest that diastematomyelia and diplomyelia represent different variations of the same malformation and share a common embryonic origin. James and Lassman's (64) original description of diastematomyelia included 11 cases of "single dural tube" malformations, eight of which contained midline intradural fibrous "bands" analogous to the osseocartilaginous spurs of the double dural tube malformations. These tethering bands also have been described by Pang et al. (Fig. 10A). The intradural bands originate in the cleft between the two hemicords and traverse the subarachnoid space to end more caudally on the dura. They are composed of tough, fibrous connective tissue, prominent blood vessels, and dystrophic median nerve roots that originate from one or both of the hemicords (103). Similar midline intradural fibrous bands were described by Herren and Edwards (52) in several cases of "diplomyelia"; cases of double and single dural tube malformations occurred with equal frequency in the series.

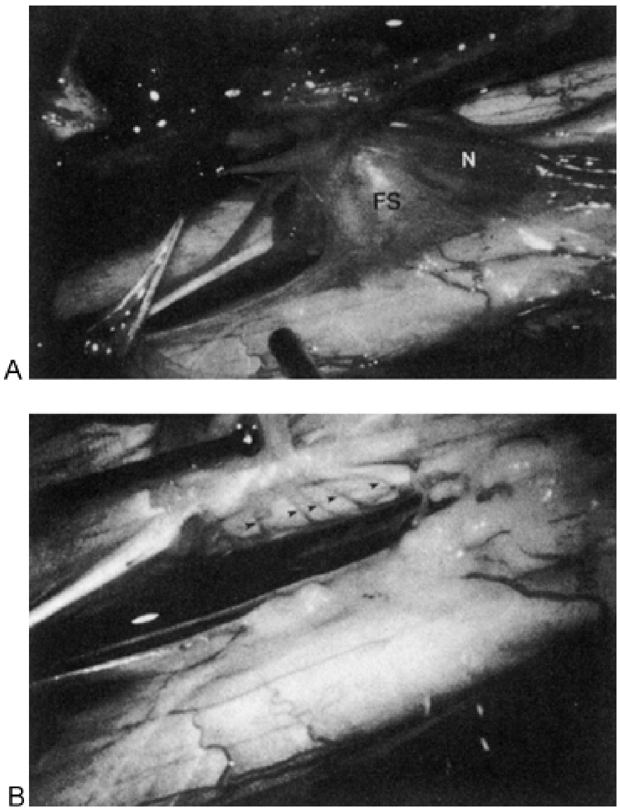

FIGURE 10. Intraoperative photographs of a split-cord malformation with a single dural sac. **A:** A thick, fibrous band (*FS*) arises from between the two hemicords and tethers them to the dorsal dura. Median dorsal nerve roots (*N*) are visible in the cranial margin of the band. **B:** After the fibrous band and dorsal roots are removed, median ventral nerve roots (*arrowheads*) course up from the ventral aspect of the left hemicord and end in the median septum. (From Pang D, Dias, MS, Ahab-Barmada M (1992): Split-cord malformation, I: a unified theory of embryogenesis for double spinal cord malformations. *Neurosurgery* 31:451–480, with permission.)

Dystrophic median nerve roots projecting from one or both hemicords have been associated with both diastematomyelia and diplomyelia (Fig. 10B) (52,64,102,103,120). These dystrophic roots originate from one or both hemicords and insert onto the midline osseocartilaginous spurs or fibrous bands. Both dorsal and ventral roots and ganglion cells have been described (102,103,120). The presence of both lateral and median sets of nerve roots strongly suggests the presence of at least partial spinal cord duplication in both malformations. Autopsies of persons who died with diastematomyelia or diplomyelia have shown neither absolute splitting nor complete duplication of the cord in any instance. Rather, the hemicords are incomplete duplications with relatively well preserved lateral halves and dystrophic medial halves (20,52,72,119,120).

All these observations suggest that diastematomyelia and diplomyelia represent a spectrum of split-cord malformations that have a common embryonic mechanism. The exact nature of the resultant malformation depends in part on the severity of the initial embryologic insult and the success of subsequent embryonic repair. Pang et al. (102,103) has classified split-cord malformations into types I and II. Type I malformations contain two hemicords, each within its own dural sheath, with an intervening extradural tethering osseocartilaginous spur (Fig. 11). Type II malformations contain the two hemicords within a single dural tube and a midline intradural fibrous tethering band (Fig. 12).

Split-cord malformations can be isolated or associated with a wide variety of malformations, including combined anterior and posterior) spina bifida, also called *split notochord syndrome*; hemimyelomeningocele; myelomeningocele, (in which SCMs are found in as many as one-third of autopsies); cervical myelomeningocele; neurenteric cyst; some instances of Klippel-Feil syndrome, iniencephaly, and caudal agenesis; and certain intestinal duplications and diverticula. All these complex dysraphic malformations have in common stereotypical anomalies that involve tissues derived from all three primary germ layers and are thought to share an embryonic origin (25,39). The following four putative embryonic mechanisms have been proposed (25).

Ectodermal-Endodermal Adhesion Theory

Beardmore and Wigglesworth (5) proposed that adhesion between the epiblast and hypoblast before or during the outgrowth of the notochordal process could split the notochord around the adhesion. The result would be a split notochord and independent development of paired neural tubes to form two hemicords. Remnants of this endodermal-ectodermal adhesion could give rise to endodermal remnants anywhere between the gut and the cutaneous ectoderm. This mechanism would work only if the notochord extended cranially from the Hensen node. If, on the other hand, the notochord is laid down as the node regresses, as has been demonstrated in the chick embryo (139), one would have to postulate an adhesion within the primitive streak caudal to the Hensen node, around which the notochord might be split during node regression (113).

Accessory Neurenteric Canal Theory

Bremer (9) studied combined spina bifida (split notochord syndrome), which is characterized by an open neural tube defect and widespread underlying vertebral anomalies. Midsagittal splitting of the involved vertebrae forms two hemivertebral columns around a central cleft. Through this cleft passes a variable amount of endodermal tissue, ranging from a neurenteric cyst to entire loops of intestine, that arises from the abdominal cavity and projects onto the dorsum of the child. The intraabdominal intestine also may contain variable duplications or diverticula. An associated split-cord malformation is invariably present; the two hemicords surround the central cleft. Visceral malformations are exceedingly common (5,12).

Both the central cleft in combined spina bifida and the neurenteric canal of normal embryos connect the embryonic endoderm and ectoderm. However, the dorsal opening of the neurenteric canal—the primitive pit—ultimately descends to the level of the coccyx, whereas combined spina bifida (and other variants of split-cord malformations) arise at more cranial levels of the neuraxis. Bremer proposed that the endoderm herniates dorsally in these malformations and splits the notochord and neural plate to produce an accessory neurenteric canal. However, the impetus for such a dorsal herniation is unknown.

Notochordal Duplication Theory

McLetchie et al. (76) and Saunders (125) suggested that the initial abnormality is a duplication of the notochord that allows a secondary endodermal-ectodermal interaction between the paired notochords. Dodds (27) suggested that during normal embryogenesis, bilaterally paired prospective notochordal cell anlagen might be integrated into a single midline structure during primitive streak regression. Feller and Sternberg (32) proposed that abnormal rests of undifferentiated cells in Hensen's node might interfere with proper midline integration and result in paired notochords. Subsequent differentiation of these cell rests might give rise to a variety of midline anomalies composed of tissues derived from any of the three primary germ cell layers.

Abnormal Gastrulation Theory

Dias and Walker (25) proposed that all these malformations arise during a time when prospective anlagen from the three germ layers are in intimate association during gastrulation. The events of this model are contrasted to those of normal development in Fig. 13 . During normal development, paired notochordal anlagen are integrated to form a single notochordal process. In contrast, during the formation of split-cord malformations, these notochordal precursors remain separate and develop independently over a variable portion of their length. During normal development, bilaterally paired prospective neuroepithelial cells likewise flank both sides of Hensen's node, and the primitive streak are integrated to form a single midline neural plate. In contrast, during the formation of split-cord malformations, these cells remain separate and develop independently to produce two hemicords. Laterally displaced somitic tissue would form an abnormally widened spinal canal with numerous associated vertebral segmentation anomalies, including sagittally clefted (butterfly) vertebrae, fused vertebrae (single or multiple, as in Klippel-Feil syndrome), hemivertebrae, absent vertebrae (single or multiple, as in caudal agenesis syndrome), or if displaced widely enough, incompletely duplicated vertebrae (as in combined spina bifida).

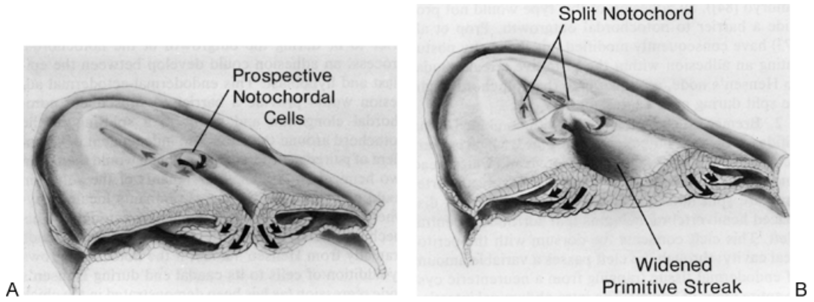

FIGURE 13. Embryogenesis of split-cord malformations. **A:** Normal gastrulation. **B:** Formation of split-cord malformation. During gastrulation, presumptive notochordal cells in Hensen's node, rather than forming a single notochordal process, become functionally separate and begin to form two separate notochordal processes. The overlying and adjacent neuroectoderm also forms two separate hemineural tubes, each of which overlies a heminotochord. Intervening cells of Hensen's node between the two hemicords have pluripotent potential and can develop into a variety of normal or abnormal tissues derived from any of the three primary germ layers (From Dias MS, Walker M (1992): The embryogenesis of complex dysraphic malformations: a disorder of gastrulation? *Pediatr Neurosurg* 18:229–253, with permission.)

The space between the paired hemicords comprises pluripotent primitive streak cells and could give rise to a variety of tissue types from any of the three primary germ layers, including enteric structures (neurenteric cysts, loops of intestine), mesenchymal tissues (bony or fibrous midline structures, blood vessels, muscle, and fat encountered in split-cord malformations; anomalous vertebrae; immature renal tissues) and ectodermal tissue (dermoid and epidermoid tumors), and even pathologic tissues such as teratomas and Wilms tumors (14,33,144). All of these clinical variations have been described. Both the clinical spectrum and embryologic theory have been reviewed by Dias and Walker (25).

Spina Bifida Occulta

Spina bifida occulta is an isolated disorder of posterior vertebral development in which a failure of posterior vertebral fusion results in absence or dysplasia of spinous processes and laminae. The malformation most commonly affects the S1 vertebral level, and is estimated to occur among as many as 30% of the population (8). The underlying spinal cord is normally formed and the findings of the neurologic examination are normal, suggesting a disorder that arises after neurulation is complete and which involves only the dorsal vertebral arch. Spina bifida occulta is therefore almost certainly unrelated pathogenetically to myelomeningocele.

Because it is an isolated anomaly, spina bifida occulta is usually of no clinical consequence. However, posterior vertebral malformations can occur in association with underlying occult spinal dysraphism. Posterior vertebral malformations usually are more extensive, and there are either cutaneous manifestations of underlying spinal dysraphism or signs and symptoms of spinal cord tethering. Isolated spina bifida occulta of the S1 lamina without other signs or symptoms of spinal dysraphism need not be investigated further; however, complex bony malformations or those that accompany signs or symptoms of spinal cord tethering should be investigated further.

Neurosurgical Management of Spinal Dysraphism

Children with spinal dysraphism comprise one of the largest groups of patients for whom pediatric neurosurgeons care. Their care is often extraordinarily complex and may require the integrated efforts of caregivers from many disciplines, including neurosurgeons, orthopaedists, urologists, physiatrists, physical and occupational therapists, orthotists, gastroenterologists, endocrinologists, speech and swallowing experts, pulmonologists, and intensive care specialists. The concept of the spina bifida team, in which a core of dedicated clinicians and staff provide coordinated, multidisciplinary care, provides the best opportunity to minister comprehensively to a child with spinal dysraphism. The medical care rendered is both higher in quality and ultimately less expensive (66) than uncoordinated care. Herein are reviewed management issues for the neurosurgical treatment of a child with myelomeningocele, lipomyelomeningocele, or split-cord malformation.

Treatment of Children with Myelomeningocele

Treatment of a child with a myelomeningocele has undergone a striking evolution over the past several decades. From the early 1900s, improvements in surgical techniques have allowed early closure of the back wound without infection. The introduction of effective CSF shunting systems in the 1950s led to dramatic improvements in the management of hydrocephalus. The introduction in 1975 of clean intermittent catheterization for the management of associated neurogenic bladder dysfunction dramatically reduced the mortality from chronic renal failure. Therapy for symptomatic Chiari malformation with posterior fossa and cervical decompression; therapy for progressive spinal cord dysfunction by means of spinal cord untethering and shunting of syringomyelia; and aggressive orthopaedic management of spinal and lower extremity deformities all have led to improved long-term function among many of these children.

Perhaps the greatest change has been in attitude. In the past, many physicians considered treatment of these children to be cruel, thinking it more merciful to allow them to die. In 1971, in an effort to better decide which patients should be treated, the Lorber criteria were developed to allow withholding of treatment from certain infants with myelomeningocele. The Lorber criteria included (a) the presence of severe hydrocephalus at birth, (b) total paraplegia, (c) spinal kyphosis at birth, and (d) any additional birth defect (73).

None of these criteria, either in isolation or in combination, is an entirely accurate predictor of outcome (79). Moreover, the outcome among children treated without regard to selection criteria (nonselective treatment) (77) compares favorably with the outcomes in Lorber's and others' series (17,45,74), in which selection was performed. In a comparison between the unselected series of McLone (77) and the selected series of Lorber and Salfield (74), the mortality for the unselected group was comparable with that for the highest-ranking infants in the selected group. The overall mortality for the unselected group was 15%, and that for the selected group, including infants thought to be at poor risk and therefore allowed to die, was nearly 70%. The IQs of the highest-ranking infants from the selected group were slightly higher than those of infants in the unselected group (15% more children had normal IQs). The higher IQs, however, were more than offset by the tremendous increase in mortality. From another perspective, 60% of the children from the selected group who were allowed to die would have been “competitive” had they been allowed to survive (80). Finally, parents rarely regret a decision to treat their child. Only 13 of 300 parents expressed regret over their decision to treat their child; remarkably, 9 of the 13 regretted an initial decision not to treat their child (79).

This is not to say that every child with a myelomeningocele should be treated. Children with multiple severe or potentially fatal associated malformations and those with severe chromosomal abnormalities may not be chosen for treatment. However, the decision to withhold treatment from any child should be individualized and made only after a frank and realistic discussion with the parents about the chances for meaningful survival. In our experience, these children are fewer than 1% of infants born with myelomeningocele.

The parents of children with myelomeningocele are initially overwhelmed with the complexity of the disorder. Confused and often frightened, they most often follow the suggestions of the treating physician. It is incumbent upon physicians, then, to present accurately the nature of myelomeningocele, the likely sequelae of the malformation, and the outlook for intellectual, sensorimotor, urinary, sexual, and societal function. Although each has a bias based on personal, ethical, or religious principles, physicians must refrain from transmitting this bias to parents. It is they rather than physicians who will ultimately care for the child.

It is important that certain facts be transmitted accurately to parents. First, almost all children with myelomeningocele survive initially with proper treatment (80,116), although a few children die each year. The most common causes of death are Chiari malformation in infancy and unrecognized shunt obstruction in later life. Among 100 unselected children with myelomeningocele consecutively treated at the Children's Memorial Hospital in Chicago for whom 8- to 12-year follow-up information was available, the overall mortality was 15%. The neonatal mortality was 2%, mortality during the first 3 years was 10%, and mortality during the first 5 years of life was 14%. Hindbrain dysfunction was the most frequent cause of death in this series because of associated stridor, apnea, and aspiration pneumonitis (85). The long-term mortality in other series has been as high as 35% to 50% by adulthood (60,62).

Between 80% and 90% of children need a shunt for control of hydrocephalus (80,81,85); 30% to 40% of these need at least one shunt revision during the subsequent year, 60% within 5 years, and 85% within 10 years (85,140). Approximately 75% of children with myelomeningocele have IQs greater than 80, and this figure is not affected appreciably by the presence of hydrocephalus (61,82,85,132,137). However, among the children with normal intelligence, 60% have learning disabilities (35,81,132).

Approximately 60% to 70% of children who survive are community ambulators (34,81,141). Ability to walk depends on and is directly correlated with sensorimotor level (34). Excluding children with severe developmental delay and hypotonia, who account for about 13% of patients, approximately 89% of preadolescent children can be community ambulators with aggressive multidisciplinary orthopaedic and neurosurgical management. This percentage includes all of those with low lumbar and sacral lesions and 63% of those with higher-level lesions (81). After adolescence, however, the proportion of children who achieve community ambulation decreases to about 50% as it becomes more energy efficient to use a wheelchair (85).

Social continence (being free of urinary incontinence in social situations, with or without clean intermittent catheterization) is achieved by about 85% of school-age children (80,110,122,138). Most have chronic constipation. Although almost all patients with myelomeningocele have abnormal genital sensation, about two thirds of boys report at least some genital sensation, and 70% to 75% report the ability to achieve erections. In an objective assessment of 15 selected male patients by Sandler et al.(123), 60% had objective evidence of at least some nocturnal erections.

Orthopaedic procedures are extremely common (10,141). In one study of 206 unselected children with 6-month to 18 year follow-up results, 64% underwent at least one orthopaedic procedure, and an average of 5.4 procedures were performed per patient (141).

Despite their disabilities, many children with myelomeningocele mature to become contributing members of society. Eighty-two percent of adults with myelomeningocele are independent in activities of daily living. Thirty percent are in, or have finished, college, but only 32% are employed (89).

The neurosurgical treatment of children with myelomeningocele is divided into three phases: (a) stabilization of the infant's condition and closure of the myelomeningocele, (b) assessment and management of hydrocephalus, when present, and (c) management of associated problems, including signs and symptoms of hindbrain (Chiari II) malformation, tethered spinal cord, and syringomyelia.

Stabilization of the Infant and Closure of the Myelomeningocele

The myelomeningocele should be protected from external mechanical trauma and desiccation, and should be kept as clean as possible, because the malformation may contain functional neural tissue and frequently leaks spinal fluid. The malformation is best covered with gauze dressings soaked in sterile saline solution. Iodine-containing compounds such as povidone-iodine (Betadine) should be avoided, because they may further injure the exposed tissues. Plastic wrap may be placed atop the gauze to keep the dressings moist.

Initial sensorimotor level can be be assessed readily by means of observation of the spontaneous movements of the lower limbs and of the response to pinprick stimulation (Table 1). Muscle imbalance produces characteristic postures of the lower limbs and is a good indicator of sensorimotor level. For example, imbalance between iliopsoas and quadriceps muscles of an infant with an upper lumbar lesion causes a flexed-hip deformity. Imbalance between quadriceps and hamstrings muscles of an infant with a midlumbar lesion produces a characteristic knee extension deformity. Imbalance between the foot dorsiflexors and plantar flexors of an infant with a low lumbar lesion produces a dorsiflexed ankle deformity.

TABLE 1. Assessment of Neurologic Level of Patients with Myelomeningocele

Level	Motor	Sensory
T10	Rectus abdominus	Umbilicus
L1–2	Hip flexion	Anterolateral thigh
L2–3	Hip adduction	Anteromedial thigh
L3–4	Knee extension	Knee, anterior shin
L4–5	Foot dorsiflexion	Dorsum of foot
L5	Extensor hallucis longus	First, second interspace
S1	Plantar flexion	Plantar aspect of foot

An open malformation should be closed in a timely manner to avoid the development of meningitis. The lesion ideally should be repaired on the first day of life; however, studies have suggested that closure can be delayed up to 48 hours without an appreciable increase in neurologic morbidity or infectious complications (17). The techniques for closure of myelomeningocele are detailed elsewhere (83) and are summarized here (Fig. 14). The neural placode is sharply dissected from the surrounding skin at the perimeter of the malformation. No cutaneous tissue should be left with the placode, or an inclusion dermoid may form (83,115). The lateral edges of the placode and its associated pial coverings are brought together in the midline to reapproximate a tubular structure. This makes subsequent untethering procedures much less difficult should they become necessary. Once the placode is repaired, the surrounding dura is dissected from the underlying fascia and reapproximated. The dural sac should be kept as capacious as possible to minimize the risk of later tethering.

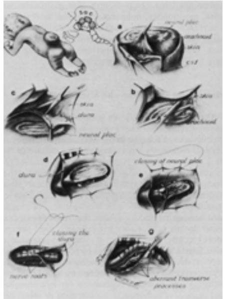

FIGURE 14. Surgical closure of myelomeningocele. *A, B*, The placode is dissected away from the surrounding skin at the arachnoid-skin interface. Care is taken not to include skin in the placode. *C, D*, The dura is dissected from the lateral aspects of the sac in preparation for closure. *E*, The neural placode is closed dorsally to reapproximate a neural tube. *F*, The dura is closed over the closed placode. The remaining fascia and skin are closed over the malformation with a vertical closure if possible. (From Reigel DH (1979): Kyphectomy and myelomeningocele repair. In: Ransohoff J, ed: *Neurosurgery. Modern techniques in surgery*, vol 13. Mt Kisco, NY: Futura, pp. 1–9, with permission.)

The lumbodorsal fascia can be closed to provide an additional layer. However, the benefits of this technique are unclear. Reigel and McLone (116) suggested that there is no additional benefit to closing the lumbodorsal musculature and fascia as a separate layer. Troup et al. (143), however, suggested that wound leakage of CSF is less frequent and that shunting is required less often after myofascial closure. If myofascial closure is performed, care must be taken not to strangle the underlying neural tissue. The overlying skin is trimmed and closed. Vertical closure is preferred because it simplifies later procedures, such as untethering and spinal fusion, should they become necessary.

Initial Treatment of Hydrocephalus

Associated hydrocephalus is present among 80% to 90% of children with myelomeningocele (85,141). Among some infants, hydrocephalus is apparent at birth. The infant has an enlarged head (greater than 2 standard deviations above the mean for age), a bulging fontanel, and split sutures. Sunsetting eyes, poor feeding, vomiting, irritability, or lethargy occasionally is present when hydrocephalus is severe. Hydrocephalus can promote or exacerbate symptoms of Chiari malformation, including lower cranial nerve dysfunction (weak or high-pitched cry, choking during feeding, poor swallowing, vocal cord palsy, aspiration pneumonitis, or facial palsy), and arm or hand weakness (see later). Cranial ultrasonography, computed tomography (CT), or magnetic resonance imaging (MRI) shows enlarged ventricles (Fig. 15). Under these circumstances, hydrocephalus should be managed when the myelomeningocele is closed, because the risk of infectious or other complications does not increase when permanent insertion of a ventriculoperitoneal shunt (VPS) is performed at myelomeningocele closure. An alternative is temporary diversion of CSF to a bedside bag by means of external ventricular drainage for several days followed by insertion of a VPS.

Hydrocephalus often is not obvious immediately after birth, because CSF is being vented from the back wound, but develops within days or weeks after closure of the myelomeningocele. In addition to the signs described earlier, CSF under increased pressure may dissect beneath, and eventually leak from, the healing wound. Any collection or leakage of CSF from the back wound should alert the clinician to the presence of hydrocephalus. When hydrocephalus develops, it should be managed promptly with a VPS.

One may reasonably ask, “Why not insert shunts in all children from the outset?” Although most children with myelomeningocele ultimately need a shunt, a VPS commits both the patient and physician to a lifelong struggle to maintain the patency of the shunt. Even a functioning shunt wreaks havoc on the patient and family. Because signs of shunt malfunction include headache, nausea, vomiting, and listlessness, every viral syndrome prompts another trip to the hospital to exclude shunt malfunction. Finally, although it is a controversial issue, some authors consider every child with a myelomeningocele and shunted hydrocephalus shunt dependent for life (118). We place shunts only in patients with demonstrated hydrocephalus.

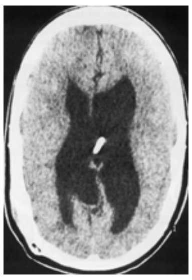

FIGURE 15. Computed tomographic scan shows hydrocephalus in a patient with myelomeningocele. The ventricles are misshapen because of developmental changes in the surrounding cerebral hemispheres from Chiari II malformation. The shunt catheter is visible within the right lateral ventricle.

A bewildering variety of shunt systems exist to manage hydrocephalus (114). The typical shunt system has three basic components—a ventricular catheter, a valve mechanism, and a variable length of distal tubing (Fig. 16). The valve can be proximally located under the skin on the scalp or distally located as simple slits in the distal catheter within the abdomen. Whatever the shape or configuration, almost all valves serve two purposes: they retard retrograde flow of spinal fluid back into the brain, and they regulate the amount of CSF that can be drained as a function of the pressure differential across the valve. Many shunts also contain a subcutaneous reservoir from which to tap the shunt if necessary to assess shunt function or to sample CSF.

The peritoneum is the overwhelming choice as the site for the distal shunt catheter. If the catheter cannot be placed within the peritoneum, children older than 5 years can undergo shunting to the pleural space, a ventriculopleural shunt, through a small incision beneath a rib and insertion through a trocar. Children much younger than 5 years do not usually tolerate a ventriculopleural shunt because they do not adequately reabsorb CSF from the pleural space. Ventriculoatrial shunts implanted into the common facial or jugular veins and threaded into the right atrium were preferable years ago. A number of serious complications, however, including sepsis, endocarditis, pulmonary emboli with pulmonary hypertension (30,36), and renal failure from shunt nephropathy, in which a chronically infected shunt incites immune complex deposition within the renal glomeruli (147), have limited their use. We reserve ventriculoatrial shunts for children younger than 5 years who cannot tolerate a VPS. In rare instances the gallbladder can be used for a shunt if the other sites are unavailable.

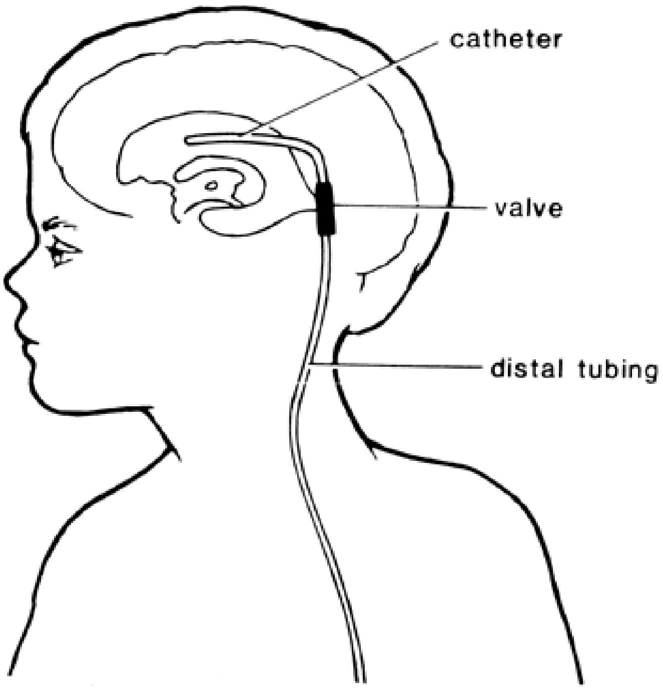

FIGURE 16. Shunt components.

The signs and symptoms of shunt malfunction in a child with myelomeningocele are legion and often can confuse even the most experienced clinician. The oft-quoted signs and symptoms of intracranial hypertension, including headache, nausea and vomiting, poor feeding, listlessness or lethargy, and sunsetting eyes or extraocular abduction palsy, although indicative of a shunt malfunction, may be absent among a large number of children. For many of these patients, a shunt malfunction may become manifest through any of the following symptoms: (a) cognitive changes such as a decline in school performance or worsening behavior, (b) the onset of or a change in the frequency of seizures without another demonstrable cause, (c) a change in motor performance such as a decrease in muscle strength, loss of previously acquired motor skills, or increase in spasticity of either upper or lower extremities, (d) a change in ambulation without another definable cause, (e) a change in urinary or bowel function, such as more frequent accidents or urinary tract infections or an increase in frequency of catheterization, (f) a change in lower cranial nerve function suggestive of hindbrain dysfunction, (g) pain in the back or legs, particularly that which occurs at the myelomeningocele closure site, and (h) worsening scoliosis or orthopaedic deformities of the lower extremity. Viewed another way, a shunt malfunction can mimic the signs and symptoms of tethered spinal cord, syringomyelia, or hindbrain dysfunction from the Chiari malformation. It is our firm belief that once a shunt is placed, any deterioration in neurologic, orthopaedic, or urologic function always should prompt an investigation of the shunt to exclude a malfunction before any other treatment is initiated. Some children with a shunt malfunction may be completely free of symptoms yet have florid papilledema on physical examination. The papilledema improves after shunt revision. A good fundoscopic examination therefore is essential to properly evaluate a child with a shunt.

The evaluation of a child with a suspected shunt malfunction includes CT or MRI to evaluate ventricular size. In many children, the ventricles are larger than they appeared on baseline scans. In some children, fortunately a minority, the ventricles may be slitlike or may not change appreciably, and the diagnosis of shunt malfunction is made solely on clinical grounds. A child with unrecognized shunt malfunction may progress to herniation and death even though a CT scan shows no change in ventricular size. Any patient whose condition is rapidly deteriorating should be assumed to have a shunt malfunction, even in the absence of a change in ventricular size, and should be examined immediately by a neurosurgeon. Patients with signs of herniation (stupor or coma, motor posturing, signs of brain stem compromise) should undergo an immediate shunt tap from the reservoir, if present, to withdraw CSF and relieve intracranial pressure. Urgent shunt exploration and either revision or external drainage are warranted immediately thereafter.

In summary, the need to keep the ventricular shunt foremost in one's mind when assessing a child with myelomeningocele cannot be overemphasized. Shunt malfunction can mimic any symptom complex in these children and can occur without any visible symptoms or demonstrable changes in the radiologic studies. Nowhere else in pediatric neurosurgery is clinical judgment so important and misjudgment so treacherous. The watchwords in evaluating any neurologic change are *always evaluate the shunt first.*

Management of the Chiari II Malformation

Almost all children with myelomeningocele have an associated hindbrain malformation that consists of caudal displacement of the cerebellar tonsils and vermis, the caudal medulla, and variably the fourth ventricle into the cervical spinal canal (Fig. 17). The malformation has been called *Chiari II malformation* to differentiate it from the Chiari I malformation, in which only the cerebellar tonsils are displaced. Chiari II malformation actually consists of a number of brain abnormalities. It is a pancerebral malformation (Table 2) that involves almost all areas of the brain. A unifying theory has been proposed to explain the origin of Chiari II malformation. Venting of CSF during the period of mesenchymal condensation to form the skull produces inadequate stimulus to skull growth, particularly for the posterior fossa surrounding the cerebellum and brain stem. Subsequent growth of the cerebellum occurs within a compartment that is too small. The result is downward displacement of the inferior cerebellum and brain stem and upward displacement of the superior cerebellum, beaking of the midbrain, and enlargement of the tentorial notch. Secondary disorders of neuronal histogenesis cause many of the other associated malformations, such as callosal dysgenesis, cortical heterotopia, and stenogyria (87,91).

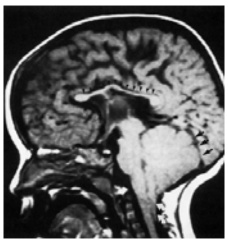

FIGURE 17. Magnetic resonance image of a child with myelomeningocele and Chiari II malformation. The tentorium is low lying (*black arrows*), and the posterior fossa is small. The cerebellar tonsils and caudal brain stem (*white arrows*) have descended through the foramen magnum at the skull base. The corpus callosum is malformed (*arrowheads*), and the cerebral cortex has several areas of abnormality.

TABLE 2. Chiari-Associated Malformations of the Central Nervous System

- Disorders of the skull
  - Lückenschädel of the skull
  - Small posterior fossa
  - Low-lying tentorium cerebelli with large incisura
  - Scalloping of the petrous bone
  - Shortening of the clivus
  - Enlargement of the foramen magnum
- Disorders of the cerebral hemispheres
  - Polymicrogyria
  - Cortical heterotopia
  - Dysgenesis of the corpus callosum
  - Large massa intermedia
- Disorders of the posterior fossa
  - Descent of the cerebellar vermis through the foramen magnum
  - Caudal displacement of the pons and medulla
  - Rostral displacement of the superior cerebellum through tentorium
  - Kinking of brain stem
  - Loss of pontine flexure
  - Aqueductal stenosis or forking
  - Beaking of tectum

Although Chiari II malformation is anatomically present in nearly every child with a myelomeningocele and many have occasional mild symptoms referable to the malformation, between 29% and 76% have grave problems (19,29,56,57,77,85,104,112). About one third need surgical treatment. Treatment should be reserved for children with symptoms and signs that suggest substantial brain stem compromise. Symptoms may develop at any age but are most common during infancy. Swallowing dysfunction is the most frequent sign. Disorders of swallowing represent injury to the lower cranial nerves or their associated brain stem nuclei. They occur more frequently during infancy and may become manifest as choking or coughing on food, nasal regurgitation during drinking, frequent vomiting, or gastroesophageal reflux (112). Other signs of lower brain stem dysfunction include frequent episodes of aspiration pneumonitis, apnea and cyanotic spells, dysarthria, inspiratory stridor, and a hoarse or high-pitched cry. Often these babies have soft, feeble cries and are therefore described as “good babies” (99). Other signs and symptoms of Chiari II malformation include weakness or spasticity of the upper extremities, headache or neck pain, cerebellar dysfunction, oculomotor problems, and scoliosis.

Chiari II malformation is best evaluated with MRI (Fig. 17). Associated hydrocephalus, syringomyelia, and spinal cord tethering can be evaluated simultaneously. Treatment includes cervical or foramen magnum (posterior fossa) decompression with dural opening and patch grafting (duraplasty). The foramen magnum in these patients usually is quite large and usually does not require substantial decompression. In our series of 43 patients, posterior fossa decompression offered no additional benefit over cervical decompression alone. Moreover, opening the posterior fossa dura entails great risk of bleeding from intradural venous sinuses. Other procedures, such as opening or stenting the fourth ventricle (105) or plugging the obex (3,37,148) have not proved to be of additional benefit. We therefore recommend simple bony decompression and duraplasty for most patients. Cervical laminectomy is performed to below the inferiormost level of the cerebellar tonsils, and a generous patch graft of periosteum, cadaver dura, or bovine pericardium is sewn to the dural edges.

Outcome depends on the age of the patient and the mode of presentation. Patients with symptoms present at birth generally fare poorly. Only 1 of 7 (14%) such patients in our series improved postoperatively. Postmortem studies of these infants often show a disorganized and chaotic brain stem architecture (41). Many infants undergo tracheostomy, Nissen fundoplication, and insertion of gastrostomy feeding tubes because of persistent swallowing difficulties, vocal cord palsy, repeated bouts of aspiration pneumonitis, and gastroesophageal reflux. Older children, however, often improve after decompression, particularly if the operation is performed before severe and irreparable damage to the brain stem has occurred (111). In our series, upper extremity weakness, cerebellar dysfunction, and pain improved in more than 80% of patients. Swallowing dysfunction, apnea, and vocal cord palsy improved in only 50%.

Postlaminectomy kyphosis can occur after cervical decompression. We do not recall treating any patient with myelodysplasia who had this complication, although an incidence as high as 40% has been reported (1). Treatment involves occipital-cervical lateral mass fusion that spans the laminectomy defect and at a minimum includes the most cranially located intact vertebral segment.

Management of the Tethered Spinal Cord

Spinal cord tethering is a well-recognized cause of neurologic deterioration. It is responsible for delayed and progressive neurologic deficits, urologic dysfunction, and orthopaedic deformities among patients with myelomeningocele (6,51,65,86,117,121,142,145). Symptoms referable to spinal cord tethering necessitate treatment of about 30% of patients with myelomeningocele (145). The pathophysiologic basis for neurologic decline among patients with spinal cord tethering was well illustrated by Yamada et al., who demonstrated changes in mitochondrial oxidative metabolism in response to spinal cord tethering both in cats during experimental spinal cord stretching and in humans during operations for untethering (152,153). In humans, growth and development of the vertebral column may progressively stretch the tethered spinal cord. The increased incidence of the tethered cord syndrome during periods of rapid growth (50,55,94,142) supports this concept. In addition, intermittent and transient traction on the tethered spinal cord may increase with flexion movements of the pelvis and spine (90) and contribute to repetitive neurologic injury. Several studies have documented improvement or stabilization of neurologic function (2,18,50,51,130,142) urologic disorders (65), and orthopaedic deformities (86,117,121) after untethering.

The importance of spinal cord tethering as a potential cause of neurologic deterioration is perhaps most evident in comparisons between the long-term neurologic outcome among patients with sacral-level myelomeningocele in two programs, one that offered untethering for patients with deterioration and another that did not. In a program offering spinal cord untethering to patients with deterioration, 62 consecutively registered patients with sacral-level lesions who underwent closure of the lesions at Children's Memorial Hospital and were observed for 18 years, no patient lost the ability to walk, and all but one (who had a severe balance deficit) were community ambulators (141). In contrast, among 36 patients with sacral-level myelomeningocele observed for an average age of 25 years (range 19 to 51 years) in a program in which spinal cord untethering was not routinely offered for deterioration, one third had a deterioration in gait, and only 24 of 35 patients (69%) who started as community ambulators remained so. Eleven patients became wheelchair users. Spinal deformities and soft tissue contractures of the hip or knee, developed in 16 patients each (44%) (10). Although these two studies are not strictly comparable in many respects, the differences in outcome suggest that untethering can prevent what appears to be otherwise inevitable deterioration for many patients with myelomeningocele. It has become increasingly evident to us that the neurologic deterioration so prevalent among patients with myelomeningocele does not represent the natural course of the disorder but reflects progressive injury from spinal cord tethering.

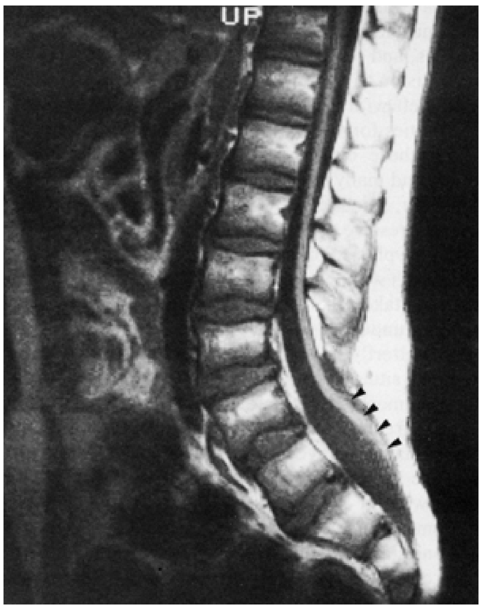

FIGURE 18. Magnetic resonance image of a child with myelomeningocele shows radiographic evidence of tethered spinal cord. The conus medullaris is low lying. The placode is displaced posteriorly and is adherent to the dorsal dura (*arrowheads*).

The diagnosis of tethered-cord syndrome in a patient with myelomeningocele is made on clinical not radiologic grounds. Almost every patient with myelomeningocele has a low-lying conus medullaris on radiographic images (Fig. 18), yet relatively few have clinical signs of tethering. Moreover, the position of the conus on MR images does not change appreciably after spinal cord untethering, yet the clinical condition of many patients improves (11). The clinical features of tethering in some cases are initially subtle and advance so slowly that parents, child, and physician do not recognize the inexorable decline. It is only after untethering and subsequent improvement that everyone recognizes, in retrospect, the extent to which the child had deteriorated. A vigilant eye, keen clinical judgment, and objective, accurate, and reproducible means of evaluating patients, such as serial manual muscle testing, urodynamic studies, and scoliosis radiographs, are necessary to properly evaluate and observe a child with a tethered spinal cord. Signs and symptoms of spinal cord tethering can be conveniently divided into six broad categories, as follows: (a) pain, either in the back or legs, (b) motor deterioration, manifested as a decrease in muscle strength or an increase in tone (spasticity), (c) a change in sensory level, (d) a change in bowel or bladder function, (e) a deterioration in gait, and (f) progressive orthopaedic deformities, either in the lower extremities (hip dislocation, pes cavus, equinovarus) or spine (scoliosis).

Pain is a relatively common presenting symptom of spinal cord tethering in our experience but is usually minor and seldom the predominant symptom. When present, pain usually accompanies other objective changes in neurologic function. The pain may be present in the back or legs and even extend even into areas that have no sensation. The pain usually is ill defined, dull, or achy in character and is often, although not invariably, exacerbated by exercise or effort. Leg pain may have a dysesthetic or neuropathic quality. We have found that pain is almost universally relieved with untethering.

A change in motor function is the most frequent manifestation of tethering. Changes in motor performance include a decrease in muscle strength or an increase in tone (spasticity). In our clinics, manual muscle testing of individual muscles performed by physical therapists at least one a year and more frequently if clinically indicated provides a quantifiable assessment of motor function. We consider a consistent decrease of at least one grade in several muscles significant. In some cases, muscles innervated by the last intact root are lost, and motor paralysis ascends to a higher level. More commonly, a more diffuse pattern of muscle weakness develops in muscles innervated by more rostral spinal levels.

In addition to weakness, muscle tone may be increased and become manifest as classic spasticity (a velocity-dependent resistance to movement that is greatest at the initiation of movement and declines thereafter—the so-called clasp-knife phenomenon), a progressive increase in muscle contractures, or a change in gait (see later). Muscle tone may reliably be assessed with the modified Ashworth scale (Table 3) (7), and contractures by means of measurement of various joint angles. We have found that untethering improves muscle strength and decreases spasticity among affected children and leads to improved ambulation and a decrease in the frequency of soft-tissue releases.

Subjective changes in sensation are common. They consist of numbness or dysesthesia in areas previously sensate. However, objective deterioration in sensation is seldom found at physical examination and when present is usually evanescent and unreliable. We therefore do not rely solely on changes in sensation to determine the need for untethering. Fortunately, changes in sensation usually are associated with other objective signs of neurologic deterioration.

TABLE 3. Modified Ashworth Scale of Muscle Tone

Score	Definition
0	Hypotonic; less-than-normal muscle tone; floppy
1	Normal; no Increase in muscle tone
2	Mild; slight increase in tone or minimal resistance to movement through less than half of range
3	Moderate; more marked increase in tone through most of range, but affected part is easily moved
4	Severe; considerable increase in tone; passive movement difficult
5	Extreme; affected part rigid in flexion or extension

Adapted from Peacock WJ, Staudt L (1991): Functional outcomes following selective posterior rhizotomy in children with cerebral palsy. *J Neurosurg* 74:380–385, with permission.

Urologic dysfunction is present among many children with myelomeningocele. Clinical signs of progressive neurourologic deterioration suggest tethering. They include increasingly frequent accidents or urinary dribbling between catheterizations of a child previously dry, an increase in the frequency of catheterizations or decrease in the volumes of urine obtained with each catheterization, and increasingly frequent urinary tract infections without another cause. Serial urodynamic testing provides objective evidence of changes in bladder function, including a smaller bladder capacity or increased bladder pressures, reduced threshold for the initiation of bladder contraction (uninhibited bladder contraction), and worsening coordination of bladder contraction with urethral sphincter relaxation (detrusor-sphincter dyssynergia). All of these urodynamic changes can suggest progressive bladder spasticity. High-pressure bladders with uninhibited contractions are of particular concern. Improvement can be expected among approximately 60% of patients after untethering (65). Although less common, abnormalities of defecation can accompany tethering. These include increasing problems with constipation and intermittent stool soilage. Most patients improve after untethering (65).

Gait abnormalities are present among almost all children with myelomeningocele. However, excluding patients with severe retardation or hypotonia, about 89% of preteens with myelomeningocele are community ambulators (89). Many continue to walk into adulthood; the exception, in our experience, is the teen-ager or adult with an upper lumbar or thoracic lesion who, although initially an ambulator, finds a wheelchair to be a more efficient means of transportation. Although they may abandon their braces for a wheelchair, these patients generally do not have accompanying changes in muscle strength or tone or any of the other changes of tethering. The change in ambulation is a personal decision rather than a change in neurologic function per se. With this single exception, ambulation among all children with myelomeningocele generally improves with advancing age. Ambulation never should regress without a good reason. Suggestions that a deterioration in gait reflects the natural course of myelomeningocele, is the result of an inevitable and therefore irreparable degeneration of the placode, or is the result of increasing weight gain are simply untrue. We have found that any deterioration in gait usually is caused by progressive muscle weakness, increasing spasticity, or orthopaedic deformities. Among many patients, these problems can be attributed to spinal cord tethering and often improve or stabilize after an untethering procedure.

Orthopaedic deformities are common among children with myelomeningocele; however, the presence of progressive deformities, especially those associated with progressive increases in muscle tone, such as progressive or recurrent hip subluxation, pes cavus, or equinovarus deformities, should prompt a thorough search for other clinical evidence of tethered cord. In most instances the presence of associated muscle weakness or spasticity, urologic abnormalities, and pain corroborates the diagnosis and makes the decision to untether easier. Some children, however, have progressive foot deformities for which no other explanation is evident. Under these circumstances, we perform untethering, and many patients improve (unpublished observations).

Spinal cord tethering can cause progressive scoliosis. Scoliosis is present among as many as 90% of patients with myelomeningocele (109,133) and is more frequent with upper lumbar and thoracic lesions (117). The cause of scoliosis is likely multifactorial. In any patient scoliosis can be caused by (a) paravertebral muscle weakness and sensorimotor imbalance, (b) structural deformities from vertebral malformations such as hemivertebrae and segmental bars, (c) pelvic obliquity or hip contracture, and (d) neurosurgical problems such as Chiari malformation, syringomyelia, and spinal cord tethering (109,117). Progressive scoliosis above a low-lying placode in a patient without underlying vertebral anomalies is most likely caused by spinal cord tethering and less frequently by Chiari malformation or hydrosyringomyelia. In a study involving 30 patients with progressive scoliosis and radiographic evidence of tethering without symptoms of Chiari malformation or hydromyelia, scoliosis improved after untethering among 21% and stabilized among 42%. Considering only children with curves of less than 50 degrees, scoliosis improved among 8 of 24 (33%) and stabilized among 15 of 24 (63%) patients. In contrast, scoliosis continued to progress and ultimately necessitated spinal fusion in 5 of 6 patients with preoperative curves greater than 50 degrees (86). In another study of 216 patients with myelomeningocele, untethering improved or stabilized scoliosis in patients with sacral and lumbar level lesions but did not halt the progression of scoliosis among patients with thoracic-level lesions (117). In a study involving children with low-level (L3 and below) lesions treated with untethering for progressive scoliosis, first-year results showed stable (60%) or improving (15%) curves. Long-term (3 to 10 years) follow-up studies showed stable (57%) or improving (7%) curves but late progression among 36% of the patients (124). The results of these studies suggest that spinal cord tethering is an important cause of scoliosis and that untethering performed early reverses or stabilizes scoliosis for selected patients.

Once tethering is suspected because of clinical evidence, manual muscle testing, urodynamic studies, and scoliosis radiographs are obtained to document associated changes that may not be evident clinically. Radiologic evaluation includes MRI to confirm tethering and to identify associated lesions such as lipoma, split-cord malformations, and hydromyelia (see later), which may contribute to neurologic deterioration. CT or MRI of the head is performed to evaluate ventricular size. Changes in ventricular size or symptoms that suggest shunt malfunction should prompt shunt revision, and untethering is deferred for 8 to 12 weeks. If signs or symptoms improve or stabilize after the shunt revision, nothing further is done; if the child's condition continues to deteriorate, untethering is performed.

Untethering is accomplished by means of reopening the wound, exposing the dural sac, and dissecting the placode from the overlying dural closure. During dissection of the placode, care is taken to remain outside the arachnoid plane to minimize injury to the nerve roots. The spinal cord cranial to the placode is freed from any bony impingement or surrounding scar. The caudal end is inspected for tethering lesions. A surprising number of patients have an unrecognized filum terminale which can also tether the placode. Any associated tethering lesions identified at preoperative MRI are repaired. The dural sac is reapproximated primarily, and the is wound closed in several layers to prevent CSF leakage. A dural graft usually is not necessary, because the thecal sac is already quite capacious in most patients, and a graft is of no demonstrated benefit in preventing retethering.

Although the situation is uncommon, some patients initially improve or stabilize after untethering only to have delayed (usually several years) signs and symptoms of retethering. These patients may benefit from a second, or even a third or fourth, untethering procedure.

Management of Hydrosyringomyelia

Hydromyelia is CSF-containing dilatation of the central canal of the spinal cord. Syringomyelia is a similar cavity of CSF that develops within the substance of the spinal cord but is still in communication with the central canal. Among patients with myelomeningocele, hydromyelia and syringomyelia occur in combination. It is impossible to differentiate one from the other with clinical or radiographic evidence (Fig. 19). Therefore the term *hydrosyringomyelia* is more appropriate. Hydrosyringomyelia is present in 50% to 80% of patients with myelomeningocele (13,75,81) and can cause progressive neurologic deterioration due to spinal cord deformation and injury. The most common presenting features include upper extremity weakness or loss of function, back pain, scoliosis, and worsening spasticity and ascending motor loss in the lower extremities. Dissociated sensory loss (loss of pain or thermal sensation with preservation of proprioception) occasionally is discerned and may follow a cape distribution (99). We have found that the latter finding though classic is uncommon. Extension of hydrosyringomyelia into the brain stem can cause lower cranial neuropathy and brain stem dysfunction. Changes in urinary function are rare and should suggest spinal cord tethering as a cause of the incontinence (99). Scoliosis caused by hydrosyringomyelia often is rapidly progressive and is thought to be caused by asymmetric anterior motor column damage (47,48,63).

Because hydrosyringomyelia is present among so many patients with myelomeningocele, one must rely on clinical judgment to determine which patients require treatment. Some patients have only a small cavity and are unlikely to have symptoms. Moreover, the risks of surgical therapy for a small cavity probably outweigh any potential benefit. We would pursue other avenues of therapy in this instance. Among other patients, symptomatic hydrosyringomyelia may be the consequence of incipient malfunction of a ventricular shunt (47,49), and symptoms resolve after shunt revision. In the absence of shunt malfunction, the initial management of symptomatic hydrosyringomyelia for these patients is controversial. One option is posterior fossa–cervical decompression if Chiari malformation is documented. This option is based on the premise that abnormal CSF dynamics at the foramen magnum (documented best among patients with Chiari I malformation) caused by the Chiari malformation allow expansion of the central spinal canal (100). An alternative is to place a shunt directly from the syrinx cavity to the peritoneum (syringoperitoneal shunt) or to the pleural cavity (syringopleural shunt). Some surgeons prefer to place a stent locally from the syrinx cavity to the spinal subarachnoid space (syringosubarachnoid shunt). In an analysis of various therapies for symptomatic hydrosyringomyelia among 50 patients with myelomeningocele, posterior fossa decompression alone was successful (syrinx unchanged or enlarging) among only 14%, whereas syringosubarachnoid shunting alone was successful among 70%. A combination of posterior fossa decompression and syringosubarachnoid shunting was successful for two patients on whom it was performed (136). These data suggest that the ideal initial therapy for symptomatic hydrosyringomyelia among children with myelomeningocele and a functioning shunt is placement of a syringosubarachnoid shunt.

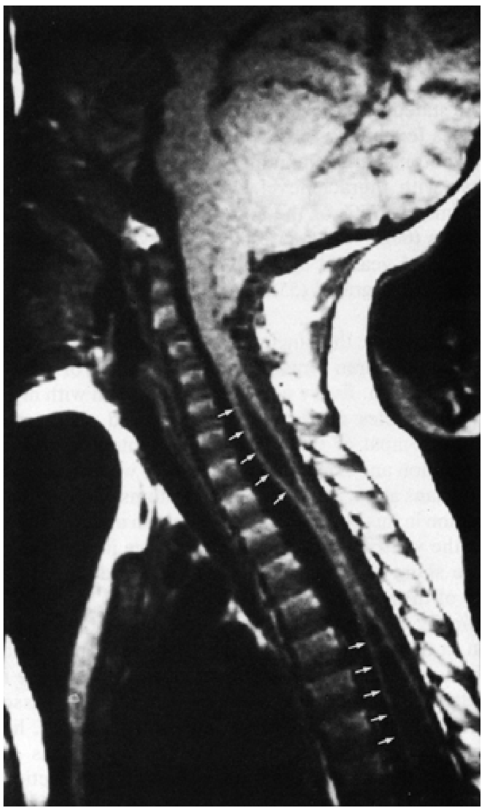

FIGURE 19. Magnetic resonance image of a child with myelomeningocele, Chiari II malformation (caudally displaced cerebellar tonsils and medulla are visible), and extensive hydrosyringomyelia (*arrows*).

In summary, the single greatest long-term neurosurgical problem among these children is maintenance of proper shunt function. Every year, several children with myelomeningocele die of unrecognized shunt malfunction. Most of these deaths can be prevented with prompt recognition of the malfunction and treatment. If we can educate other physicians about the signs and symptoms of shunt malfunction among this population and impart an understanding that the size of the ventricle on CT scans may not change in the face of acute shunt malfunction, we have advanced the care of these children considerably.

We reject the concept that delayed deterioration among these children is simply the natural course of this disorder. We emphasize that neurologic decline can be controlled in many cases. Aggressive management of associated neurosurgical disorders such as Chiari malformation, hydrosyringomyelia, and spinal cord tethering have improved ambulation and urinary function, prevented a large number of orthopaedic deformities, and in many cases eliminated the need for spinal fusion for scoliosis and soft-tissue release for lower limb spasticity. With further advances, the outlook for these children remains ever more hopeful.

Treatment of Children with Lipomyelomeningocele

Lipomyelomeningocele (LMC; also called spinal lipoma) is the most common occult dysraphic malformation. It accounts for 20% to 50% of cases of occult spinal dysraphism and for 35% of skin-covered lumbosacral masses (90). Most of these lesions involve the conus medullaris and the caudal end of the spinal cord. In rare instances LMC involves the thoracic or cervical region, where they arise from the dorsal aspect of the underlying spinal cord.

Because lipoma is a disorder of premature dysjunction with the lipoma that arises from the central canal of the neural tube (Fig. 9), the stalk of the lipoma therefore lies between the entrance of the dorsal roots (which arise from neural crest cells at the edges of the closing neural folds) to the spinal cord and extends into the central canal of the spinal cord through this dorsal dysraphic defect. Knowledge of this anatomic arrangement is crucial to the safe removal of a LMC.

For LMCs that extend beyond the dura and have a large subcutaneous portion, a subcutaneous mass often is obvious at birth. The mass is sometimes eccentric and may reflect an embryologic origin from only one neural fold. Other associated cutaneous abnormalities include cutaneous dimples, dermal sinuses, hemangiomas, hairy patches, and skin tags. These skin lesions may appear with or without an associated subcutaneous fatty mass. For a purely intradural LMC that lacks a subcutaneous component, these skin lesions may be the only clue to the presence of an underlying dysraphic abnormality. Finally, cutaneous markers may be absent in as many as 15% of patients with lipoma, and the first manifestation of the problem may be the development of neurologic abnormalities, urologic dysfunction, or orthopaedic deformities from tethering.

Neurologic abnormalities usually are lacking among neonates with LMC, but progressive neurologic deficits and associated urologic and orthopaedic abnormalities develop regularly with advancing age. In one surgical series, only 3% of children had no symptoms after the first year of life, and none did so after the second year. Among 87 children with symptomatic LMC, 54% had weakness as the initial symptoms, 7% had spasticity, 13% had gait abnormalities, 18% had pain, 10% had numbness, 38% had incontinence, 9% had urinary retention, 15% had foot deformities, and 12% had scoliosis (some patients had more than one symptom) (70).

Among 197 children with LMC treated at Children's Memorial Hospital, sensorimotor function was preserved among nearly two thirds of patients younger than 9 months when they came to medical attention. Function was intact among only 12% of children 9 months or older. By the age of 2 years, more than 50% of children have marked sensorimotor loss. A similar trend of increasing dysfunction with advancing age was observed for both urologic abnormalities and orthopaedic deformities. More than 50% of children had marked bladder dysfunction by 4 years of age, and 50% had orthopaedic deformities (small or asymmetric feet, pes cavus, claw toe deformity, and equinovarus being the most common) by 7 years of age (unpublished observations). It therefore appears that with advancing age untreated children with LMC most often have, in chronologic order, neurologic deficits, urologic abnormalities, and orthopaedic deformities.

Lipoma is best imaged with MRI. The lipoma is readily visible on T1-weighted images as a hyperintense mass in continuity with the distal spinal cord (Fig. 20). The lipoma usually is dorsal to the conus and often extends caudad to the conus as well. The finding of a low-lying conus medullaris confirms spinal cord tethering. The conus occasionally is rotated 90 degrees with the lipoma oriented dorsolaterally rather than immediately dorsally to the rotated spinal cord. The lipoma in these rare cases often drapes asymmetrically over the spinal cord into the lateral gutters of the thecal sac, and the nerve roots may run through the fatty mass. This configuration makes complete untethering difficult or even impossible. Neurologic deficits in children with laterally situated lipoma, if present, usually are asymmetric and are worse on the side to which the lipoma is attached.

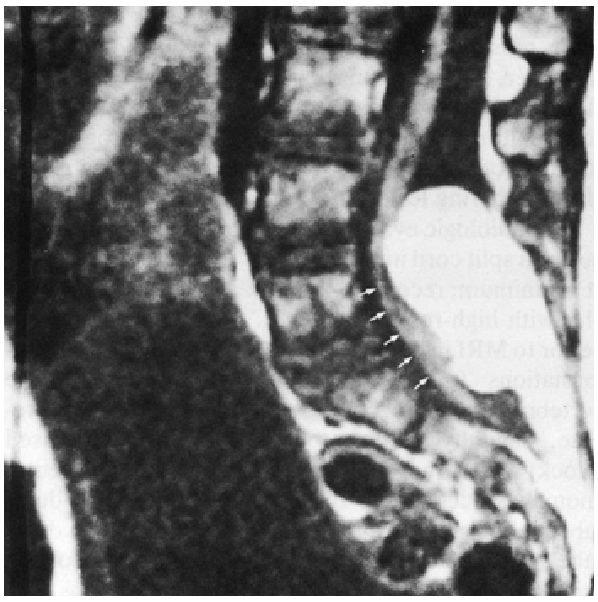

FIGURE 20. Midsagittal magnetic resonance image of a patient with a spinal lipoma. The spinal cord (*arrows*) is low-lying at the sacral level, indicating tethering. The lipoma, which is *white* on this T1-weighted image, is dorsal to the spinal cord.

Additional preoperative tests include manual muscle testing, urodynamic evaluation, and comprehensive orthopaedic assessment of both the spine and lower extremities. Manual muscle testing confirms the presence of individual muscle weakness or change in function. Urodynamic studies may show a small- or large-capacity bladder, uninhibited bladder contraction, detrusor-sphincter dyssynergia, or other evidence of a neurogenic bladder. Orthopedic deformities of the lower extremities and scoliosis may be evident at physical examination or on radiographs.

Repair of LMC usually is straightforward. The subcutaneous portion of the lipoma, if present, often can be readily differentiated from the surrounding subcutaneous fat and is dissected down to the lumbodorsal fascial defect. The lumbodorsal fascia is opened, and the laminae and spinous processes are exposed. Dysraphic posterior elements are common. The stalk of the lipoma enters the dura through a dorsal dural defect (duraschisis). The dura is opened around the stalk, and the stalk is followed to its attachment to the spinal cord, where it inserts between the more laterally situated dorsal roots as they enter the spinal cord. Dissection of the fibrofatty stalk is limited laterally by these roots (Fig. 8). The lipoma is gently dissected from within, from dorsal to ventral with bipolar cautery and scissors, ultrasonic aspirator, or carbon dioxide laser (78). Dissection continues from within the lipoma as it approaches the central canal of the spinal cord. Dissection of the more laterally situated lipoma can be more difficult and dangerous. As the anatomic features become distorted by the rotated spinal cord and the root sleeves are misplaced, the fat extends laterally or even ventrolaterally to the cord and obscures the roots. The roots may even run within the fat itself.

Spinal lipoma is essentially an intramedullary spinal cord tumor, although not a neoplasm, with a dorsal exophytic component. Untethering usually involves incomplete removal of the fat as it arises from the spinal cord substance. If a carbon dioxide laser is being used, one can see a distinct change in the response of the tissues as the interface between the fat and the normal spinal cord substance is approached. The bubbling of the vaporized fat ceases as normal spinal cord tissues are approached. Once most of the lipoma has been removed, the normal tubular contour of the spinal cord is reconstructed by means of reapproximation of the exposed pial surfaces. The dura is closed either primarily or with a dural patch graft.

The results of untethering depend on whether dysfunction has evolved before intervention. In a series of 213 children with lipoma (55 children with lipoma of the filum and 158 with LMC), no patient who had normal neurologic function preoperatively was permanently worsened by the operation. For the 158 children with LMC and preexisting deficits, 29% had marked improvement in all symptoms after surgical treatment (12% returned to normal condition), and 69% had improvement in at least one symptom or remained in stable condition. Two patients with preexisting deficits were in worse condition after the operation (70).

Patients with sensorimotor deficits and pain were most likely to improve—66% of those with preoperative weakness, 83% of those with spasticity, 79% of those with pain, and 100% of those with gait disturbances improved postoperatively. Patients with preexisting urologic dysfunction improved less frequently; 38% of those with preoperative urinary retention and 29% of those with incontinence improved postoperatively. Patients with orthopaedic deformities were least likely to improve; 22% of patients with preoperative foot deformities and none of those with scoliosis improved postoperatively. However, 72% of patients with foot deformities and 95% of those with scoliosis were in stable condition postoperatively (70). These results emphasize the importance of early detection and therapy for LMC, before neurologic, urologic, or orthopaedic dysfunction intervenes.

Clinical deterioration due to spinal cord retethering continues to be a problem, occurring among 10% to 47% of patients (21,70,107,108). Because essentially all patients with lipoma have radiographic signs of tethering at follow-up MRI, the diagnosis of recurrent tethering is not made on the basis of MRI findings alone. All patients with lipoma should ideally be observed carefully in a multidisciplinary setting with serial neurologic examinations, urodynamic studies, and orthopaedic evaluations to detect early evidence of clinical deterioration.

Treatment of Children with Split-Cord Malformations

Like those with occult dysraphic malformations, many children with split-cord malformations are born with normal or nearly normal neurologic function. When examined carefully, however, many are found to have subtle neurologic abnormalities that suggest spinal cord dysfunction. More important, with growth and development, almost all patients have insidious and progressive neurologic deficits, urologic dysfunction, and orthopedic deformities of the legs or spine or both (46,102). It is very rare to encounter an adult who is truly free of symptoms. Children younger than 2 years often look healthy or have only subtle abnormalities. More than one half of those older than 2 years, however, and nearly all adults have developed considerable neurologic dysfunction that can be attributed to spinal cord tethering (102). Once they occur, neurologic deficits often do not improve even after resection of the tethering malformation (46,102). For this reason, we and most pediatric neurosurgeons recommend early repair of the malformation, before deficits occur. In particular, patients in being considered for an operation to correct scoliosis should absolutely be evaluated by a neurosurgeon familiar with developmental anomalies. The underlying split-cord malformation should be addressed before orthopaedic intervention. Without prior untethering, corrective spinal surgery may cause sudden and disastrous neurologic loss.

Most children with split-cord malformations (88% in the series of Pang et al. [101, 102, 103]) have associated visible cutaneous signs that suggest the diagnosis before neurologic deficits occur. Cutaneous and mesenchymal lesions include hypertrichosis (hairy patch) among 20% to 55% of patients, capillary hemangioma, dermal sinus (approximately half of which have an associated intraspinal dermoid tumor), and obvious bony malformations of the dorsal arch (46,68,101,102). Hypertrichosis is the most common, and the most specific, indicator of an underlying split-cord malformation (102).

Neurologic abnormalities include motor dysfunction, sensory loss, and pain. Muscle weakness usually is insidious and progressive but can be acutely precipitated by means of sudden stretching of the spinal cord, as occurs, for example, with a jackknife posture during a sporting event or auto accident or during the lithotomy position for surgery or obstetric delivery (67,92). Weakness can be symmetric or predominantly or even exclusively unilateral. Asymmetric motor deficits are observed in two groups: (a) patients in whom the two hemicords are asymmetrically divided resulting in one larger and one smaller hemicord (102) and (b) patients with hemimyelomeningocele, in which one hemicord fails to properly close, manifests as an open neural placode, and causes ipsilateral sensorimotor deficits while the other hemicord remains within the spinal canal and provides more normal innervation to the contralateral leg (28).

Associated changes in motor tone and vegetative sensorimotor functions are common and include spasticity, muscle atrophy, and even sympathetic dystrophy with hairlessness, anhidrosis, dependent rubor, thickened toenails, nonhealing ulcers, and recurrent osteomyelitis. Muscle imbalances can cause progressive secondary orthopaedic difficulties, such as pes cavus, claw toe, and equinovarus deformities (68,102).

Sensory disturbances occur most frequently in combination with motor weakness. Both altered sensation and sensory loss may be apparent. Sensory symptoms include paresthesia (spontaneously occurring disagreeable sensations such as pins and needles or burning), dysesthesia (unpleasant sensory responses to innocuous sensory stimuli), and hyperpathia (heightened painful responses to painful sensory stimuli). Pain is more common among adults than children. It characteristically involves the legs, perineum, or perianal region and usually has an unpleasant paresthetic or dysesthetic quality (102).

Urinary dysfunction is more frequent with advancing age (102). Symptoms of progressive bladder disturbance include intermittent accidents or urinary dribbling, frequent urinary tract infections, and difficulty with toilet training. Among toddlers who have not yet mastered toilet training, progressive loss of bladder function may become apparent only in retrospect, when the child later does not achieve urinary control. Urodynamic testing (see earlier) may provide important information regarding preoperative urinary function and should be a part of every evaluation.

Scoliosis is a common presenting feature of split-cord malformations and its cause is likely multifactorial. Underlying causes of scoliosis include associated underlying vertebral anomalies such as unbalanced hemivertebrae and segmental bars (58), underlying static muscle imbalance or tonal asymmetry, and asymmetric neurologic dysfunction. In particular, spinal cord tethering, either from the split-cord malformation or an associated foreshortened filum terminale, has been proposed as a potential cause of scoliosis. There remains considerable and lively debate about the degree to which spinal cord tethering contributes to progressive scoliosis. Several authors have suggested that scoliosis among patients with split-cord malformations is most commonly the result of underlying vertebral malformations and that untethering is unlikely to change the progression of the curve (44,54,58,67,92,150). In a series of 27 patients referred to Winter et al. (150) because of scoliosis and split-cord malformations, all but one patient had multiple underlying vertebral abnormalities. Most curves were congenital (10 were present at birth, and the average age at presentation was 3 years), and the scoliosis was most commonly at the level of the underlying vertebral malformations (150). In a study of 34 patients conducted by Hilal et al. (54), scoliosis among untreated patients progressed gradually and was most severe among those with multiple underlying vertebral malformations. Among 20 patients described by Keim and Greene (67), most of whom had malformations of the vertebral bodies, 14 came to medical attention with scoliosis. Twelve of these underwent resection of the bony spur, and 6 of the 12 needed subsequent surgery to correct the scoliosis. In a series of 30 patients described by Gower (44), 7 came to medical attention with scoliosis. Surgery for correction of the split-cord malformation stabilized progressive scoliosis for 1 patient, did not halt progression for 2, and had no effect on stable scoliosis for 4 (44). In Keim and Greene's series, however, scoliosis in 6 of 12 patients remained stable after untethering. Among 39 patients described by Pang (102), 5 of whom had progressive and 16 nonprogressive scoliosis, 4 of 5 children with progressive scoliosis achieved stability, and 1 of 5 had progression. Fourteen of 16 patients with stable scoliosis remained stable postoperatively, whereas 2 of 16 eventually needed corrective surgery for scoliosis.

These studies all had a variety of problems. First, the reported correlation between malformations of the vertebral bodies and scoliosis among patients with split-cord malformations does not necessarily imply a causal relation. Second, details regarding the following factors and a host of other variables were neither adequately described nor systematically examined in any of the studies: level and extent of the malformation; severity and progression (if any) of the curves at diagnosis; ages of the patients at diagnosis; presence or absence of additional presenting features, such as neurologic deterioration, urologic worsening, or orthopaedic deformities of the lower limbs; the nature, severity, and extent of underlying vertebral malformations; and the extent of untethering surgery and associated spinal cord malformations. Third, some patients underwent untethering and some did not, introducing a potential element of bias. Fourth, as Pang (101,102) pointed out, there are often multiple sites of tethering in these patients. For example, many split-cord malformations have an associated thickened filum terminale, 10% to 15% have tandem lesions at other levels of the neuraxis, others have hidden ventral tethering elements in addition to the obvious dorsal elements, and still others may have other malformative tethering elements, such as median nerve roots that attach to or pass through the dura (so-called myelomeningocele manqué), lipoma, dermal sinus, neurenteric cyst, teratoma, and a variety of other malformations. The conditions of patients with type II malformations, who previously have been thought to harbor no tethering element, do indeed deteriorate, and the deterioration would complicate surgical results. Earlier surgical series are much more likely to have missed these associated elements. The result is partially controlled malformations and ongoing deterioration.

Scoliosis among patients with split-cord malformations no doubt is multifactorial and probably most often is related to underlying vertebral malformations. However, in a child with a split-cord malformation and progressive scoliosis but without underlying vertebral malformations, tethering should be strongly considered a potential cause of the scoliosis. No comprehensive, systematic studies have examined either the contribution of tethering to scoliosis or the effect of spinal cord untethering on stabilizing or improving scoliosis among these patients. Nevertheless, there appears to be agreement among most authors that (a) nearly all patients with split-cord malformations eventually have neurologic deterioration, (b) untethering in patients without symptoms will likely avert the development of neurologic deterioration and improve some and stabilize almost all patients with symptoms, and (c) therapy for scoliosis without first untethering the malformation can cause abrupt neurologic deterioration. For these reasons, we and others recommend that the split-cord malformation be untethered before patients undergo corrective scoliosis surgery, even if the scoliosis is thought to be unrelated to the underlying spinal cord malformation.

The radiologic evaluation of a child with a suspected split-cord malformation should include both MRI and CT through the entire area. The CT scan shows any bone spurs to better advantage. Myelography with high-resolution CT (CT myelography) may be superior to MRI in demonstrating some of the details of these malformations (102). Whether this provides practical information that would justify the additional discomfort and risk is debatable. Vertebral malformations such as hemivertebrae, sagittally clefted (butterfly) vertebrae, fused (block) vertebrae, and missing vertebrae are more frequent in type I (double dural tube) than the type II (single dural tube) malformations (102). The midline osseous spur in type I malformation is almost always evident at MRI or CT myelography, whereas the midline fibrous bands of type II malformations are present among fewer than one third of patients (102). Median nerve roots occasionally are visible projecting from the hemicords to the intervening fibrous band (102) (Fig. 10).

For a patient with a type II malformation, both the dura surrounding the hemicords and the intervening osseous or fibrocartilaginous spur tether the spinal cord (Fig. 21). Both the spur and the surrounding dural cuff must be removed. As would be predicted, the tethering spur in these patients usually transfixes the spinal cord at the caudal end of the malformation, where the two hemicords reunite to form a single caudal spinal cord, although they may be present anywhere within the split segment. The spur may be attached either ventrally to the underlying ventral dura and vertebral body, dorsally to the lamina, or at both ends. The spur is removed with rongeurs before the dura is opened. Vigorous bleeding may occur from vessels within the spur, and the surgeon should be prepared to control this with bone wax and bipolar cautery. After the spur is removed, the cuff of dura is excised. Adherent, nonfunctional median nerve roots that project from the hemicords to the dural sleeve are carefully sectioned. The ventral dura is difficult to close and usually is left open, and the dorsal dura is closed in a watertight manner.

Type II malformations lack a visible extradural osseous spur and traditionally have not been thought to contain tethering lesions (20,52,131). However, the intradural midline fibrous bands in single dural sheath malformations can tether the spinal cord in a manner analogous to that of the osseous spurs of double dural tube malformations (102,103). Like the osseous spurs of type I malformations, the intradural fibrous bands in type II malformations (Fig. 10) often are located at the caudal end where the hemicords reunite, although they may be found anywhere within the split segment. The bands pass from the cleft between the hemicords to the adjacent dorsal and ventral dura. They are resected to untether the hemicords. A thickened filum terminale also is frequently present and must also be sectioned. Among 11 patients with single dural sheath malformations, all had fibrous bands at surgery that were thought to be tethering the hemicords. Therefore, all split-cord malformations, regardless of type, should be explored operatively (102).

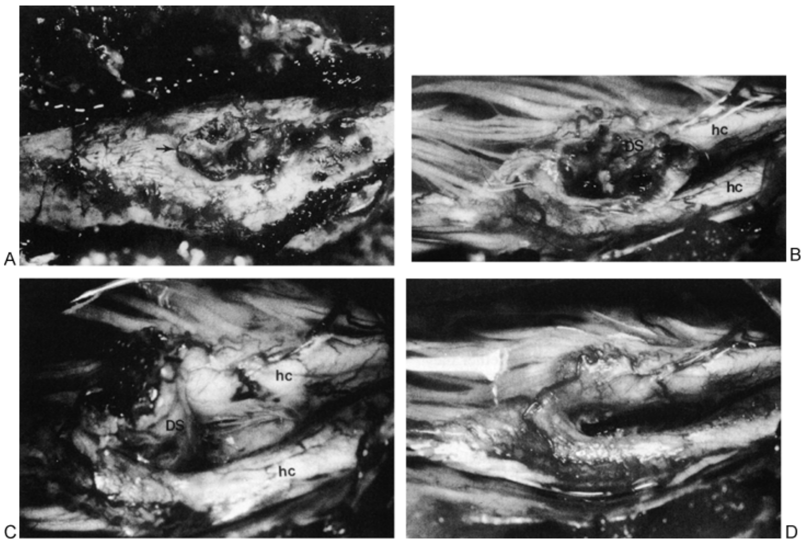

FIGURE 21. Surgical management of a double dural sac malformation. **A:** Partial resection of the osseous spur (*arrows*). **B:** The dura has been opened. The median cuff of the dural sheath (*DS*) is visible adherent to the two hemicords (*hc*). **C:** The dural sleeve (*DS*) is retracted caudally to show its cranial base. **D:** After complete removal of both the osseous spur and surrounding dural sheath, the two hemicords lie freely within a common dural sac. (From Pang D (1992): Split-cord malformation, II: the clinical syndrome. *Neurosurgery* 31:481–500, with permission.)

The results of treatment depend largely on whether untethering is performed before or after neurologic deficits have intervened. Surgical morbidity is acceptable (7% in one series) when untethering is performed on patients without symptoms and is lower for type II than type I malformations (102). For patients with symptoms, pain is relieved by means of untethering in almost all cases. However, once they develop, neurologic, urologic, and orthopaedic deficits are frequently stabilized but less frequently are improved by means of surgery. Preoperative sensorimotor deficits in one series improved in 38%, stabilized in 59%, and worsened in 3% of cases. Progressive deficits of recent onset were much more likely to improve than were static, long-standing deficits. For example, progressive sensorimotor deficits improved in 58% and stabilized in 42% cases, whereas static deficits improved in no cases, stabilized in 82%, and worsened in 9%. Progressive bowel and bladder dysfunction likewise improved in 45%, stabilized in 45%, and worsened in 10% of cases, whereas static urologic abnormalities improved in none, stabilized in 90%, and worsened in 10%. Scoliosis improved in no cases, stabilized in 86%, and progressed (requiring spinal fusion) in 14% (102).

Summary

It is increasingly apparent that neurologic and related urologic and orthopaedic dysfunction among children with both myelomeningocele and occult dysraphic lesions such as lipomyelomeningocele and split-cord malformations are the result of progressive and in some cases irreversible injury due to spinal cord tethering. Animal studies have implicated progressive spinal cord ischemia as the pathophysiologic mechanism underlying progressive injury from cord tethering in humans. The improvements that follow untethering for all types of dysraphic malformations strongly support a vigilant and aggressive neurosurgical approach to dysraphic malformations. For children with myelomeningocele, untethering should be considered whenever objective clinical evidence of neurologic dysfunction becomes evident, provided that incipient shunt malfunction has been excluded. For children with an occult dysraphic malformation, the mere presence of a potentially tethering lesion is reason for neurosurgical intervention. Untethering is best performed before dysfunction becomes evident and sensorimotor changes, urologic dysfunction, and orthopaedic deformities intervene. The operation should be performed by a neurosurgeon experienced with such malformations.

The Spine in Skeletal Dysplasias

Paul D. Sponseller

P.D. Sponseller: Pediatric Medicine, Johns Hopkins University, Baltimore, Maryland 21287.

Skeletal dysplasia is a group of disorders caused by a systemic defect in the formation of the skeleton. The mutations and the mechanisms by which they cause dysplasia have been greatly elucidated in the past few years (3). Almost all affect either the matrix of cartilage or the process of endochondral ossification. There are several ways of classifying dysplasia. The more traditional method, the International Classification of Skeletal Dysplasias (1), is summarized in Table 1 . The more recent method of grouping dysplasia according to families of similar mutation is summarized in Table 2 (37). The group of skeletal types of dysplasia merges with other types of disorders such as connective tissue disorders and metabolic disorders. For instance, disorders that affect cartilage oligomeric matrix protein affect not only cartilage but also ligament, and mucopolysaccharidosis is both metabolic derangement and skeletal dysplasia. Therefore it is somewhat debatable which conditions should be included. This chapter emphasizes principles common to all types of skeletal dysplasia and discusses unique features of each of the most common disorders. These are summarized in Table 3 .

For persons treating patients with skeletal dysplasia, it is not uncommon to be faced with syndromes that are rare or even new to the practitioner. This is unavoidable. However, certain patterns of problems occur that are common to many types of skeletal dysplasia. These are instability, deformity, and stenosis. They may occur in different planes and at different levels of the spine, but it is helpful to think of these classes of problems when approaching the care of a patient with a skeletal dysplasia. Almost every type of dysplasia may manifest any or several of these problems, with the following exceptions: cervical kyphosis occurs only in diastrophic dysplasia and Larsen syndrome, and symptomatic stenosis is by far most common in achondroplasia. Another phenomenon that confounds the practitioner is the phenotypic variability of genetic disease. Some patients with achondroplasia have severe thoracolumbar kyphosis, whereas others do not have any at all despite the presence of a reasonably constant mutation. That makes it all the more important to be open-minded when evaluating these patients for the first time. However, some useful generalizations are as follows.

Instability most commonly occurs at the atlantoaxial level. It may be caused by os odontoideum, odontoid hypoplasia or aplasia, or laxity of the transverse ligament. This is most common in mucopolysaccharidosis (7), spondyloepiphyseal dysplasia (11), and metatropic dysplasia. It is helpful for the novice to recognize that this problem is quite rare in that most common of all dysplasia, achondroplasia. Plain radiographs should be obtained of the cervical spines of most patients with dysplasia, especially if an intervention is to be performed. The odontoid process should be clearly visualized. Not all patients with a radiographic anomaly have clinical instability, however. If an anomaly is found, active flexion-extension lateral radiographs of the cervical spine should be obtained. If it is not clear whether cord compression or impingement is developing, magnetic resonance imaging (MRI) in neutral, flexion, and extension is the next step. During MRI any pathologic changes are likely to be underestimated because imaging is performed in a confined space in a lateral position. Sometimes the images show an additive compressive effect from cervical stenosis at the same levels. If translation between the most caudal portion of the arch of C1 and the anterior-superior cortex of C2 is more than 8 mm, atlantoaxial fusion usually is recommended. If the translation is between 5 and 8 mm, observation may be justified unless the patient is very small, is at higher-than-average risk of trauma, has neurologic signs indicating cord compression, or is poorly compliant.

Among patients who need atlantoaxial fusion, it is desirable to preserve atlantooccipital motion, unless this level is already fused or ankylosed or is stenotic and in need of decompression. Computed tomography (CT) can be helpful in assessing the shape of the posterior ring of the atlas, because this structure often is bifid and may even be missing. If the bone size and quality are of adequate condition for internal fixation, there are many techniques of stabilization to choose from. These are left to the surgeon's discretion. However, it is wise to have several options available because the anatomic features may not appear as expected. If internal fixation is not feasible, graft and fusion with halo-vest immobilization are quite successful in the care of young children (45). Graft sources may include one or both iliac crests and the proximal tibial metaphysis if needed. Reliance on allograft is inadvisable, because there is a high risk of pseudarthrosis (88).The upper cervical spine is best stabilized in a halo device. Postoperative immobilization in a halo vest should take into account the patient's age as well as any cranial anomalies. Patients younger than 6 years should have the halo pins tightened to 2 to 4 inch-pounds, and more than four pins are recommended for patients younger than 4 years (17).

TABLE 1. International Classification of Skeletal Dysplasias (1992 Partial List)

A. Defects of the tubular and flat bones of the axial skeleton
  - Achondroplasia group
    - Achondroplasia
    - Hypochondroplasia
    - Thanatophoric dysplasia
  - Metatropic dysplasia
  - Atelosteogenesis and diastrophic dysplasia group
  - Osteogenesis imperfecta
  - Kneist-Stickler group
  - Spondyloepiphyseal dysplasia congenita group
  - Other spondyloepi (metaphyseal) dysplasia groups
  - Storage disorders
    - Mucopolysaccharidosis
    - Mucolipidosis
  - Multiple epiphyseal dysplasia
  - Metaphyseal dysplasia
  - Dysplasia with defective mineralization
    - Hypophosphatasia
    - Hypophosphatemic rickets
    - Neonatal hypoparathyroidism
  - Dysplasia with increased bone density

B. Disorganized development of cartilaginous and fibrous components of the skeleton
  - Multiple cartilaginous exostosis
  - Dysplasia epiphysealis hemimelica
  - Enchondromatosis
  - Fibrous dysplasia

C. Idiopathic osteolysis

TABLE 2. Etiologic Classification of Dysplasia

- FGFR3 group (Fibroblast Growth Factor Receptor 3, a local regulator of cartilage growth)
  - Achondroplasia
    - Hypochondroplasia
    - Thanatophoric dysplasia
- COL1A group (collagen 1, structural osseous protein)
  - Osteogenesis imperfecta
- COL2A 1 group (collagen 2, structural cartilage protein)
  - Spondyloepiphyseal dysplasia (SED) congenita
  - Kneist dysplasia
  - Stickler dysplasia
  - Strudwick dysplasia
  - SED tarda
- DDST group (Diastrophic Dysplasia Sulfate Transport, defective sulfate transport enzyme)
  - Diastrophic dysplasia
  - Achondrogenesis
- COMP group (cartilage oligomeric matrix protein, structural cartilage protein)
  - Multiple epiphyseal dysplasia (MED)
  - Pseudoachondroplasia
- Storage disorders
  - Mucopolysaccharidosis
  - Mucolipidosis

TABLE 3. Spinal Disorders in Skeletal Dysplasia

Condition	Instability	Cervical Deformity	Scoliosis	Kyphosis	Stenosis	Comments
Achondroplasia	None	None	None	Thoracolumbar	Foramen magnum Lumbosacral greater than thoracic or cervical	Brace if not resolved at 2–3 years of age
Hypochondroplasia	Rare	None	None	Rare	Rare	
Metatropic	Yes	None	Yes	Yes	None	
Diastrophic	Rare	Kyphosis	Yes	Yes	Yes	Cervical kyphosis may resolve; spina bifida may affect other levels
Kneist	Yes	No	Yes	Yes	No	Scoliosis usually mild
Spondyloepiphyseal dysplasia	Yes	No	Yes	Yes	No	
Pseudoachondroplasia	Yes	No	Yes	No	No	Cervical instability rare
Chondrodysplasia punctata	Yes	No	Yes, congenital	No	Cervical (rhizomelic)	
Metaphyseal dysplasia	Rare	No	Rare	No	No	
Cleidocranial dysplasia	No	No	Yes	No	No	Scoliosis may be associated with syrinx
Larsen Syndrome	Rare	Kyphosis	Yes	Yes	No	Spina bifida occulta Lumbar spondylolysis possible
Stickler Syndrome	Rare	No	Yes	Yes	No	

Rotatory instability, such as spondyloepiphyseal dysplasia and metatropic dysplasia can occur with skeletal dysplasia. Subaxial instability can occur in Larsen syndrome or more rarely in other conditions. Evaluation and treatment should proceed according to the principles described earlier.

Deformity in the cervical spine takes the form of cervical kyphosis. This is most common in Larsen syndrome and diastrophic dysplasia (36,41,74). In both conditions, deformity arises in conjunction with cervical spina bifida and hypoplasia of the midcervical vertebrae. One contrast between the two conditions is that in diastrophic dysplasia, kyphosis can reverse spontaneously (36). In Larsen syndrome this has not been reported. Bracing does not have a clear-cut role in the management of this deformity. In either case, if the deformity becomes severe, myelopathy can occur (41,49,60). Anterior and posterior decompression is indicated if this complication develops.

The most common deformity in dysplasia is thoracic or thoracolumbar kyphosis. This is most severe when it is focal and not associated with scoliosis. The value of brace treatment has not been proved with clinical research. The rarity and variability of these conditions makes a controlled trial difficult. If a patient is young and there is flexibility in the curve, a Milwaukee brace can be corrective (7,68). Surgical treatment depends on the magnitude of the curve and the associated scoliosis. If kyphosis is greater than 60 to 70 degrees, anterior and posterior fusion may be necessary (7).

Scoliosis is most common in diastrophic, spondyloepiphyseal, Kneist, and metatropic dysplasia. Bracing remains an option, although the rate of successful stabilization is unknown. When the curve exceeds 50 to 69 degrees, bracing does not have much value. Surgery is indicated if a curve is unbalanced or associated with severe kyphosis. Low-profile instrumentation is indicated, and the hooks must be carefully placed. If pedicle screws are used, preoperative CT of the pedicles is recommended to evaluate size.

Stenosis most commonly involves achondroplasia. It can occur from the foramen magnum to the sacrum (see later). If frequent claudication or neurologic deficit is present, decompression must extend to the sacrum. If stenosis extends proximally across a kyphosis, this area also must be fused. Stenosis also occurs among diastrophic persons and in rare instances is clinically symptomatic (43,72). Stenosis at the ring of the atlas can complicate spondlyoepiphyseal dysplasia.

The surgical treatment of a patient with skeletal dysplasia poses problems for the anesthesiologist (90,91), who should be experienced in this area and extra time should be allowed for induction. Intravenous access may be difficult, especially central access. Intubation is complex because of abnormal oropharyngeal anatomic features, mandible or neck stiffness, and, in some cases, cervical instability. Intraoperative positioning must be geared to the patient's size and unique anatomic features. Postoperative management is complicated because the patient often has coexisting disabilities. Inpatient rehabilitation sometimes is necessary after spinal surgery. These considerations should be taken into account in surgical planning.

Specific Disorders

Achondroplasia

Achondroplasia is the most common skeletal dysplasia. The incidence is about 1 case per 30,000 livebirths (28). Although the most noticeable involvement is rhizomelic shortening of the extremities, the length of the spine is at the lower limits of normal. This disorder is autosomal dominant, but for 70% of affected persons this disorder is a spontaneous mutation. The genetic defect is a specific mutation in fibroblast growth factor receptor protein 3 (62,80). This protein has an inhibitory effect on cells in the proliferative zone of the growth plate. The mutation increases the inhibitory effect. The growth of the vertebrae normally occurs from the two neurocentral synchondroses (growth plates) in the vertebral body near the bases of the pedicles (53,63) (Fig. 1). They are obliquely oriented and provide growth in width of the spinal canal as well as length of the pedicles. Growth does not occur in these regions of persons with achondroplasia, and a canal develops that is narrow in all dimensions.

Radiographic Findings

The cervical spine rarely displays deformity or instability in achondroplasia, in contrast to the features of many of types of skeletal dysplasia. However, in the spine of a person with achondroplasia the posterior vertebral body cortex is close to the lamina, indicating stenosis. Anteroposterior radiographs show narrowing of the pedicles from the upper lumbar spine to the sacrum in contrast to the normal widening (70) (Fig. 2). All areas of the spine from skull base to sacrum are prone to stenosis. The lumbar spine is more lordotic than normal, an alignment that worsens the stenosis. The vertebral bodies are taller than they are wide in the mediolateral or anteroposterior dimension, and the posterior margins are scalloped. There is often mild, residual thoracolumbar kyphosis, which persists into adulthood.

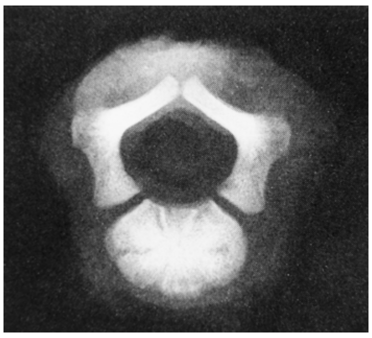

FIGURE 1. Pedicles in a person with achondroplasia come closer together in the more distal parts of the spine. This is in contrast to the usual pattern, in which there is greater interpediculate distance in the distal portions of the spine.

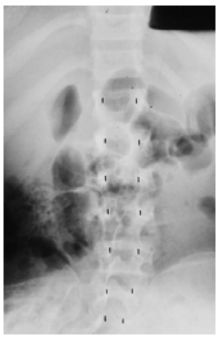

FIGURE 2. Growth of each vertebra and the pedicular separation is determined by the growth plates labeled *neurocentral synchondroses.* These grow by means of endochondral ossification and are therefore impaired in achondroplasia.

Clinical Problems

Foramen Magnum Stenosis

The base of the skull around the foramen magnum, being formed from endochondral bone, is congenitally stenotic in almost all infants with achondroplasia but usually improves with age (33,35). In some infants this stenosis becomes critical and causes symptoms of sleep apnea, hypotonia, aspiration, or generalized developmental delay. If a child does not meet milestones or displays respiratory problems, a sleep study may confirm brain stem compression (66,104,112). Foramen magnum decompression by an experienced neurosurgeon usually improves the symptoms noticeably. This is necessary in the care of fewer than 10% of persons with achondroplasia. Along with the posterior edge of the foramen magnum, usually only the ring of the atlas is removed during this procedure. No postoperative immobilization is needed. Late sequelae have not been seen. However, if two or more laminae are removed, it is necessary to monitor for upper cervical kyphosis.

Thoracolumbar Kyphosis

Mild to moderate thoracolumbar kyphosis occurs among 80% of infants in the sitting position. Contributory factors most likely include hypotonia of the trunk extensors, ligamentous laxity, the largeness of head in relation to the rest of the body, and delayed standing. Most instances of kyphosis resolve spontaneously at about the time the child begins to stand (65). Those that do not resolve tend to occur among children with greater hypotonia, often those who needed foramen magnum decompression. The vertebrae, usually the T12 and L1, tend to become progressively wedged (Fig. 3). There are several reasons why this kyphosis should be corrected. First, it causes mild pressure on the conus, which may add to other factors in causing symptoms. Second, it necessitates an increase in compensatory lower lumbar lordosis, which increases stenosis there (82). Third, because adolescents or adults with achondroplasia often need decompressive laminectomy of the entire lumbar spine, any kyphosis present may markedly increase after posterior decompression (Fig. 4).

Pauli et al. (65) recommend prohibition of sitting at an angle greater than 69 degrees. I believe this leads to greater flexion force at the thoracolumbar junction, because patients try to sit up anyway. We recommend observing kyphosis until 2 years of age or walking age, whichever comes first. Patients who do not improve or who have neurologic signs and symptoms should be treated with a brace. I recommend a modified Knight double-upright thoracolumbosacral orthosis (TLSO) with a movable posterior pad to be placed at the apex and to be raised as the patient grows (Fig. 5). If this treatment fails or the patient is noncompliant, serial hyperextension casts can be applied over the course of a few months. The extension moment is gradually increased while the patient is allowed to stand and walk. This therapy has the advantage that the cast must be worn full time, and constant correction is applied. If a satisfactory response has been obtained (correction of more than 50% after 3 to 4 months), the patient can be placed in a TLSO for additional correction and transition to active spinal support (Fig. 6). For patients with thoracolumbar kyphosis greater than 30 to 40 degrees that persists beyond 5 years of age, consideration should be given to posterior fusion in situ over this region to stabilize the spine or allow it to grow straighter (96) (Fig. 7).

Spinal Stenosis

Stenosis is common among persons with achondroplasia; the prevalence is 80% to 90% (110). Symptoms usually develop in late teens to early adult years but may begin even in early adolescence. The most common symptoms is cramping or fatigue

in the thighs, knees, or legs after walking that is relieved by leaning forward and resting hands on the knees in a crouched position (52). Not being able to walk more than a block or two indicates considerable stenosis. Numbness or partial foot drop may complicate more serious cases. A thorough neurologic examination should be performed to evaluate hyperreflexia, weakness, hypoesthesia, and bowel and bladder function. If a deficit is found, or symptoms limit daily activities, posterior decompression probably is indicated. The level of the block is best determined with myelography and CT myelography, because MRI shows stenosis over such a wide region that the level of critical impingement is difficult to determine. The myelographic contrast agent is best introduced from the cervical region. CT usually shows that the canal is reduced to barely more than a slit at the lumbosacral level (Fig. 8). The decompression should be performed carefully. A burr is used to develop a trough on each side near the facets, and the laminae are carefully removed with a fine rongeur (98). Partial facetectomy is performed if needed, but most of the pathologic changes are central. Laminectomy should extend from one to two levels above the block, all the way to the sacrum. The lumbosacral area is difficult to expose for two reasons. First, lumbosacral lordosis is often greater than normal (Fig. 9). Second, the ilia are very prominent posteriorly, and this configuration increases the distance to the laminae (Fig. 10). The dura is thin and often is adherent to the laminae, and dural tears are common. If a tear occurs, the lumbar nerve roots often protrude through it and are difficult to replace.

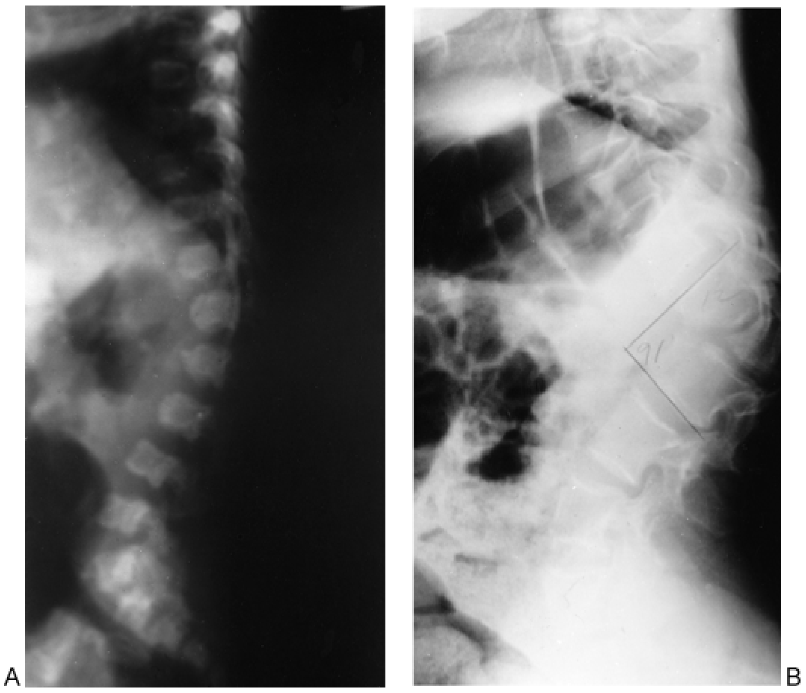

FIGURE 3. Thoracolumbar kyphosis in achondroplasia is mechanically induced rather than congenital. **A:** This patient had moderate thoracolumbar kyphosis at 6 months of age. The typical flaring of the vertebral body at the apex is evident. No treatment was given. **B:** At 12 years of age, severe kyphosis with marked vertebral wedging has developed.

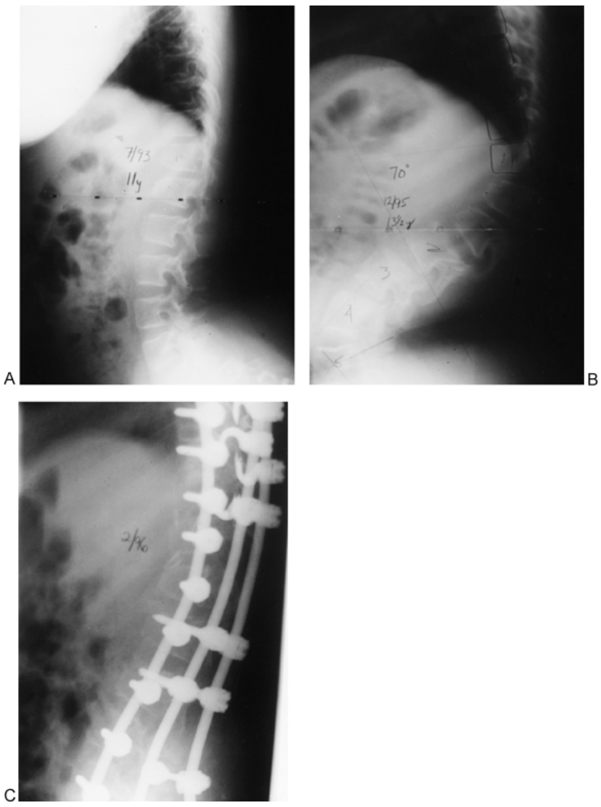

FIGURE 4. Images of a patient with achondroplasia and spinal stenosis that necessitated laminectomy of T10–S1 during adolescence. **A:** At the time of decompression, no stabilization had been performed. **B:** Ten months later, kyphosis of the thoracolumbar junction had progressed and was painful. **C:** Anterior and posterior stabilization was chosen because of the extreme kyphosis and limited size of posterior elements.

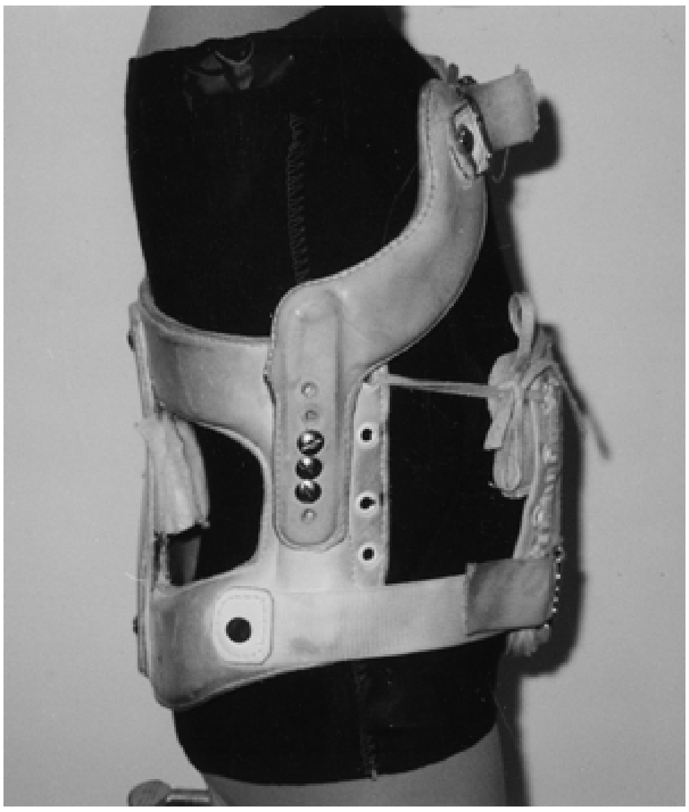

FIGURE 5. A chair-back brace is especially suitable for achondroplastic kyphosis because it does not impair abdominal movement and can be adjusted with growth. The posterior pad over the apex of the curve can be adjusted under direct vision.

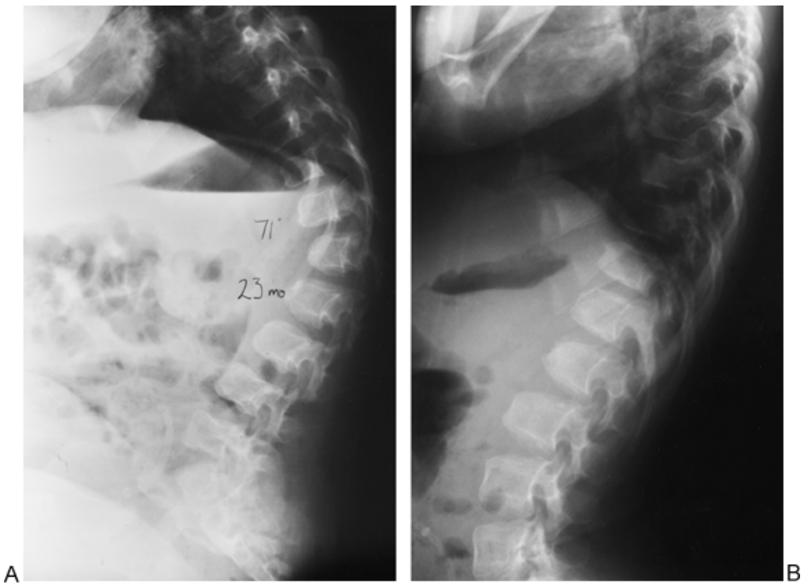

FIGURE 6. A: Image of a 5-year-old child who had a 71-degree curve that had not resolved. Severe thoracolumbar kyphosis improved with bracing. **B:** A hyperextension cast was used for 3 months and a brace for 1 year. The curve decreased to less than 20 degrees.

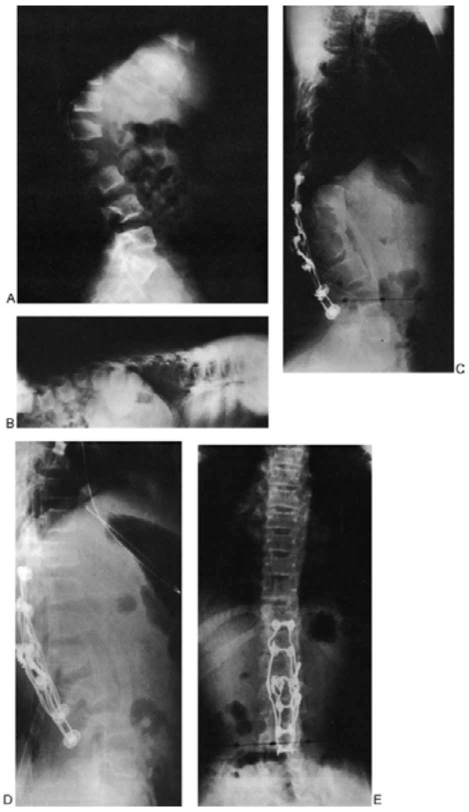

FIGURE 7. Lateral spinal radiograph of an 8-year-old child with achondroplasia shows residual 50-degree kyphosis with wedging of the apical vertebrae at L1 and L2. Resolution of kyphosis after this age is not expected. **B:** Prone lateral radiograph of the child in **A** shows partial correction of kyphosis. **C:** Lateral radiograph of the spine obtained immediately after anterior and posterior spinal fusion. Postoperative casting was used for 6 months. The patient could walk in the cast. **D:** Lateral spinal radiograph obtained 19 months after surgery shows residual 30-degree kyphosis and solid bony fusion. The child was free of symptoms. **E:** Anteroposterior radiograph of the spine 19 months after anterior and posterior spinal fusion shows method of wiring used posteriorly between the spinous processes to act as a tension band and provide partial correction.

The degree of difficulty increases markedly if there is kyphosis along with the stenosis. If kyphosis is more than 20 to 30 degrees, fusion and instrumentation should be added to treatment. Pedicle screws should be used whenever possible; 5-mm screws may be necessary. Hooks should not be placed inside the canal wherever there is stenosis (Fig. 11). Correction should be minimal, if any; stabilization is the goal. Spinal cord monitoring should be conducted. The distal extent of fusion is a matter of controversy. Some surgeons believe fusion should extend to the sacrum to prevent junctional stenosis. Others believe it should extend to L4. Sacral screws are difficult to insert because of the narrowness of the sacrum and the prominence of the ilia. Iliac screws are another option. The historical incidence of postoperative neurologic deficits with this combined decompression and fusion is among the highest reported in spinal surgery, but it can be minimized by experience. The course of untreated stenosis is one of further worsening (73).

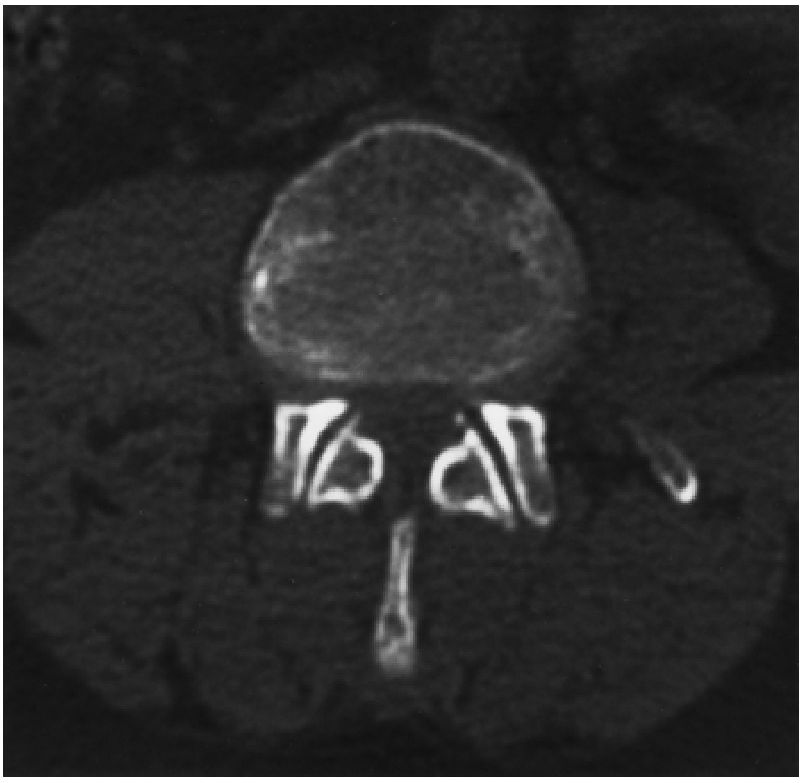

FIGURE 8. Computed tomographic scan of the lumbar spine of a patient with achondroplasia shows both central and foraminal stenosis.

Hypochondroplasia

Hypochondroplasia is a disorder distinct from but related to achondroplasia. Like achondroplasia, hypochondroplasia is caused by a mutation in fibroblast growth factor receptor protein 3, but the mutation occurs in a different domain (57). Stature is not as diminished as in achondroplasia and may reach the low normal range (3,19). Midfacial hypoplasia is not noticeable. Spinal involvement is rare; only a small number of patients have caudal narrowing of the pedicles or kyphosis (24,26,78) (Fig. 12). Spinal decompression rarely is indicated, but when it becomes necessary, the principles of management of achondroplasia should be followed (see earlier).

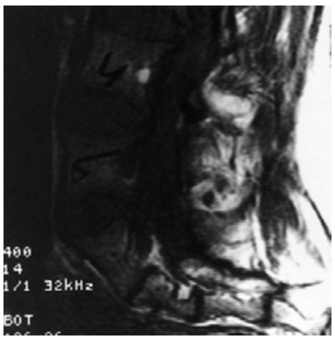

FIGURE 9. Lordosis of the lumbosacral junction in achondroplasia can be severe.

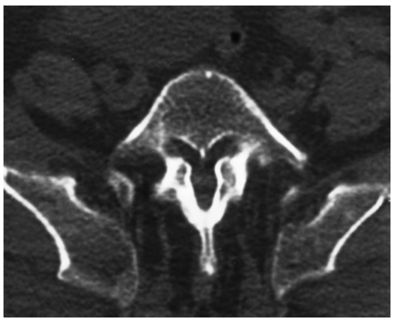

FIGURE 10. The posterior iliac crests in achondroplasia often project far posteriorly, and this configuration produces a deep space. Stenosis of the sacral canal is evident.

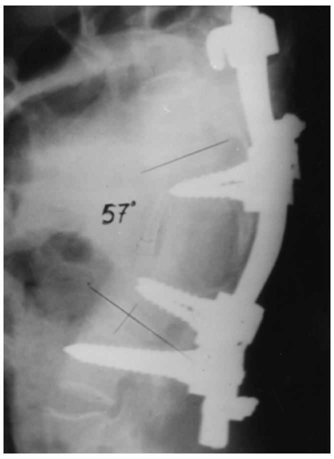

FIGURE 11. Appearance of the patient in Figure 3 after anterior and posterior decompression for symptomatic stenosis. Myelopathy had developed when the spine was corrected to a greater degree. The instrumentation was removed with complete neurologic recovery. One week later correction had occurred to the degree shown here.

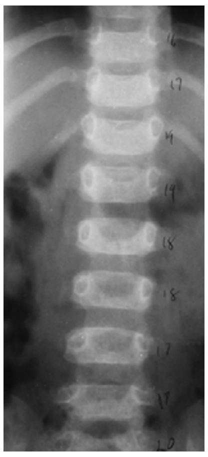

FIGURE 12. The spine of a 2-year-old with hypochondroplasia lacks the caudal narrowing of the pedicles typical of achondroplasia. However, the pedicles do not widen normally either. Mild platyspondyly is present.

Metatropic Dysplasia

Metatropic dysplasia is a rare disorder with a high infant mortality due to thoracic hypoplasia. It also is characterized by enlarged metaphyses, joint contractures, and a long, skin-covered coccygeal “tail.” Spinal involvement is prominent with radiographic findings of flattening of all vertebrae. Some patients have odontoid hypoplasia with cervical instability. Scoliosis, often with kyphosis at the junction between curves, develops early among most patients (Fig. 13).

Treatment Implications

The cervical spine should be imaged in a neutral position when the patient is first examined to rule out subluxation (4,77,81), although lack of ossification may make it difficult to see detail at an early age. The radiographs should be obtained in flexion and extension when the patient is older to rule out odontoid hypoplasia. If atlantoaxial translation is more than 5 mm on these radiographs, clinical signs of myelopathy should be sought or MRI performed in flexion. If clinical or radiographic evidence of cord compression is present, posterior fusion is indicated. Posterior fixation is not always possible if the patient is young or the bone quality is poor. Halo cast or halo vest immobilization is indicated until the fusion is solid. For young patients, halo pin torque has to be decreased to 2 to 4 inch-pounds (17).

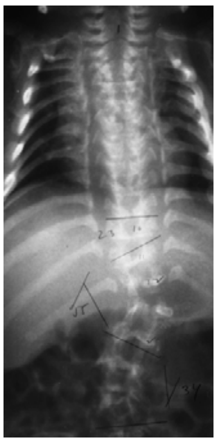

FIGURE 13. Radiograph of a patient with metatropic dysplasia shows early scoliosis, delayed vertebral mineralization, and hypoplasia of the thorax.

Scoliosis has often been reported to exceed 90 degrees and to become quite rigid in adulthood. Paraparesis caused by the kyphotic component has been reported (7). Because these curves often arise in quite young children, it would be useful to know the efficacy of brace treatment. Unfortunately, no studies on this topic have been conducted. It is probably futile to brace curves greater than 45 degrees because of rigidity and lack of mechanical effectiveness. Larger curves should be managed surgically when they exceed this magnitude to prevent worsening of kyphosis. Indications for anterior release in addition to posterior fusion include skeletal immaturity or the presence of a rigid curve. Correction has been achieved by a period of carefully monitored halo traction between the two steps (7). Correction is nevertheless limited by the rigidity of the spine.

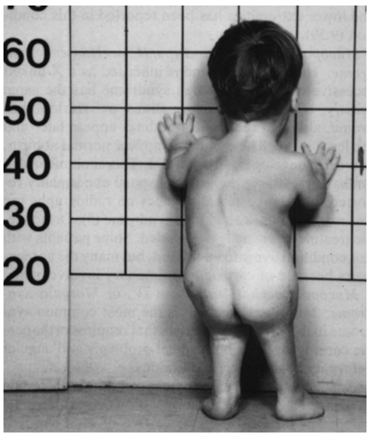

FIGURE 14. Image of a 2-year-old boy with diastrophic dysplasia and progressive severe thoracolumbar kyphosis. (Courtesy of Vernon T. Tolo, MD.)

Diastrophic Dysplasia

Diastrophic dysplasia has possibly the most widespread and unique manifestations throughout the skeleton of any dysplasia (39,102). Patients show abducted (hitchhiker) thumbs, cauliflower ears, equinovarus feet, and multiple joint contractures with epiphyseal dysplasia (48,54) (Fig. 14). Possible spinal problems include cervical kyphosis, thoracolumbar scoliosis, and kyphosis. The genetic defect has been shown to be a defect in sulfate transport through all cartilage; the result is undersulfation of proteoglycans (31,32). The defect is transmitted in an autosomal recessive condition. The highest concentration of patients with this condition occurs in Finland, as do most clinical reports.

Clinical and Radiographic Findings

Throughout the spine, the vertebrae of persons with diastrophic dysplasia are relatively flat. The foramen magnum is abnormally wide. In the cervical spine, there is relative stenosis (6,102), but it rarely becomes clinically significant as it does in achondroplasia. Spina bifida may be present at any region of the spine, but it is usually in the form of occult clefts in the lamina. The discs appear underhydrated throughout life on MR images (75), most likely because of decreased sulfation of proteoglycans and a resultant decrease in water binding. Stiffness and degenerative changes begin relatively early. Trunk height remains very short throughout life.

The cervical spine of persons with diastrophic dysplasia usually does not have atlantoaxial instability, although a case has been reported (76). The most common neck problem is kyphosis in the midcervical spine. This occurs among about 15% of persons with diastrophic dysplasia (74,75). It is associated with spina bifida occulta of the same region. The vertebral bodies at the apex are hypoplastic. It is not clear whether the hypoplasia is primary or whether the bodies become underossified because of kyphosis. Amazingly, some cases have been reported to improve spontaneously, even with curves as large as 85 degrees (6,36). Some cases, however, do progress; they may exceed 100 degrees and can cause myelopathy (43).

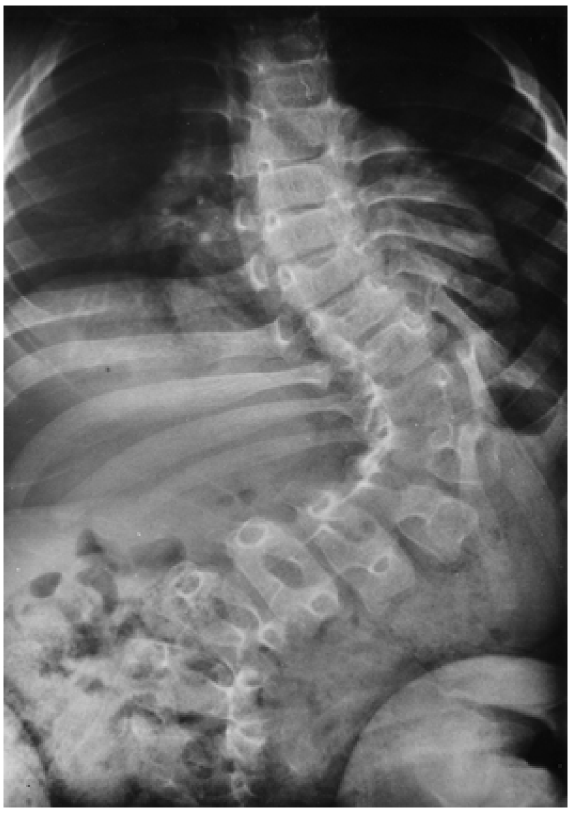

FIGURE 15. Image of a 6-year-old child with diastrophic dysplasia is advanced but resembles idiopathic scoliosis.

The prevalence of scoliosis varies from 50% in some series (72) to 100% in others (6). The latter cases may be influenced by referral bias. Two types have been described—a gradual, idiopathic type of curve (Fig. 15) and a sharper, dystrophic curve, which is more difficult to manage (97).

Orthopaedic Treatment

Cervical Kyphosis

Frequent neurologic examinations should be performed. Cervical kyphosis initially should be followed to see whether it resolves spontaneously. Many cases do (6,36) (Fig. 16). The risk of kyphosis is greater if the curve exceeds 50 degrees (74). If progression is observed, treatment with a Milwaukee brace has been associated with improvement. If the brace is not tolerated or treatment is not successful, surgical fusion may be necessary. Posterior fusion may allow spontaneous correction through anterior growth. Care should be exercised during the surgical approach because of the bifid posterior elements. Postoperative immobilization should be in a halo cast or halo vest. The best position achieved by means of careful passive stretching can be maintained with gentle distraction and use of a posterior pad behind the apex and suspended from the halo uprights. Immobilization should be continued until fusion can be documented radiographically, usually about 4 months. Additional protection in an orthosis can be carried out until the surgeon is confident of solid fusion. If the patient has myelopathy, anterior decompression may be indicated along with strut grafting and posterior fusion (6). This operation can be difficult, however, because of the small size of the patient and of the vertebrae at the time this problem develops. If postoperative pseudarthrosis at the apex develops, it should be corrected when it is detected, or recurrent deformity may develop.

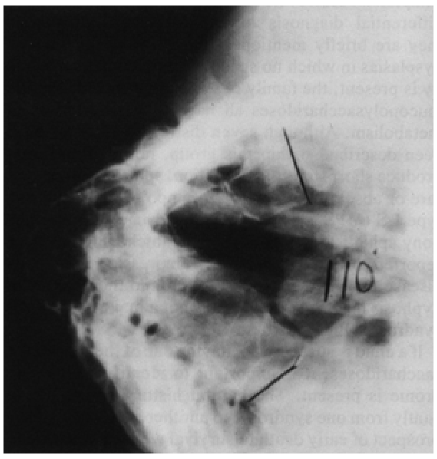

FIGURE 16. Kyphosis in diastrophic dysplasia can be focal. (Courtesy of Vernon T. Tolo, MD.)

Kyphosis

Kyphosis can develop in isolation or at the junction between two scoliotic curves. Improvement in the former type has been reported, usually with use of a Milwaukee brace. Because of the compact size of the patient, the brace must be carefully fitted and must be adjusted with age to maintain the corrective potential. If the kyphosis is severe and focal, surgery may be indicated to prevent neurologic compromise (Fig. 17).

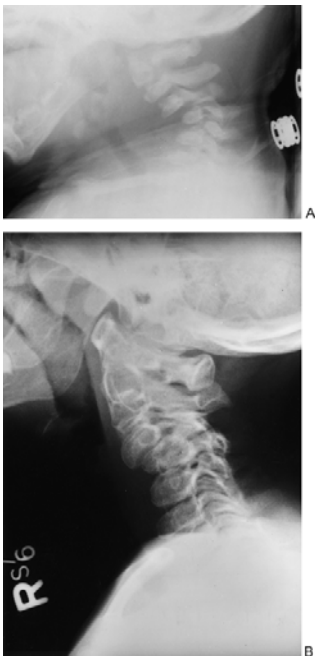

FIGURE 17. Images of a child with diastrophic dysplasia at 9 months **(A)** and 5 years **(B)** of age. Cervical kyphosis improved over time without treatment. At no time did the patient have evidence of myelopathy.

Scoliosis

Scoliosis can be managed with a Milwaukee brace if it is not too great. Posterior fusion with instrumentation usually is indicated for larger curves. This procedure usually is combined with instrumentation. Sublaminar hook fixation can be used with care (97). For patients who are too small, halo cast immobilization can provide correction and stabilization. Spinal stenosis has not been reported to become a surgical problem (72).

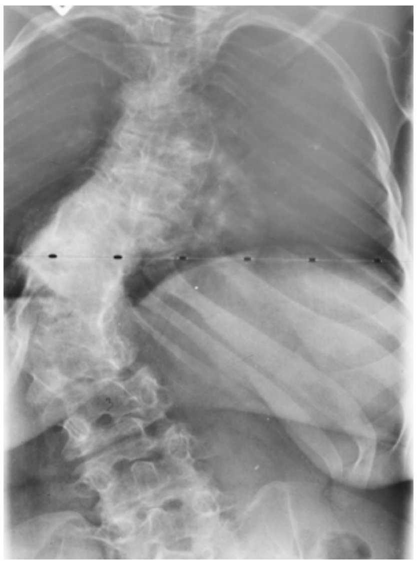

FIGURE 18. Image of a 35-year-old patient with Kneist syndrome shows scoliosis that has been stable at 46 degrees since the patient reached maturity.

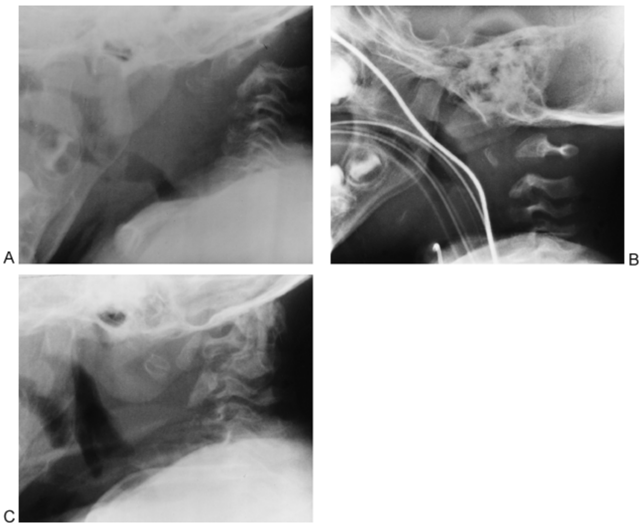

FIGURE 19. Images of a 3-year-old child with spondyloepiphyseal dysplasia congenita who had markedly delayed milestones and clonus show odontoid aplasia with atlantoaxial instability and stenosis at C1. **A:** Neutral upright showing subluxation. **B:** Repositioned in operating room. **C:** Solid fusion after C1 decompression and occipital-C2 fusion. Standing and walking improved gradually, although they remained limited by hip and knee contractures.

Kneist Dysplasia

Kneist dysplasia is a disorder of type II collagen (12,71,105). It commonly results in enlarged, stiff joints (23,44,87). Many patients are disabled by retinal detachment (83,85). Radiographic changes include odontoid hypoplasia and severe platyspondyly with irregular end points as well as scoliosis, which usually is mild to moderate.

Orthopaedic Treatment

Patients should be observed with neurologic examinations and periodic lateral radiographs of the cervical spine (59). If marked instability is detected with either method, posterior fusion is indicated to prevent neurologic damage. Internal fixation may not be possible because of small bone size or young age, so halo cast immobilization may be indicated. Scoliosis rarely necessitates surgical treatment, possibly because the stiffness of the spine prevents curves from becoming too large (Fig. 18).

Spondyloepiphyseal Dysplasia Congenita, Tarda

Spondyloepiphyseal dysplasia is caused by a defect in type II collagen resulting from a mutation in COL2A1 at a location different from that of Kneist dysplasia (30,94,111). Spondyloepiphyseal dysplasia congenita causes more pronounced skeletal involvement and is inherited in an autosomal dominant pattern. The tarda form usually is X linked and therefore more common among boys and men (42,106,108). Severely short stature often results because of altered growth in both the spine and epiphyses.

Several different spinal problems can develop, as can degenerative arthritis of the major joints. Retinal detachment can occur with spondyloepiphyseal dysplasia congenita. Radiographic findings include decreased vertebral and intervertebral height and posterior flattening of the vertebrae to form a pattern called *pear shaped* (86). The end plates are irregular. The second cervical vertebra may show os odontoideum, hypoplasia, or aplasia, although in many patients it is not unstable. The ring of C1 is stenotic in some patients. Kyphosis or scoliosis each develops in about one half of patients (7).

Orthopaedic Treatment

Approximately one third of children with spondyloepiphyseal dysplasia congenita have atlantoaxial instability. Cervical radiographs should be obtained at the initial evaluation. Flexion-extension lateral radiographs should be obtained if no static abnormality is present or if the shape of the odontoid cannot be determined from the plain radiographs. If an abnormality is present but is stable, radiographs still should be obtained periodically during follow-up care. If more than 5 mm of translation of the most cranial portion of the anterior arch of C1 with respect to the cranial portion of the body of C2 is seen on flexion-extension views and the findings of the neurologic examination are normal, the patient should be examined especially frequently. If the examination findings are abnormal or the translation is greater than 8 mm, the atlantoaxial interval should be fused in a reduced position (Fig. 19). If it cannot be reduced or if there is severe stenosis, the posterior arch of the atlas should be decompressed and the fusion extended to the occiput.

Thoracolumbar Spine

Kyphosis, which occurs among about one half of patients, responds to treatment with a Milwaukee brace among some patients during the growing years (7). If fusion is performed, the surgeon should consider anterior and posterior fusion or verify the solidity of the fusion mass, because considerable loss of correction has been reported after pseudarthrosis (7). The most common pattern of scoliosis is a double curve, which may become quite severe (Fig. 20). It is not as responsive to brace treatment as kyphosis is. Surgery may be indicated for large or progressive curves near adulthood (Fig. 21). Low-profile, segmental instrumentation should be used. Because of the rigidity of the curves, permanent correction is not impressive; it averaged only 17% success at follow-up evaluation in one series (7). Spondyloepiphyseal dysplasia tarda involves mild flattening of the thoracolumbar vertebrae and their disc spaces but rarely produces marked spinal deformity (42,69). If kyphosis or scoliosis develops, however, it should be managed as described earlier (Fig. 22).

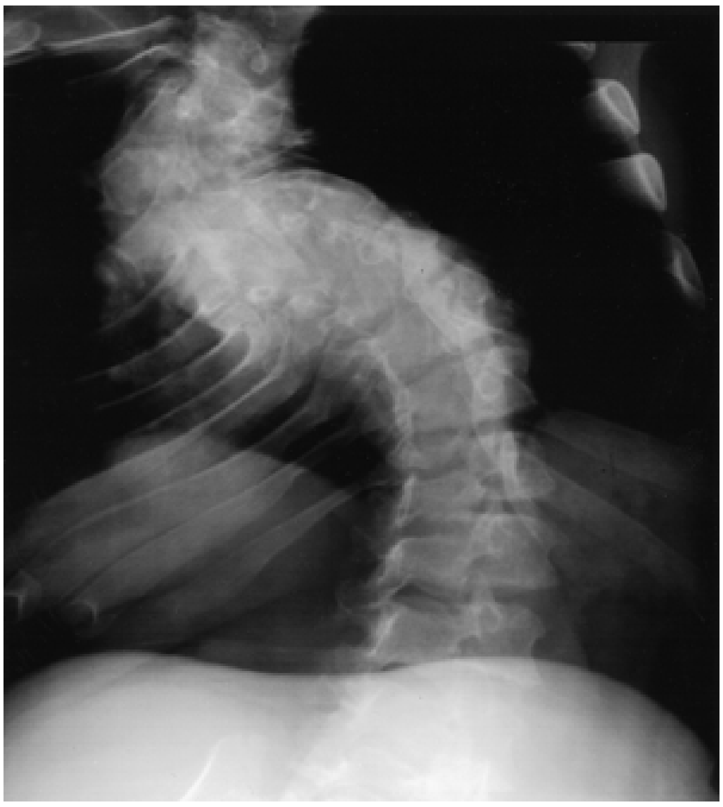

FIGURE 20. Image of a patient with spondyloepiphyseal dysplasia congenita shows severe, focal scoliosis.

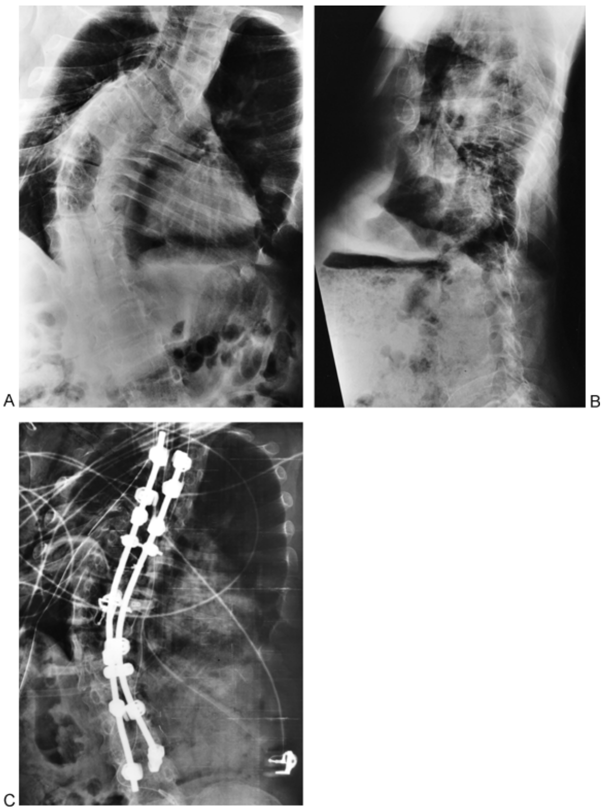

FIGURE 21. A, B: Images of a patient with spondyloepiphyseal dysplasia congenita who had progression of scoliosis during adulthood. **C:** After anterior release and posterior instrumented fusion, correction was achieved to the limit of the stiffness of the curve. (Courtesy of Michael C. Ain, MD).

Pseudoachondroplasia

Pseudoachondroplasia is caused by a defect in cartilage oligomeric matrix protein, an extracellular protein that is present in the territorial matrix of chondrocytes (13,15,34,67,89). Patients have nearly normal stature at birth, but stature lags with growth as abnormal matrix products accumulate (38,57,58,109). The patients have characteristic deformities, especially of the knees, which may become windswept (20,27,29,46).

The atlantoaxial segment can become unstable, although this is not common. Nevertheless, patients should be checked for this instability before undergoing surgery on the knees or hips. Treatment guidelines are the same as for spondyloepiphyseal dysplasia. Scoliosis of a mild degree may develop (Fig. 23). It should be managed with a brace if it exceeds 25 to 30 degrees (7). Surgery is not commonly needed.

Chondrodysplasia Punctata

Chondrodysplasia punctata refers to a series of disorders that produce punctate epiphyseal calcifications and generalized skeletal dysplasia (2,14,56,61). The most common forms are the Conradi-Hünermann type (18,84) and the rhizomelic type (22). The cause of the former is not known; the latter is an enzyme defect (79,107). The latter type is more severe and is most commonly fatal in infancy (103). It may be characterized by os odontoideum or odontoid hypoplasia (5). Cervical stenosis has been found in the recessive type, but whether to do anything to manage the stenosis depends on the patient's medical condition. We are not aware of any patients who undergone treatment of this disorder. The Conradi-Hünermann form may be associated with congenital vertebral malformations such as congenital scoliosis or congenital kyphosis. Patients with this disorder should be observed with periodic radiographs and undergo fusion if the condition is progressive.

Metaphyseal Chondrodysplasia

There are several types of metaphyseal chondrodysplasia (47). They are characterized by metaphyseal irregularities and bowing of the long bones. These conditions resemble rickets. The two most common types are Schmid type and McKusick type (55,92,99). The latter may also be associated with gastrointestinal and immune disturbances in childhood and with malignant disease in adulthood. Both types have been reported (7) to cause atlantoaxial instability in rare instances, so it is probably worth obtaining a cervical spinal radiograph to screen for this disorder.

Cleidocranial Dysplasia

Cleidocranial dysplasia is a condition characterized by complete or partial absence of the clavicles and a widened cranium (8,25,40). The genetic defect is in the CBFA1 gene, which induces osteoblast differentiation (21,51,64). The stature usually is at the lower end of normal. A small proportion of these patients have been reported to have scoliosis associated with syringomyelia (16,93,100). Therefore they should be screened for scoliosis, and MRI should be performed if a marked curve develops.

Larsen Syndrome

Larsen syndrome is a condition best known for dislocation of multiple joints, including the elbows, hips, and knees, and the presence of equinovarus feet (49,50,101). Bifid posterior elements may occur at any level of the spine (9). Facial features include hypertelorism and a depressed nasal bridge (95). There usually is an accessory ossification center of the calcaneus. Because of the profound deformities of the skeleton, any developmental delay often is ascribed to them, and serious problems in the spine often are overlooked. This problem is severe cervical kyphosis that may develop along with cervical spina bifida; it may worsen to cause paraparesis (41). Spina bifida occulta is present in most patients, and the kyphosis is present in 12% to 50% of patients. The fourth and fifth cervical vertebral bodies may be extremely hypoplastic, either primarily or perhaps as a result of the pressure of kyphosis. Spontaneous improvement has not been reported to occur in this condition as it has in kyphosis occurring with diastrophic dysplasia (9,41). Symptoms include hypotonia, delay in motor milestones, or apnea. Sudden death has been reported among children with this syndrome. The deaths probably are caused by kyphosis (49,60). Other findings in the spine include atlantoaxial instability, spondylolysis of the lumbar spine, and scoliosis.

Orthopaedic Treatment

All patients with Larsen syndrome should have a cervical spinal radiograph obtained at the first orthopaedic visit. If the cervical kyphosis is greater than approximately 40 degrees, strong consideration should be given to posterior fusion in situ, so that correction can occur by means of anterior growth. Often this decision must be made when the patient is very young (less than 2 years) (41). If fusion is not performed at this time, the patient should be observed very closely so that any worsening can be detected and controlled. The fusion should extend from the neutral vertebrae above to those below the kyphosis. Care should be exercised in exposing the vertebrae because of the presence of bifid laminae. Postoperative immobilization should be performed with a halo cast or vest or with a Minerva cast. The solidity of the fusion mass should be visualized radiographically because pseudarthrosis can cause loss of correction (41). If the kyphosis is allowed to progress to more than 60 degrees, the likelihood of a successful posterior fusion diminishes.

Patients with myelopathic findings should undergo MRI. If marked cord compression is present, anterior decompression and anterior and posterior fusion should be performed (41).

Patients should be observed for atlantoaxial instability and scoliosis. Fewer than 5% to 10% of patients need surgical treatment of either of these conditions (9). Painful lumbar kyphosis also has occurred (9).

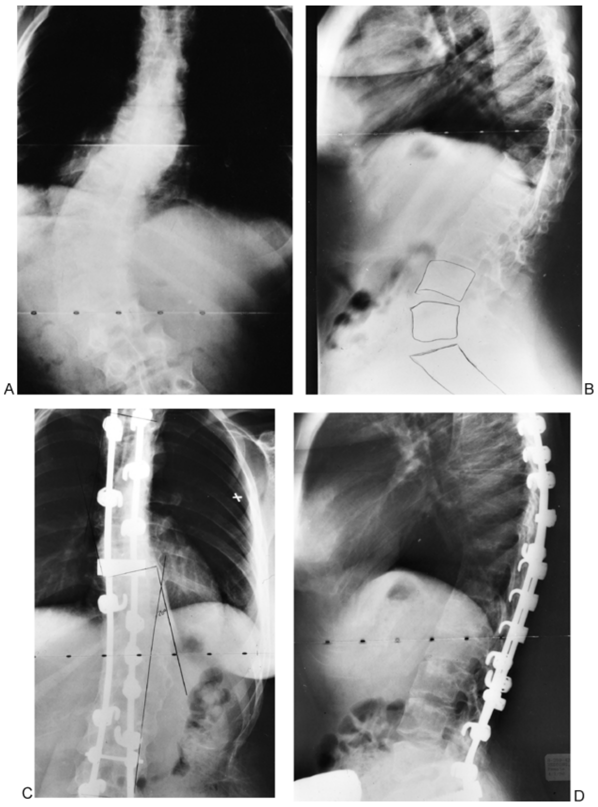

FIGURE 22. A to D: Spondyloepiphyseal dysplasia tarda can be associated with marked curvature of the spine, such as this painful, progressive kyphoscoliosis in a 15-year-old patient. Fusion was carried down to the sacrum because of painful degenerative changes in this area.

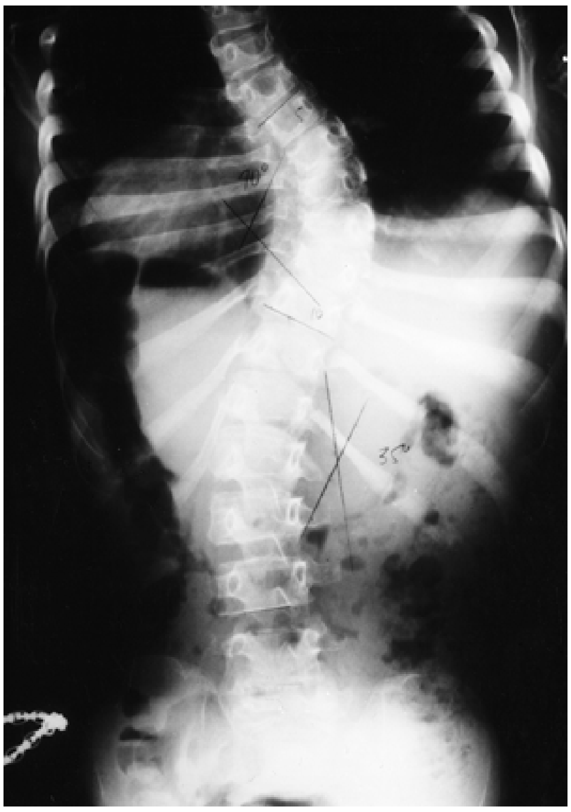

FIGURE 23. Scoliosis with pseudoachondroplasia.

Mucopolysaccharidosis

In mucopolysaccharidosis, a group of almost a dozen conditions, enzyme defects lead to intracellular buildup of metabolites. The skeletal effects may not become apparent until later in childhood, by which time other children may have been born into the family. Although specifics vary from subtype to subtype, the general pattern is short stature, organomegaly, epiphyseal abnormality, and risk of odontoid hypoplasia or upper cervical instability. The most common of these is the Hurler syndrome (mucopolysaccharidosis type I, which produces mental retardation and often death by the end of the first decade. With the advent of bone marrow transplantation, many patients live longer than this. In this condition, besides the upper cervical instability, marked kyphosis with vertebral translation may develop at the thoracolumbar junction and may necessitate treatment with a brace or surgery (Fig. 24). If the kyphosis is flexible, posterior reduction and stabilization are an option for treatment. Morquio syndrome (mucopolysaccharidosis type IV) is another disorder that usually involves spinal problems. The vertebrae are flattened, often with a characteristic flame-shaped pattern of ossification. There patients have not only scoliosis and kyphosis of the thoracolumbar spine but also atlantoaxial instability. These patients often are limited by cardiopulmonary compromise, and evaluation should proceed if surgery is necessary.

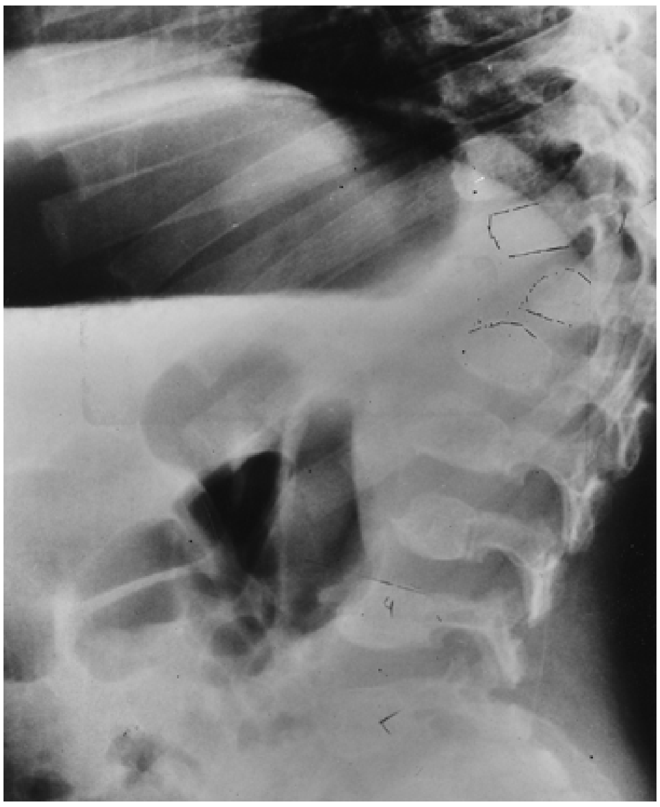

FIGURE 24. Thoracolumbar kyphosis with apical translation is common at the thoracolumbar junction in Hurler syndrome.

Stickler Syndrome

Also known as *hereditary arthroophthalmopathy,* Stickler syndrome is characterized by myopia, risk of retinal detachment, tall stature, and premature degenerative joint disease. Inheritance is autosomal dominant. A defect in type II collagen is the basis of the disorder. A number of spinal abnormalities have been described, including block vertebrae, scoliosis, kyphosis, and narrowing of the intervertebral disc space. Some success with bracing has been reported. The main value of recognizing the syndrome is to encourage routine ophthalmologic follow-up evaluation.

Jarcho-Levin Syndrome

In 1938, Jarcho and Levin described a patient with numerous thoracic vertebral malformations, including hemivertebrae and bars, fused and absent ribs, a short trunk, and respiratory distress. A more common term for these conditions is *spondylothoracic* or *spondylocostal dysplasia.* Although many cases are sporadic, both autosomal recessive and dominant transmission have been observed (Fig. 25). The congenital spinal curve may be progressive, although there are many instances in which the vertebral malformations balance each other out, causing no net curvature. If net progression of considerable degree is observed, localized fusion over the progressive area is indicated, according to the guidelines for congenital scoliosis. The role of the fused ribs in progression of the deformity has not been conclusively shown. Do they act as a tether, or do they grow en masse with the spine? Does managing the bony rib dysplasia help either the curve or the patient's respiratory status? A clinical trial is ongoing to explore the effect of titanium rib expanders in the care of patients with infantile thoracic hypoplasia. The investigators' hypothesis is that both areas can be helped (10).

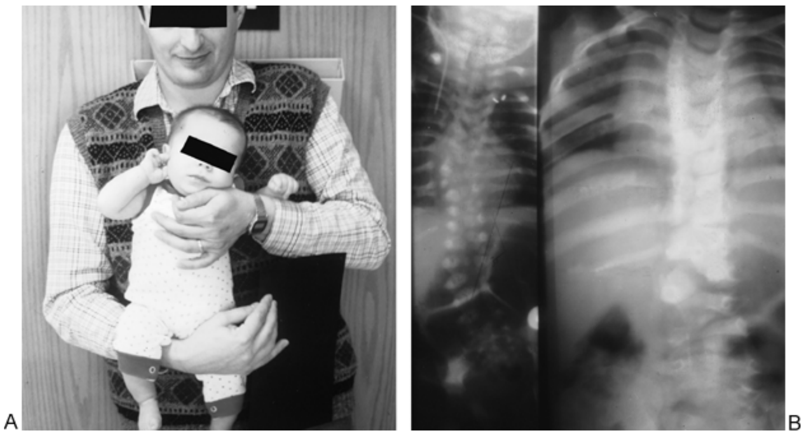

FIGURE 25. Spondylocostal dysplasia often is familial, as shown in this father-son **(A)** pair. A radiograph of the father at the same age is shown next to that of the son **(B)**.

Conclusion

The subject of spinal disorders in skeletal dysplasia has become much better understood in the past two decades. This understanding has been fueled by the development of the specialty of medical genetics, which has improved diagnosis and centralized care. Nevertheless, gaps in our knowledge remain. In many disorders, we still do not know which thoracolumbar curves respond well to bracing and which may not. For many disorders there have been no outcome studies to show that surgery improves patients' health status, although in many cases it is reasonable to expect improvement. Research into these questions is hampered by the rarity of the conditions and by the substantial variation in expression of many of these disorders. For these reasons, it is important that care of persons with skeletal dysplasia be provided in centers experienced and interested in these conditions. Continued research into the clinical care and basic science of skeletal dysplasia is critical and should yield more answers to these questions.

Section VI Developmental Abnormalities

15

Developmental Abnormalities of the Cervical Spine

Randall T. Loder

Robert N. Hensinger

R.T. Loder: Shriners Hospital for Children, Minneapolis, Minnesota 55414.

R.N. Hensinger: Section of Orthopaedic Surgery, University of Michigan Medical School, Ann Arbor, Michigan 48109.

Torticollis

Torticollis is a combined head tilt and rotatory deformity. Pure torticollis indicates a problem at C1–2, whereas a head tilt alone indicates a more generalized problem in the cervical spine. The differential diagnosis of torticollis (Table 1) is large.

Nonosseous Types

Congenital Muscular Torticollis

Congenital muscular torticollis is the most common cause of torticollis among infants and young children. A disproportionate number of these children have a history of primiparous birth or breech or difficult delivery. The deformity is caused by contracture of the sternocleidomastoid muscle. The head tilts toward the involved side, and the chin rotates toward the opposite shoulder (Fig. 1). If the child is examined during the first 4 weeks of life, a mass or “tumor” may be palpable in the neck (43). This mass usually is a nontender, soft enlargement beneath the skin and attached to or located within the belly of the sternocleidomastoid muscle. This tumor reaches its maximum size within the first 4 weeks of life and gradually regresses. After 4 to 6 months of life, only the contracture and the torticollis remain. Because there is an association with developmental dysplasia of the hip (43), a careful hip examination should be performed. If the deformity is progressive, deformities of the skull and face (plagiocephaly) can develop, often within the first year of life. The facial flattening occurs on the side of the contracted muscle. If a child is untreated for many years, the levels of the eyes and ears become unequal and there is considerable cosmetic deformity.

The cause of congenital muscular torticollis is unknown. One theory is that it is a compartment syndrome caused by compression on the soft tissues of the neck during delivery. The histopathologic features of resected surgical specimens suggest that the lesion may be caused by occlusion of the venous outflow of the sternocleidomastoid muscle (8) with edema, degeneration of muscle fibers, and fibrosis of the muscle body. The amount of fibrosis is variable. It has been suggested that the clinical deformity is related to the ratio of fibrosis to remaining functional muscle. If ample muscle remains, the sternocleidomastoid will probably stretch with growth, and the child will not have torticollis. If fibrosis predominates, there is little elastic potential, and torticollis will develop. With the passage of time, the fibrosis of the sternal head may entrap the branch of the spinal accessory nerve to the clavicular head of the muscle; the result can be a later progressive deformity (63). Another theory is in utero crowding, because three of four children have the lesion on the right side and there is an association with developmental hip dysplasia. The final theory concerns remnant mesenchymal cells in the sternocleidomastoid from its embryogenesis (73). After birth, environmental changes stimulate these cells to differentiate, and the sternocleidomastoid tumor develops. If the myoblasts undergo normal development and differentiation, no persistent torticollis occurs and conservative treatment will likely succeed. If the myoblasts mainly undergo degeneration, the remaining fibroblasts produce large amounts of collagen with sternocleidomastoid contracture and typical torticollis.

Radiographs of the cervical spine should be obtained to rule out congenital vertebral anomalies. These are always normal among children with muscular torticollis, aside from the head tilt and rotation. If there is any concern about the hips, appropriate imaging should be performed.

Treatment consists of nonoperative measures first and surgical measures when those fail. A success rate as high as 90% success can be expected with stretching exercises alone (5). The exercises are performed by the caregivers and guided by a physiotherapist. The ear opposite the contracted muscle should be positioned to the shoulder, and the chin should be positioned to touch the shoulder on the same side as the contracted muscle. When adequate stretching has occurred in the neutral position, the exercises should be graduated up to the extended position, which will achieve maximum stretching and prevent residual contractures. Other treatment consists of modifying the child's toys and crib so that the infant will extend his or her neck when reaching for or looking at objects of interest.

Surgery is recommended after 1 year of age, because stretching measures are then usually unsuccessful (17). Established facial deformity or a loss of more than 30 degrees of motion usually precludes a good result with stretching alone, and surgery is needed to prevent further facial flattening and cosmetic deterioration. Asymmetry of the face and skull can improve as long as adequate growth potential remains after the deforming pull of the sternocleidomastoid is removed.

TABLE 1. Differential Diagnosis of Torticollis

- Congenital
  - Occipitocervical anomalies
  - Basilar impression–primary
  - Atlanto-occipital anomalies
  - Asymmetry of occipital condyles
  - Unilateral absence of C1 facet
  - Odontoid anomalies (aplasia, hypoplasia, os odontoideum)
  - Klippel-Feil syndrome
  - Familial cervical dysplasia
  - Pterygium colli
  - Congenital muscular torticollis
- Acquired
  - Basilar impression–secondary
  - Idiopathic/inflammatory
  - Atlantoaxial rotary displacement, subluxation, fixation
  - Neurogenic
  - Spinal cord tumors
- Cerebellar tumors, posterior fossa tumors
  - Syringomyelia
  - Ocular dysfunction
- Bulbar palsy
  - Arnold-Chiari malformation
- Inflammatory
  - Cervical adenitis, Grisel syndrome, retropharyngeal abscess
  - Juvenile rheumatoid arthritis, rheumatoid arthritis
- Disc space calcification
- Tuberculosis
- Neoplasm
  - Osteoid osteoma
  - Aneurysmal bone cyst
- Sandifer syndrome

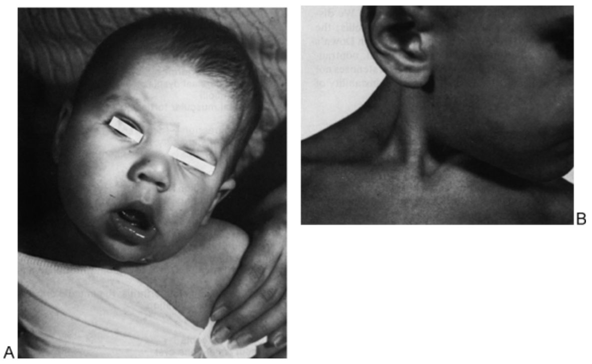

FIGURE 1. A: A 6-month-old infant with right-sided congenital muscular torticollis. Rotation of the skull and asymmetry and flattening of the face on the side of the contracted sternocleidomastoid are evident. **B:** An older child with a right-sided congenital muscular torticollis. Prominence of the sternal and clavicular heads and the tight and shortened belly of the sternocleidomastoid muscle are evident.

Surgical options include a unipolar release at either the sternoclavicular or mastoid pole, bipolar release, and even complete resection. Bipolar release (Fig. 2) combined with Z-plasty of the sternal attachment yielded 92% satisfactory results in one series, whereas only 15% satisfactory results were obtained with other procedures (17). The Z-plasty maintains the *V* contour of the neck for improved appearance. Care must be taken during surgery not to transect the spinal accessory nerve, the anterior and external jugular veins, the carotid vessels and sheath, or the facial nerve. Skin incisions should never be located directly over the clavicle because of unacceptable scar spreading. The incisions should be made one finger breadth proximal to the medial end of the clavicle and sternal notch and in line with the cervical skin creases. The postoperative protocol can vary from simple stretching exercises to cast immobilization, depending on the severity of the torticollis, the ease and amount of correction achieved intraoperatively, and the cooperation of the child with stretching exercises.

Sandifer Syndrome

Sandifer syndrome involves gastroesophageal reflux with abnormal posturing of the neck and trunk, usually torticollis (58). It is common among infants or children with cerebral palsy. The torticollis is the child's attempt to decrease the discomfort of gastroesophageal reflux. The incidence of gastroesophageal reflux among infants is as high as 40% (7). The principal symptoms are vomiting, failure to thrive, recurrent respiratory disease, dysphagia, various neural signs, torticollis, and even respiratory arrest. In careful examination of these infants, the tight and short sternocleidomastoid muscle or its tumor is not seen, eliminating congenital muscular torticollis. If further evaluation excludes dysplasia and congenital anomalies of the cervical spine, postinfectious causes, central nervous system and ocular disorders, Sandifer syndrome should be considered.

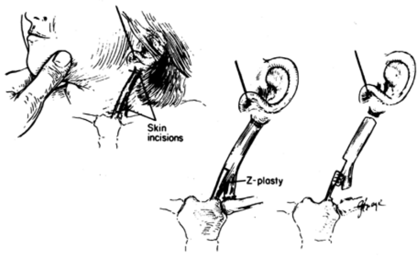

FIGURE 2. Z-plasty for torticollis. **A:** Location of the skin incisions. **B:** The clavicular and mastoid attachments of the sternocleidomastoid muscle are cut, and Z-plasty is performed. The medial aspect of the sternal attachment is preserved. (From Ferkel RD, Westin GW, Dawson EG, et al. (1983): Muscular torticollis: a modified surgical approach. *J Bone Joint Surg Am* 65:894–900, with permission.)

Radiographs of the cervical spine, which are normal in Sandifer syndrome, should be obtained to rule out congenital anomalies or dysplasia. Contrast studies of the upper gastrointestinal tract demonstrate hiatal hernia or gastroesophageal reflux. An esophageal pH study also may be necessary (32). Treatment, once the diagnosis has been made, starts with medical therapy. When this fails, fundoplication can be considered.

Neurogenic Causes

Although neurogenic causes are rare, they should be considered in the differential diagnosis of any torticollis that is unusual, especially when it is unresponsive or progressive in the face of appropriate therapy. The major neurogenic causes are central nervous system tumors, syringomyelia, Arnold-Chiari malformation, ocular dysfunction, and paroxysmal torticollis of infancy.

Posterior fossa tumors can manifest as torticollis (72) and may mimic a local ocular inflammatory condition (37). Tumors of the cervical spinal cord also can manifest as torticollis, often early in their course. Signs of such tumors that often are overlooked are spinal rigidity, early spinal deformity, and spontaneous or induced vertebral pain (24). Among young children the pain may be expressed as irritability and restlessness. Imaging of a child with a potential central nervous system tumor should consist of plain radiography of the skull and cervical spine followed by magnetic resonance imaging (MRI). Vertebral angiography also may be needed for neurosurgical planning.

The Arnold-Chiari malformation is downward displacement of the medulla oblongata with extrusion of the cerebellar tonsils through the foramen magnum. It is encountered among older children (12) and often is associated with headaches and paracervical muscle spasm. The evaluation of a child with a potential Chiari malformation consists of plain radiography of the skull and cervical spine followed by MRI. Treatment is neurosurgical.

Ocular dysfunction can cause atypical torticollis (61,80). The face may be simply turned about a vertical axis; the head may be tilted to one shoulder with the frontal plane of the face remaining coronal; or the chin may be elevated or depressed. The abnormal head position is assumed to optimize visual acuity or maintain binocularity. A detailed ophthalmologic examination established the diagnosis. Therapy for ocular torticollis usually is surgical.

Paroxysmal torticollis of infancy is a rare, episodic type of torticollis that lasts for minutes to days with spontaneous recovery (53). The attacks usually occur in the morning, last from 10 minutes to 14 days (variable within and between individuals), and have a frequency of less than one per month to three or four per month. The attacks can be associated with lateral trunk curvature, eye movements or deviations, and alternating sides of torticollis. The children are more commonly girls (71%). The average age at onset is 3 months (range 1 week to 30 months), and the average time of recovery is 24 months (range 6 months to 5 years). Paroxysmal torticollis of infancy may be an equivalent of a migraine headache—29% of patients have a family history of migraine—or a forerunner of benign paroxysmal vertigo of childhood. Whatever the cause, paroxysmal torticollis usually is self-limiting and does not necessitate therapy.

Inflammatory Causes

Juvenile Rheumatoid Arthritis

The subtypes of juvenile rheumatoid arthritis that usually involve the cervical spine are those of polyarticular or systemic onset; the pauciarticular type rarely affects the cervical spine (27). These children come to medical attention with neck stiffness, usually in the first 1 to 2 years after onset of the disease. Pain and torticollis are rare; when they occur, causes other than arthritis, such as fracture, infection, or tumor, should be suspected (27). Neurologic findings are infrequent.

The radiographic features (27) consist of the following seven types (Fig. 3): anterior erosion of the odontoid process, anterior-posterior erosion of the odontoid process (apple-core lesion), subluxation of C1 on C2, focal soft-tissue calcification anterior to the ring of C1, apophyseal joint ankylosis, growth abnormalities, and subaxial subluxations between C2 and C7. Although mild hypermobility at C1–2 may exist, true instability or myelopathy is rare. Basilar invagination, common in adult rheumatoid arthritis, is rare in juvenile rheumatoid arthritis. The radiographic findings of juvenile rheumatoid arthritis that are most different from those of adult rheumatoid arthritis are late destruction of articular cartilage and bone, growth disturbances, spondylitis with associated vertebral subluxation, apophyseal joint ankylosis, and micrognathia (27). Other imaging studies are occasionally needed in the evaluation of a child with juvenile rheumatoid arthritis and pain to look for occult fractures, infections, and bony tumors. Bone scans can pinpoint the exact anatomic location of activity, and computed tomography (CT) can be used to study the anatomic features in detail.

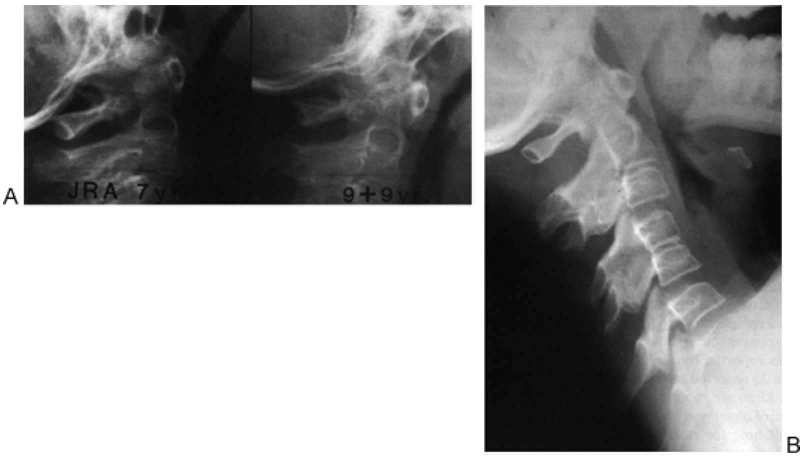

FIGURE 3. A: Images of a boy with polyarticular juvenile rheumatoid arthritis who at age 7 years shows only slight erosion in the anterior portion of the odontoid process. By 9 years of age there is anterior and posterior erosion of the odontoid process, called the *apple-core lesion.* **B:** Image of a 13-year-old girl with polyarticular juvenile rheumatoid arthritis. Posterior ankylosis is present at C2–3 and C3–4. The vertebral bodies are small, and the disc space between the involved segments is of minimal height. (From Hensinger RN, DeVito PD, Ragsdale CG (1986): Changes in the cervical spine in juvenile rheumatoid arthritis. *J Bone Joint Surg Am* 68:189–198, with permission.)

The presence of inflammatory synovitis and pannus of the synovial ring around the odontoid process causes odontoid erosion. This pannus erodes both anteriorly and posteriorly but leaves the apical and alar ligament attachments free, producing an apple-core lesion. This apple-core lesion is susceptible to fracture. Ankylosis of the apophyseal joints often affects young children. This posterior ankylosis of the immature cervical spine acts as a tether to prevent further anterior growth; the result is a decrease in disc space height and the size of the vertebral bodies (both longitudinally and circumferentially).

Treatment generally is nonsurgical in conjunction with good rheumatologic care. A cervical collar is recommended for patients those with involvement of the odontoid process or subaxial subluxation whenever they are in an automobile or other vehicle. If these patients need surgery for any reason, intubation can be difficult because of micrognathia, flexion deformity, and neck stiffness. Cervical fusion should be reserved for the rare child with documented instability and progressive neurologic deterioration.

Intervertebral Disc Calcification

More than 100 cases of intervertebral disc calcification have been reported in the literature (70). The cause is unclear. Theories include antecedent trauma and recent upper respiratory infection. There is no evidence to suggest a metabolic disorder or an accelerated aging process. This disorder is slightly more common among boys than among girls (7:5 ratio). The average age at presentation is 8 years (range 8 days to 13 years). Calcification is most common in the cervical spine, where it is especially symptomatic. About one half of children have neck pain (70) as the initial symptoms; torticollis occurs among approximately one fourth of patients. The onset of symptoms is abrupt, 12 to 48 hours, and 23% of patients have a fever when they come to medical attention. Decreased cervical motion and spinal tenderness also can occur. Radicular signs and symptoms are rare but never without local symptoms. Myelopathy is very rare.

Calcified deposits delineate the nucleus pulposus (Fig. 4A). The number of calcified discs averages 1.7 per child (70). Children without symptoms do not have protrusions, but children with symptoms frequently have detectable protrusions. MRI may show involvement of the vertebral body (29) (Fig. 4B).

Two thirds of children are symptom free within 3 weeks, and 95% by 6 months. Regression or disappearance of the calcific deposits occurs among 90% of patients; about one half of this improvement occurs within 6 months. Children without symptoms may not have radiographic regression even when observed for long periods. Children with multiple lesions have different rates of regression at the different disc levels.

Because of the course of the disorder, treatment is symptomatic in the absence of spinal cord compression. Analgesics, sedation, and cervical traction can be used, depending on the severity of symptoms. A short trial of a soft cervical collar also may be helpful. Surgical intervention is needed only for myelopathy or severe radiculopathy (49,69).

Tuberculosis

Mycobacterium tuberculosis infection of the cervical spine is rare compared with that of the thoracolumbar spine. Because of an increase in immigration from countries where tuberculosis is prevalent, the rise of HIV infection, and the emergence of drug-resistant strains, North America will most likely see an increase in the number of cases of tuberculosis. There have been two thorough reviews of this subject (15,30).

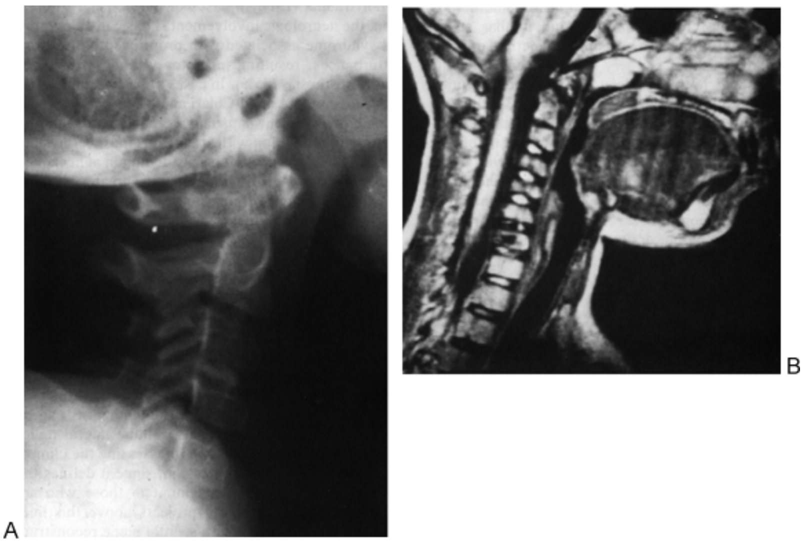

FIGURE 4. A: Lateral radiograph of a child with cervical disc calcification at the C3–4 interspace. **B:** Lateral magnetic resonance image of a child 1 month after onset of pain from cervical disc calcification. Disc abnormalities and decreased signal of the body of C6 are present. (From Herring JA, Hensinger RN (1988): Cervical disc calcification: instructional case. *J Pediatr Orthop* 8:613–616, with permission.)

Children with tubercular involvement of the upper cervical spine have neck pain and stiffness. Torticollis also may be present along with headaches and constitutional symptoms. Neurologic symptoms vary from none to severe tetraparesis. Children with involvement of the lower cervical spine also may have dysphagia, asphyxia, inspiratory stridor, and kyphosis. Among children younger than 10 years, more diffuse and extensive involvement occurs with large abscesses but with a decreased incidence of paraplegia and quadriplegia. The neurologic symptoms have a gradual onset over a period of 4 to 8 weeks. Sinus formation is not a prominent feature because of the thickness of the cervical prevertebral fascia, which contains the abscess.

Radiographs show osteolytic erosions and an increase in the width of the retropharyngeal soft-tissue space. Instability at C1–2 can occur; rarely is there fixed C1–2 rotatory subluxation. One fourth of patients with lower cervical spine involvement have kyphosis. Cord compression is caused by the abscess or the kyphosis. Because the infection is anterior, most patients with spinal tuberculosis have spinal cord compression or paralysis if left untreated.

All children receive antituberculous chemotherapy. Chemotherapy alone is the established method of controlling tuberculosis in the thoracic and lumbar spine (14). Surgery is recommended for patients with tuberculosis of the cervical spine, because the pain, upper respiratory obstruction, and spinal cord compression resolve rapidly. Débridement is performed with or without grafting. Most children need halo traction with reduction before drainage, if possible. Children younger than 2 years usually do not need grafting. Anterior transoral drainage and fusion across the lateral facet joints can be considered in the care of children with upper cervical spine involvement.

Osseous Types

Occipitocervical synostosis, basilar impression, and odontoid anomalies are the most common developmental malformations of the occipitovertebral junction. These lesions arise from faulty development of the neocranium and adjacent vertebral skeleton during formation of the mesenchymal anlage. The basilar portion of the occiput, along with lateral masses and posterior arches of the atlas, is derived from the mesenchyma of the most caudal occipital sclerotome, also known as the *proatlas* (66). The ossiculum terminale also arises from this sclerotome. These areas of primitive mesenchyma separate from each other during fetal growth and then undergo chondrification and subsequent ossification as distinct units. An abnormality in formation of the mesenchymal anlage can thus produce malformation of the occipitovertebral junction.

Basilar Impression

Basilar impression is an osseous deformity at the margin of the foramen magnum. The skull floor is indented by the upper cervical spine; the odontoid tip may even protrude into the opening of the foramen magnum. This may encroach on the brain stem, with potential for neurologic damage from injury, vascular compromise, or alteration of flow of cerebrospinal fluid (74).

There are two types of basilar impression: primary, which is by far the most common, and secondary. Primary basilar impression is a congenital abnormality often associated with other vertebral defects, such as Klippel-Feil syndrome, odontoid abnormalities, atlantooccipital fusion, and atlas hypoplasia. Secondary basilar impression is a developmental condition attributed to softening of the bone at the base of the skull. The primary type has been discussed in other chapters and is not addressed here.

Secondary basilar impression (9) can occur with any osseous softening disorder. This includes metabolic bone diseases such as Paget disease, renal osteodystrophy, rickets, and osteomalacia; bone dysplasia and mesenchymal syndromes such as osteogenesis imperfecta, achondroplasia, hypochondroplasia, and neurofibromatosis; and rheumatologic disorders such as rheumatoid arthritis and ankylosing spondylitis.

Patients with secondary basilar impression have a short neck (9), but it is only an apparent shortness because of the basilar impression. They also may show asymmetry of the skull or face, a painful range of cervical motion, and torticollis. Neurologic signs and symptoms often are present (42). Many children have acute onset of symptoms precipitated by minor trauma (75). In cases of pure basilar impression, the neurologic involvement is a pyramidal syndrome that causes motor weakness or limb paresthesia. In cases of basilar impression associated with Arnold-Chiari malformation, the neurologic involvement usually is cerebellar and causes motor incoordination with ataxia, dizziness, or nystagmus. There may be cranial nerve involvement, particularly of nerves that emerge from the medulla oblongata—trigeminal (V), glossopharyngeal (IX), vagus (X), and hypoglossal (XII). Ataxia is a common finding among children (75). Hydrocephalus may develop from obstruction of flow of cerebrospinal fluid by the odontoid process at the foramen magnum.

Basilar impression is difficult to assess radiographically. The most commonly used lines are the Chamberlain, McRae, and McGregor (Fig. 5). The McGregor line is best for screening, because the landmarks can be clearly defined at all ages on a routine lateral radiograph. The McRae line is helpful in assessing the clinical significance of basilar impression, because it defines the opening of the foramen magnum. Among patients without symptoms, the odontoid process projects above this line. CT with sagittal plane reconstructions can show the osseous relations at the occipitocervical junction more clearly, and MRI can show impingement on the neural structures.

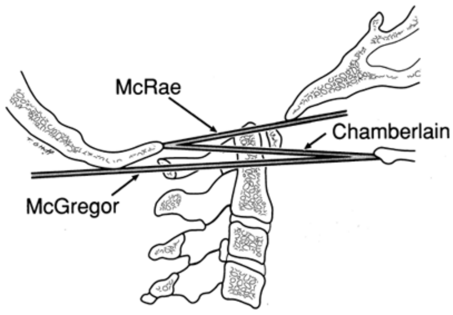

FIGURE 5. Lateral craniometry. These are the three lines commonly used to determine basilar impression. The Chamberlain line is drawn from the posterior lip of the foramen magnum to the dorsal margin of the hard palate. The McGregor line is drawn from the upper surface of the posterior edge of the hard palate to the most caudal point of the occipital curve of the skull. The McRae line defines the opening of the foramen magnum. The McGregor line is best used for screening, because the bony landmarks can be defined clearly at all ages on a routine lateral radiograph. (From Hensinger RN, Fielding JW (1990): The cervical spine. In: Morrissy RT, ed. *Lovell and Winter's Pediatric Orthopaedics.* Philadelphia: JB Lippincott, pp. 703–739, with permission.) (28)

Management of basilar impression is difficult and requires a multidisciplinary approach (orthopedics, neurosurgery, neuroradiology) (77). In rare instances the symptoms can be relieved with custom-made orthotic devices (31), but the primary treatment is surgical. If the symptoms are caused by hypermobility of the odontoid process, surgical stabilization in extension at the occipitocervical junction is needed. Anterior excision of the odontoid process is needed if the hypermobility cannot be reduced (41), but this step should be preceded by posterior stabilization and fusion. If the symptoms are caused by posterior impingement, suboccipital decompression and often upper cervical laminectomy are needed. The dura often has to be opened in a search for a tight posterior band (9,77). Posterior stabilization should be performed. These are general statements, and each case should be considered individually.

Atlantooccipital Anomalies

The appearance of these children is similar to that of those with Klippel-Feil syndrome. They have short, broad necks and restricted neck movement, a low hairline, high scapulae, and torticollis (2). The skull may be deformed. These children may have associated anomalies, including dwarfism, funnel chest, jaw anomalies, cleft palate, congenital ear deformities, hypospadias, genitourinary tract defects, and syndactyly. Neurologic symptoms can occur during childhood but more often occur at 40 to 50 years of age. The most common signs and symptoms, in decreasing order of frequency, are neck and occipital pain, vertigo, ataxia, limb paresis, paresthesia, speech disturbances, hoarseness, diplopia, syncope, auditory malfunction, and dysphagia (25). These symptoms can be initiated by traumatic or inflammatory processes and progress slowly and relentlessly.

Plain radiographs are difficult to interpret because of fixed bony deformities and overlapping shadows from the mandible, occiput, and foramen magnum. If the x-ray beam is perpendicular to the skull rather than to the cervical spine, a satisfactory view of the occipitocervical junction usually can be obtained (Fig 6). CT is used to further study the bony anatomy. The anterior arch of C1 is commonly assimilated to the occiput, usually in association with a hypoplastic posterior ring. The variable decrease in height of C1 allows the odontoid process to project upward into the foramen magnum (primary basilar impression). The position of the odontoid relative to the opening of the foramen magnum was described by McRae. The distance measured is that from the posterior aspect of the odontoid to the posterior ring of C1 or the posterior lip of the foramen magnum, whichever is closer (40). This distance should be determined with the patient in flexion, because this position maximizes the reduction in the space available for the cord. If this distance is less than 19 mm, a neurologic deficit usually is present. Associated C1–2 instability has been reported to develop among 50% of these patients. Lateral flexion-extension radiographs of the upper cervical spine often show as much as 12 mm of space between the odontoid process and the C1 ring anteriorly. This instability is determined when the distance is greater than the normal 4 mm between the anterior aspect of the odontoid and the posterior aspect of the anterior ring of C1 in children, compared with the 3-mm value used for adults. The 1-mm difference in normal values is a result of the considerably more cartilaginous nature of both structures (incomplete ossification) and of the greater laxity among children. The odontoid process also may be misshapen or maldirected posteriorly. As many as 70% of these children have congenital fusion between C2 and C3. Occipital vertebrae and condylar hypoplasia also may be present.

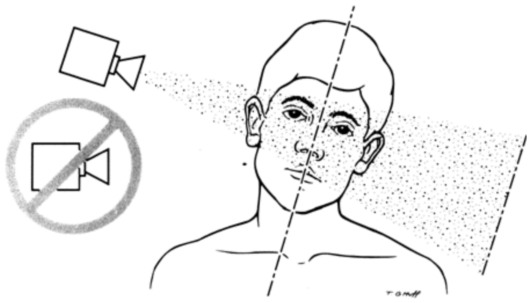

FIGURE 6. A lateral radiograph of the skull gives a satisfactory view of the occipitocervical junction, even in the presence of fixed bony deformity or a patient's inability to cooperate, because the ring of C1 stays with the occiput. (From Hensinger RN, Fielding JW (1990): The cervical spine. In: Morrissy RT, ed. *Lovell and Winter's Pediatric Orthopaedics.* Philadelphia: JB Lippincott, pp. 703–739, with permission.)

MRI is used to examine the neural structures. The upper spinal cord or medulla often is encroached posteriorly by a dural constricting band. Cerebellar tonsil herniation also can occur. Anterior compression of the brain stem or upper cervical cord occurs from a backward projecting odontoid process. Pyramidal tract signs and symptoms (spasticity, hyperreflexia, muscle weakness, gait disturbances) are most common, although cranial nerve involvement (diplopia, tinnitus, dysphagia, auditory disturbances) may be seen. Compression from the posterior lip of the foramen magnum or dural constricting band can disturb the posterior columns with a loss of proprioception, vibration, and tactile senses. The commonly occurring nystagmus also is probably caused by posterior cerebellar compression. Vertebral artery disturbances can cause syncope, seizures, vertigo, and unsteady gait. The altered mechanics of the cervical spine may cause dull, aching pain in the posterior occiput and neck with intermittent stiffness and torticollis.

Treatment of patients with atlantooccipital anomalies is difficult, and surgery carries a higher morbidity and mortality than does surgery for anomalies of the odontoid process (2,46). Nonoperative methods should be attempted initially, such as cervical collars, braces, and traction. These often help those with persistent head and neck pain that occurs after minor trauma or infection. Immobilization may achieve only temporary relief if neurologic deficits are present.

When symptoms or signs of instability of the C1–2 complex are present, posterior C1–2 fusion is indicated. Preliminary traction to attempt reduction is used if necessary. If reduction is possible and there are no neurologic signs, surgery has an improved prognosis (2,25). The role of concomitant posterior fusion has not yet been determined, but if decompression, whether anterior or posterior, could destabilize the spine, concomitant posterior fusion should be considered. Results vary from complete resolution to increased deficits and death (2,25).

Unilateral Absence of C1

This congenital malformation is hemiatlas, or congenital scoliosis of C1. It often is associated with other anomalies common with congenital spine deformities, such as tracheoesophageal fistula. Dubousset (11) described a series of 17 patients who did not have a C1 facet.

Two thirds of cases of unilateral absence of C1 are present at birth. In the other one third torticollis develops, and the anomaly is noticed later. A lateral shift of the head on the trunk with variable degrees of lateral tilt and rotation is the most striking finding. It is best appreciated from the back. Instead of sternocleidomastoid muscle tightness, aplasia of the muscles in the nuchal concavity of the tilted side is noticed. Neck flexibility is variable and decreases with age. Plagiocephaly can occur and increases as the deformity increases. About one fourth of patients have neurologic signs (headaches, vertigo, myelopathy).

Standard anteroposterior and lateral radiographs rarely give enough information for a diagnosis, although the open-mouth odontoid view may provide a clue. Tomograms or CT scans provide the information necessary to see the anomaly (Fig. 7). There are three types. Type I is an isolated hemiatlas. Type II is partial or complete aplasia of one hemiatlas with other associated anomalies of the cervical spine, such as fusion of the third and fourth vertebrae or congenital bars in the lower cervical vertebrae. Type III is partial or complete atlantooccipital fusion and symmetric or asymmetric hemiatlas aplasia with or without anomalies of the odontoid process or lower cervical vertebrae.

Radiographs of the entire spine should be obtained to rule out other congenital vertebral anomalies.

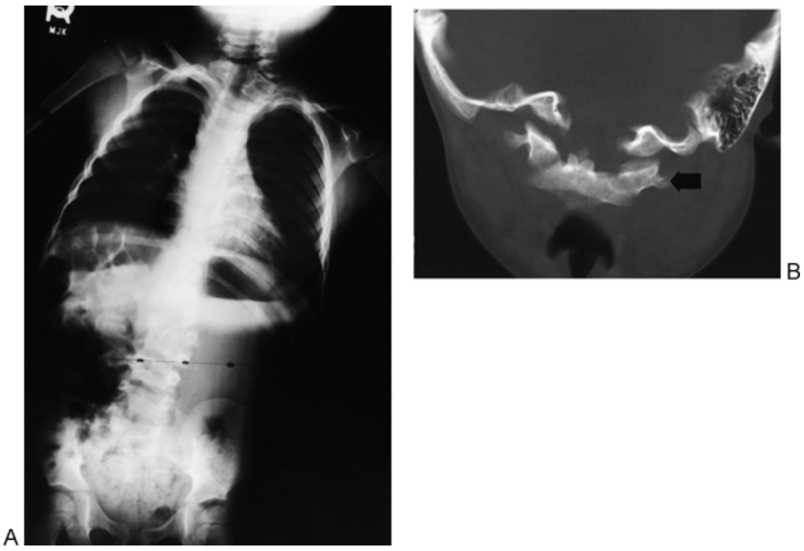

FIGURE 7. Images of a boy with VATER syndrome who was born with imperforate anus, absent right kidney, ventricular septal defect, and spinal anomalies. Physical examination showed mild scoliosis and right head tilt. **A:** Standing posteroanterior radiograph of the spine shows congenital vertebral anomalies at the cervicothoracic junction and the lower thoracic and upper lumbar spine. Head tilt to the right is apparent. **B:** Computed tomographic scan of the cervical spine. The right occipital condyle is superiorly located because of hypoplasia of the left lateral mass of C1 (*arrow*).

Vertebral angiography should be performed if operative intervention is undertaken. Arterial anomalies, such as multiple loops and abnormal routes between C1 and C2, often are found on the aplastic side. MRI should also be performed before surgery, because these children may have stenosis of the foramen magnum or Arnold-Chiari malformation.

The deformity should be followed for progression. Bracing does not halt progression of the deformity. Surgical intervention is recommended for children with progression or severe deformities. Preoperative halo cast correction is used until correction has been achieved. It is followed by posterior fusion from the occiput to C2 or C3, depending on the extent of the anomaly. Decompression of the spinal canal is performed if the canal size is inadequate or if it is projected to be inadequate in the future. The ideal age for posterior fusion is 5 to 8 years.

Familial Cervical Dysplasia

The clinical presentation of familial cervical dysplasia (62) varies. It can be an incidental finding, a passively correctable head tilt, suboccipital pain, or decreased cervical motion. In rare instances clunking of the upper cervical spine is noticed. Plain radiographs are often difficult to interpret. The anatomic features are best seen with CT and three-dimensional reconstruction (Fig. 8). Partial absence of the posterior ring of C1 is most common. Various anomalies of C2 also exist, usually a shallow hypoplastic left facet. Other forms of dysplasia of the lateral masses, facets, and posterior elements and occasionally spondylolisthesis can occur. Occiput-C1 instability is common; C1–2 instability is rare. When symptoms of instability are present, MRI in flexion and extension is recommended to assess the presence and magnitude of neural compression.

Nonsurgical treatment is close observation for the development of instability. Surgical intervention is recommended for persistent pain, torticollis, and especially neurologic symptoms. Posterior fusion from the occiput to C2 typically is required after gradual preoperative reduction with an adjustable halo cast.

Atlantoaxial Rotary Displacement

Atlantoaxial rotary displacement is one of the most common causes of childhood torticollis. It has several causes. Rotary displacement is a characteristic pediatric problem but also can occur among adults. Because they are the same for all pediatric causes, the radiographic findings and treatment regimens are discussed as a unit. Individual exceptions are mentioned when necessary.

The terminology is confusing. It includes *rotary dislocation, rotary deformity, rotational subluxation, rotary fixation*, and *spontaneous hyperemic dislocation* (20). These multiple terms indicate a lack of understanding of the pathophysiologic and pathoanatomic aspects of the anomaly. *Atlantoaxial rotary subluxation* is probably the most accepted term. *Subluxation* can be misleading, however, because cases of subluxation usually occur within the normal range of motion of the atlantoaxial joint. *Rotary displacement* is a more appropriate and descriptive term. If the deformity persists, the children have resistant and unresolving torticollis, and it is best termed *atlantoaxial rotary fixation* or *fixed atlantoaxial displacement.* Gradations exist between mild, easily correctable rotary displacement and rigid fixation.

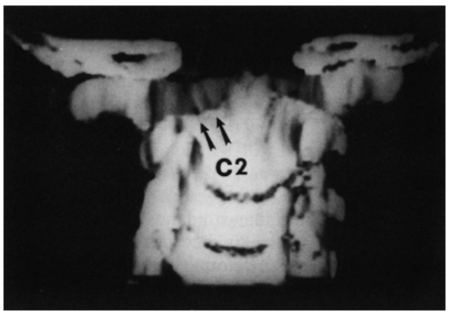

FIGURE 8. Three-dimensional CT scan of the upper cervical spinal cord of a child with familial cervical dysplasia. The left superior facet of C2 is shallow and hypoplastic (*arrows*). (From Saltzman CL, Hensinger RN, Blane CE, et al. (1991): Familial cervical dysplasia. *J Bone Joint Surg Am* 73:163–171, with permission.)

Atlantoaxial rotary displacement can occur spontaneously after minor or major trauma, upper respiratory infection, or head and neck surgery. The child has cocked robin torticollis and resists attempts to move the head because of pain. The associated muscle spasm is noticed on the side of the long sternocleidomastoid muscle because the muscle is attempting to correct the deformity. This is opposite the situation with congenital muscular torticollis. When the deformity becomes fixed, the pain subsides and the torticollis persists along with reduced neck motion. In long-standing cases, plagiocephaly and facial flattening may develop on the side of the tilt.

The radiographic findings of rotary displacement sometimes are difficult to see because positioning for the study is painful. With rotary displacement torticollis, the lateral mass of C1 that has rotated forward appears wider and closer to the midline (medial offset). The opposite lateral mass is narrower and away from the midline (lateral offset). The facet joints may be obscured because of apparent overlapping. The lateral view shows the wedge-shaped lateral mass of the atlas lying anteriorly where the oval arch of the atlas normally lies, and the posterior arches fail to superimpose because of the head tilt (Fig. 9). These findings may suggest occipitalization of C1 because with the neck tilt the skull may obscure C1. The normal relation between the occiput and C1 is believed to be maintained among children with atlantoaxial rotary displacement. Thus a lateral radiograph of the skull may show the relative position of C1 and C2 more clearly than a lateral radiograph of the cervical spine.

The dilemma is differentiating the position of C1 and C2 of a child with subluxation from that of a healthy child whose head is rotated; both give the same picture. Open-mouth views are difficult to obtain and interpret. Cineradiography has been recommended, but the radiation dose is high, and patient cooperation can be difficult because of muscle spasms (18). Dynamic rotational CT is helpful in this situation (22). Views with the head maximally rotated to the right and then to the left show atlantoaxial rotary fixation when there is a loss of normal rotation (Fig. 10).

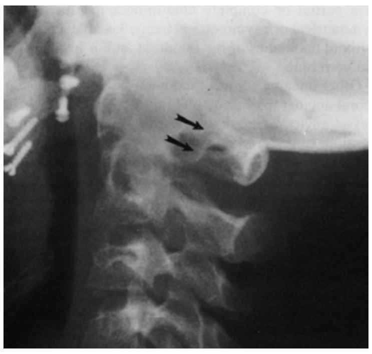

FIGURE 9. Lateral cervical spine radiograph of the child in Figure 10. The posterior arches do not superimpose because of the head tilt (*arrows*).

The four types of rotary displacement (20) are as follows (Fig. 11). Type I is simple rotary displacement without an anterior shift. Type II is rotary displacement with an anterior shift of 5 mm or less. Type III is rotary displacement with an anterior shift greater than 5 mm. Type IV is rotary displacement with a posterior shift. The amount of anterior displacement considered to be pathologic is greater than 3 mm among older children and adults and greater than 4 mm among younger children (19,36). Type I is the most common type among children. It usually is benign and commonly resolves on its own. Type II is potentially more dangerous and must be approached carefully. Types III and IV are rare, but because of the potential for neurologic involvement and even instant death, management must be approached with great caution.

The cause of atlantoaxial rotary displacement is multifactorial and still not totally known (38,52). Rotary displacement can occur spontaneously after minor or major trauma, upper respiratory infection (Grisel syndrome), or after operations on the oral pharynx, mostly tonsillectomy and adenoidectomy. A direct connection exists between the pharyngovertebral veins and the periodontal venous plexus and suboccipital epidural sinuses (52). This provides a route for hematogenous transport of peripharyngeal septic exudates or postsurgical inflammatory products to the upper cervical spine, which causes atlantoaxial hyperemia. Regional lymphadenitis causes spastic contracture of the cervical muscles. This muscle spasm, combined with ligamentous laxity caused by hyperemia due to pharyngovertebral venous drainage can lock the overlapping edges of the articular facets. This prevents easy repositioning and causes atlantoaxial rotary displacement. Highly vascular meniscus-like synovial folds occur in the atlantooccipital and lateral atlantoaxial joints of children but not those of adults, and the dens-facet angle of the axis is steeper in children than in adults (34). Excessive C1–2 rotation due to this steeper angle, compounded by ligament laxity from underlying hyperemia, allows the meniscus-like synovial folds to become impinged in the lateral atlantoaxial joint, leading to rotary fixation.

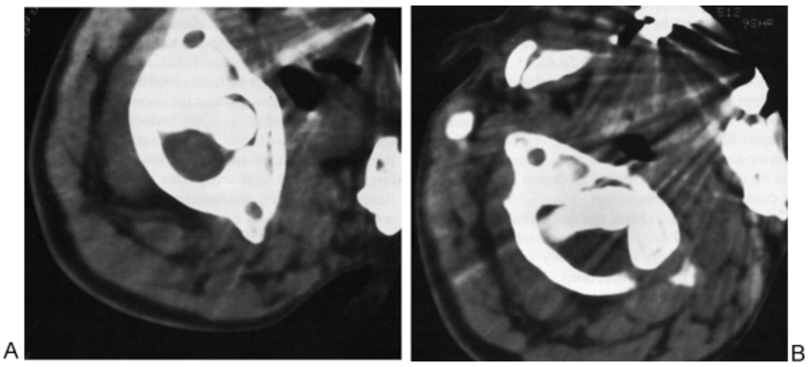

FIGURE 10. Dynamic CT scan of a 9-year-old girl with fixed atlantoaxial rotary displacement. **A:** The head maximally rotated to the left. **B:** The head maximally rotated to the right, which in this case is not even to the midline. The ring of C1 is still in the same relation to the odontoid as in **A**, indicating fixed rotary subluxation.

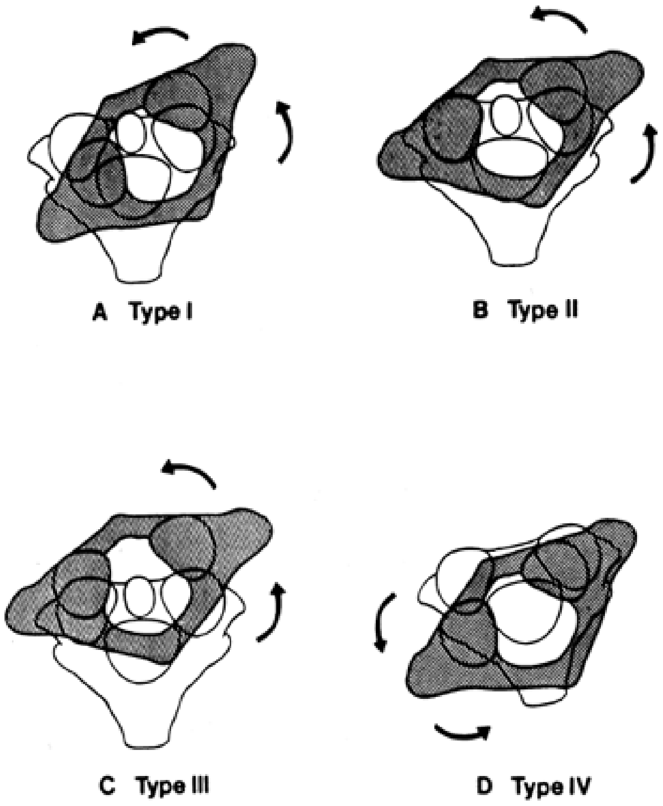

FIGURE 11. The four types of atlantoaxial rotary displacement. (From Fielding JW, Hawkins RJ (1977): Atlanto-axial rotatory fixation. *J Bone Joint Surg Am* 59:37–44, with permission.)

Most atlantoaxial rotary displacements resolve spontaneously. If the deformity becomes fixed, the pain subsides but torticollis remains. The duration of symptoms and deformity dictates the recommended treatment (54). Patients with displacement of less than 1 week's duration can be treated with immobilization in a soft cervical collar and rest for about 1 week. Close follow-up evaluation is mandatory. If reduction does not occur spontaneously with this initial treatment, hospitalization and the use of halter traction, muscle relaxants, such as diazepam, and analgesics is the next step. Patients with rotary subluxation of greater than 1 week's but less than 1 month's duration should be immediately hospitalized for therapy with cervical traction, muscle relaxants, and analgesics. Halo traction occasionally is needed to achieve reduction. After reduction is documented clinically and confirmed with dynamic CT, cervical support is continued until symptoms have subsided. If there is anterior displacement, immobilization is continued for 6 weeks to allow ligamentous healing. Patients with rotary subluxation that lasts longer than 1 month need cervical traction, usually halo skeletal, for up to 3 weeks, but the prognosis is guarded. These children usually fall into two groups. The first is children with rotary subluxation that can be reduced with halo traction but who despite a prolonged period of immobilization have a reoccurrence of the resubluxation when immobilization is stopped. The second is children with subluxation that cannot be reduced and is fixed.

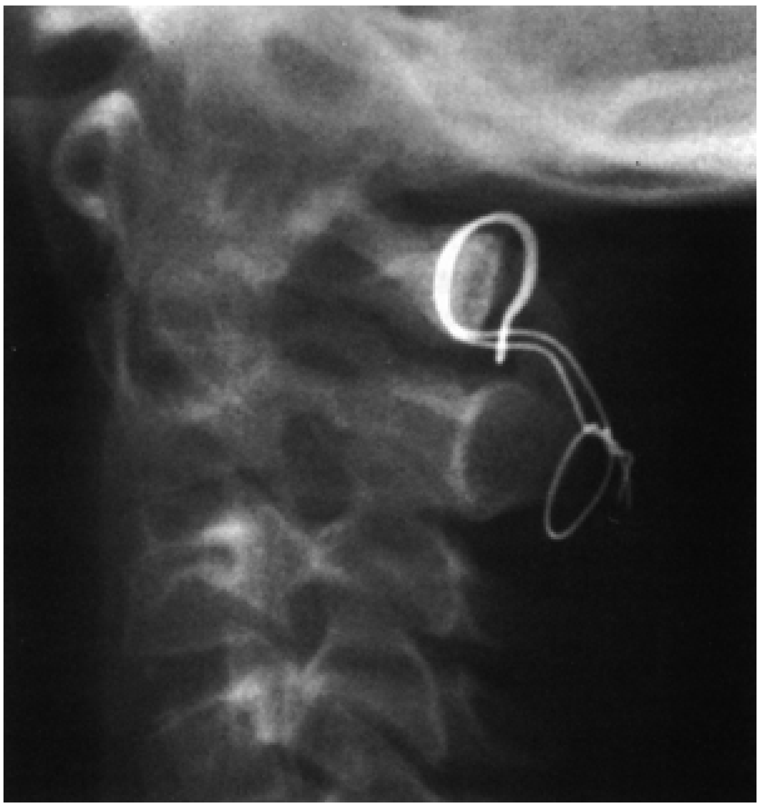

FIGURE 12. The child from Figures 9 and 10 did not respond to traction treatment, including halo traction, because the deformity had been fixed for 6 months after maxillofacial surgical reconstruction for deformities associated with Goldenhar syndrome. She underwent posterior C1–2 Gallie-type fusion. Nine months after the operation she had 80-degree rotation to the left, 45-degree rotation to the right, and a solid arthrodesis.

When the deformity is fixed, especially when anterior C1 displacement is present, the transverse atlantal ligament is compromised and there is potential for catastrophe. In this situation, posterior C1–2 fusion should be performed. The indications for fusion are neurologic involvement, anterior displacement, failure to achieve and maintain correction, presence of the deformity for more than 3 months, and recurrence of the deformity after an adequate trial of conservative management, at least 6 weeks of immobilization after reduction. Forceful or manipulative reduction should not be performed. Simple positioning in a halo cast or vest should be done after fusion and can be expected to provide satisfactory alignment. We prefer Gallie-type fusion (21) with sublaminar wiring at the ring of C1 and through the spinous process of C2 (Fig. 12) to Brooks-type fusion, in which the wire is sublaminar at both C1 and C2. Brooks fusion carries a higher risk of neurologic injury.

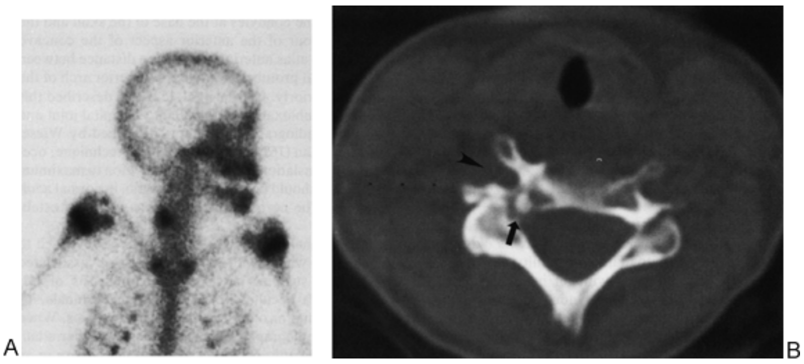

FIGURE 13. A: Bone scan of a 9-year-old girl with a 3-month history of neck pain, which was worse at night, and torticollis. The pain responded to aspirin. The scan shows markedly increased uptake on the right side of C5. **B:** Computed tomographic scan of the same patient shows a nidus with surrounding lucency (*arrow*). The nidus is close to the vertebral artery (*arrowhead*). It was successfully excised through a posterior approach.

Neoplasms

The most common neoplasm that causes childhood torticollis is osteoid osteoma. The incidence of torticollis among children with cervical osteoid osteoma ranges from 10% to 100% (1,35,45). The pain classically responds to aspirin or other nonsteroidal antiinflammatory medications. The intense inflammatory nature of these lesions and their proximity to the neural elements likely causes nerve root irritation with pain and muscle spasm; the result is torticollis.

Osteoid osteoma is not easily seen on plain radiographs. A radionuclide bone scan is intensely hot with an osteoid osteoma. This study can be followed with CT to localize the lesion (Fig. 13). Osteoid osteoma causes a sclerotic reaction in the surrounding bone but usually does not invade the epidural space. This tumor is most commonly located in the laminae.

Osteoid osteoma does not undergo malignant transformation. However, continued torticollis and pain can cause fixed spinal deformities. For this reason, we advocate surgical resection. Prophylactic fusion should be performed if resection renders the spine unstable. Pain relief with complete resection is dramatic. Reports of postoperative pain as severe as the preoperative pain indicate either incomplete resection or recurrence.

Down Syndrome

Because of underlying collagen defects among children with Down syndrome, cervical instabilities can develop at both the occiput-C1 and C1–2 levels. The instability may occur at more than one level and in more than one plane, such as the sagittal and rotary planes.

Atlantoaxial instability among children with Down syndrome was first reported in 1961. Sine then there have been many reports on this instability. None, however, documents the true incidence of atlantoaxial dislocation in contrast to instability, and no long-term studies have been conducted on the course of this problem. Organizers of the Special Olympics have concerns about the participation of children with Down syndrome. The appropriate approach to the problem of upper cervical instability among these children is unclear.

The incidence of atlantoaxial instability among children with Down syndrome varies from 9% to 22% (6,56,76). It is a gradually progressive lesion (3). The incidence of symptomatic atlantoaxial instability has been reported to be much lower, 2.6% among a series of 236 patients with Down syndrome (56). Progressive instability and neurologic deficits are more likely to develop among male patients older than 10 years (3). Children with Down syndrome have a high incidence of cervical skeletal anomalies, especially persistent synchondrosis and spina bifida occulta of C1, than do other children (57). These spinal anomalies may be a contributing factor in the cause of atlantoaxial instability among these children. Children with Down syndrome who have atlantoaxial instability have a higher frequency of cervical spinal anomalies than do children with Down syndrome who do not have these anomalies (57).

The incidence of occiput-C1 instability has been reported to be as high as 60% among children with Down syndrome (76). Measurement reproducibility is poor (33), but a Power ratio less than 0.55 is likely to be associated with neurologic symptoms (51). No guidelines exist regarding the frequency of periodic screening or indications for atlantooccipital fusion except when symptoms are present. Treatment of these children depends on the amount of room available for the cord rather than absolute values of displacement for both atlantoaxial and atlantooccipital instability (76). This area requires further investigation.

Most cases of atlantoaxial or occipitoatlantal hypermobility are asymptomatic (6,39). When symptoms occur, they usually are pyramidal tract symptoms, such as gait abnormalities, hyperreflexia, easy fatigability, and tetraparesis. Local symptoms, such as head tilt, torticollis, neck pain, or limited neck mobility, occasionally exist. The neurologic deficit is not necessarily caused by hypermobility of the atlantoaxial or occipitoatlantal joint. Neurologic symptoms in one series of adult patients with Down syndrome were equally as common among those with an large atlantodens interval as among those with a normal atlantodens interval (16). Further evaluation with flexion-extension CT or MRI to assess for cord compression is needed in this situation.

In the past, screening of patients with Down syndrome by means of lateral flexion-extension radiographs had been recommended. However, symptomatic atlantoaxial instability is extremely rare, and the chances of a sports-related catastrophic injury are even rarer. The reproducibility of radiographic screening for atlantoaxial and occipitoatlantal mobility is poor (33,65). The radiologic signs also can change gradually, most frequently from abnormal to normal. Because of all these factors, and the absence of any evidence that a screening program is effective in preventing symptomatic atlantoaxial and occipitoatlantal mobility, lateral cervical radiographs are of unproven value. The American Academy of Pediatrics has retired its recommendation that screening radiographs be obtained.

Sudden catastrophic death rarely occurs. Nearly all of the patients who have sustained catastrophic injury to the spinal cord have had weeks to years of preceding, less severe neurologic abnormalities. In a recent review by the American Academy of Pediatrics, 41 cases of symptomatic atlantoaxial instability were compiled. In only three of these 41 children did the initial symptoms or worsening of symptoms of atlantoaxial instability occur after trauma during organized sports (6).

Ascertaining which patients have symptoms or signs of symptomatic spinal cord injury is more important than obtaining radiographs. Neurologic examination often is difficult to perform and interpret for these children (76). Parental education about the early signs of myelopathy is extremely important. A thorough history and neurologic examination are more important before participation in sports than are screening radiographs. However, further research is needed into this confusing matter. Because of persistent concerns, the Special Olympics does not plan to remove its requirement that all athletes with Down syndrome undergo radiography of the cervical spine before participating.

Spinal radiographs often are obtained without neurologic symptoms. When these radiographs are available, they should be reviewed to determine whether there are associated anomalies, such as persistent synchondrosis of C2, spina bifida occulta of C1, ossiculum terminale, os odontoideum, or other less common anomalies. When the plain radiographs indicate atlantoaxial or atlantooccipital instability of 6 mm or more in a patient who does not have symptoms (Figs. 14, 15), CT and MRI in flexion and extension can help determine the extent of neural encroachment and cord compression.

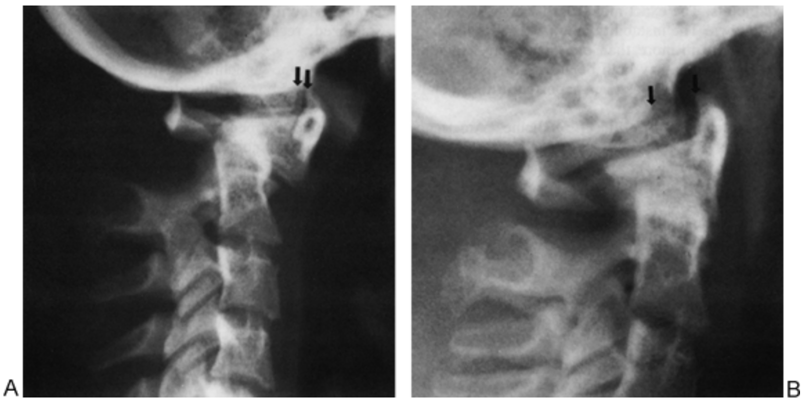

FIGURE 14. A: Lateral flexion radiograph of the cervical spine of a 20-year-old woman with Down syndrome who had no symptoms. The atlantooccipital distance measured 2 mm (*arrows*). According to the method described by Tredwell et al. (76), the relation is measured as the distance between the anterior margin of the condyles at the base of the skull and the sharp contour of the anterior aspect of the concave joint of the atlas. The atlantodens distance measures 8 mm. **B:** Lateral extension radiograph shows posterior subluxation at the atlantooccipital joint. The distance measures 9 mm (*arrows*), greater than the 4-mm upper limit of normal according to Tredwell (76). The atlantodens distance is reduced to 1 mm. This patient has both atlantooccipital and atlantodens hypermobility.

Once a patient with Down syndrome has radiographic instability, what treatment should be instituted? Patients with asymptomatic atlantoaxial or occipitoatlantal hypermobility probably should undergo repeated neurologic examinations. The role of repeated radiographs is unclear. Because the risk of catastrophic spinal cord injury is extremely low among children with Down syndrome who do not have neurologic findings and participate in organized sports, avoidance of high-risk activities must be individualized. For children with sudden onset or recent progression of neurologic symptoms, immediate fusion should be undertaken if appropriate imaging confirms cord compromise. The most difficult question concerns patients with upper cervical hypermobility who have minimal or nonprogressive chronic symptoms. Before arthrodesis is undertaken, imaging with flexion-extension MRI (78) or CT scans should be performed to confirm the presence of cord compression from the hypermobility and to eliminate other central nervous system causes of neurologic symptoms. Even if stabilization is successful, patients with chronic symptoms often have little symptomatic improvement after arthrodesis (55).

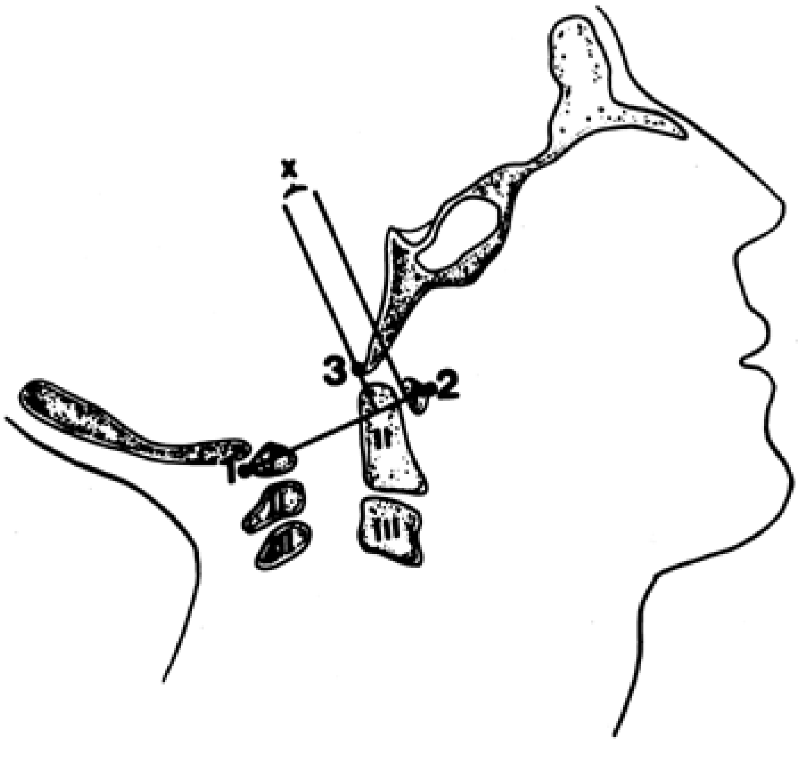

FIGURE 15. Method of measuring atlantooccipital instability according to Wiesel and Rothman (79). The atlantal line joins points 1 and 2. A perpendicular line to the atlantal line is made at the posterior margin of the anterior arch of the atlas. The distance from point 3, which is the basion, to the perpendicular line is measured in flexion and extension. The difference represents the anteroposterior translation at the atlantooccipital joint. For a healthy adult, this translation should be no more than 1 mm. (From Gabriel KR, Mason DE, Carango P (1990): Occipito-atlantal translation in Down's syndrome. *Spine* 15:996–1002, with permission.) (23)

Posterior cervical fusion at the levels involved is the recommended surgical treatment. The classic technique for posterior C1–2 fusion entails autogenous iliac crest bone grafting with wiring and postoperative halo immobilization. Internal fixation with wiring provides protection against displacement, shortens the time of postoperative immobilization, allows the consideration of using less rigid forms of external immobilization, and is reported to aid in obtaining fusion. However, internal fixation with sublaminar wiring poses added risk. If the instability does not decrease on routine extension radiographs, the patient is at high risk of development of iatrogenic quadriplegia during sublaminar wiring and acute manipulative reduction (48). Satisfactory results can be obtained with onlay bone grafts and rigid external immobilization without internal fixation (60). For this reason it has been recommended that preoperative traction be used to effect the reduction. If reduction does not occur with traction, only an onlay bone grafting should be performed without sublaminar wiring (48). Sublaminar wiring at C2 is not recommended regardless of the success of reduction—sublaminar wiring at C2 was associated with the only death at our institution (67,68). If wiring is to be performed, pliable, small-caliber wires should be used.

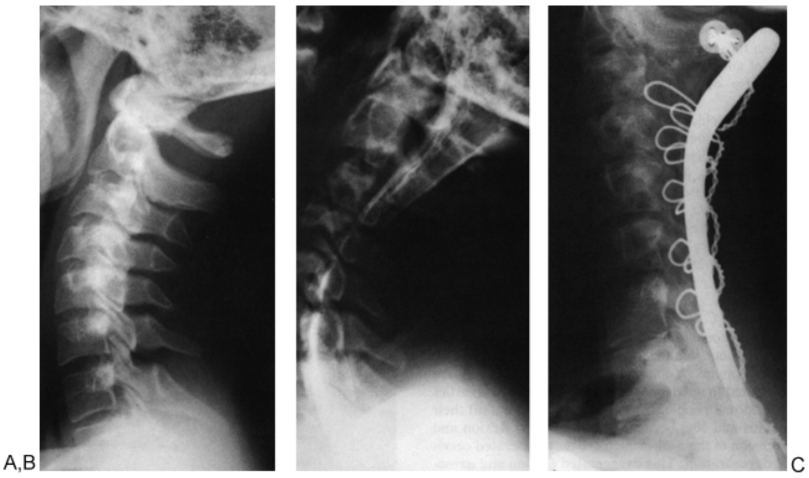

FIGURE 16. Images of a girl 14 years, 6 months of age with spastic tetraparesis and progressive loss of upper-extremity function, which affected her ability to feed herself and control her wheelchair. She also had mild neck pain. **A:** Lateral radiograph shows marked stenosis at C3–6 with decreased space available for the cord. **B:** Myelogram shows near-complete block of the column of contrast material from C3 to C5. The patient underwent posterior laminectomy from C3 to C7, posterior cervical fusion from C2 to T1, and Luque rectangle fixation with wiring spinous processes and facet joints. **C:** Lateral radiograph obtained 8 months after the surgical procedure shows stable fixation and facet joint fusion. By this time the patient had a marked increase in upper-extremity strength and was able to feed herself.

In a study of the results of surgical fusion among 35 children with Down syndrome who had symptoms, eight made complete recoveries, 14 showed improvement, seven did not improve, four died, and the outcome for two is unknown (56). Patients with long-standing symptoms and marked neural damage had no or little postoperative improvement, whereas patients with more recent onset of symptoms usually had an excellent recovery. Patients with Down syndrome are at higher risk of postoperative complications, neurologic and otherwise, after fusion (10,64,68). Neurologic complications can range from complete quadriplegia and death to Brown-Séquard syndrome (68). Other complications are loss of reduction despite halo immobilization and resorption of the bone graft with a stable fibrous union or unstable nonunion (60,64). Persons with Down syndrome who undergo short cervical fusion are at risk of development of instability above the level of fusion, such as occiput-C1 after C1–2 fusion or C1–2 after lower-level fusion (44).

Developmental Cervical stenosis: Cerebral Palsy

Cervical radiculopathy and myelopathy in cerebral palsy (13,59) were first described in the athetoid types and now has been described in the spastic types. Patients with athetoid cerebral palsy experience cervical disc degeneration at a younger age than do otherwise healthy persons. This degeneration progresses rapidly and involves several levels. Angular and spondylolisthetic instability also are more frequent and appear at a younger age (26) than they do among otherwise healthy persons. The combination of disc degeneration and spondylolisthetic instability predisposes these patients to a relatively rapid, progressive neurologic deficit.

The symptoms of cervical spondylotic myelopathy in cerebral palsy are brachialgia and weakness of the upper extremity with limited functional use or an increase in paraparesis or tetraparesis. Among persons with cerebral palsy who can walk, loss of ambulatory ability often is the initial symptom. Occasional loss of bowel and bladder control also occurs.

Radiographic findings (Fig. 16) are narrowing of the spinal canal and premature development of cervical spondylosis; malalignment of the cervical spine with localized kyphosis, increased lordosis, or both; and instability of the cervical spine manifested as spondylolisthesis. Flattening of the anterosuperior margins of the vertebral bodies and beak-like projections of the anteroinferior margins are radiographic findings of spondylosis. Myelography shows stenosis, disc protrusion, osteophyte projection, and blocks in dye flow, most commonly at the C3–4 and C4–5 levels.

The kyphosis, herniated discs, and osteophytes compress the nerve roots and cord. It is believed that these young adults with cerebral palsy have degenerative cervical stenosis at an earlier age than persons without cerebral palsy. Among the latter whom stenosis develops in the late fourth and fifth decades of life because of exaggerated flexion and extension of the neck, which accelerate cervical degeneration. Exaggerated flexion and extension occur among patients with athetosis and writhing movements. Difficulty with head control also can cause exaggerated flexion and extension among patients with spastic cerebral palsy.

Treatment is primarily surgical. Anterior discectomy, resection of osteophytes, and interbody fusion have been the most effective methods. Posterior spinal fusion also may be needed. Postoperative immobilization can be a problem, but a halo seems to be best and is well tolerated by patients with athetosis (47). For this reason, some authors recommend adding posterior fusion and wiring to minimize the duration of postoperative immobilization is needed. Posterior laminectomy alone (47) is contraindicated because this increases instability.

Pseudoinstability and Subluxation of the Cervical Spine

It is known that the C2–3 and, to a lesser extent, C3–4 interspaces of children have a normal physiologic displacement. In a study involving 161 children, Cattell and Filtzer (4) documented that marked anterior displacement of C2 on C3 occurred among in 9% of children between 1 and 7 years of age. In some children, the anterior physiologic displacement of C2 on C3 is so pronounced that it appears pathologic. To differentiate this from true pathologic subluxation, Swischuk described a differentiating line drawn from the anterior cortex of the posterior arch of C1 to the anterior cortex of the posterior arch of C3, called the *posterior cervical line* (Fig. 17) (71). In pathologic dislocation of C2 on C3, the posterior cervical line misses the posterior arch of C2 by 2 mm or more.

During growth, the facets of the lower cervical spine change from 55 to 70 degrees, whereas the upper cervical spine facets (C2–4) may have initial angles as low as 30 degrees that gradually change to 60 to 70 degrees (50). This variation in facet orientation is an important factor in pseudosubluxation among infants and young children, as are normal looseness of the soft tissues and intervertebral discs and the greater size and weight of the skull in relation to the trunk. No therapy is needed for this normal physiologic pseudosubluxation.

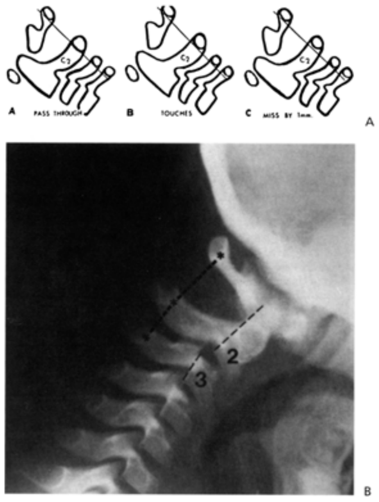

FIGURE 17. A: The posterior cervical line of Swischuk shows the normal limits. *A*, Passing through or just behind the anterior cortex of C2. *B*, Touching the anterior aspect of the cortex of C2. *C*, Coming within 1 mm of the anterior aspect of the cortex of C2. (From Swischuk LE (1977): Anterior displacement of C2 in children: physiologic or pathologic—a helpful differentiating line. *Radiology* 122:759–763, with permission.) **B:** Lateral cervical radiograph of a child with pseudosubluxation at C2–3. The step-off at C2–3 is present, but the posterior cervical line of Swischuk is normal.

Early-Onset Idiopathic Scoliosis

Robert A. Dickson

R.A. Dickson: University Department of Orthopaedic Surgery, St. James University Hospital, Leeds LS9 7TF, United Kingdom.

Idiopathic scoliosis traditionally has been divided into three categories according to age of onset: infantile (0 to 3 years), juvenile (4 to 9 years), and adolescent (10 years to maturity) (19). These three ages of onset were supposed to mirror the three phases of increased growth velocity during childhood and adolescence. Although growth velocity increases during infancy and adolescence, it is steady during the juvenile period. Accordingly, juvenile-onset scoliosis is uncommon and does not merit a category of its own. What is crucial about age of onset is whether a substantial thoracic deformity is present before the age of 5 years, in which case there is a real risk of cardiopulmonary compromise (4). Therefore idiopathic scoliosis should be divided into two subgroups: early onset (0 to 5 years) and late onset (after the age of 5 years). Late-onset idiopathic scoliosis is solely a question of appearance and deformity, although patients with large deformities can be socially and psychologically disadvantaged. Patients with early-onset scoliosis not only have the deformity but also can have serious organic health problems.

Untreated Idiopathic Scoliosis

In the 1960s, several reports of patients with untreated scoliosis appeared to attribute to adolescent idiopathic scoliosis a high morbidity and mortality from cardiopulmonary problems. However, these investigations were confusing and open to misinterpretation. The 102 patients traced by Nilsonne and Lundgren (33) had a curve magnitude greatly in excess of that normally associated with late-onset idiopathic scoliosis. The proper interpretation of this important investigation is that a large number of these patients had early-onset scoliosis. The finding of increased cardiac and pulmonary disease, which accounted for 60% of deaths, therefore is not surprising. In Nachemson's (32) oft-quoted study, some of the patients did not have idiopathic scoliosis but had congenital and miscellaneous etiologic factors. Nevertheless, a small subset with late-onset idiopathic scoliosis was identified, and the organic health of these patients was no different from that of their straight-backed counterparts.

The study by Collis and Ponseti (7) was retrospective, and had a recall rate of only 30%. However, the finding that two thirds of patients with thoracic curves greater than 60 degrees had diminished vital capacity appeared to support the notion of intervening surgically in idiopathic scoliosis once that curve magnitude has been reached. An alternative interpretation of these data is that many of Collis and Ponseti's patients had early-onset idiopathic scoliosis with marked curves. The theory that early-onset deformities threaten cardiopulmonary function was entirely, although accidentally, supported in a study of scoliosis and cor pulmonale (41). Twenty patients with cor pulmonale and an average Cobb angle of 135 degrees participated in the study. Six had paralytic scoliosis, seven had congenital scoliosis, and five had early-onset idiopathic scoliosis. Meanwhile, several long-term studies involving patients with late-onset idiopathic scoliosis clearly demonstrated that pulmonary function remains normal even if curve magnitude exceeds 100 degrees (14,21,34).

The chest abnormalities of scoliosis among patients with cardiopulmonary compromise has been thoroughly investigated. The studies showed that if the deformity was of considerable magnitude at the time of development of the pulmonary parenchyma, evidence of cardiopulmonary dysfunction could be expected (10,35). If severe deformities developed after this time, the tendency toward cardiopulmonary compromise was mitigated. Therefore the old-fashioned figure of 60 degrees as a threshold to proceed with surgical intervention is of real relevance only when age of onset also is taken into consideration. The old view that the lungs at birth are a smaller but fully developed version of the adult organs is wrong. At birth, the development of all the conductive airways is complete, but only a small number of the respiratory bronchioles and alveoli exist. Branching of these final orders of the respiratory tree continues until the age of 8 years, when the full 23 generations of airways of adults are present (15,16,35). It is estimated that at birth there are 20 million alveoli. This number increases rapidly, reaching 250 million by the age of 4 years. The full adult complement is reached by the age of 8 years.

Restriction of the available space in the thoracic cavity has a variable effect on lung development, depending on the time of onset of considerable restriction. If onset is before birth, development of the major airways is limited; the earlier this occurs, the more serious is the problem. The best example is the pulmonary hypoplasia that occurs in the presence of a major congenital diaphragmatic hernia, in which respiratory failure can cause death. Pathologic studies of these lungs have shown the lack of airway development (3). Even congenital spinal deformities do not reach such a degree at birth to cause major pulmonary hypoplasia. From birth until the age of 8 years, the effect is on the number of alveoli rather than the airways, and this number has been shown to be considerably reduced among children with early-onset scoliosis. In this situation, the alveoli are of normal size and outline. This finding suggests reduced formation rather than secondary atrophy or simple compression (10).

Pulmonary arterial hypertension accompanies respiratory failure among persons with scoliosis, so it is appropriate to consider the development of the pulmonary vascular tree. Development and remodeling of this vasculature appears to by secondary to development of the alveoli. The arteries develop to a size appropriate to the size of the lung rather than to the patient's age. There also is evidence of abnormal distribution of muscle in the walls of these vessels. This is probably caused by the initial restriction in growth of the arteries. Subsequent development of hypoxemia leads to secondary arterial muscle hypertrophy and extension into the acinus itself (10). Right heart hypertrophy and failure (cor pulmonale) are the inevitable complications of pulmonary hypertension.

In a long-term study of uncontrolled idiopathic scoliosis, Branthwaite (4) conducted a follow-up study with several hundred of the late Dr. Phillip Zorab's patients with particular reference to heart and lung function. Branthwaite showed quite clearly that only if the onset of scoliosis was before the age of 5 years was there any risk of subsequent cardiopulmonary compromise. The occasional case of cardiopulmonary compromise encountered among patients with late-onset scoliosis was attributable not to the deformity but to another serious heart or lung problem, such as congenital heart disease or excessive smoking. The belief that surgery is indicated because of a risk of lung dysfunction in an adolescent whose curve reaches 60 degrees is erroneous. The real risk of death of idiopathic scoliosis concerns thoracic deformity that develops in the first year of life and progresses relentlessly (Fig. 1).

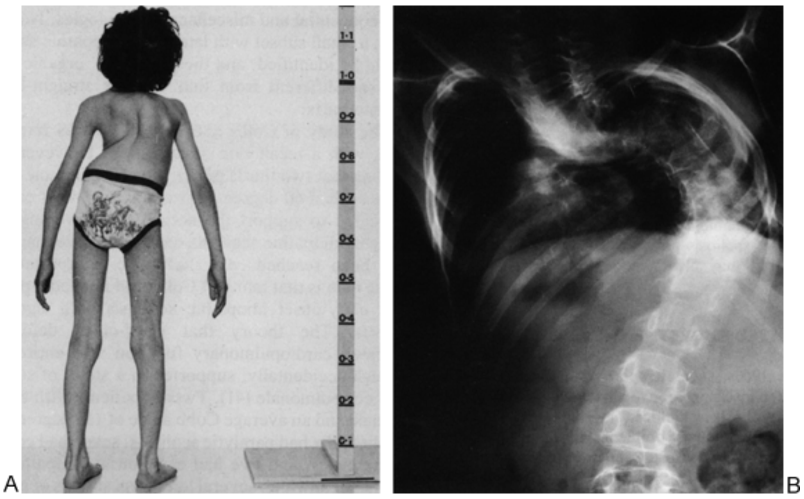

FIGURE 1. A: Clinical photograph. **B:** Posteroanterior radiograph of the spine of a 4-year-old boy with a severe early-onset thoracic curve. Just over a year earlier the deformity measured only 30 degrees.

Clinical Features

Although early-onset idiopathic scoliosis is clearly not a new condition, it was described for the first time only 60 years ago (17). Since then the course of the condition has changed dramatically, particularly regarding the percentage of cases that resolve or progress. In 1951, James (18) found that only 4 cases among his 33 patients resolved. He later reported 52 cases (19) and then a total of 212 (20); in the latter group, 64% of cases progressed and 36% resolved. Scott and Morgan's (39) figures from Oxford indicated that four times as many cases progressed as resolved.

Then, for no apparent reason, things changed for the better. In the 1960s, published series showed that a convincing majority of cases resolving spontaneously (26,43), 92 of 100 cases in the London series resolving (25). Since then, not only has the resolving proportion remained very high, but also the incidence rate of the condition has rapidly declined.

There are two main notions as to how the deformity develops—intrauterine molding and postnatal pressure due to a constant oblique supine position. Browne (5,6) first put forward the intrauterine molding view and also thought that this might cause the associated deformities of plagiocephaly, plagiopelvy, and limited hip abduction. This view was supported by Mehta (29). The problem with this hypothesis is that the scoliosis and associated deformities are not present until after birth. This led Mau (26) to the belief that it was the infant's position in the crib that provided pressure molding. He suggested that the oblique supine position favored in Europe, as opposed to the prone position favored in North America, was responsible for the marked difference in incidence between these two continents. That the side of the plagiocephaly was related to the convex side of the scoliosis, the side of the hip dysplasia, the side of the bat ear, and the side of the sternomastoid tightness supported the pressure-molding theory (44), as did Wynne-Davies's (45) observation that 97 of her 134 cases developed curves during the first 6 months of life. In contrast, only just over one fourth of healthy children were found to have an asymmetric skull.

Mehta (29) found that a floppy hypotonic baby was much less able to resist deformation than was a normal–birth-weight normotonic baby going through its milestones at the usual rate. Added congenital malformations (8), such as hiatal hernia, and mental retardation (45) are risk factors for progression. Wynne-Davies (45) also observed a higher prevalence of congenital heart disease, breech delivery, inguinal hernia, older mothers, and developmental dysplasia of the hip. She also found the prevalence of scoliosis among the parents and siblings of affected infants was 30 times greater than expected, suggesting that there is no great difference genetically between early- and late-onset idiopathic scoliosis.

Boys are affected more commonly than girls. Unlike the situation in late-onset idiopathic scoliosis, three fourths of thoracic curves are convex to the left. Thoracic and thoracolumbar curves tend to resolve, but double structural curves with a thoracic component have a definite progression potential. Not surprisingly, initial curve size and the amount of associated rotation are prognostic factors. Girls with right-sided thoracic curves have a worse prognosis (42).

Mehta (28) found that by looking at the inclination of the ribs on each side of the apical vertebra, progressive curves could be differentiated from resolving ones (Fig. 2). She measured the apical rib-vertebra angles as the angles subtended by the neck of the rib on each side of the apical vertebra with reference to its vertical axis. On the convex side of the curve, the angle is more acute; on the concave side, it is more obtuse. If the difference between the angles—the rib-vertebra angle difference (RVAD)—exceeds 20 degrees, the curve is likely to be progressive. It is important in trying to determine the prognosis that serial radiographs be obtained and the RVAD calculated on more than one occasion (29).

For practical purposes, an infant referred to a scoliosis clinic with a suspected spinal deformity should be carefully examined for the presence of a scoliosis and the other associated abnormalities of the head, neck, pelvis, and hips. A history should be obtained regarding birth weight and milestone development. If possible, a neurologic examination should be performed, but plain radiographs should help differentiate idiopathic from congenital scoliosis. Another important prognostic determinant is the degree of curve rigidity. The child should be suspended to assess flexibility and laid horizontally over the examiner's knee with the convex side downward to assess whether the curve will correct with lateral pressure. Then the RVAD should be calculated. In the double structural thoracic and lumbar curve pattern, the RVAD at the apex of the upper curve often is minimal; the presence of the lower curve may not always be perceptible as a lateral curvature on a posteroanterior radiograph. The presence of a negative RVAD at the level of T12 confirms the presence of a double structural curve. A negative RVAD means that the rib-vertebra angle is smaller on the side of the concavity of the thoracic curve when measured at the level of T12 (Fig. 3).

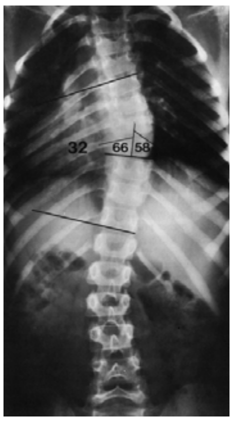

FIGURE 2. Posteroanterior radiograph of a 32-degree early-onset right thoracic curve. The rib-vertebra angle difference at the apex is only 8 degrees, strongly suggesting that the deformity is of the spontaneously resolving variety.

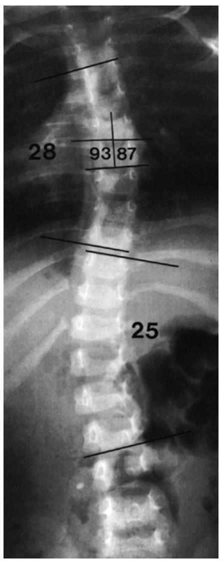

FIGURE 3. Posteroanterior radiograph of an early-onset double structural curve. Although the rib-vertebra angle difference (RVAD) of the upper curve is minimal, the twelfth rib on the left side is directed very obliquely downward, indicating a large negative RVAD and the presence of a double structural curve.

Over the past 18 years, more than 150 cases of early-onset idiopathic scoliosis have been referred to my center. The sex ratio was 3.5 boys to 1 girl. Seventy percent of curves were single thoracic and three fourths of these were left sided. Age at presentation ranged from 2 months to 5 years. Evidence of body molding, such as plagiocephaly or bat ear, was equally distributed by curve site, side, and sex. There was no appreciable association between Cobb angle and sex, side, site, presence of molding, or even age at presentation. Curves with an RVAD greater than 20 degrees were considerably larger than curves with smaller RVADs. An RVAD greater than 20 degrees was the single most important factor predicting progression. Fifty percent of patients with an RVAD greater than 20 degrees had an increase in Cobb angle of 10 degrees or more compared with less than 15% when the RVAD was less than 20 degrees. Fifty percent of single right thoracic curves progressed, and only 15% of left thoracic curves did so. The presence of molding features and the absence of psychomotor retardation were more common in resolving curves. It would certainly appear that early-onset idiopathic scoliosis is pursuing a more benign course with the passage of time.

Increasing attention is being paid to the appearance of the spinal cord at magnetic resonance imaging (MRI) of patients with idiopathic scoliosis, at least younger patients. However, the need or value of this particular investigation in routine cases is by no means certain, no matter what the age of onset. Experienced scoliosis surgeons readily recognize suspicious cases as being unusual curve patterns (e.g., right lumbar or left thoracic), unusual patients (e.g., a boy with a progressive curve), or unusual symptoms (e.g., serious spinal pain, night pain, or headache). These suspicious cases alert the surgeon. At physical examination, a slight but objective neurologic abnormality often confirms the initial suspicion. These patients *must* undergo appropriate spinal cord imaging—usually MRI. Although patients with suspect findings certainly should undergo appropriate spinal cord imaging to rule out a syrinx or neoplasm, the need to perform MRI on all idiopathic scoliosis patients has not been validated.

Just as with late-onset idiopathic scoliosis, these deformities are lordoscoliosis (1,11,13,37,40) (rotated lordosis). What happens in the future is to a large extent determined by whether normal thoracic kyphosis redevelops.

Management

Until relatively recently, therapy for early-onset idiopathic scoliosis was disappointing. Milwaukee bracing, or a look-alike, was empirically prescribed, although there has been no convincing evidence that the course of scoliosis was favorably affected. Posterior spinal fusion was prescribed for larger curves or those “not responding” to brace treatment (24,27). Performing posterior spinal fusion for early-onset scoliosis when the principal deformity is lordosis is about as logical as performing posteromedial fusion for clubfoot (Fig. 4). Not surprisingly, the back of the spine is further tethered, and there is more rapid progression of the three-dimensional deformity. Fortunately, both conservative and operative treatments are now more logical and effective.

Serial elongation derotation flexion (EDF) casting is the conservative treatment of choice. Even deformities with all the hallmarks of progression can be made to resolve or at least remain static (30). Clearly not all cases require casting, but if a low birth-weight, floppy child has evidence of other associated deformities, a large curve and RVAD, and relative curve rigidity, an EDF cast should be applied without delay. This is best done in the operating room with a standard Cotrel EDF casting frame under light general anesthesia on an outpatient basis. Manual pressure over the convex rotational prominence while the cast is drying facilitates derotation, as does a window cutout on the concave side posteriorly and the convex side anteriorly. The cast is generally well tolerated, and it is surprising how easy the inner stockinette can be changed to maintain hygiene. A cast can generally be tolerated for 3 or 4 months before it must be changed. Skin care is essential while the cast is in place, but it may be necessary to remove the cast a week or so before it is due to be changed to allow adequate skin cleansing. Casting is repeated until the deformity has been seen to improve or even resolve completely, which may take 3 or 4 years (Fig. 5).

The earlier casting is commenced, the quicker the results. Unfortunately, there often is quite a delay between the parents' first noticing the spinal asymmetry and their bringing the child to a scoliosis surgeon. In this respect, physicians can be worse than parents, often reassuring the parents that the “rib asymmetry” will go away with growth when the reverse can occur (9).

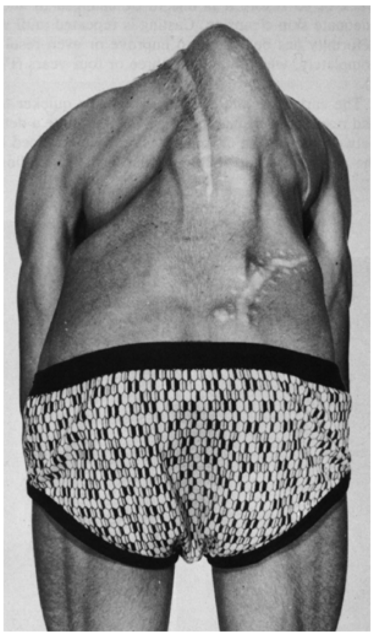

FIGURE 4. Forward bending view of a 16-year-old boy who had undergone posterior fusion for an early-onset progressive curve 10 years previously. The lordosis has been further tethered in bone, which has increased the progression potential of the curve. It is difficult to conceive of a more deleterious procedure than posterior fusion for early-onset scoliosis.

There is little point in continuing cast treatment after the age of 4 or 5 years. By then infantile growth velocity has reached a plateau. Beyond the age of 5 years, children should be examined regularly as outpatients. Radiographs should be obtained sparingly; any change is better perceived by means of inspection or measurement of surface shape. With curves that resolve either spontaneously or with treatment, the rotational component often takes several years to disappear when the spine has become straight in the frontal plane.

If the curve is deemed clinically and radiographically of the resolving variety, casting is not required. Should there be any uncertainty, the child should be examined again in 3 months, radiography should be repeated, and the RVAD should be further assessed. Even if the RVAD was more than 20 degrees initially, improvement at the second visit indicates the possibility of spontaneous resolution. The child should be examined again in 3 months and radiography repeated. In this manner, those who really need EDF cast treatment can be identified.

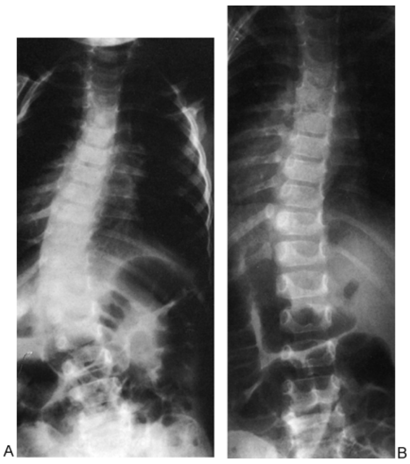

FIGURE 5. Posteroanterior radiographs of an early-onset progressive curve before **(A)** and after **(B)** serial EDF casting show the benefits of conservative treatment when the cast is applied promptly.

At my center more than 50 young children have had a series of EDF casts. The ability of casting to greatly reduce curve size has been impressive, even when the cast is applied at somewhat older than optimum age (Fig. 6).

Operative Treatment

Should serial EDF casting be unsuccessful in preventing progression, surgical treatment is necessary. Surgery can, however, make matters worse, and posterior fusion alone is contraindicated. The essence of treatment should be to reduce anterior spinal growth, and there is relatively little time available (vertebrae are half the adult size by the age of 2 years) (Fig. 7). Both Somerville (40) and Roaf (37), who understood perfectly well that lordosis was the driving force in the production of structural scoliosis, recommended that anteroposterior spinal growth imbalance be addressed surgically. Roaf (36) had the idea of anteroconvex epiphysiodesis—stopping the growth of the leading edge of the spine—but unfortunately, by the time epiphysiodesis had actually occurred, the unfavorable biomechanics of buckling lordosis had overcome his biologic intentions. Andrew and Piggott (2) clearly demonstrated that such a technique was ineffective in the management of either congenital or idiopathic lordoscoliosis but was effective for hemivertebrae, which exist principally in the coronal plane with little or no associated rotation.

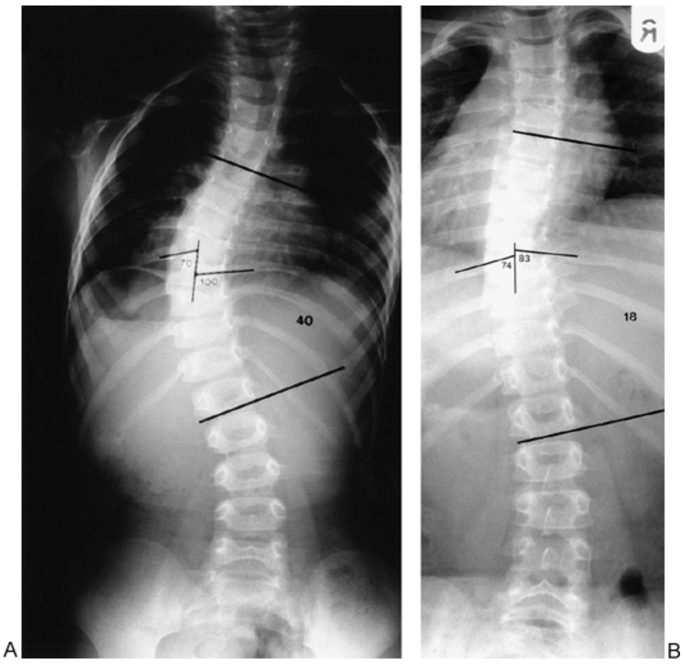

FIGURE 6. A: Early onset progressive curve at age three with a big Cobb angle and RVAD. Four EDF casts were prescribed. **B:** Eight years later—satisfactory resolution is occurring.

To reduce anterior spinal growth, the discs and growth plates must be excised completely over the four or five apical segments (24) (Fig. 8). Although these children are small and much of the spine is cartilaginous, this procedure through a standard thoracotomy is simple and straightforward. In a second-stage posterior procedure, "growing instrumentation" can be inserted to allow the back of a spine to continue to grow and, it is hoped, catch up with the front. The subcutaneous Harrington rod is no more effective than an ordinary Harrington rod, because it does not affect rotation (38). Luque trolley-type instrumentation as recommended by Leatherman, who spent a lifetime trying to alter the forces of the young deforming spine, and Dickson (23) is one possible procedure. Standard sublaminar wiring to two Luque L rods is performed. With growth, the rods separate on the vertical axis, because subperiosteal exposure does not necessarily lead to bony fusion (Fig. 9). A similar effect can be achieved with a single distraction rod and concave sublaminar wiring to a kyphotic Harrington rod configuration (Leeds procedure) (12). Fusion is withheld at this young age, although it may have to be added later if spontaneous fusion does not eventually occur (Fig. 10). It is, however, worthwhile to try another round of EDF casting after the anterior growth-arresting multiple-discectomy procedure. The possible tethering effect of posterior surgery can then be obviated or at least delayed.

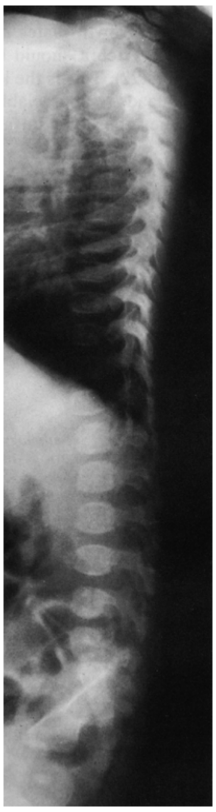

FIGURE 7. Lateral radiograph of a patient with early-onset progressive thoracic scoliosis shows apical lordosis. If the patient is to be treated successfully, this anterior leading edge must be shortened.

For children with inexorable progression to considerable severity, even a growth-equalizing attempt is insufficient. In addition to multiple discectomy with removal of growth plates over the apical segments, closing-wedge removal of the apical vertebra should be performed (22). This is the keystone vertebra, and its removal leads to appreciable three-dimensional correction when the bony surfaces above and below are coapted.

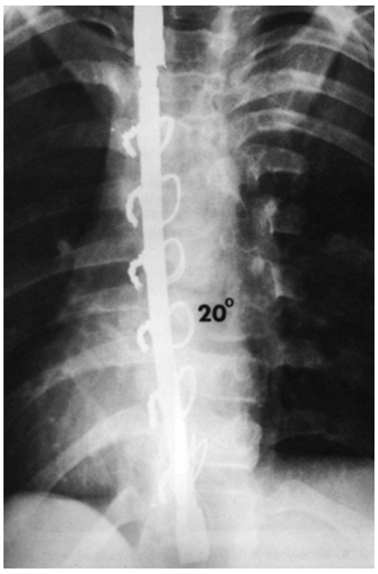

FIGURE 8. Posteroanterior radiograph of a patient with an early-onset idiopathic thoracic scoliosis managed by means of of thoracotomy and excision of the five apical discs and growth plates. In the second posterior stage, thoracic kyphosis was reproduced with a single kyphotic Harrington rod and concave sublaminar wires (Leeds procedure).

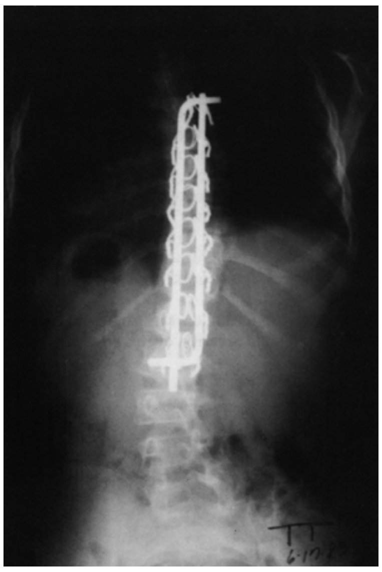

FIGURE 9. Posteroanterior radiograph of a patient with early-onset progressive thoracic curve managed in the second stage by means of Luque trolley instrumentation without fusion. Leatherman was the first to perform this procedure (23).

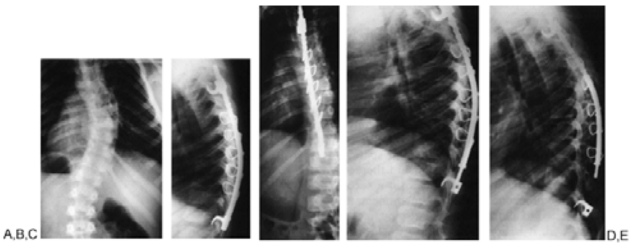

FIGURE 10. Nine-year follow-up results for a boy treated with growing instrumentation. **A:** Posteroanterior radiograph obtained at 5 years of age shows early-onset right thoracic idiopathic curve with a great deal of apical rotation and a large rib-vertebra angle difference. **B:** Lateral radiograph obtained after one-stage posterior reproduction of thoracic kyphosis without fusion. **C:** Postoperative posteroanterior radiograph shows curve correction in three planes. **D:** Lateral radiograph obtained 2 years after **C** shows migration of the rod from the lower hook. **E:** Lateral follow-up radiograph shows considerable distance between the lower end of the rod and the lower hook. The thoracic kyphosis has been maintained. No deformity was discernible at clinical examination.

Tackling progressive early-onset scoliosis surgically by means of both anterior and posterior surgical approaches may appear to be a daunting prospect, but it is far better to perform an operation that addresses the three-dimensional lordoscoliotic deformity than to see considerable disfigurement and morbidity result from less aggressive approaches.

Juvenile Idiopathic Scoliosis

William C. Warner Jr.

W. C. Warner, Jr.: Department of Orthopaedic Surgery, University of Tennessee—Campbell Clinic, Memphis, Tennessee 38103.

Idiopathic scoliosis is divided into three distinct age-related types: infantile, juvenile, and adolescent (6,45). Infantile scoliosis occurs between birth and 3 years of age, juvenile scoliosis occurs between the ages of 4 and 10 years (39), and adolescent scoliosis occurs among children older than 10 years. Idiopathic scoliosis has been divided into these three age-related types because of distinct differences in the course of the condition, although some overlap may occur between infantile and early juvenile types and between the late juvenile form and adolescent form. Mehta (63) suggested that any classification based on the age of the child at detection is only a statement of the level of awareness and skill of the person who detects the scoliosis, the circumstances of detection, and the magnitude of the deformity when it is discovered. This may explain some of the overlap among the three types. These age-based divisions of juvenile idiopathic scoliosis still are useful because they allow generalizations about risk of progression and response to both nonoperative and operative treatment.

Because of the overlap of infantile and adolescent idiopathic scoliosis, juvenile idiopathic scoliosis may manifest as a spontaneously resolving curve, similar to that in infantile scoliosis, as a slowly progressive curve that responds to nonoperative treatment, or as a progressive curve that does not respond to nonoperative treatment, similar to that of adolescent scoliosis.

Many articles in the orthopaedic literature have delineated the course and management of adolescent idiopathic scoliosis. Infantile idiopathic scoliosis also has received much attention, especially in the British literature. Although it has not received as much attention, juvenile idiopathic scoliosis has a distinct course that provides a basis for treatment recommendations. The same questions that are asked about other types of scoliosis apply to juvenile idiopathic scoliosis: Which curves will progress? Which will require treatment? What will occur with no treatment? What effect can be expected from treatment? A knowledge of the usual course of this condition is essential to answer these questions.

The effect of spinal growth on scoliosis has been well documented. Adolescent idiopathic scoliosis progresses most rapidly during a peak growth spurt of the spine. Because patients with juvenile scoliosis already have a marked curve before this growth spurt, they are at high risk of curve progression.

Dimeglio (18) identified two periods of rapid spinal growth: between birth and 5 years of age and the onset of puberty during the adolescent growth spurt. Between these two periods of rapid growth, there is a relative plateau of spinal growth, during which the spine continues to grow but not at the rapid rate it does during the first several years of life and during the adolescent growth spurt. Treatment of patients with juvenile idiopathic scoliosis must consider the remaining spinal growth of these children.

Epidemiology

Juvenile idiopathic scoliosis is reported to occur among 12% to 21% of patients with idiopathic scoliosis (11,39,45,56,61). Several authors have reported an increased familial occurrence of juvenile idiopathic scoliosis (101) similar to that of adolescent idiopathic scoliosis (14,15,51,80,82). Figueiredo and James (27) found that 13% of their patients had family histories of scoliosis. The only report of conditions associated with juvenile idiopathic scoliosis was by the same authors (27), who found that 12% of their patients had mental deficiencies and 2% had epilepsy. Magnetic resonance imaging (MRI) has shown an association between juvenile scoliosis and intraspinal pathologic changes, most commonly Arnold-Chiari malformation and syringomyelia (3,34,47,85,89,93).

Juvenile idiopathic scoliosis differs from adolescent and infantile forms not only in age at onset but also in its varied presentation. Adolescent scoliosis occurs most often among girls and most frequently manifests as a right thoracic curve that progresses during the adolescent growth spurt. Brace treatment arrests progression for many patients with adolescent scoliosis (10,23,43,49,64). Infantile scoliosis occurs most frequently among boys and is most often a left thoracic curve; most curves resolve spontaneously (45,61,63).

In contrast to the clear differences between adolescent and infantile idiopathic scoliosis, the juvenile form may resemble either of these two forms. There is a gradual transition from the characteristics of infantile curvature to those of adolescent curvature. The reported overall female to male ratio for juvenile idiopathic scoliosis ranges from 2:1 to 4:1 (27,56,92). However, a more detailed analysis by age belies this predominance of female patients. Among children between the ages of 3 and 6 years, the female to male ratio is almost 1:1. The higher frequency among boys in this age group may represent infantile curves that have progressed and have been detected after 3 years of age. This is supported by the findings that left thoracic curves are more frequent among this younger group (less than 6 years of age) and that curves that are resolving are diagnosed at a younger age (61,65). Mannherz et al. (56) also found that these resolving curves tended to be left thoracic and left lumbar curves. Among children between the ages of 6 and 10 years, girls are more frequently affected, with a ratio ranging from 8:1 to 10:1 (27,56), which is similar to that for adolescent scoliosis. McMaster (61) found that the average age of boys at diagnosis of juvenile scoliosis was 5 ± 8 years and of girls 7 ± 2 years. That girls usually mature earlier than boys adds to the evidence that juvenile idiopathic scoliosis among boys tends to resemble more closely the infantile type and among girls the adolescent type.

The curve patterns of juvenile idiopathic scoliosis usually resemble those of adolescent scoliosis, with right thoracic and double major curve patterns predominating. The ratio of right thoracic curves to left thoracic curves is about 3:1 (16,27,56,61), although McMaster (61) found that among patients younger than 6 years, left and right curves occurred with equal frequency. Among their patients with juvenile scoliosis, Figueiredo and James (27) found that thoracic curves were most frequent (62%), followed by double thoracic (22%), thoracolumbar (15%), and lumbar (1%) curves (15). Mannherz et al. (56) found similar percentages of thoracic, double major, thoracolumbar, and lumbar curves.

Identifying the curve type can be difficult. As the child grows, the primary curve may extend, the end vertebra in the curve changes. McMaster (61) found that even though the end vertebra may change over time, the apical vertebra remains the same. Single thoracic curves have been reported to change to double major curves over time despite active brace treatment (27,56).

Etiology

The cause of juvenile idiopathic scoliosis is unknown. Excluding the increased incidence of syringomyelia and Arnold-Chiari malformation among patients with juvenile scoliosis, the proposed causes of juvenile scoliosis are the same as those of adolescent idiopathic scoliosis. It is possible that scoliosis is a symptom of several distinct processes.

The most popular etiologic theories have entailed mechanical (17,77,78,79), neuromuscular (4,42,97), central nervous system (55), or neurohormonal abnormalities (52,53,54). Mechanical causes of scoliosis are believed to be a discrepancy between anterior and posterior spinal growth that produces a relatively lordotic spinal segment. As it rotates laterally, this lordotic segment causes scoliotic deformity. Neuromuscular and central nervous system causes have been suggested by the findings of proprioceptive and vibratory abnormalities, which may indicate posterior spinal column dysfunction (4,42,97). Changes in somatosensory evoked potentials and the findings of brain stem asymmetry during MRI suggest a central nervous system cause of scoliosis (55). A deficiency in the hormone melatonin has been proposed as a neurohormonal cause of scoliosis (52,53,54), and abnormalities in development of bone (13) and collagen (22,26) have been implicated. At present the exact cause of scoliosis is unknown. Because the cause of juvenile idiopathic scoliosis is unknown and scoliosis therefore cannot be prevented, a knowledge of the course of the condition is essential for making treatment recommendations and giving the family and patient reasonable expectations about how treatment will affect the scoliosis and what to expect if no treatment is instituted.

History and Clinical Examination

The history and clinical examination are extremely important in the evaluation of a patient with juvenile idiopathic scoliosis. Because of the increased frequency of spinal cord disorders among children with scoliosis, any underlying causes of the curvature must be eliminated before the diagnosis of juvenile idiopathic scoliosis is made. Several important questions should be answered. How was the curve discovered? Is the condition painful? Does it interfere with the child's activities? Is there numbness? Are there bowel or bladder changes? Has the curve progressed rapidly? A positive response to any of these questions requires the physician to make a more thorough evaluation for intraspinal pathologic changes. Has the child undergone any surgical procedure? Some surgical procedures, such as thoracotomy and other operations on the chest, cause curves to be more progressive and less responsive to nonoperative treatment (24). Is the child's development normal? A developmental abnormality can be an early clue to an underlying neurologic condition.

The clinical examination starts with evaluation of the back for spinal deformity. Any midline dimples or hairy patches should be documented and should prompt further investigation of the spinal cord. A complete neurologic evaluation is performed to find any subtle neurologic changes or signs. Special attention is paid to the sensory and motor examinations. A cavus foot deformity can be an early sign of a neurologic cause of the scoliosis (71). Hugus et al. (38) reported that the loss of abdominal reflexes was sometimes the only clinical finding besides scoliosis for a patient with a syrinx (Fig. 1).

The initial radiographic examination should include unshielded posteroanterior and lateral views of the spine, but subsequent radiographs should be obtained with a shield because of the linear nature of accumulated radiation exposure (71). Supine bending views are not necessary unless surgery is being considered or the distinction between a compensatory and a structural curve is essential to treatment decisions. Bone-age radiographs can be obtained to correlate bone age with chronologic age but generally are needed only when there is a discrepancy between the patient's size and his or her chronologic age. The Risser sign is generally 0, and other signs of maturity, such as Tanner stages, are absent (Fig. 2).

Serial Cobb angle measurements (12) are used to measure progression, which is usually considered to be a change of 5 degrees or more. Morrissy et al. (72) and Carman et al. (9) emphasized the importance of using the same end vertebra and

having the same person make the measurement at each examination.

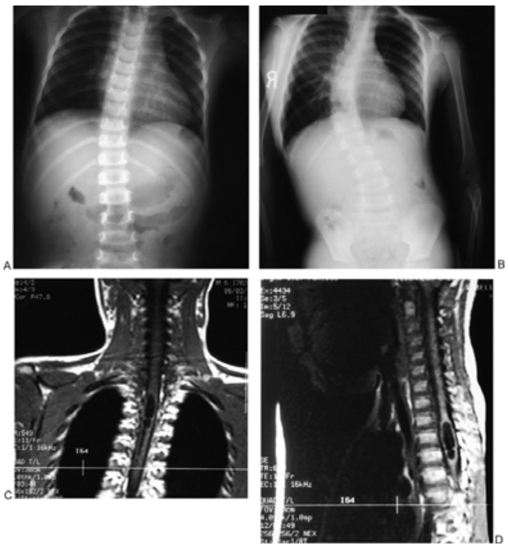

FIGURE 1. A: Child with mild scoliotic curve. **B:** Marked curve progression occurred over the next 4 months. **C, D:** Magnetic resonance images show syrinx.

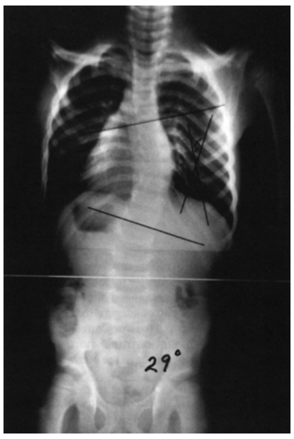

FIGURE 2. Nine-year-old boy with juvenile idiopathic scoliosis.

Mehta (62) divided the stages of the curvature into two phases. The first phase is characterized by separation of the head of the rib from the vertebral body at the apex on both sides. As the curve progresses into phase 2, the rib head overlaps the vertebral body on the convex side. The measurement of the ribvertebra angle is made in phase 1. A line perpendicular to the apical vertebral end plate is drawn, and another line is drawn from the midneck to the midhead of the corresponding rib. The angle formed by the intersection of these two lines is the rib-vertebra angle. The rib-vertebra angle difference (RVAD) is the difference between the values of the rib-vertebra angles on the concave and convex sides of the curve (Fig. 3). Although the Mehta RVAD (34) has been used to predict progression of infantile scoliosis, it has not proved as useful for predicting progression of juvenile scoliosis. Serial RVAD measurements, however, have been useful in predicting response to brace treatment of children in this age group (56,92). McMaster (61) found that a progressive RVAD was indicative of a progressive curve and that resolving curves had improved RVADs. This may actually reflect the nature of the curve, because increasing vertebral rotation causes an increase in the RVAD.

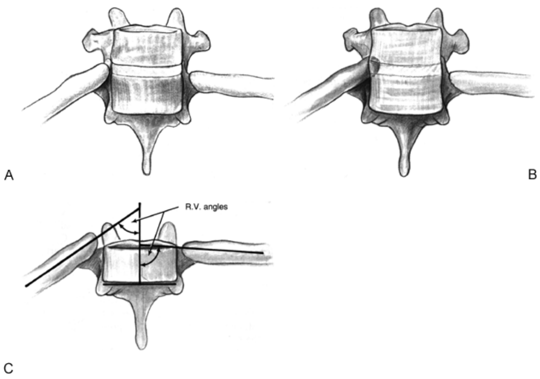

FIGURE 3. Mehta phase 1 **(A)** and phase 2 **(B)**. **C:** Measurement of rib-vertebra angles.

Other authors have described other indicators of progression. Mannherz et al. (56) found kyphosis of less than 20 degrees on the initial lateral radiograph to be a strong risk factor for progression. Kahanovitz et al. (41) found that all patients with curves of more than 45 degrees at the beginning of brace treatment ultimately needed surgery, as did one half of those with curves of more than 35 degrees.

Further evaluation, which may include MRI examination, is indicated when there are abnormal findings in the history or physical examination, such as back pain that interferes with sleep or the child's normal activities, rapid curve progression (more than 2 to 3 degrees per month), left thoracic curves, focal neurologic abnormalities, cavus feet, abnormal abdominal reflexes, and any changes in bowel or bladder function. Because of the frequency of neural axis abnormalities among children with scoliosis (4% to 30%), Lewonowski et al. (47) recommended routine MRI examination of all children with scoliosis who are younger than 11 years. Gupta et al. (34) also recommended MRI examination of patients with juvenile idiopathic scoliosis who have curves of more than 20 degrees. Other authors have recommended performing MRI only if abnormalities are found in the history or physical examination, in particular any abnormal neurologic findings. Because of the increased incidence of abnormalities in this age group, I usually obtain an MRI in patients younger than 10 years of age.

Differential Diagnosis

Juvenile idiopathic scoliosis is a diagnosis of exclusion. Before the diagnosis of juvenile idiopathic scoliosis is made, other conditions that cause scoliosis among young patients must be considered. Differential diagnoses should include neurofibromatosis (16,88), benign bone tumors (such as osteoid osteoma) (98), malignant or benign intraspinal tumors (16,88), spinal infection (66,98), connective tissue disease (such as Marfan syndrome and Ehlers-Danlos syndrome), chromosomal abnormalities (such as Down syndrome), congenital scoliosis, syringomyelia, tethered cord syndrome, metabolic bone disease, degenerative neurologic conditions (such as Friedreich ataxia) (16,27), primary muscle disease, and intervertebral disc abnormalities (31). Once these other possible causes of scoliosis in a young patient have been excluded and the diagnosis of idiopathic juvenile scoliosis is made, the parents can be informed of the distinct course of this condition, and treatment recommendations can be made.

Course of Disease

A relative plateau in the growth of the spine occurs between the ages of 5 and 10 years. Periods of rapid spinal growth occur between 0 and 5 years and during the adolescent growth spurt (6). A unique characteristic of juvenile idiopathic scoliosis is the tendency toward progression during the growth plateau and rapid progression during the growth spurt. Because of this tendency toward progression, the course of juvenile idiopathic scoliosis is much more aggressive than that of adolescent idiopathic scoliosis. Approximately 70% of curves among patients with juvenile scoliosis progress and necessitate treatment; about one half of patients with curve progression need surgery (27,50,56,61,92).

Curve progression is not surprising, considering the considerable amount of spinal growth remaining in these patients. According to the probabilities of progression described by Lonstein and Carlson (48), almost all juvenile scoliotic curves should progress; however, a small number do not. In the study by Mannherz et al. (56), 6 of 12 uncontrolled curves resolved spontaneously. Tolo and Gillespie (92) reported that 6 of 59 curves did not progress, even without treatment. McMaster (61) reported 5 resolving curves among 109 patients. All five were younger patients (less than 6 years) with little vertebral rotation and RVADs less than 20 degrees. These resolving curves may represent a variant of infantile idiopathic scoliosis.

Knowing that most juvenile curves progress, what is the expected rate of progression? Tolo and Gillespie (92) found that uncontrolled curves progressed about 6 degrees a year during the juvenile growth period. McMaster (61) reported that among juvenile curves managed with a brace, the rate of progression decreased to 1 to 3 degrees a year during the juvenile period and increased to 4.5 to 11 degrees a year during the adolescent growth spurt.

How does this progression affect patients with juvenile scoliosis? Pehrsson et al. (76), in a study of mortality and its causes among 115 patients with uncontrolled scoliosis, found that mortality was significantly higher among patients with infantile and juvenile scoliosis than it was among those with adolescent scoliosis. The higher risk was apparent when patients became 40 to 50 years of age and was related to respiratory and cardiovascular disease. Weinstein and Ponseti (96) also documented that curves greater than 50 to 60 degrees will continue to progress even after skeletal maturity.

Classification

Robinson and McMaster (83) classified juvenile curves into four types according to the apical vertebra (Fig. 4). The apical vertebra was used because the tendency toward extension of the primary curve can change the end vertebra, and compensatory secondary curves tend to become fixed primary curves or double major curves. Group I curves were progressive thoracic curves with an apex at T8. This group was divided into IA and IB subtypes. Group IA was a single midthoracic curve, and group IB was a midthoracic curve and a secondary minor lumbar curve. Group II curves had the apical vertebra at T8, T9, or T10. Unlike vertebrae in group I curves, the lumbar vertebrae were rotated in the same direction as in the primary curve and a compensatory lumbar curve did not develop. Patients with this type of curve had a severe list and unsightly deformity. Group III curves were long thoracolumbar curves with the apex at T12. Group IV curves were primary lumbar curves and secondary thoracic curves. The importance of this classification is that 73 (97%) of 75 of Robinson and McMaster's patients classified as having group I or II curves needed operative treatment. The 20 patients with group III or IV curves had much slower curve progression, and only 3 (15%) needed surgery.

Treatment

Nonoperative Treatment

As with other forms of scoliosis, treatment depends on the severity of the curve and the rate of its progression. In general, the indications for nonoperative management of juvenile scoliosis are more liberal than those for management of adolescent scoliosis. Curves of more than 25 degrees that are first detected in the juvenile years and curves with documented progression are indications for instituting a brace treatment program. Brace treatment also may be indicated for some patients with thoracic curves of 20 degrees or more when they come to medical attention because of the high rate of progression of these curves. A Milwaukee brace or a modified Boston brace is generally preferred for children with juvenile idiopathic scoliosis because these braces do not cause chest wall compression. Rib cage distortion is possible with the use of a total-contact thoracolumbosacral orthosis (TLSO) because the child must wear the brace for a long time (6). Bending braces worn at night, such as the Charlestown brace, have been reported to be effective in the management of some adolescent idiopathic curves (25), but the effectiveness in juvenile idiopathic scoliosis has not been proved.

(From Robinson CM, McMaster MJ (1996): Juvenile idiopathic scoliosis: curve patterns and prognosis in one hundred and nine patients. *J Bone Joint Surg Am* 78:1140–1148, with permission.)

General principles of bracing are as described by Tolo and Gillespie (92). The brace is worn full time at first, except for 2 hours each day, for at least 1 year. Radiographs are obtained every 4 to 6 months. If stabilization of the curve is apparent, brace wear becomes part time; the brace can be removed for 4 hours each day. If the curve does not progress, brace wear is decreased in 2- to 4-hour increments until the device is worn only during sleep. Tolo and Gillespie used serial measurements of the RVAD to evaluate the success of brace treatment. If RVAD values declined as treatment continued, part-time brace wear was deemed adequate. Patients with RVAD values near or less than zero at the time of diagnosis progressed from full-time to part-time wear in a relatively short time. If the RVAD did not decrease to less than 10 degrees, progression could be expected and full-time brace wear was continued. An increase in RVAD was sometimes seen before any change occurred in the Cobb angle. If the curve responded to brace treatment, part-time wear was continued until maturity.

The reported success of bracing programs in the management of juvenile scoliosis has been variable. Kahanovitz et al. (41) reported an excellent prognosis with part-time bracing for curves of less than 35 degrees and RVADs of less than 20 degrees. Patients with curves of more than 45 degrees and RVADs of more than 20 degrees had a poorer prognosis for successful brace treatment. Among patients with curves between 35 and 45 degrees, the response to brace treatment was unpredictable. Tolo and Gillespie (92) found that only 19% of their patients needed surgery, but other authors have reported much higher percentages of patients who needed surgery despite bracing: Figueiredo and James (27), 62%; Dabney and Bowen (16), 33%; Mannherz et al. (56), 80%; and McMaster (61), 86%.

If the curve progresses despite brace treatment, the goal of bracing changes. Bracing is then used to slow progression of a curve of 45 to 50 degrees so that surgery can be delayed until more growth has been completed. The hope is to avoid the crankshaft phenomenon, which often occurs when posterior spinal fusion with instrumentation is performed on an immature spine. Bracing should be used only if the patient and parents understand that the goal is to delay—not prevent—surgery. Close follow-up care and patient compliance are necessary.

Reported problems with brace wear include skin pressure problems, rib cage deformity with the use of a total-contact TLSO, and change of a single thoracic curve to a double curve.

Electrical stimulation has been recommended as an alternative to brace treatment. Several authors have reported favorable results with electrical stimulation (7,28,60), but others have found this modality less effective than bracing (8,21,32,74,90). At present, electrical stimulation is not a recommended therapeutic alternative for juvenile idiopathic scoliosis.

Operative Treatment

The indications for surgical management of juvenile scoliosis are generally the same as for other forms of scoliosis (5,6). Surgery is recommended for progressive curves of more than 40 to 45 degrees, although some surgeons may continue bracing until the curve reaches 50 degrees in younger patients.

When surgical management of a curve that has not been controlled by bracing is being considered for a young patient, the amount of spinal growth remaining is of prime importance. How spinal fusion affects spinal growth is a controversial topic. Many authors initially believed the immature posterior fusion mass possessed biologic plasticity and had potential for longitudinal growth (91), but several studies have demonstrated that the posterior fusion mass does not grow longitudinally (40,46,70,81). Anterior growth of the spine continues despite solid posterior fusion, which explains some of the findings among young patients who have undergone posterior fusion. Anterior growth of the vertebral body initially causes loss of disc space height. If the disc space height does not decrease at one or more levels after posterior fusion, pseudarthrosis is likely present. Marjedtoko (58) found a gradual deterioration of clinical results with continued anterior vertebral body growth, including progressive apical rotation and apical deviation, increased prominences of the ribs or paraspinal muscles, and increased Cobb angles. This was initially reported as “bending of the fusion mass.” It was found that the younger the child, the more likely were these clinical findings. The period of highest risk was during the adolescent growth spurt.

Hefti and McMaster (36) also described this phenomenon of anterior spinal growth and subsequent clinical deterioration. Dubousset et al. (19) called this process the *crankshaft phenomenon.* Sanders et al. (86) found that patients with a Risser 0 sign and open triradiate cartilages are at high risk of crankshaft phenomenon if a posterior fusion alone is performed. The crankshaft phenomenon occurred among 45% of patients who had open triradiate cartilages and only 5% who had closed triradiate cartilages. The description of the crankshaft phenomenon has changed the recommendations for posterior spinal fusion among juvenile and young adolescent patients with progressive scoliosis. To prevent the crankshaft phenomenon, anterior growth arrest and fusion have been recommended in addition to posterior fusion.

When operative management of juvenile scoliosis is chosen, an important consideration is the expected loss of growth caused by the fusion. Dimeglio (18) described two periods of rapid spinal growth: from birth to 5 years and from 10 to 16 years of age. From 5 to 10 years of age the spine grows at a steady rate but not at the rapid rate that is does during the other two periods of growth. Dimeglio found that during the 5- to 10-year period of growth, each spinal segment averages 0.05 cm of growth each year. After the age of 10 years, growth increases to 0.11 cm per segment per year. As emphasized by Anderson et al. (2), the growth remaining in sitting height is determined by contributions from the head; the cervical, thoracic, and lumbar portions of the spine; and the pelvis. Fifty percent of the sitting height is from T1 to S1, the thoracic spine contributing two thirds and the lumbar spine one third. At 5 years of age the T1-S1 segment has reached about 66% of its definitive size among boys and 69% among girls. At this point there should be about 15 cm of growth remaining, including an average of 10 cm in the thoracic spine and 5 cm in the lumbar spine. The deficit in sitting height caused by spinal fusion can be calculated with this information (Fig. 5).

Winter (79) used the calculations of Anderson et al. (2) to devise a formula for determining potential shortening after spinal fusion: Amount of shortening in centimeters equals 0.07 multiplied by the number of segments fused multiplied by the number of years of remaining growth. This formula allows the surgeon to inform the family of the estimated shortening to be expected after spinal fusion. The family should understand that even without fusion, some height will be lost because of the scoliotic deformity (Fig. 6).

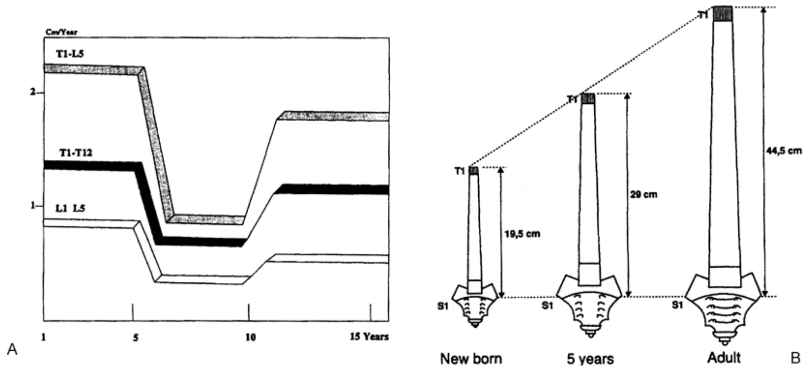

FIGURE 5. A: Growth velocity of T1–L5 segment, thoracic segment T1–12, and lumbar segment L1–5. **B:** Evolution of the T1–S1 segment. The figures are average values to indicate extent of the phenomenon. (From Dimeglio A (1992): Growth of the spine before age 5 years. *J Pediatr Orthop B* 1:102–107, with permission.)

The goal of surgery is to halt progression of the scoliotic curve. This may be obtained by any of several methods: (a) posterior instrumentation with fusion, (b) anterior instrumentation with or without fusion, (c) posterior instrumentation with both anterior and posterior fusion, (d) posterior instrumentation without fusion, (e) anterior fusion without instrumentation, and (f) posterior fusion in situ.

Posterior Fusion with Instrumentation

The smaller the child, the more difficult it is to insert a spinal instrumentation system safely. The current hook and rod systems may be too large to be safely used in the care of a young patient, but several spinal instrumentation systems come in pediatric sizes that are better suited for young patients. Because these rods are more flexible than the adult instrumentation systems and the hooks may not give as secure a purchase for correction of the deformity, postoperative immobilization may be necessary. If posterior fusion and instrumentation are considered, several questions must be answered. How flexible is the curve, and how much correction can be expected with the instrumentation? How much anterior growth is expected after surgery? What amount of crankshaft deformity will occur after surgery? Is the curve a single curve or a double curve? Is there a marked compensatory curve that might require postoperative bracing?

Posterior fusion and instrumentation alone cause some loss of correction among young patients because of continued anterior growth of the vertebral bodies. With the loss of correction, there will be an associated increase in rotation of the apical vertebra and an increase in the rib prominence. Dubousset et al. (19) reported that curves progressed after posterior spinal fusion in all their patients younger than 10 years, including those with idiopathic and neuromuscular curves. Among those with idiopathic curves, average progression in Cobb angle was 13 degrees; the increase in rotation, as measured by means of the Perdriolle method (77,78), was 11 degrees. At final follow-up examinations, some patients still had Risser 0, so further progression could be expected. Hefti and McMaster (36) reported that after posterior fusion the disc spaces initially bulge before decompensation of the curve, so there may be a period during which continued anterior growth is absorbed by the disc spaces and no correction is lost. If posterior fusion alone is performed for a patient with juvenile scoliosis, some increase in deformity should be expected. The younger the patient, the greater is the increase in deformity. At present the exact amount of postoperative progression cannot be predicted preoperatively, but some degree of progression should be expected after posterior instrumentation and fusion (Figs. 7, 8).

Anterior Fusion with or without Instrumentation

Good results have been reported after anterior fusion and instrumentation of the thoracic spine in certain types of adolescent idiopathic scoliosis, but whether this technique can be used in the care of patients with juvenile scoliosis is unknown. Because the vertebral bodies are smaller, safe insertion of anterior vertebral body screws may be more difficult in operations on younger children. This approach is attractive because it solves the problem of continued anterior growth and may help improve the associated thoracic hypokyphosis usually present in this condition. In thoracolumbar and lumbar curves, anterior instrumentation may be possible if the vertebrae are large enough. Anterior fusion and instrumentation in management of these curves have the advantage of saving mobile lumbar segments while correcting

the scoliotic deformity. One disadvantage is that kyphosis can be produced in the thoracolumbar or lumbar area. This problem can be lessened with the use of a rigid rod construct anteriorly.

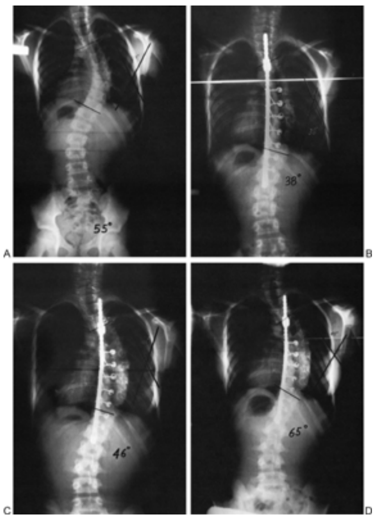

FIGURE 8. Clinical example of crankshaft phenomenon. **A:** Nine-year-old patient with a 55-degree curve. **B:** One year after posterior spinal fusion and instrumentation, curve is 38 degrees. **C:** At 2.5 years after fusion, curve is 46 degrees. **D:** Five years after fusion, curve is 65 degrees despite solid posterior fusion.

Combined Anterior and Posterior Fusion

Anterior fusion followed by posterior instrumentation and fusion is currently recommended for patients with progressive juvenile scoliosis. Although performing two procedures increases morbidity, the possibility of the occurrence of the crankshaft phenomenon is eliminated, and better correction of the primary curve is obtained. Shufflebarger and Clark (87) reported no loss of correction or progression of rotational deformity after combined fusions among patients who were at high risk of development of the crankshaft phenomenon after posterior fusion alone. Anterior fusion can be done through a thoracoscopic approach, which allows good exposure of the anterior vertebrae and disc spaces. Reported fusion rates after use of the thoracoscopic approach are equal to those with open methods (33,37,73,84,95), and a thoracoscopic approach has the advantages of less morbidity and smaller incisional scars than open techniques. Disadvantages are that there is a learning curve with this technique and that the assistance of a general surgeon trained in this technique is required. If such assistance is not available, a standard thoracotomy can be used.

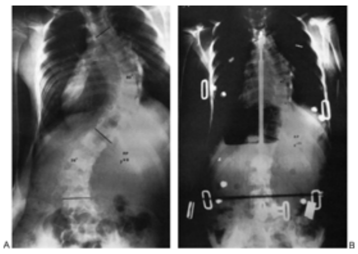

FIGURE 9. **A:** Boy 7 years 6 months of age with an 80-degree curve. **B:** One year 5 months after insertion of a Moe subcutaneous rod with fusion at hook sites. (Courtesy of Stuart L. Weinstein, MD.)

Instrumentation without Fusion or with Limited Fusion

Another alternative for control of curves during growth is instrumentation without fusion of the curve or with fusion of only the end vertebra into which the hooks are inserted (20,29,30,75). Harrington (35) first described this technique in the 1960s. Moe (67,68), who used it specifically on growing children, called it the subcutaneous Harrington rod technique. Moe (67,68) designed a rod for this purpose, and Moe et al. (69) reported using a Harrington rod in this manner. Several companies have developed so-called growth rods that can be lengthened periodically to maintain curve correction, and the technique has been modified to replace subcutaneous placement of the rods with subfascial insertion. Problems with the use of growth rods include the necessity for a surgical procedure every 6 to 12 months to lengthen or exchange the rod. Most surgeons recommend postoperative full-time brace wear to prevent rod breakage or hook dislodgment. Despite these problems, this method is an alternative for controlling curves until the child is mature enough for definitive posterior fusion (Fig. 9).

Another alternative is to combine subcutaneous or subfascial posterior rod fixation with localized anterior fusion of the apical vertebrae (1,44,94). This technique has the advantage of providing partial correction with instrumentation. Localized anterior fusion stops progression of the curve and growth of the apical vertebra, which may help lessen any increase in deformity caused by continued vertebral rotation. This combined approach helps control progression of scoliosis while the child continues to grow in the unfused segments. Several authors have reported good results with this technique because it allows some spinal growth and control of the progressive curve before definitive fusion is performed. Vanlommel et al. (94) reported that the initial intraoperative correction averaged 25 degrees, but this decreased to only 8 degrees of correction at final lengthening. The authors suggested that the spine became stiffer with each lengthening and that the stiffness made subsequent correction more difficult. Klemme et al. (44) also found that the curve response tended to decline with consecutive lengthenings. Among their patients the growth of the unfused spinal segments averaged 3.1 cm over a treatment period of 3.1 years.

A technique with Luque rods and wires without fusion (the so-called Luque trolley) has been described as a way to correct the curve and still allow spinal growth (46,59). Extraperiosteal spinal dissection and segmental fixation with Luque rods and sublaminar wires are performed. Although extraperiosteal dissection is used, the incidence of spontaneous fusion is high. Mardjetko et al. (59) reported that nine patients treated with the Luque trolley without fusion all had spontaneous fusion. This method has the advantage of providing segmental fixation, but the risk of passing sublaminar wires, the difficulty of removing the wires, the possibility of wire breakage, and the high incidence of spontaneous fusion preclude recommendation of this technique.

Technique of Insertion of Subfascial Rods

After induction of general anesthesia, the patient is placed prone on a four-poster frame (1). The back is prepared and draped in the usual sterile manner. The proper level for exposure is identified on a radiograph before the incision is made. A radiograph must be obtained to mark both the upper and lower vertebrae that are to be instrumented. The neutral vertebrae at each end of the curve are selected, and after infiltration of 1:500,000 epinephrine solution, a 3- to 4-cm incision is made over the lamina at each level to be instrumented. An alternative method is to make the skin incision the length of the curve but to expose only the fascia overlying the spine that is to be instrumented with hooks (Fig. 10). Moe et al. (69) initially described subcutaneous placement of the rod, but now the rod is placed beneath the dorsal fascia to improve stability and to reduce the potential for skin problems (1).

Dissection is carried down to the lamina and spinous process of the end vertebra on the concave side. A Cobb elevator is used to expose the lamina on the concave side, and care is taken not to cut the interspinous ligament or to extend the dissection past the midline. The facet joints at the sites selected for hook insertion are exposed. The ligamentum flavum is stripped from the underside of the selected lamina at each end.

A claw-type construct can be used at the upper and lower levels. If the Harrington rod system is used, a special pediatric hook is used; otherwise, a 1254 hook without a sharp edge is preferred. A rod of the appropriate length is contoured to accommodate thoracic kyphosis and lumbar lordosis. If a Harrington rod is used, the ratchet end of the rod is placed at the lower hook site to prevent prominence of the unused portion of the rod. The rod is placed in the hook sites, and distraction is applied to correct the deformity. Somatosensory evoked potentials or a wake-up test is used for neurologic evaluation.

With the newer growth rod system, two rods are used. One rod is attached to the upper hooks and one to the lower hooks. These two rods are allowed to overlap and are connected with a growth connector. Distraction is achieved by means of lengthening the two rods at the connector site. In addition, so called end fusions, as described by Marchetti and Faldini (57), are performed at the initial instrumentation in most patients. Akbarnia and McCarthy (1) place a subfascial distraction rod on the concave side and an additional subfascial compression rod on the convex side of the curve (Fig. 11).

After the operation, a Milwaukee brace is worn full time for external support. Ambulation is begun within 48 hours, and the patient is discharged from the hospital. Winter and Lonstein (99,100) recommended repetition of lengthening 3 months after the initial rod insertion rather than waiting for curve deterioration before lengthening. After the second lengthening, subsequent rod lengthening should be done every 3 to 6 months. Posteroanterior and lateral radiographs are obtained to evaluate the status of the rod and correction of the deformity. Only the area over the growth connectors has to be exposed for the lengthening. This technique is a method of temporarily managing the curve. Definitive spinal fusion is required when the patient is more mature.

Complications

Complications of management of juvenile scoliosis are similar to those of management of adolescent scoliosis: pseudarthrosis, wound infection, paralysis, and malalignment after fusion with instrumentation. Complications that are more frequent among patients with juvenile scoliosis include trunk shortening, the crankshaft phenomenon, and progression of unfused curves.

The amount of trunk shortening can be accurately predicted with growth charts and growth-remaining tables or Winter's (99) formula (see earlier). Although trunk shortening is a consideration when with surgical treatment, the family should understand that even without surgery the trunk will be short and deformed because the spine is not growing straight. After correction of a single curve, careful follow-up evaluation is necessary to determine whether bracing is necessary for secondary curves. What were believed to be compensatory curves during brace treatment can progress after surgery (for example, a primary single curve can become a primary double major curve).

The crankshaft phenomenon remains a major problem after operations for juvenile scoliosis. Although the loss of correction in the coronal plane and the increase in vertebral rotation cannot be accurately predicted at this time, it is known that this will

occur after almost all posterior fusions among patients who have a Risser sign of 0 (19) and an open triradiate cartilage. To avoid this problem, clinical judgment must be exercised to determine whether brace treatment should be continued for a longer time and for a larger curve, for example curves of 50 to 55 degrees. If brace treatment cannot control the curvature, instrumentation without fusion should be considered to allow continued growth of the spine before definitive fusion. If fusion is planned for a patient with juvenile scoliosis, circumferential fusion is recommended to avoid the crankshaft phenomenon.

Summary

Juvenile idiopathic scoliosis occurs between the ages of 4 and 10 years without any known cause of the curvature. A detailed history and examination are required to exclude other known causes of scoliosis among this age group. Curves less than 20 to 25 degrees are simply observed. If the curve progresses, brace treatment is begun. The RVAD is used to help follow the response of the curve to brace treatment. If the curve continues to progress in the brace, bracing can be continued in an attempt to delay surgery. If surgery is needed, instrumentation without fusion can be used to control the curve until the spine is more mature. If surgical fusion of the immature spine is needed, anterior fusion and posterior fusion with instrumentation are recommended to prevent loss of correction and deterioration of appearance caused by the crankshaft phenomenon.

Adolescent Idiopathic Scoliosis: Etiology

Nancy H. Miller

N. H. Miller, M.D.: Johns Hopkins University, Baltimore, MD 21287-9553.

Definition

Adolescent idiopathic scoliosis is a structural lateral curvature of the spine evident in the late juvenile or adolescent period in otherwise normal children (63). The diagnosis is frequently suspected through screening examinations for the presence of back asymmetry. Confirmation of a positive diagnosis can only be obtained through evidence of a 10-degree lateral curvature with vertebral rotation on a standing upright radiograph of the spine (63). The definition of a 10-degree lateral curvature is based on the fact that a graph of scoliosis prevalence among the general population is a smooth exponential function in which the sharpest change in slope occurs at 10 degrees (63). Multiple topographic methods have been used to study back asymmetry; however, there is no definitive correlation with underlying bony structure (5,21). Radiographic analysis is the definitive methodology for documentation of the true idiopathic nature of the scoliosis from one of alternative origins and for measurement of curve magnitude (5,112). Finally, careful history and clinical examination must eliminate features of alternative disorders that are known to have an increased incidence of scoliosis (i.e., Marfan syndrome, osteogenesis imperfecta) to maintain the true idiopathic nature of the diagnosis (18,32,69,113).

Prevalence studies indicate that 2% to 3% of children have idiopathic scoliosis (20,24,64). Curves of small magnitude are of equal prevalence in both males and females. As curve size increases, however, the female-to-male incidence ratio is about 4:1. Additionally, the overall prevalence of the disorder decreases to 0.2% for curves of a magnitude of more than 30 degrees and to less than 0.1% for curves greater than 40 degrees (20,63,71,127,131,136). Despite the overwhelming prevalence of idiopathic scoliosis diagnosed through screening, studies of the natural history of this disorder indicate that less than 10% of the positively screened patients require active treatment (20,71,83,102,136).

In 1984, Lonstein and Carlson (71) correlated the Risser sign, a sign of skeletal maturation, with curve progression. They found that immature patients (Risser grades 0 and 1) with a spinal curvature measuring less than 20 degrees had a 22% probability of progression, whereas small curves in mature patients had only a 1.6% chance of progression. As curve magnitude increased to 20 to 29 degrees, immature patients had a 68% probability of progression, whereas patients closer to maturity (Risser grades 2 to 4) had a 23% probability of progression. A second long-term follow-up of 102 patients with idiopathic scoliosis demonstrated that 68% of all diagnosed curves progressed after spinal maturity (130). Curves measuring less than 30 degrees at maturity were least likely to progress, whereas curves measuring 30 to 50 degrees progressed an average of 10 to 15 degrees over a normal lifetime. Those measuring 50 to 75 degrees at maturity progressed steadily at a rate of about 1 degree per year. A report from the Scoliosis Research Society confirmed that a younger age at detection and a larger curve magnitude correlate with a higher probability of progression (85). Multiple studies have shown, however, that girls maintain 10 times the risk for curve progression as compared with boys (6,22,71,102,127,129).

Research Directed To Etiology

Despite significant research efforts directed to the etiology of adolescent idiopathic scoliosis, the cause of this disorder remains elusive. Multiple hypotheses have been proposed, with no one model supported by significant convincing evidence. Different observations, such as connective tissue abnormalities, differing growth patterns, neuromuscular aberrations, central nervous system asymmetries, and hormonal variations, have been noted in select patient populations. Studies have failed, however, to establish conclusively any one factor as the causative agent of the scoliotic condition (10,25,42,44,47,66,79,96,106,141,147). The primary disadvantage of the past work is the difficulty of differentiating an observation as the primary etiologic factor of a disorder from secondary changes that may result from the deformity. Despite this disadvantage, this research is important not only in potentially revealing the etiologic factors of scoliosis but also in adding to our knowledge of the effects of the scoliotic deformity on the immature skeleton.

Genetics

Although the specific cause of idiopathic scoliosis has not been determined, the role of hereditary or genetic factors in the development of this condition is widely accepted (12,16,37,43,59,134,137,143). Clinical observations and formalized population studies have documented scoliosis within families, with a higher incidence of the condition within relatives as opposed to the general population (41,49,51,55,72,100,101,143). Harrington (59) studied women whose scoliotic curves exceeded 15 degrees and found a 27% incidence of scoliosis among their daughters. Population studies involving index patients and their families indicate that 11% of first-degree relatives are affected, as are 2.4% and 1.4% of second- and third-degree relatives, respectively (100).

Twin studies have consistently shown monozygous twins to maintain a high concordance rate of about 73% for the condition. Dizygous twins may or may not be concordant in the expression of the disease and have a concordance rate of 36% (27,41,54,62,65,78,84,110). This value is consistently higher than that reported of a first-degree relative from more global population studies (100,143). This may be related to the high rate of radiographic confirmation of affectation status within twin studies as compared with that of large population studies of families. Radiographic confirmation of disease potentially lowers the false-negative rate because small scoliotic curves undetectable by clinical examination would then be ascertained as positive.

Despite the documentation of the familial nature of this condition, the mode of inheritance has been debated within the literature. Studies based on a wide variety of populations have suggested an autosomal dominant, X-linked, or multifactorial inheritance pattern (9,14,19,28,39,48,53,55,69,80,82). Wynne-Davies and Riseborough (100,143) published studies of 2,000 and 2,869 individuals, respectively. The first work suggested a dominant mode of inheritance; however, a major percentage of individuals lacked radiographic confirmation of disease. The second series performed with a more rigidly defined population was more consistent with a multifactorial inheritance pattern.

In 1972, Cowell and colleagues (37), noting the paucity of male to male transmissions in the literature, selected 17 families (192 individuals) for examination and radiographs and reported a pattern consistent with X-linked inheritance. With the advent of statistical analysis directed to the potential linkage of genes to known disorders (genetic linkage analysis), Miller and associates (80) investigated X-linkage in 14 families (136 individuals). Overall results did not support X-linkage within the population as a whole.

An alternative statistical method directed to the clarification of a genetic model and penetrance of a familial disease is complex segregation analysis. This methodology is applied to an unscreened population and can confirm clinical observations that a genetic determination exists for a specific disorder. Aksenovich and associates (3,7) used complex segregation analysis (as implemented in S.A.G.E. (103) to study a population of 101 families (788 individuals). The initial results supported a genetic model; however, the best-fitting genetic model was equivocal. When the authors excluded 27 families with probands with mild scoliosis, a mendelian model with sex-dependent penetrance could not be rejected when compared with a general model ($P < .1$), whereas an environmental model was strongly rejected ($P < .001$). These results are similar to those reported by Bonaiti and coauthors (19), suggesting either an autosomal mode of inheritance with incomplete penetrance (higher in girls than in boys) or a genetic model with a mixture of dominant and multifactorial modes of inheritance.

Advances in the mapping of the human genome and current genetic methodology now allow screening of the entire genome of an individual with known genetic markers evenly spaced along the chromosomes. This type of analysis can be performed on individuals or populations in an effort to associate a genomic area with a disease trait. Wise and associates (139) in a genomic scan of a single extended family with idiopathic scoliosis (seven affected individuals) reported suggestive evidence for linkage of the disease state on chromosomes 6, 10, 12, and 18. When these candidate genomic regions were studied in four additional families, one family showed supporting evidence again of genetic linkage on chromosome 10. An additional family showed a suggestive linkage on chromosome 2.

The above studies collectively attempt to indicate that scoliosis is a single gene disorder that follows the simple patterns of mendelian genetics. This is dependent on specific features characteristic to the study population. The simple patterns of mendelian inheritance, however, are known to be susceptible to the genetic principles of variable penetrance and heterogeneity. The wide prevalence of scoliosis associated with high clinical variability is potentially a result of significant locus or intrafamilial heterogeneity. This would confound interpretation of data and possibly conflicting results. As a result of these principles, the genetic mode of inheritance of a disorder may not be clearly evident within a smaller family or group but rather may demand the study of an extensive, well-characterized population through genomic wide-scanning methodology.

Connective Tissue

As a functional biomechanical unit, spinal stability relies on the structural integrity of its various constituents (bone, disc, and ligamentous elements), all of which are composed of the viscoelastic connective tissue elements of collagen, proteoglycan, elastic fibers and additional extracellular matrix components. Because scoliosis is a phenotypic characteristic of multiple connective tissue disorders, such as the Marfan syndrome and osteogenesis imperfecta, the hypothesis that a defect within the connective tissue is the etiologic factor of adolescent idiopathic scoliosis is plausible (18,58,113). Investigators have addressed the issue from two different approaches, that is, a localized defect within one tissue element, or a generalized extracellular matrix abnormality.

Enneking and Harrington in 1969 (47) studied the histology and ultrastructure of the vertebral elements of the scoliotic spine and found no abnormalities as compared with those of controls. This, in conjunction with the fact that long-term studies of idiopathic scoliosis show increasing deformity after completion of vertebral growth (33,43), suggests that the deformity may be secondary to an extraosseous cause and that the change in the vertebral bone and cartilage may be secondary adaptations.

Work focusing on the proteoglycan and collagen of the intervertebral discs has conflicting results. Beard and colleagues in 1981 (13) identified a decrease in type III collagen but no significant differences in type I and II collagen within scoliotic discs. Pedrini and coauthors (96) reported a 25% decrease in the glycosaminoglycan content and a 25% increase in collagen in the nucleus pulposus of scoliosis patients. This finding was supported in 1980 by Taylor and Slinger (126) and Zaleske and colleagues (150). An increase in lysosomal activity of the discs of patients with scoliosis was also documented. In contrast to these reports, Oegema and coauthors (94) did not find any difference in absolute concentrations of proteoglycans in discs of patients with scoliosis from those of controls.

In an effort to view a potential connective tissue abnormality as a more global etiologic factor in adolescent idiopathic scoliosis, Francis and associates studied collagen cross-linking within the skin of patients with scoliosis (52). They found a decrease in the stability of extracted skin polymeric collagen from patients with scoliosis as compared with controls; however, in more mature affected patients, the collagen appeared to be normal. Echenne and colleagues (46) studied the role of an elastic fiber abnormality in the skin of patients with idiopathic scoliosis. A significant number of patients maintained abnormalities in the middle and deep dermis; however, muscle fiber type I abnormalities were also observed in half of patients. Hadley-Miller and coauthors in 1994 (58) focused on the elastic fiber system within the ligamentous structures of patients with idiopathic scoliosis and found a significant number of patients exhibiting elastic fiber abnormalities as compared with controls. Further study in vitro of harvested fibroblasts indicated a potential failure of matrix incorporation of elastic fiber components in a select number of scoliotic patients.

Two works by Carr and colleagues (28) and Miller and associates (80) are directed to the genes responsible for the structural components of the extracellular matrix system. Both groups selected families in which scoliosis was expressed in an autosomal dominant pattern. Through a candidate gene approach the structural genes of collagen types I and II, fibrillin (FBN1) and elastin were excluded as potential causative factors of idiopathic scoliosis within the studied populations.

Muscle and Platelet

Multiple authors have postulated a generalized growth or functional defect within the skeletal muscle as a factor in the etiology of adolescent idiopathic scoliosis (26,50,68,104,119,122,147,148). Documented changes in the morphology, ultrastructure, and biochemistry have been described; however, many appear to be localized to specific areas, that is, the convexity or concavity of the spinal curvature.

Morphologically, Spencer and Eccles (122) were the first to record a decrease in type II (fast-twitch) muscle fibers as compared with type I (slow-twitch) fibers in patients with idiopathic scoliosis. They postulated a denervation or myopathic process as a causative factor. Other investigators have found abnormalities in fiber size and fiber type distribution in the paraspinous muscle areas of affected patients as compared with controls; however, they differ in their observations (26,50,104,119,147,148). Fidler and Jowett (50) noted atrophy of type II fibers on the concave aspect of the scoliotic deformity and a greater number of type I fibers on the convexity. Bylund and colleagues (26), in a comparative study including patients with idiopathic scoliosis and healthy age-matched controls, did not observe any difference in fiber type on the convex side of the curve but did note a relative decrease in type I fibers on the concave side of the curve. In an effort to support a global myopathy, Yarom and Robin (147,148) and Sahgal (104) studied skeletal muscle from alternative sites (gluteus medius, deltoid, and trapezius muscles). Both groups reported myopathic changes or a fiber-type disproportion at these more distant sites. These myopathic changes were further documented through histologic work to include myofilament disarray, central core formation, and fiber splitting at both the light and electron microscopy levels.

Biochemical analyses of the muscle in patients with idiopathic scoliosis have focused on tissue enzyme activity and protein synthesis. Activity of multiple enzymes, including aspartic and thiol proteinase and adenosine triphosphatase, were found to be decreased on the concave aspect of the curve, in addition to increased levels of calcium (17,36). Investigators postulate a potential defect in the calcium pump across the cellular membrane as a contributing factor of the scoliotic deformity.

Muscle protein synthesis as detected by the uptake of radioactive L-leucine was noted to be higher at the apex of the curve on the convex side than on the concave side of the curve in nine patients with idiopathic scoliosis (57). These changes are potentially consistent with a simple increase in muscle contractile activity and muscle immobilization, which occurs on the concave aspect of the curve.

Because of the physiologic relationship of the muscular contractile proteins and that of the thrombocyte, the thrombocyte or platelet has been a focus of etiologic research of scoliosis. The platelet is also not localized to the skeleton but found systemically, which intuitively suggests that any abnormalities may be primary, not secondary, in nature.

Wong and associates in 1977 (140) and Yarom and Robin in 1979 (148) reported elevations in platelet intracellular calcium and phosphorous concentrations in patients with idiopathic scoliosis as compared with age-matched controls. This elevation is believed to be localized to the “dense bodies,” a platelet intracellular histologic finding. In a second study, Yarom and colleagues (146) compared histologic findings of patients with mild scoliosis (less than 15 degrees) and those with more severe scoliosis (greater than 20 degrees). The number of dense bodies was found to be increased in patients with scoliosis in direct proportion to the degree of curvature. These findings collectively have led to a hypothesis of a calcium transport defect of the cellular membrane or contractile complex as a factor. More recently, investigators have reported abnormalities in levels of platelet calmodulin, a calcium-binding protein, among patients with scoliosis as compared with age-matched controls (31,67). Calmodulin interacts with actin and myosin and mediates calcium flux through the sarcoplasmic reticulum. Thus, it is a known regulator of the contractile properties of muscles and platelets. In a comparison of patients with idiopathic scoliosis and matched controls, Kindsfater and coauthors (67) found that skeletally immature patients with progressive curves maintained significantly higher levels of platelet calmodulin than did controls and those patients with stable curves. The significance of this finding and its relationship to parallel research related to melatonin, a hormone known to bind and enhance the action of calmodulin, is unknown.

Neuromotor Mechanisms

Immature patients with known neuromotor disorders are subject to the development of scoliosis; therefore, a subclinical dysfunction or anatomic abnormality of the neurologic system has been hypothesized as an etiologic factor related to adolescent idiopathic scoliosis. In clinical studies, authors have tested a wide range of functions, including proprioception, postural equilibrium, the oculovestibular complex, and vibratory sensation. Multiple techniques have been used, including electronystomography, electroencephalography, and electromyography in select affected patient populations in an effort to distinguish any potential neuromotor differences from those of controls (11,70,106,141,142,144). Abnormal findings are hampered by the inability to determine whether they are a cause or an effect of the scoliosis. Through intuitive scientific deduction, many reports are, rightfully or wrongfully, considered to be a secondary phenomenon of the scoliotic deformity.

Wyatt and colleagues (142) and Barrack and associates (10) evaluated vibratory sensation with a BioThesiometer in patients who had scoliosis and suggested a lesion of the dorsal columns. The reliability of the BioThesiometer used, however, is now considered questionable. Yekutiel and associates in 1981 (149) tested proprioception in scoliotic patients through a wide range of tests and concluded that no abnormality could be consistently demonstrated in patients with scoliosis as compared with age-matched controls.

Early studies by Yamamoto (1982) (145) suggested postural equilibrium dysfunction among scoliotic patients. Further work by Lidstrom and colleagues (1988) (70) demonstrated that the abnormalities parallel the deterioration of the curve, and, further, that as a patient matures, the postural sway corrects itself. In conclusion, the observed equilibrium abnormality is now believed to be secondary to the curve and indicates a compensatory phenomenon of a normal immature neurologic system.

Multiple spinal and central monitoring techniques have been used to localize a defect within the brain stem or higher cortical function within patients with scoliosis (29,77,105,106,107). One of interest is that of oculovestibular function. Work by Sahlstrand and colleagues (105,106) showed an abnormal nystagmus response through calorific testing among patients with idiopathic scoliosis, indicating an oculovestibular abnormality. Herman and MacEwen (60) showed consistent oculovestibular dysfunction present in affected patients and proposed a defect in the sensory input involved in the visual and vestibular areas of the hindbrain. Conversely, children with vestibular dysfunction have been shown to have a lower incidence of idiopathic scoliosis than is seen in age-matched control populations (141).

The advent of neuromotor and sensory monitoring during the surgical intervention of patients with severe scoliosis has led investigators to question whether the cerebral cortex may be a source of the scoliotic deformity (29,77). Asymmetric latency potentials have been correlated with the direction of the scoliotic deformity and, to some degree, with the progression of the curvature in some patients.

Research related to the neuroanatomy of scoliosis is focused in two areas: first, clinical work related to the identification of a central asymmetry or abnormality related to the scoliotic condition, and, second, experimental work related to the development of an animal model for scoliosis. Geissele and colleagues in 1991 (56) and Stevens in 1992 (124) reported asymmetries of the midbrain and hindbrain in patients with scoliosis as compared with controls. Because of the limited number of controls and the relatively new application of magnetic resonance imaging to illustrate subtle size differences within areas of the central nervous system, this work needs further investigation.

Animal studies have focused on the development of a bipedal animal model for the experimental study of scoliosis. The production of localized and asymmetric lesions of the spinal cord through selective posterior rhizotomies can lead to a scoliotic deformity; however, its features are that of a neuropathic etiology (125). A well-publicized series of works by Machida and colleagues (73,74,75) reported a chicken animal model that, after pinealectomy, developed a significant scoliotic deformity paralleling that of an idiopathic type. The pineal gland is the primary source of melatonin, a neurohormone whose function is not clearly understood. The authors additionally observed abnormal cortical evoked somatosensory potentials within the pinealectomized animals and hypothesized an abnormality of somatosensory conduction as a primary etiologic factor in the development of the scoliotic condition.

Growth and Hormonal System

The relationship of growth and idiopathic scoliosis has been well recognized (129,130). Growth is essential to the development and progression of a structural scoliosis, and small scoliotic curves stabilize after maturity. However, growth as a primary or a secondary factor in the etiology of scoliosis remains undetermined. Multiple longitudinal and cross-sectional studies from Scandinavia documented an increased standing height in girls with idiopathic scoliosis both before and after correction for the loss of height due to the scoliotic deformity (89,118,132) This finding was confirmed by other authors in differing ethnic populations (40,45). Further study by Willner (134) indicated that in those children who developed scoliosis, the growth rate the year before the onset of curvature was markedly elevated as compared with those children who did not develop scoliosis. However, this difference did not seem to persist, and the initial difference in height between the two groups decreased at the end of the growth period. Although multiple anthropometric studies have found that scoliotic patients are taller than nonscoliotic controls, other authors have found no association with height or rate of growth between children with or without scoliosis (40,45,126). These variable results may reflect differences in study methodology because some studies do not correct for the loss of height resulting from the spinal curvature.

The possibility that a disproportionate relationship exists between the length of the trunk and that of the lower extremities has been studied in scoliotic patients in comparison with controls (87,133). No difference in the proportion of legs to trunk, sitting height, suprapelvic height, or weight has been found in female patients with idiopathic scoliosis as compared with controls.

The accelerated growth in the prepubertal growth period observed in girls with idiopathic scoliosis as compared with age-matched controls indicates a potential deviation in the normal growth pattern. This observation has led to the study of growth-stimulating hormones within scoliotic patients (2,117,135). Skogland and Miller (117) noted an increase in release of growth hormone in scoliotic patients between the ages of 7 and 12 years. Similar findings have been found by other groups (2,135). Misol and colleagues (81) and Yamada and coauthors (144) report no difference in growth hormone levels between scoliotic and nonscoliotic girls; however, the ages of the study groups either was not reported or the study population was mature at the time of study. The fact that growth hormone secretion after experimental stimuli and in relation to pubertal maturation is episodic in nature significantly limits the comparison of the studies. Evidence exists that a differential growth pattern secondary to growth hormone stimulation may be present within the scoliotic population and requires additional investigation.

A second hormonal system under investigation within the scoliotic population is that of melatonin (76). As discussed previously, the pinealectomized chicken has been used as an experimental animal model for idiopathic scoliosis (73,74). Melatonin is the primary hormonal product of the pineal gland and is known to have an effect on the control of circadian rhythms (35). In this role, it has been available to the general public as a solution to jet lag. A second interaction of melatonin is on calcium regulation through an interaction with the calmodulins (15). As mentioned previously, peripheral calmodulin levels are under investigation as a potential marker for patients with progressive scoliosis.

Patients with scoliosis do produce melatonin. Machida and coauthors (74,76) have reported that patients with severe and progressive scoliosis maintain significantly decreased nighttime levels of melatonin levels as compared with controls and patients individuals with stable scoliosis. These findings, however, have not been confirmed by other authors (8,61). Although the association between melatonin and the etiology of idiopathic scoliosis is speculative, the given ubiquitous nature of this hormone and its involvement in multiple cellular regulatory processes warrants further investigative efforts.

Biomechanics

As a functional biomechanical unit, spinal alignment and stability rely on the integrity of the tissue elements, the functional load applied to the spinal column, and the growth pattern of the immature vertebrae. The fact that the loss of structural integrity of the supporting elements, as seen in known connective tissue disorders, leads to scoliosis indicates that specific biomechanical factors are essential for normal spinal development (18,113). The potential that biomechanical factors initiate the development of idiopathic scoliosis has been suggested.

Individual elements of the spine (i.e., the vertebral bodies, the rib and trunk muscles, the ligaments and intervertebral discs) have been investigated for an alteration in their intrinsic mechanical properties that would lead to an abnormal response to biomechanical loading. A subtle alteration in the laxity or stiffness of the tissues would cause the column to buckle when load is applied to the spinal column in the bipedal state. As reviewed previously, multiple authors have identified changes within the musculature or within the extracellular matrix of the spinal ligaments or intervertebral discs (25,38,58,59,88,94,97 —99). Most concluded, however, that the observed differences were most likely secondary to the scoliotic deformity rather than a primary etiologic factor (59,97,114). Decreased bone density in patients with idiopathic scoliosis has been documented in several studies (30,34,108,128). Although poor bone quality (osteoporosis) is known to contribute to some existing scoliotic deformities, the role of decreased bone density in the development of idiopathic scoliosis in the immature skeleton is unknown.

Clinical observation has shown that with the loss of normal thoracic kyphosis, a structural scoliosis may develop. In 1952, Somerville (121) suggested that a growth differential between the anterior and posterior columns of the spine or vertebrae could lead to hypokyphosis. This, in turn, would cause a biomechanical rotational abnormality of the spine producing the scoliosis. This theory has been furthered by marked circumstantial evidence (23,43,44,120,138). However, the technical inability to study differential growth patterns of immature vertebrae in children and the lack of a good animal model make this theory difficult to test.

A fundamental mechanism for the development of scoliosis is potentially the asymmetric application of loading forces as one assumes the bipedal state. A series of work by Normelli and colleagues (90,91,92,93) focus on the asymmetry of the rib structure, anterior thoracic wall, and vascular supply to the chest within patients with right thoracic scoliosis as compared with controls. Their results indicate significant differences between the left and right sides, particularly within the size of the ribs and breasts. They hypothesized that the increased vasculature to the left could lead to increased growth potential and result in asymmetric loading of the spine. In turn, collapse of the right side and a scoliotic condition develop. Sevastik and coauthors (111) reported asymmetric growth of the pedicle elements within spines with vertebral rotation. Further support for the theory of growth asymmetry has been generated by the successful production of scoliosis in a rabbit animal model through the unilateral stimulation of rib overgrowth (1).

Although spinal stability is primarily considered a static configuration, the biomechanics of spinal stability, particularly in relationship to the immature skeleton, is a dynamic process. As a person moves and grows, spinal stability is a continuous realignment of the head over the pelvis. This mechanical process is dependent on the integration of static and dynamic elements in both a localized area and on a more unified structural level. Although the dynamic process of the spinal stability is recognized, research within this area is now directed to the innovative application of computerized technology to develop mathematical models of the spine (4,86,95,109,115,116,123).

Summary

Adolescent idiopathic scoliosis is a prevalent disorder that is known to occur within families for unknown reasons. Knowledge of the natural history of this disease process has shown us that through clinical assessment, specific patient groups maintain certain risks and patterns of progression. The role of genetic factors is widely documented; however, the genetic mode of inheritance of familial idiopathic scoliosis is undetermined. Multiple areas have been investigated for the potential etiology of this disorder, with no one element showing definitive evidence as the primary etiologic factor. Abnormalities have been documented in the skeleton, neuromotor system, connective tissue, biomechanics, and hormonal system. The primary difficulty of most investigations is whether the observed abnormalities are primary or secondary features in the pathogenesis of this disorder. Genetic studies directed to a wide population may aid in the delineation of a primary etiologic factors through modern genotyping techniques. A better understanding of the etiology of idiopathic scoliosis and factors related to the clinical variability of this disorder should improve the ability to assign a more specific prognosis and modify current treatment regimens.

Adolescent Idiopathic Scoliosis: Natural History

Stuart L. Weinstein

S. L. Weinstein: Department of Orthopaedics, University of Iowa Hospitals, Iowa City, IA.

All treatment decisions about disease entities are ideally made in light of a thorough knowledge of the natural history of the condition. These treatment decisions must be critically and continually assessed in light of outcome studies on patients treated with various nonsurgical and surgical methods. All treatments must alter natural history in a positive way. This chapter is concerned only with those patients who carry the diagnosis of late-onset scoliosis or what is more commonly referred to in North America as *adolescent idiopathic scoliosis* (AIS). Understanding the natural history enables physicians to make thoughtful and appropriate management decisions that will alter the course of the disease in a positive way.

The literature on the natural history of idiopathic scoliosis has many shortcomings. First and foremost among these is the paucity of information on the topic (7,37,41,42,54,55,63,69,78,84,91,97,101,124,129,130). Most long-term follow-up studies are retrospective in nature and suffer the faults of all retrospective studies, particularly lost patients. Most studies include small numbers of patients, and thus “significant” findings may not be statistically significant. Patients with other etiologies for their spinal deformity and patients with early-onset idiopathic scoliosis are often included. Patients with scoliosis of varying etiologies and those with idiopathic scoliosis of early onset cannot be compared with the specific group of patients with adolescent onset of their spinal deformity. The effects of spinal deformity can be profound on the growth of the spine as well as on adjacent structures and internal organs, such as the ribs and pulmonary parenchyma. Curve patterns, gender, magnitude, and other factors affect outcome, and this information is often lacking in the literature. Other variables include whether the patient was actually seen and examined and the variability and reliability of questionnaires used to assess outcome parameters.

By definition, AIS is a structural lateral curvature of the spine that occurs at or near the onset of puberty for which no cause can be established (65,123). The diagnosis of AIS is generally suspected by the presence of body asymmetries in the standing position. These asymmetries may include variance in shoulder height (acromioclavicular [AC] joint level), scapular prominences, chest prominences, or decompensation by a plumb line from C7 (121,132,134). The rotational asymmetries are best detected by the Adams forward-bending test (2). Unfortunately, all the screening tests used to make the diagnosis of AIS (e.g., moiré topography, Integrated Shape Imaging System (ISIS) scanning, forward-bending test) are sensitive for detecting body asymmetries but are not specific for scoliosis or curve magnitude (6). Hence, the diagnosis can be confirmed only by the presence of a curvature of at least 10 degrees, measured by the Cobb method, on a standing upright radiograph of the spine (65). By this criterion, the prevalence of AIS in the at-risk population (children 10 to 16 years of age) is about 2% to 3% (8,16,17,18,21,22,50,51,65,66,81,82,92,94,95,105,107,109,110,114,115,129). As curve magnitude increases, the overall prevalence of the condition decreases (Table 1). There is an overall female predominance of 3.6:1. The male-to-female ratio of patients with small curves in the range of 10 degrees is about equal. In curves of larger magnitude, however, there is an overwhelming female predominance (8,16,17,21,22,36,66,73,74,110,117,133,134,138,140) (Table 1). There had been some question about whether the incidence and hence natural history of AIS had changed in recent years. Montgomery and Willner (82), however, demonstrated in a longitudinal cross-sectional analysis that in a cohort of children followed over a 15-year period, there was no support for a change in the natural history of scoliosis.

Epidemiologic and natural history studies indicate that less than 1% of the screened population and less than 10% (range 3% to 9%) of positively screened patients (curve greater than 10 degrees) require active treatment (8,16,17,74,81,107,134). This small group of patients with curves greater than 10 degrees is the focus of the remainder of this chapter.

It is well known that the prognosis of scoliosis varies according to the etiology. The natural history of patients with untreated AIS does not necessarily apply to the natural history of scoliosis with known etiologies. The various natural histories of curves with different etiologies, as well as their associated problems, may have a significant bearing on the ability of patients to meet the demands of daily life and work.

Curve patterns must be taken into consideration when reviewing the natural history. The four main curve patterns in AIS are thoracic, lumbar, thoracolumbar, and double major

(Figs. 1, 2, 3, 4). There may be some confusion in the literature when differentiating curve patterns; many authors put some thoracolumbar curves in the lumbar group, and vice versa. The definitions used here specifically refer to the location of the apical vertebrae. Each curve has its own particular characteristics, predicted course, and outcomes (12,23,24,28,29,40,62,72,84,96,97,100,102,124,126,128,129). Other, less common curve patterns include the cervicothoracic, double thoracic, and thoracic thoracolumbar (102).

TABLE 1. Adolescent Idiopathic Scoliosis Prevalence

Cobb Angle (degrees)	Female-to-Male Ratio	Prevalence (%)
>10	1.4–2:1	2–3
>20	5.4:1	0.3–0.5
>30	10:1	0.1–0.3
>40		<0.1

Patients with AIS and their families are often upset by misinformation about the condition and its ultimate effect on their lives. There are few natural history studies available on AIS. Most that do exist are retrospective and are open to criticism on various points (7,41,42,63,69,84,91,97,103,124,129).

In 1968, Nachemson (84) and Nilsonne and Lundgren (91) published long-term follow-up studies that expressed a grim prognosis for patients with untreated scoliosis. Nachemson reported a 38-year follow-up of 130 patients with untreated scoliosis. Thirty percent claimed disability because of their deformity. There was a 100% increase in the mortality rate compared with that of the general population, and 16 of the 20 deaths were due to cor pulmonale. Thirty-seven percent of the patients had constant backache, and 14% complained of cardiopulmonary symptoms. Only 59 patients (45%) in this study, however, had idiopathic scoliosis; the remainder included patients with congenital scoliosis, paralytic scoliosis, and scoliosis secondary to tuberculosis, neurofibromatosis, and other miscellaneous diseases. Only 12 patients were actually seen in that particular follow-up study. Of the 16 deaths due to cor pulmonale, only three occurred in patients with idiopathic scoliosis, and it is uncertain whether these patients had adolescent-, juvenile-, or infantile-onset idiopathic scoliosis. Although no radiographs were available, Nachemson postulated that the constant backache in these patients was probably caused by osteoarthritis (84).

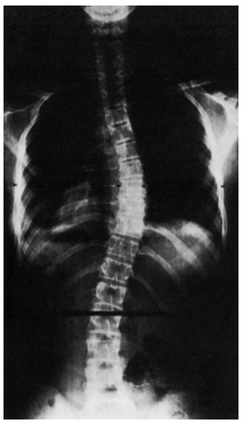

FIGURE 1. Thoracic curve. Ninety percent right convexity involving an average of six vertebrae: apex T8, T9; upper end vertebrae T5, T6; lower end vertebrae T11, T12.

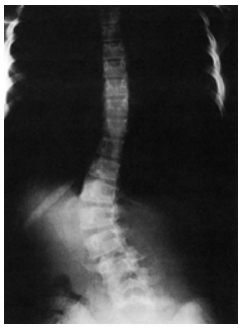

FIGURE 2. Lumbar curve. Seventy percent left convexity involving an average of six vertebrae: apex L1, L2; upper end vertebrae T11, T12; lower end vertebrae L3, L4.

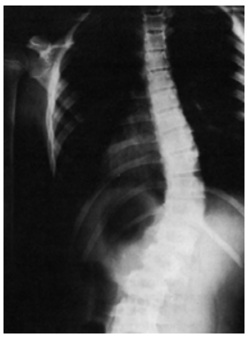

FIGURE 3. Thoracolumbar curve. Eighty percent right convexity involving an average of six to eight vertebrae: apex T11, T12; upper end vertebrae T6, T7; lower end vertebrae L1, L2.

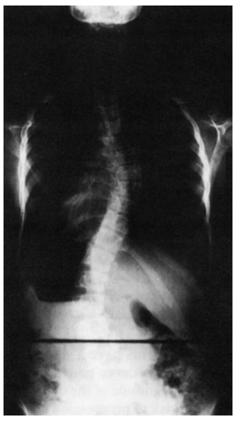

FIGURE 4. Double curve. Ninety percent right thoracic convexity and left lumbar convexity. Thoracic component averages four vertebrae: apex T7, upper end vertebrae T5, T6; lower end vertebrae T10. Lumbar component averages three vertebrae: apex L2, upper end vertebrae T11; lower end vertebra L4.

In a more recent and further follow-up study, Pehrsson and associates (97) reported on 115 patients with scoliosis born between 1902 and 1937: 30 patients had infantile-onset scoliosis, 31 juvenile-onset, and 52 adolescent-onset; 26 had polio, 19 had rickets, and in 69, the etiology was unknown. The average age at death was 54 years (range, 16 to 75 years). Sixty patients were alive at follow-up. All patients were younger than 30 years of age at their first visit, with a mean age of 14 years (0 to 30 years). Of the 55 patients who died, 21 died of respiratory failure and 17 of cardiovascular disease. The study confirmed an increased mortality rate in untreated scoliosis if one considers all the etiologies together. However, no patient with adolescent-onset scoliosis of unknown etiology (AIS) died from respiratory failure. Therefore, respiratory failure and premature death may develop in idiopathic scoliosis, but there is no indication from this study that this will occur in patients who have adolescent-or late-onset idiopathic scoliosis.

Nilsonne and Lundgren (91) reported a 50-year follow-up of 113 patients. This group had a mortality rate that was twice the rate in the general population. Sixty percent of the deaths were attributed to cardiopulmonary disease. Of the living patients, half were unable to work, 76% were unmarried, 90% had back symptoms, 30% were on disability pensions for back pain or scoliosis, and 17% were disabled but not on pensions. The major shortcoming of this study was that Nilsonne and Lundgren had no radiographs to ascertain the etiology of scoliosis in their patients. In addition, it is uncertain whether any of the patients were actually examined on follow-up.

A study by Fowles and associates (51) was based on 65 patients who were followed for an average of 23 years. Ten patients had died; of the rest, 22% were unemployed, 40% had intermittent backache, 22% had frequent backache, 9% were on disability pensions, and 63% of the women were unmarried. This study included patients with scoliosis of mixed etiologies, including idiopathic scoliosis, paralytic scoliosis (secondary to poliomyelitis), congenital scoliosis, and kyphosis. Only 24 (44%) of the 55 living patients had idiopathic scoliosis.

In a recent four-part follow-up of a scoliosis cohart from Ste. Justine in Montreal (54,55,78,101), the authors reported on a 14-year follow up survey on surgically and nonsurgically treated patients. Seventy-one percent of the cohort returned the questionnaire. In the nontreated patient group, there was a 45% incidence of current back pain. The authors concluded that patients with scoliosis perceived themselves as less healthy than other people of the same age, and they experienced limitations in certain activities, such as lifting, walking long distances, standing and sitting for periods of time, and being able to travel and socialize outside of the home. The scoliosis patients also reported more current back pain and pain that was more intense than did controls. Among the shortcomings of this study was that most of the information was obtained by a telephone survey and questionnaire. Although the authors used many validated questionnaire instruments, the patients were not reevaluated personally or radiographed at follow-up. More important, the population-based control group was made up of patients randomly selected from the telephone directory but not actually seen and screened to exclude the presence of spinal deformity.

A study by Dickson and colleagues (37) following a group of 81 surgically treated adults with AIS for an average of 5 years after surgery also included a group of 30 patients who declined surgery. These two groups were then compared with a group of nonscoliotic patients. At 5-year follow-up, the surgically treated patients reported significantly more improvement in self-image and ability to perform physical functional and positional tasks than did untreated patients. It is questionable, however, whether this small group, who presented as adults for evaluation, who refused surgical treatment for progression or pain, and who were followed for only 5 years, would constitute a natural history study or could be compared with untreated patients followed longitudinally.

The remainder of this chapter synthesizes what is currently known about the natural history of AIS in patients not treated surgically. We examine outcomes referable to curve progression, pulmonary function, mortality, back pain and disability, psychosocial effects, and effects of and on pregnancy.

Curve Progression

The main concern in the skeletally immature patient relates to curve progression. In this group, nonsurgical and operative treatment decisions are generally made on the basis of curve progression or the probability thereof. It is often assumed by treating physicians that progressive curves will eventually lead to pain, diminution of pulmonary function, and psychosocial problems. The long-term sequelae related to these topics are discussed later in the chapter.

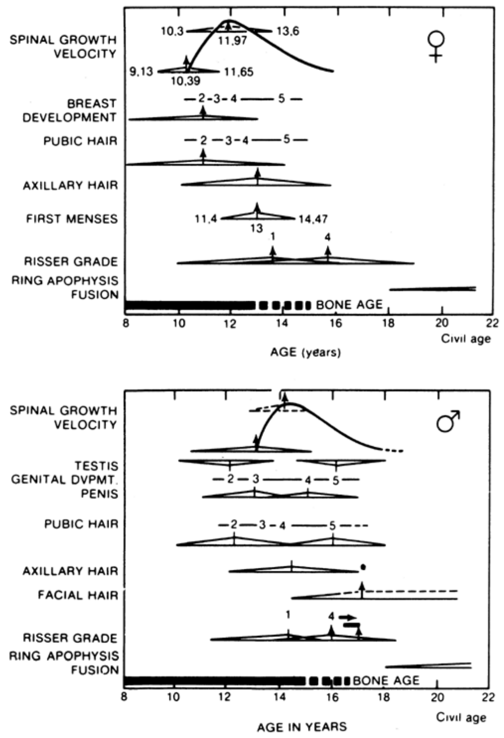

FIGURE 5. The relationship of spinal growth velocity to maturity landmarks and the events of puberty in girls **(A)** and boys **(B)**. Numbers above breast development, pubic hair, axillary hair, and genital development refer to Tanner stages. (Modified from Trevor S, Kleinman R, Bleck EE (1980): Growth landmarks and the evolution of scoliosis: a review of pertinent studies on their usefulness. *Dev Med Child Neurol* 22:675, with permission.)

In the immature patient, the risk for progression is related primarily to specific curve factors and growth potential. Assessment of growth potential is essential for prognostication regarding curve progression. The relationship of spinal growth to the events of puberty (Fig. 5) must be evaluated in the skeletally immature patient (118).

Most information available on curve progression is from studies of girls, particularly those with thoracic curves. From these studies, six factors have been determined to influence the probability of progression in the skeletally immature patient. Four of these factors are related to growth potential; the remaining two are related to the particular curve. The curve factors include the following:

1. Double-curve patterns have a greater tendency to progress than single-curve patterns.
2. The larger the magnitude of the curve at detection, the greater the risk for progression (19,20,24,34,40,67,74,87,108,134,139).

The growth factors are as follows:

1. The younger the patient at the time of diagnosis, the greater the risk for progression.
2. There is a greater risk for progression before the onset of menarche in girls.
3. The lower the Risser grade at curve detection, the greater the risk for progression.
4. Boys with comparable curves have about one tenth the risk for progression as girls (7,8,19,24,39,74,87,89,107,123,124,125, 128,129,134,140). A recent study (57) refutes this point.

In 1982, Nachemson and colleagues (87) calculated the probability of curve progression before skeletal maturity based on all known prognostic factors available at the time (Table 2).

Lonstein and Carlson (74) evaluated the probability of progression based on Risser grade (Table 3). These studies show that risk for curve progression decreases with increasing skeletal maturity. With larger-magnitude curvatures, however, there may be a considerable risk for progression despite maturity.

Another factor that no doubt has some influence on the likelihood of curve progression is the loss of thoracic kyphosis. The importance of loss of thoracic kyphosis has been demonstrated by Dickson and others (33,35,99,113). How the loss of thoracic kyphosis affects curve progression is yet to be determined. Thoracic hypokyphosis also causes diminution of pulmonary function and may affect nonoperative as well as operative treatment decisions (43,45,135,136,137).

It was once thought that when the patient reached skeletal maturity, there would be no further curve progression (27,104). The study by Duriez (39) and several subsequent studies (7,41,102,124,128,129,130) demonstrated, however, that curves may continue to progress throughout life.

In a review of 102 patients followed for an average of 40 years at the University of Iowa, 68% of the curves progressed after maturity (124,125,128,129). This trend has continued in a 50-year longitudinal study (130). From this group of patients, multiple factors that lead to curve progression after maturity were identified (Table 4). In the thoracic curve pattern, patients with curves of less than 30 degrees at maturity tended to have apical vertebral rotation of less than 20 degrees (89) and Mehta angles (79) of less than 20 degrees; these curves did not progress. Thoracic curves of more than 30 degrees at maturity progressed an average of 19 degrees during the 40-year follow-up period. The most marked progression was noted in curves between 50 and 75 degrees at maturity. These continued to progress at 0.75 to 1 degree per year during the follow-up period (Fig. 6). All these patients had Mehta angles of greater than 20 degrees and apical vertebral rotation of more than 30% (125,128) (Fig. 7). The Mehta angle appears to be influenced by extreme degrees of vertebral rotation (98,99).

TABLE 4. Progression Factors in Curves Greater Than 30 Degrees at Skeletal Maturity

Thoracic	Lumbar	Thoracolumbar	Combined

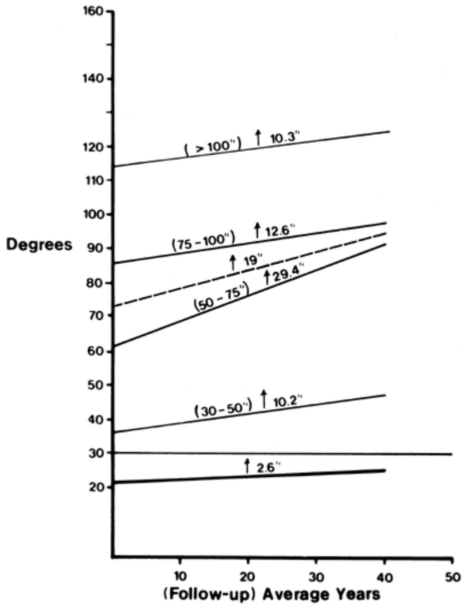

FIGURE 6. Thoracic curve progression after skeletal maturity. The *thick black line* represents average curve progression for all curves less than 30 degrees at skeletal maturity. The *thick dashed line* represents average curve progression for all curves of more than 30 degrees at skeletal maturity. The *thin black lines* represent average curve progression for each range in parentheses. Progression is not necessarily linear. Lines connect average values at maturity and at average 40-year follow-up. (Adapted from Weinstein SL, Ponseti IV (1983): Curve progression in idiopathic scoliosis: long-term follow-up. *J Bone Joint Surg Am* 65:447, with permission.)

The importance of the rib cage to spinal stability has been demonstrated by Langenskiold and Michelsson in a study of rabbits in which resection of the costovertebral ligaments or the dorsal rib ends reliably produced scoliosis (71,80). Farkas (49,103) indicated that intrasegmental movement of the vertebral body in scoliosis is caused by relaxation of the costovertebral joints. Andriacchi and colleagues (4) demonstrated that the rib cage markedly increases the axial stability of the spine.

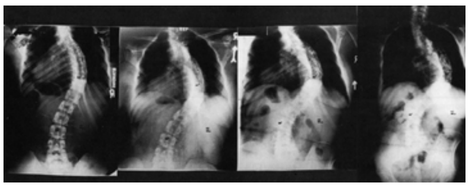

FIGURE 7. Natural history scenario of a thoracic curve. At maturity (21 years of age), the patient's curve measured 53 degrees. Note the slow steady progression of about 1 degree per year (age 43 years, 67 degrees; age 53 years, 86 degrees) to her current curve of 94 degrees at age 66 years.

In the lumbar curve pattern, curves of less than 30 degrees did not progress after skeletal maturity (Fig. 8). In our series (75), only one patient with a lumbar curve of less than 30 degrees progressed from 24 degrees at 18 years of age to 45 degrees at 54 years of age. This patient had an apical vertebral rotation of more than 33% and a high-riding fifth lumbar vertebra (the intercrest line passed through the body of the fifth lumbar vertebra). A translatory shift of the third lumbar vertebra on the fourth developed, with lateral tilting of the fourth lumbar vertebra on the fifth (Fig. 9).

All lumbar curves of more than 30 degrees at maturity had apical vertebral rotation of more than 33%. All but four of these curves progressed; no progression was seen in two patients in whom the fifth lumbar vertebra was deeply seated and in two other patients in whom the fifth lumbar vertebra was sacralized. These four curves were the only ones that did not develop translatory shifts at follow-up. Thus, in lumbar curves, the factor leading to progression is a curve greater than 30 degrees at maturity, particularly one with apical vertebral rotation of more than 33%. If the fifth lumbar vertebra is high riding, translatory shifts develop at the third lumbar vertebra on the fourth, with lateral tilting of the fourth lumbar vertebra on the fifth. Right lumbar curves tend to progress twice as often as left lumbar curves. The reasons for this could not be determined (125,128).

Farfan and colleagues (47,48) demonstrated that annular tears are the result of torsional rather than compressive failures. MacGibbon and Farfan (75) demonstrated in 554 patients that a high intercrest line (an interiliac crest line falling at or above the fourth or fifth lumbar disc space; in this situation, L5 is said to be well seated) is an antitorsional device, which reduces the risk for annular tears and disc degeneration. A low intercrest line provides no antitorsional protection to the discs between the fourth and fifth lumbar vertebrae and the fifth lumbar and the first sacral vertebrae (75). When the fifth lumbar vertebra is not well seated and there is a high percentage of vertebral rotation, the curve tends to progress; significant translatory shifts (lateral listhesis) occur at the lower end of the curve, often accompanied by tilting of the fourth and fifth lumbar vertebrae toward the convexity of the curve (128) (Fig. 10). The roles of torsional rotation were investigated by Perdriolle and Vidal (98,99,100) and were found to be prognostic factors in progression of the thoracic curves.

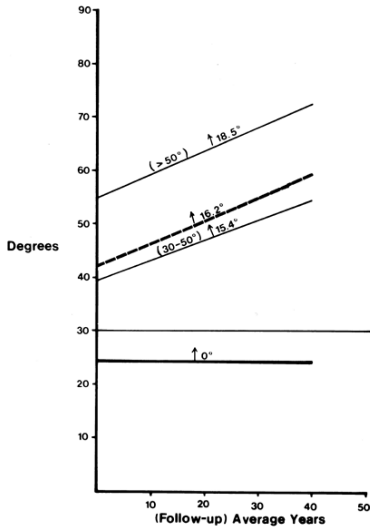

FIGURE 8. Lumbar curve progression after skeletal maturity. The *thick black line* represents average curve progression for all curves of less than 30 degrees at skeletal maturity. The *thick dashed line* represents average curve progression for all curves of more than 30 degrees at skeletal maturity. The *thin black lines* represent average curve progression for each range in parentheses. Progression is not necessarily linear. Lines connect average values at maturity and at average 40-year follow-up. (Adapted from Weinstein SL (1987): The natural history of scoliosis in the skeletally mature patient. In: Dickson JH, ed. *Spinal deformities*, vol. 1, no. 2: *Spine, state of the art reviews.* Philadelphia: Hanley and Belfus, pp. 195–212, with permission.)

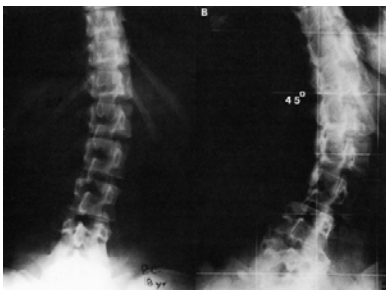

FIGURE 9. Progressive right lumbar curve. **A:** At 18 years of age, the right lumbar curve measures 24 degrees. The apical vertebral rotation is 33%, and the fifth lumbar vertebra is riding high in relation to the intercrest line. **B:** At 53 years of age, the curve measures 45 degrees, vertebral rotation has increased to 41%, and there is a translatory shift of the third lumbar vertebra on the fourth.

The thoracolumbar curve pattern manifested the most significant amounts of apical vertebral rotation (40% to 65%) of any curve pattern (Fig. 11). This rotation increased with increasing curve severity. As with lumbar curves, patients with thoracolumbar curve patterns develop translatory shifts at the lower end of the curves. The marked vertebral rotation, in combination with translatory shifts at the lower end of the curve, leads to significant curve progression.

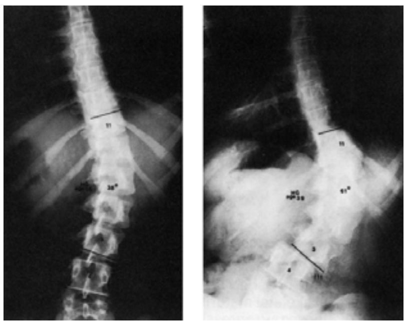

FIGURE 10. Sixteen-year-old girl with 38-degree right lumbar curve from T11 to L3 *(left)*. Her skeletal maturity is assessed as grade 5 on the Risser scale. At 39 years of age, her right lumbar curve has increased to 61 degrees *(right)*. Note the translatory shift of L3 on L4 *(arrows)*. (From Weinstein SL, Ponseti IV (1983): Curve progression in idiopathic scoliosis: long-term follow-up. *J Bone Joint Surg Am* 65:447, with permission.)

In our recent 50-year follow-up of untreated patients, the number of translatory shifts increased dramatically over time, with 20% having at least one translatory shift at maturity, increasing to 71% having at least one translatory shift at 50-year follow up (130).

In double (combined) curves, there were no correlative factors for curve progression after maturity. The apical vertebral rotation tended to be less than that in thoracolumbar curves. The ribs remain level in the thoracic component; therefore, the Mehta angles were usually low. There was no prognostic value in the relationship of the fifth lumbar vertebra to the intercrest line in combined curves (125,128) (Fig. 12). Of note is the fact that at maturity, the magnitude of the thoracic component of the double major curve pattern tends to be larger than the lumbar component; with time, however, there are selectively greater increases in the lumbar curve magnitude as compared with the thoracic curve to balance the patient better. In addition, all patients tend to compensate better with time by increases in their secondary curvatures (125,128).

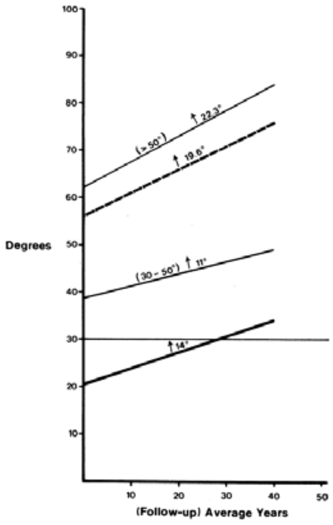

FIGURE 11. Thoracolumbar curve progression after skeletal maturity. The *thick black line* represents average curve progression for all curves of less than 30 degrees at skeletal maturity. The *thick dashed line* represents average curve progression for all curves of more than 30 degrees at skeletal maturity. The *thin black lines* represent average curve progression for each range in parentheses. Progression is not necessarily linear. Lines connect average values at maturity and at average 40-year follow-up. (Adapted from Weinstein SL (1987): The natural history of scoliosis in the skeletally mature patient. In: Dickson JH, ed. *Spinal deformities*, vol. 1, no. 2: *Spine, state of the art reviews.* Philadelphia: Hanley and Belfus, pp. 195–212, with permission.)

Ascani and coauthors (7) published the results of a multicenter Italian study of 187 patients followed for 34 years. The results of this study and the Iowa study (118,120) are similar concerning the amount of progression during the follow-up period for each specific curve pattern. Thus, in considering postmaturity curve progression, curves of less than 30 degrees at skeletal maturity regardless of curve pattern tend not to progress in adult life. Many curves, however, do continue to progress throughout adult life, in particular thoracic curves between 50 and 80 degrees.

Back Pain

The incidence of back pain in the general population is varied and is questionnaire dependent (52). Howe and Frymoyer (60) evaluated 207 patients who were followed a minimum of 10 years after a single lumbar disc operation. They used 14 different questionnaires measuring surgical outcomes and demonstrated that outcome depends on the questionnaire design. In their review, satisfactory outcomes for the procedure ranged from 97% to 60%, depending on the questionnaire (statistically significant). The authors concluded that the reported outcomes for lumbar spinal surgery are significantly manipulated by the criteria selected for the assessment of end results.

The incidence of back pain in the general population is reported to range from 60% to 80% (13,30,52,58,61,70,85,88,129). Jackson and colleagues (61) reported the incidence of back pain in the general population to be 80%; Kostuik and Bentivoglio (70) reported a 60% incidence. Horal (58), in an epidemiologic study of back pain in Gothenburg, Sweden, found that 81% of the population had some spinal pain, with 66% complaining of lumbar pain. Bjure and Nachemson (13) reported a 66% incidence of back pain in the general population, and Frymoyer and coauthors (52) reported a 67% incidence in 292 subjects in a randomly selected group of 1,221 men, with 20% of these subjects having severe pain.

The incidence of back pain in patients with scoliosis is comparable to the incidence of back pain in the general population. In the Iowa long-term follow-up study of 161 living patients with AIS (average follow-up, 40 years), 80% complained of some backache (127,129). In a control group of 100 patients who were age and sex matched and did not have scoliosis, 86% reported backache. Twenty-four percent of the patients with scoliosis had been to a doctor because of back pain, and 6% had been hospitalized for backache. In the control group, 30% had been to a doctor for backache, and 16% required hospitalization (Table 5). The incidence of frequent or daily backache was slightly higher in the scoliosis group (37%) compared with the control group (25%). Patients with lumbar or thoracolumbar curves, particularly those with translatory shifts at the lower end of their curves, tended to have a slightly greater incidence of backache than did patients with other curve patterns. The presence of translatory shifts on radiographs is associated with backache (129).

TABLE 5. Back Pain in Scoliotic Patients

Clinical findings	Scoliotic Patients[a] (Percentage at 40-year follow-up; *N* = 161)	Scoliotic Patients[b] (Percentage at 50-year follow-up; *N* = 106)	Controls[a] (Percentage; *N* = 100)
Never have pain	20	13	14
Rare pain (one to five times in life)	19	13	25
Occasional pain (few days per year)	24	33	36
Frequent pain (few days per month)	20	22	19
Daily pain	17	19	6

[a] Data adapted from Weinstein SL, Zarala DC, Ponseti IV (1981): Idiopathic Scoliosis: Long-term follow-up and prognosis in untreated patients. *J Bone Joint Surg Am* 63: 702–712.

[b] Data adapted from Weinstein SL, Dolan LA, Spratt KF, et al. (1998): Natural history of adolescent idiopathic scoliosis: back pain at 50 years. Presented at the SRS meeting, New York City, September 17, 1998.

In a recent 50-year follow up of these same patients, patients filled out the same questionnaire they filled out at 30- and 40-year follow-up, in addition to filling out a more detailed questionnaire using validated instruments (130). This allowed us to make solid inferences over time and compare the group against an age- and gender-matched group of controls who were all screened physically to make certain they had no evidence of spinal deformity. Our study demonstrated an incidence of current back pain in 77% of scoliotic patients compared with 37% of controls. The incidence of chronic back pain was 61% in scoliotic patients compared with 35% in controls. The ability of these patients to perform activities of daily living and work was similar to that of controls. When patients rated their pain at 30, 40 and 50 years on a scale of 1 (none) to 5 (daily), the frequency of back pain was rated as 3 (occasional) during each study period.

An estimated 1% of patients with scoliosis eventually require surgery specifically for backache, an incidence similar to that for the general population (30,85). Horal (58), in his epidemiologic study, showed that scoliosis cases did not represent a disproportionate number of disability pensions. Furthermore, the three Swedish long-term follow-up studies of AIS, all with follow-up periods of longer than 30 years and all with more than 90% of the patients traced, demonstrated that low back pain is not a significant problem in these patients (69,84,91). The most common complaints of patients with scoliosis include backache at the end of a strenuous day or after unusual activities, with pain generally relieved by rest. The location of the pain is variable and generally unrelated to the location or magnitude of the curve (Fig. 13).

In the Iowa long-term series, at skeletal maturity, only 2% of the patients had any evidence of osteoarthritis. At 40-year follow-up, 38% of the patients had radiographic evidence of degenerative joint disease of the spine (129), and at 50-year follow-up, osteoarthritic changes were seen in 91% of patients (130). The history of back pain in this scoliotic group was generally unrelated to the severity of the radiographic osteoarthritic changes, except in areas of translatory shifts in thoracolumbar and lumbar curves. These changes ranged from minimal osteophyte

formation and mild narrowing at the intervertebral disc space to moderate facet joint sclerosis and rarely to spontaneous fusion on the curve concavity. At 50-year follow-up, more than 90% of the patients had osteoarthritic changes in the spine. Radiographs continued to be unrelated to the duration or intensity of pain (130).

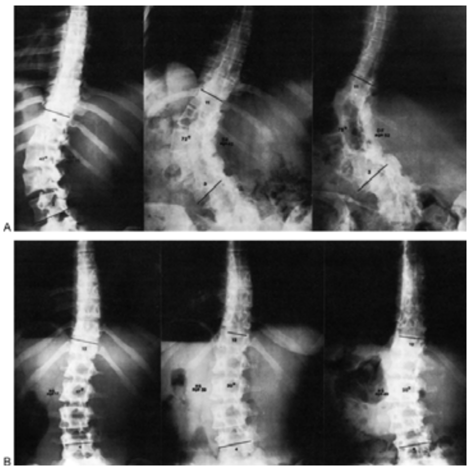

FIGURE 13. A: Fifteen-year-old girl (Risser grade 4) with a 42-degree left lumbar curve from T11 to L3 *(left)*. At 42 years of age *(center)*, the patient's curve has increased 30 degrees to 72 degrees. At 52 years of age *(right)*, the patient's curve has increased 6 degrees, to 78 degrees. Patient never had backache. (From Willner S (1984): Prevalence study of trunk asymmetries and structural scoliosis in 10 year old school children. *Spine* 9:644–647, with permission.) **B:** Seventeen-year-old girl (Risser grade 5) with a 17-degree left lumbar curve from T12 to L4 *(left)*. At 39 years of age *(center)*, the patient's curve has increased 3 degrees, to 20 degrees. At 49 years of age *(right)*, the patient's curve remains stable at 20 degrees. The patient reports daily low backache for as long as she can remember. (From Weinstein SL (1987): The natural history of scoliosis in the skeletally mature patient. In: Dickson JH, ed. *Spinal deformities*, vol. 1, no. 2: *Spine, state of the art reviews.* Philadelphia: Hanley and Belfus, pp. 195–212, with permission.)

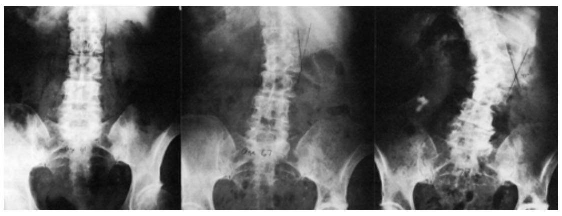

FIGURE 14. Degenerative scoliosis (supine radiographs) at 61 years of age *(left)*, 67 years of age *(center)*, and 77 years of age *(right)*. Note the development of a severe lumbar curve with marked degenerative changes. Clinically, the patient reported increasing back pain. (From Weinstein SL (1987): The natural history of scoliosis in the skeletally mature patient. In: Dickson JH, ed. *Spinal deformities*, vol. 1, no. 2: *Spine, state of the art reviews.* Philadelphia: Hanley and Belfus, pp. 195–212, with permission.)

Back pain may develop in the compensatory curves below lumbar and thoracolumbar curves (30,38,61,85). It must not be assumed that a scoliotic patient's back pain is related to the curve. It is incumbent on the physician to determine whether the cause of pain is curve related or not before treatment decisions are made.

Kostuik and Bentivoglio (70) and Robin and associates (106) demonstrated that lumbar and thoracolumbar curves may arise de novo in adult life. This “degenerative” scoliosis may cause severe pain and discomfort requiring treatment. This type of scoliosis and its related problems should not be confused with the natural history of untreated AIS (Fig. 14). The cause of back pain in the adult scoliotic patient is unknown, but it may be spondylogenic or discogenic in origin.

Pulmonary Function

Only in thoracic curves is there a direct correlation between curve magnitude and effects on pulmonary function (1,9,15,31,32, 53, 56, 59, 64, 72, 76, 77, 83, 93, 96, 111, 112, 120, 129, 131, 137, 141). Pulmonary function studies in patients with untreated AIS demonstrate that only in patients with thoracic curves is there a direct correlation between decreased pulmonary function and increasing curve severity. Vital capacity and forced expiratory volume in 1 second decreased as the severity of thoracic curves increased (Fig. 15). The same correlation applies to PaO_2 (Fig. 16). In all other curve patterns, there was no correlation between curve severity and loss of pulmonary function.

The pattern of pulmonary disease in affected patients is uniformly that of restrictive lung disease (129). Smokers are generally affected much more severely than nonsmokers. Most studies show that significant limitations of forced vital capacity in nonsmokers do not occur until the curve approaches 100 to 120 degrees. The presence of thoracic hypokyphosis, however, increases the loss of pulmonary function associated with curve severity (137). Thus, curves of lesser magnitude with significant hypokyphosis may cause significant diminution of pulmonary function.

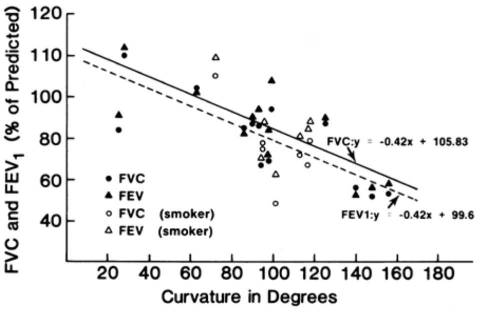

FIGURE 15. Relationship between forced vital capacity (FVC), forced expiratory volume in 1 second (FEV_1), and size of the curve in 20 patients with thoracic scoliosis, using a line of regression. (From Weinstein SL, Zavala DC, Ponseti IV (1981): Idiopathic scoliosis: long-term follow-up and prognosis in untreated patients. *J Bone Joint Surg Am* 63:702–712, with permission.)

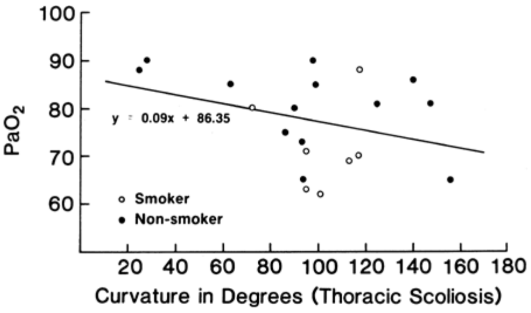

FIGURE 16. Relationship between PaO_2 and size of curve in 20 patients with thoracic scoliosis using a line of regression. (From Weinstein SL, Zavala DC, Ponseti IV (1981): Idiopathic scoliosis: long-term follow-up and prognosis in untreated patients. *J Bone Joint Surg Am* 63:702–712, with permission.)

Mortality

Mortality rates in patients with AIS are comparable to those in the general population (129). Previous natural history studies of scoliosis (84,91) claimed an exaggerated mortality rate for patients with idiopathic scoliosis.

In the aforementioned study by Pehrsson and coauthors (97) on 115 patients with scoliosis of mixed etiology, the average age at death was 54 years (range, 16 to 75 years). Sixty patients were alive at follow-up. All patients were less than 30 years of age at their first visit, with a mean age of 14 years (0 to 30 years). Of the 55 patients who died, 21 died of respiratory failure and 17 of cardiovascular disease. The study confirmed an increased mortality rate in untreated scoliosis if one considers all the etiologies together. No patient with adolescent-onset scoliosis of unknown etiology (AIS), however, died from respiratory failure. Therefore, respiratory failure and premature death may develop in idiopathic scoliosis, but there is no indication from this study that this will occur in patients who have AIS (15,32,97).

In AIS, only patients with high-angle thoracic curves of more than 100 degrees are at increased risk for death from cor pulmonale and right ventricular failure. In the Iowa 40-year long-term study, the mortality rate was 15%, and in only one case was cor pulmonale secondary to scoliosis implicated as the cause of death. Actuarial data for patients born in the same years as the study patients coincided (119,129). At 50-year follow-up, the number of deaths increased as expected but was no different than actuarial predicted rates for patients born in the same years. In only two additional cases could scoliosis be implicated as a contributing cause of death.

Psychosocial Effects

Scoliosis causes varying degrees of cosmetic deformity secondary to spinal rotation. Psychological effects of scoliosis do not appear to manifest in childhood unless curve magnitude is severe. Unhappiness with the rib prominence is often a concern of young patients with severe rotation and rib prominence of more than 3 cm. The same concerns are often expressed by patients treated surgically with large residual rib prominences. The psychological effects of scoliosis have been widely studied (3,5,25,26,46,90), particularly with reference to attitudes toward operative and nonoperative treatment (44). Psychological effects of scoliosis appear to be better tolerated by middle-aged patients than by teenagers (129). Some adults, however, with moderate to severe deformity may become mentally disabled by the deformity (12,129). There is no correlation between the location or degree of the curvature and the extent of the psychosocial effect (129).

Many patients with minimal curvatures have severe limitations psychosocially. These limitations are often expressed as buying clothing to try to hide the deformity. Other patients with severe deformities express little psychosocial limitation and are more accepting of their conditions. There are many studies on the psychological effects, but most conclusions are based on clinical judgment rather than empirical data (12,44). Significant radiographic changes of curvature may not occur over the course of time in many untreated patients. Increase in rotation, however, as manifested by increased rib or paraspinous muscle prominence may develop in the absence of significant changes of the Cobb angle on radiographs (7,130), causing changes in the patient's appearance. In adult patients with untreated AIS, the main concerns are often cosmetic; this is often the major reason these patients seek surgical consultation (68,116). The cosmetic aspects of the disorder should not be underplayed.

Pregnancy

There has been great controversy about whether curves progress during pregnancy and whether scoliotic women can have normal reproductive experiences. With respect to the effects of pregnancy on scoliosis, Nachemson and colleagues (86) demonstrated a statistically significant effect on curve progression in patients who had multiple pregnancies before 23 years of age. They recommended avoidance of pregnancy in the early 20s, particularly in brace-treated patients. Blount and Mellencamp (14) and Berman and coauthors (10) also demonstrated that scoliosis progressed as a result of pregnancy. Blount and Mellencamp related this effect to the curve stability. Bunnell (19), however, was unable to detect any deleterious effect of pregnancy on scoliosis in his natural history study group. In the Iowa series (129), there were only two women who required cesarean sections. Significant complications during pregnancy or delivery were subjectively attributed to the women's spinal deformities (129).

Betz and associates (11) examined the charts and radiographs on 355 affected patients who had reached skeletal maturity (Risser grade 4). These patients were divided into two groups: 175 patients who had had at least one pregnancy (group A), and 180 who had never been pregnant (group B). The groups were comparable with regard to treatment. Curve progression of more than 5 degrees was seen in 25% and progression of more than 10 degrees in 10% of patients in each group. The age of the patient at the time of her first pregnancy did not influence the risk for progression, and the stability of the curve before pregnancy did not decrease the risk for progression during pregnancy.

The authors concluded that pregnancy does not increase the risk for progression of a scoliotic curve in a patient whose curve is not severe. The risk for progression was unaffected by the age of the patient at the time of first pregnancy, the number of pregnancies, or curve stability.

From the obstetric point of view, a recent study by Visscher and associates (122) demonstrated that reproductive experiences of scoliotic women do not differ from those of nonscoliotic women. In addition, in the Betz series (11), the effect of pregnancy and delivery was evaluated in 175 women who had had at least one pregnancy. No specific problems were directly related to the scoliosis, except in four patients in whom delivery posed difficulties. The incidence of cesarean section was half of the national average, and no cesarean sections were directly related to the mother's scoliosis. The authors concluded that mild to moderate scoliosis does not have a deleterious effect on pregnancy or delivery. The incidence of delivery by cesarean section and health problems in children of women who have scoliosis is no greater than that for the nonscoliotic population. These findings mirror the results of the Iowa long-term follow-up study (129).

Summary

Increased public awareness about scoliosis, national scoliosis associations, and screening clinics have resulted in an increased number of children being referred for orthopaedic opinion, less severe curves at initial detection, and early institution of treatment. The natural history data presented in this chapter, particularly with reference to curve progression, are based on limited numbers of patients and are generally based on information from female patients with thoracic curves. Even in patients with progressive curves, we do not know, for example, whether the natural history of a progressive 30-degree curve would be to progress to 38 degrees or to 78 degrees.

Therefore, the conclusions presented in this chapter represent generalities. Decisions for each patient must be individualized, taking into consideration the probabilities of curve progression based on curve magnitude, skeletal maturity, sexual maturity, and age. Appropriate decisions for AIS require a thorough knowledge of natural history. Long-term results of various treatments, surgical or nonsurgical, for AIS must be viewed in light of the natural history of the disorder.

Adolescent Idiopathic Scoliosis: Nonsurgical Techniques

Kenneth J. Noonan

K. J. Noonan, M.D.: Indiana University, Department of Orthopaedic Surgery, Riley Children's Hospital, Indianapolis, IN.

This chapter outlines the different methods of nonoperative treatment in immature patients with adolescent idiopathic scoliosis (AIS). Most of this chapter focuses on bracing because this is the main nonoperative treatment used today. Emphasis is placed on commonly used braces and their pertinent biomechanics, brace manufacture, indications, and brace use. Compliance and complications are discussed. Review of the results of previous studies using nonoperative therapy centers on the effectiveness of treatment in meeting objectives and altering the natural history of AIS.

Physical Therapy

Most would agree that isolated physical therapy has no role in the treatment of AIS. In a controlled study of patients with mild scoliosis, Stone and associates (92) found that progression of scoliosis was not affected by an exercise protocol consisting of pelvic tilts, situps, leg lifts, and trunk strengthening. Only half of their patients were found to be compliant with the protocol. Others have also noted poor compliance with exercises in combination with bracing (64).

It is controversial whether physical therapy in conjunction with bracing has an important effect on halting curve progression. Originally, exercises (pelvic tilts, back extensions, lateral shifts, and chest expansion) were performed in and out of the Milwaukee brace and were considered integral in maximizing treatment. Subsequently, Carman and colleagues (22) evaluated 24 compliant patients treated with bracing—12 who performed exercises as described by Blount and Moe with 12 who performed no exercises. Both groups were similar in age and curve magnitude, yet no difference in outcome was documented. Based on these findings, specific exercises are no longer routinely prescribed to prevent curve progression. Currently, however, patients are encouraged to participate in athletic activities even in the brace. Removal of the orthosis during extreme or contact sports is allowed so that the patient can enjoy the obvious physical and psychological benefits of these activities. Some authors promote specific exercises to avoid atrophy of the paraspinal and abdominal muscles (20) and to prevent possible hip flexion contractures resulting from prolonged brace treatment (33).

Electrical Stimulation

Experimental studies in laboratory animals demonstrated that electrical stimulation could produce scoliotic deformities (9). Extrapolation to human subjects showed that electrical stimulation along the convexity of a curve produces variable initial correction. Because of this, several centers started to use electrical stimulation as an alternative to orthotic treatment in the nonoperative management of immature patients with AIS. Proponents of these systems have theorized better patient acceptance and therefore greater compliance than braced patients (30,54). Immature patients are stimulated for 8 to 12 hours per night in the prone position. This is continued until maturity or failure to halt curve progression.

Originally, some investigators used electrodes that were surgically implanted and controlled by means of external transmitters (15,51). The potential cost and morbidity (including need for removal, infection, or pneumothorax [51]) of implantable systems paved the way for transcutaneous stimulator units. Single (single-curve) or double (double-curve) channeled devices are placed laterally along paraspinal muscles in the convexity of the scoliosis. Greater initial correction of curves is noted with lateral placement of electrodes compared with paraspinal placement. Worsening of curves is possible by placing an electrode in the concavity of a compensatory curve (9).

Several studies reported good results by halting curve progression in 72% to 84% of cases (6,8,15,17,37,51,66). Many were preliminary reports, had poor follow-up, or included patients at low risk for curve progression (6,8,17,37,51,66). Those studies that published results of patients at higher risk for progression or with longer follow-up demonstrated curve progression in up to 56% (21,42,94). O'Donnell and coauthors (80) reported 62 fully compliant patients and noted progression of 8 to 18 degrees in 83% of patients. Similar to natural history studies, greater rates of failure were noted in thoracic and double major curves and in curves with greater magnitude. Other authors have also reported poor results (progression in 50% to 86% of patients), suggesting that electrical stimulation does not alter the natural history of AIS (3,28,76). In addition, with further follow-up, the potential benefit of increased compliance in comparison to bracing has not held true, with rates of noncompliance of 24% to 50% (21,42,54). Decreased compliance is secondary to poor patient tolerance as a result of back pain, difficulty sleeping, and skin irritation because of electrode placement (6,16,21,30,37,51,54). There are currently no indications for electrical stimulation in the treatment of AIS.

Bracing

History of Bracing

The modern history of orthotic treatment in AIS began in the 1940s when external devices were used in the postoperative stabilization of in situ fusion of spinal deformities. In 1946, Blount and Schmidt introduced the Milwaukee brace to be used as alternative to casting after such procedures. In 1958, they suggested that the Milwaukee brace may be useful in the nonoperative treatment of AIS provided the existing deformity would be acceptable at skeletal maturity (14). The Milwaukee brace was the first orthosis to be widely used in AIS; and although many physicians still use this brace, many other types of orthoses have been designed and are currently in widespread use.

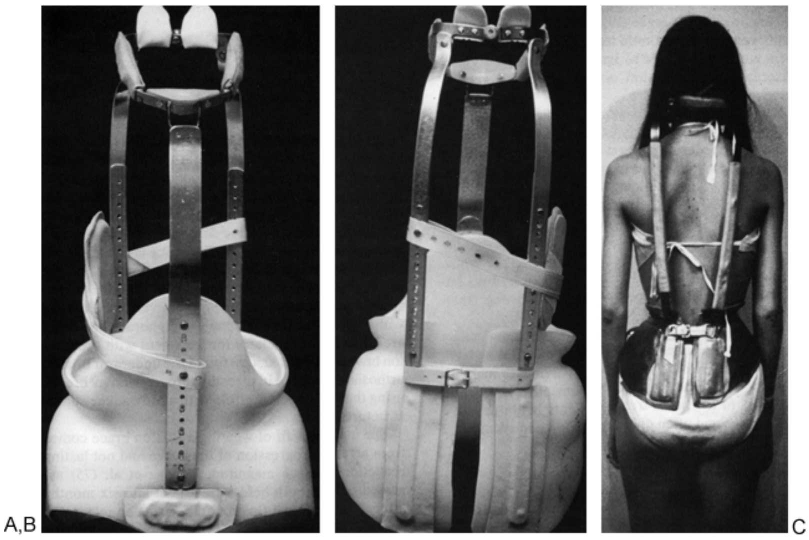

FIGURE 1. The Milwaukee brace. **A:** Front view of the Milwaukee brace, showing the pelvic girdle and lateral rib pad. **B:** Posterior view of the Milwaukee brace. **C:** A patient wearing the Milwaukee brace.

Types of Braces

One type of orthosis used in AIS can be classified as a CTLSO (cervical-thoracic-lumbar-sacral orthosis), for which the Milwaukee brace is the standard. Lower-profile braces that do not immobilize the cervical spine were later developed and are considered thoracic-lumbar-sacral orthoses (TLSOs). TLSOs were primarily designed to circumvent the objectionable appearance of the cervical extension present with the Milwaukee brace, which is associated with poor compliance (20,98). TLSOs can also be classified as *high profile* (higher trim lines) or *low profile* according to their potential for holding curves with apices higher in the thoracic region. Examples of common TLSOs include the Boston brace, the Wilmington brace, and the Miami brace. Other TLSOs have been developed but are not discussed in this chapter (see Chap. 52). Although the Charleston bending brace is technically a TLSO, it is designed to unbend the structural curves and must be worn at night only.

Theoretically, bracing works by applying external forces to the trunk, which imparts corrective force to the spine. Resultant decreases in deformity, as measured by the Cobb method, are thought to alter the growth in some unknown manner, preventing significant progression. Forces that have been used include longitudinal traction and lateral pressure from pads, straps, or the brace itself.

Milwaukee Brace

The original Milwaukee brace consisted of a molded pelvic leather girdle with an attached metal superstructure positioned in slight lumbar flexion (Fig. 1). Over time, the leather pelvic module was replaced by custom-made or prefabricated thermoplastic pelvic modules that are easier and less expensive to construct. To correct lumbar scoliosis, pads are often incorporated into the pelvic portion. Pressure pads (thoracic curves) and trapezius pads and axillary slings (for high thoracic curves) can be attached to the superstructure with leather straps and are adjusted in relationship to curve location. Axillary slings provide a point of counterpressure for thoracic curves with apices from the fifth to the eighth thoracic vertebra (T5 to T8); in addition, they prevent increased pressure at the throat mold. Pad placement is critically analyzed and expected to be below the apical rib with posterolateral pressure.

The superstructure consisting of three metal uprights was chosen to minimize thoracic pressure, possibly leading to pulmonary problems in postoperative polio patients. Attached to the superstructure was a fixed mandibular and occipital assembly used to stabilize the head. Because of potential orthodontic deformity, the mandibular component was later replaced by a throat mold, which serves to position the head over the thorax and the occipital pads. A lower profile design of the Milwaukee brace has been developed for use in patients with lower apical vertebrae.

The patient is thought to produce traction and improve spine correction by actively extending against the occipital pads with movement and prescribed exercises. This theory has not been supported by Galante and colleagues (40), who demonstrated maintenance of corrective forces even during sleep. Forces produced by traction have been estimated to be 10 to 20 Newton, with twice that seen with lateral pads. Subsequent biomechanical studies have demonstrated that correction generated through traction in the occipital and mandibular support or throat mold is possible for minor or moderate curves (40,74). Most of the corrective forces are due to direct pressure from the lateral pads (particularly in larger curves) (5) or backward tilt of the pelvis.

Boston Brace System

The Boston brace system was developed at Boston Children's Hospital in the 1970s and consisted of six standardized prefabricated polypropylene pelvic and thoracolumbar modules lined with soft foam polyethylene. With time, a total of 16 to 20 prefabricated modules became available. It is estimated that 95% of children can be braced with the entire prefabricated inventory, and most children (80%) can be fitted with one of the six original modules. Originally, a cervical superstructure (Boston-Milwaukee brace) was added for curves with an apex above T10 (98).

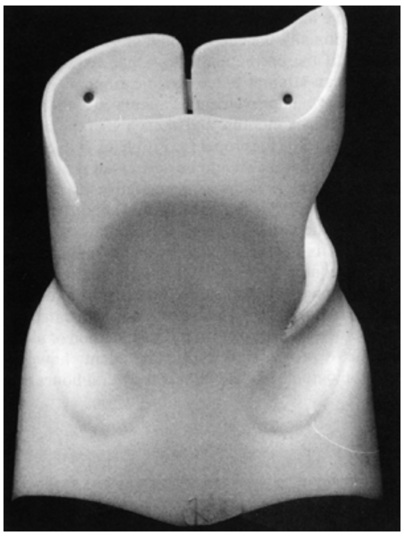

FIGURE 2. The Boston brace.

A brace blueprint is constructed from the radiographs for correct pad placement and trim-line planning. The prefabricated pelvic girdle is trimmed, and pressure pads for derotation are inserted according to the location of the apex on radiographs (Fig. 2). Areas of relief or voids are present opposite pads, allowing passive and possibly active curve movement away from the pads. Lumbar lordosis is purposefully reduced by flexing the spine in the brace with an abdominal concavity and flattening the posterior lumbar contours with low posterior trim lines. Trim lines can be further altered to control the curves with posterosuperior extension (for hypokyphosis) or trochanteric extension (for lower lumbar curves).

The Boston brace system consists of variations according to the curve to be braced and include Boston-thoracic, Boston-thoracolumbar, and Boston-lumbar braces. The Boston-thoracic brace was developed to control thoracic curves with a higher apex (up to T7) without using a superstructure. This was accomplished by adding an axillary support on the concave side with lateral pressure from a convex pad (53,61,96). The main difference in the Boston-thoracolumbar and Boston-lumbar types is due to pad placement and trim lines designed to control each of these curve patterns.

Advantages of the Boston brace include decreased construction time of 2 to 3 hours (98); uniform initial curve correction in the brace greater than 50% (47,98); and better patient acceptance than with the Milwaukee brace (47). The Boston brace diminishes curve magnitude through the use of decreased lumbar lordosis and direct pressure from lateral pads and from the brace itself, which was originally molded on children without scoliosis. Several reports have documented a decrease in the initial Cobb angle measurement of 33% to 50% resulting from a decrease in lumbar lordosis alone (2,62,95,96). In the early 1990s, the original brace design with no lumbar lordosis was modified by incorporating 15 degrees of lordosis into the pelvic module. In a preliminary study, Olafsson and associates (81) documented no difference in initial Cobb angle correction (62% to 65%) between the two different brace designs. However, better derotation of the curves were noted with the later design. Addition of lateral pads with pressure on ribs or the transverse processes in the lumbar spine also contributes to the correction of the curves, with greater effects in minor or moderate curves of less than 50 degrees (24,95).

Wilmington Brace

In the early 1970s, the Wilmington brace was independently developed at Wilmington Children's Hospital in Delaware as an alternative to the Milwaukee brace (Fig. 3). This brace is fabricated from Orthoplast after making a mold of the patient, whose curvature is reduced on a Cotrel or Risser table with transverse forces and longitudinal traction. Transverse reduction forces are produced during the molding at the apices of the curves. After molding the brace, trim lines are cut high in the axilla and low to capture the pelvis yet are trimmed in a manner to allow hip flexion while sitting. The brace is designed as a body jacket with an anterior opening secured with Velcro straps; a cotton undergarment is worn because of its intimate fit. Advantages to this system include greater patient acceptance and relatively inexpensive and rapid production as compared with the Milwaukee brace. The fact that the Orthoplast jacket tended to break down and that there is little room for growth can be counted as relative disadvantages to this system. Commonly, patients would require manufacture of at least two braces during the treatment time period (20). Other centers have used the same brace design principles but have increased durability with polypropylene (48).

Miami Brace

Originally designed in 1975, the Miami brace is a custom-made TLSO constructed of polypropylene with built-in Plastizote pads (Fig. 4). The brace is designed to allow lateral motion away from the curve concavity and promote some hip flexion but limit hip extension. Advantages of this system include a relatively rigid nature and areas of concave pressure relief that stimulate active correction and assist with ventilation in warmer climates. The brace is not adaptable for curves with apices higher than T7 or for kyphotic deformities (67). Preliminary results in 20 patients who have completed treatment have been favorable, but no large studies with longer follow-up have been published to date (67).

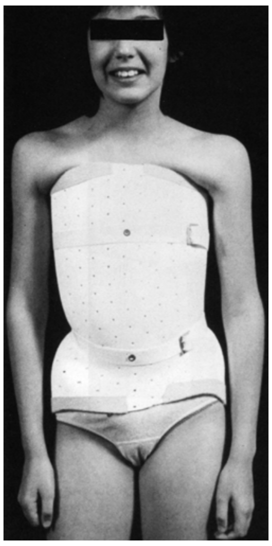

FIGURE 3. The Wilmington jacket.

Charleston Bending Brace

The Charleston bending brace is a custom-made orthosis that was originally developed as an alternative to full-time brace wear (86). During brace production, the orthotist maintains pressure at the apex while applying an unbending force above the curve. A positive mold is made with soft foam padding in areas of maximal pressure. The brace is constructed from two lateral halves riveted in the back to allow anterior opening only. Because of the awkward positioning, this brace is designed for nighttime use only.

Single curves are the easiest to brace, and trim lines are carefully cut to produce maximal unbending of the primary curves without increasing the compensatory curves. In patients with double major curves, it is crucial to determine whether the pattern is consistent with King type I or II curves. In King type I curves, the trim line should be below the rib of the apex of the thoracic curve. If one prescribes a brace with a higher trim line into the axilla (King type II), the thoracic curve is exaggerated. The importance of adequate brace fitting cannot be underestimated, and the manufacturers currently arrange educational seminars for physicians who are unfamiliar with its design and use. At brace fitting, a supine anteroposterior radiograph is obtained in the brace with the Velcro straps sufficiently tightened. Initial correction is considered adequate if there is greater than 75% correction of the primary curve and 20% correction of compensatory curves (Fig. 5). For very stiff curves, it is reasonable to accept the amount of correction seen on side-bending films.

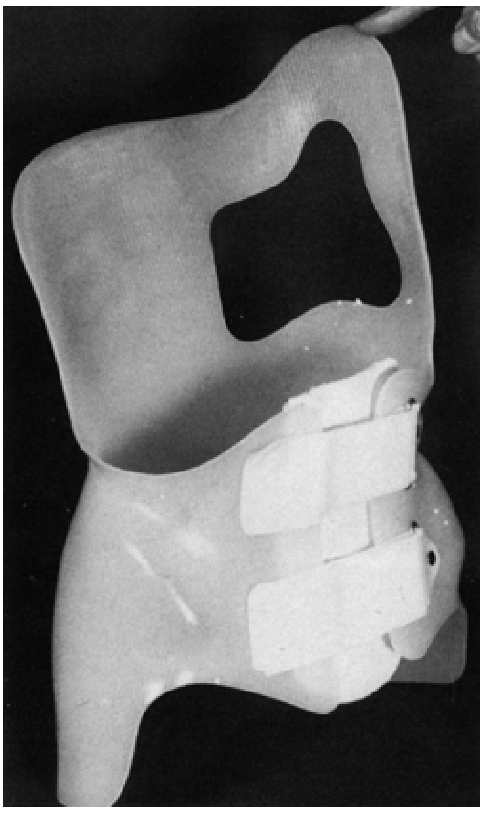

FIGURE 4. The Miami brace.

Indications for Bracing

Before bracing, several key variables must be assessed and determined to be appropriate before recommending treatment in patients with AIS. These variables include maturity, curve magnitude by Cobb measurement, and curve pattern. Bracing is designed to prevent curve progression during the adolescent growth spurt and therefore is not indicated in patients who are skeletally mature. Mature patients are those who have complete capping of the iliac apophysis, have had menses for at least 1 year, and have had no increase in height for at least 6 months.

Bracing is recommended for curves in immature patients (Risser grade 1 or less) with a minimal magnitude of 25 degrees at bracing onset. Curves of less than 25 degrees should be braced only after there is documented progression of 5 degrees or more in patients who are Risser grade 1 or less. Scoliosis greater than

40 to 45 degrees usually continues to progress despite adequate bracing, especially if the patient is relatively immature (Risser grade 1 or less or premenarchal). In patients with well-balanced curve patterns (40 to 45 degrees) (33), it is reasonable to recommend bracing to the patient and family, yet they should be made aware of the increased chance of failure and the possible need for surgery. Curves in immature patients with AIS of greater than 45 to 50 degrees meet indications for surgery and should not be braced.

The use of bracing in more mature patients (greater than Risser grade 2 or who have begun menses within the last 6 months) should be individualized for each patient. Curves that are 35 to 40 degrees should probably be braced. Continued observation in these “more mature” patients with curves of less than 35 degrees is reasonable. In this instance, families should be educated on the diminished likelihood of progression into a surgical range compared with the cost and transient psychosocial effects of bracing. After this discussion, the choice of bracing versus observation is made and is usually more palatable to the patient and family. Additionally, it is important to realize that rates of noncompliance tend to be higher in the more mature patient as opposed to the younger patient (27). Clearly, a brace should not be prescribed to a patient with a social situation that precludes compliant brace wear. Other relative contraindications include severe thoracic lordosis, massive obesity, or insensate or fragile skin.

Finally, the type of curve pattern affects bracing indications. Most believe that curves with an apex at or above the seventh thoracic (T7) vertebra are not amenable to braces without a superstructure, such as that seen with a Milwaukee brace or one of the TLSOs with an attached superstructure. Because the results of bracing with CTLSOs improve in curves with more caudal apices (below T7), some authors question whether any orthosis can alter the natural history of more proximal curves (23,33,64). Additional evidence suggests that not all braces are equally efficacious for all curve patterns. Katz and coauthors (56) compared the results of the Charleston bending brace with the Boston brace in 319 patients. They found the Boston brace system to be more effective in larger curves and in thoracic or double major curve patterns (56). As such, the remaining indication for the Charleston bending brace may be isolated lumbar or thoracolumbar curves of moderate magnitude, for which both braces were found to be equally effective. Double curves may not be as amenable (as compared with single major curves) to bracing because maximal correction of one curve necessarily decreases the correctability of the adjacent curve.

Full-Time Bracing Protocol

After the patient has received a brace, he or she should be examined to ensure that the orthosis fits reasonably well with minimal gaps (less than 1 finger), that the pelvis is adequately captured, and that there are no significant pressure points. Patients are allowed an initial adjustment period of 5 to 10 days, during which the straps can be incrementally tightened, and to increase brace wear up to 22 hours per day. After 1 month of progressive brace wear, the patient should have a standing radiograph in the brace after it is appropriately tightened. This radiograph documents accurate pad placement as well as initial curve correction of the primary and compensatory curves. Most orthopaedists do not prescribe a detailed exercise program, and the brace may be removed for 1 to 2 hours per day for athletic activities, bathing, and swimming. The brace is not designed to be socially restrictive, and the patient should be allowed the opportunity to abstain from brace wear during the occasional special event.

The patient should return every 4 to 6 months for an interview and assessment of problems and compliance. The trunk is examined for signs of skin irritation and pressure points. Most authors recommend follow-up radiographs out of the brace, and some have recommended removal of the brace for a standard time period before radiographs (45). Regardless of preference, radiographs should be done in a standard fashion at each clinic appointment. Full-time bracing is continued until skeletal maturity if the patient remains compliant and there is no significant progression. Some orthopaedists allow decreasing brace wear if there is at least 50% correction after 9 months of full-time brace wear (33).

The typical course of bracing can be summarized in Figure 6 . After bracing is started, the structural curve decreases to a variable magnitude dictated by several factors. These include curve flexibility, presenting curve magnitude, and the unique ability of each brace to correct the curve initially. Greater initial correction is routinely documented with more modern TLSOs (30% to more than 60%) (10,33,53,56,67,96,98,101) as opposed to the Milwaukee brace (less than 30% to 40%) (65,69,78,79,96). In addition, greater initial correction may be expected in younger patients as opposed to older patients (18). It appears from follow-up reports of bracing that better initial correction correlates with improved long-term outcome and decreased risk for progression (23,78,81,82).

With continued bracing, the curve continues to progress from maximal initial correction until the brace is stopped. In the successfully braced patient, the curve magnitude at brace cessation is less than or equal to curve magnitude at presentation. Brace weaning is begun based on certain radiographic or chronologic features. Most authors recommend full-time bracing until Risser grade 4 in girls. In boys, continued curve progression has been noted until Risser grade 5; therefore, boys should be braced until full healing of the iliac apophysis (55). Other indicators of maturity can be used when the Risser status is difficult to evaluate or is discordant with other features. Full-time bracing is recommended until there is cessation of longitudinal growth for at least 6 months, the vertebral ring apophyses have fused, female patients have had menses for at least 1 year, or a skeletal age of 15 to 16 years has been reached according to the Gruelich and Pyle atlas. After skeletal maturity is documented, the patient is started on gradual daytime weaning to nighttime brace wear over 8 to 12 months. Brace wear is encouraged during the night until the brace breaks or no longer fits.

After skeletal maturity and complete stoppage of brace wear, the patient should have radiographs at increasing intervals to assess for curve progression. The degree of curve progression after bracing varies between each study and depends on curve magnitude when the brace is stopped. Postbrace progression may average up to 3 degrees a year (49), yet most reports document progression to be less than 1 to 3 degrees per year (10,23,65,69,73,78,79,84,93).

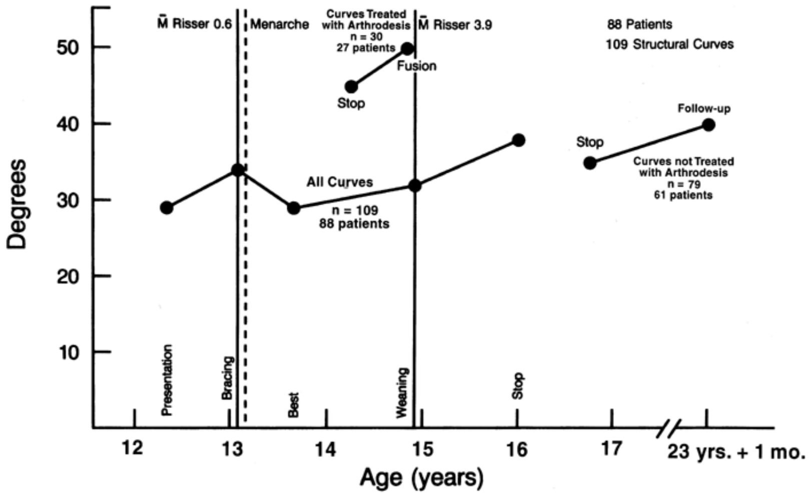

FIGURE 6. Graph of the results of Milwaukee bracing for all structural curves from the report by Noonan and colleagues (78). After brace initiation, there is progression from the time of the best correction in the brace *(Best)* to the time when bracing was stopped *(Stop).* There is also continued progression of the curves that were not treated with an arthrodesis from the time when bracing was stopped to the time of follow-up. In successfully managed patients, the initial curve is equal to that at the time of brace cessation.

The total magnitude of progression obviously depends on the available length of follow-up in the literature. Most practitioners follow patients for several years after brace cessation to determine whether the curve progresses to a surgical magnitude. Montgomery and colleagues (73) studied the degree of progression in 168 patients for an average of 6.9 years after successfully brace management. The average progression was 5.1 degrees, and they concluded that progression of the curve may continue into the 20s. They determined, however, that follow-up of 2 years is sufficient to detect and treat malignant progression in 97% of cases.

Compliance With Full-Time Brace Wear

It is difficult to assess the degree of treatment compliance resulting from uniform patient dissatisfaction with bracing. The disparity of actual and reported brace wear remains unknown because no compliance meter is widely used. Each patient is caught in a conflict of trying to please parents and physicians with the unpleasantness of bracing; especially during school hours (27). Patients are at higher risk for adjustment and compliance problems if they have lower overall intelligence or if they are not adequately educated to the benefits of bracing versus the implications of further curve progression (33,99). Other risk factors include concurrent personal or family strife (50); older versus younger adolescence at treatment onset (27,46); treatment with a CTLSO versus a TLSO (98); and longer duration of treatment (27,75). Authors report some noncompliance in 10% to 85% of patients (20,23,26,27,31,36,46,57,67,71,75,78,81). The wide disparity is due to variable ways of defining complete compliance, partial compliance, and noncompliance. Compliance is probably increased with supportive families and a medical team that fully educates each patient to the benefits of bracing. Scheduling clinic appointments with other patients who are similarly treated decreases the sense of isolation and stimulates patient acceptance and understanding.

Another approach to brace wear is to assume a certain degree of noncompliance and to make the brace more acceptable by decreasing the number of prescribed hours. DiRaimondo and Green (27) compared 38 patients who were prescribed full-time brace wear with 38 patients who were prescribed part-time brace wear. After 2 years of treatment, all patients were wearing the brace only 8 to 9 hours per day irrespective of their bracing schedule. Whether decreasing the number of hours of prescribed brace wear effects outcome is subject to some debate. From a practical standpoint, however, noncompliance with full-time bracing is probably underestimated, and it is unclear how many hours of actual brace wear are required to alter the natural history of immature patients with AIS.

Results of Bracing

Postural Changes With Bracing

In addition to the main goal of preventing curve progression, braces have been reported to improve spinal decompensation, posture, and cosmetic appearance (57,79). Moe and Kettleson (71) had noticed in some patients with double curves that bracing had improved cosmesis with less rib prominence and better balance despite little improvement in Cobb angle measurement. Further studies with the Milwaukee brace have documented variable short-term and long-term improvements in spinal decompensation (90) or truncopelvic alignment (4). Rudicel and associates (90) examined 22 patients with lumbar or thoracolumbar curves treated with the Milwaukee brace and found no predictable improvement in this small study. In a larger study by Andrews and coauthors (4), an improvement in “truncopelvic alignment” (lateral trunk shift) was documented in 14.6% at brace cessation. Although 49% of patients demonstrated an improved alignment at follow-up, the correction was considered unpredictable and the actual correction in centimeters was small. In a thesis from the Netherlands, Styblo (93) failed to demonstrate any significant predictable improvement in rib hump after treatment with the Milwaukee brace. On the other hand, he recorded some improvement in spinal dysbalance at follow-up; most improvement was noted in patients with imbalance greater than 1 centimeter at treatment.

Two studies of the Wilmington brace have documented improvements in lateral trunk shift and spinal decompensation. Bassett and colleagues (11) defined lateral trunk shift as the radiographic distance from the center of the trunk to a line connecting C7 to the center of the sacrum. Before bracing, trunk shift averaged 1.9 to 2.2 cm, with slightly more shift noted in lumbar or thoracolumbar curves. At an average follow-up of less than 2 years, these authors documented an average improvement of trunk shift to 0.9 to 1.2 cm. In 61% of patients, there was an improvement in lateral trunk shift that was independent of curve progression. A later study from the same institution (12) documented improvement in spinal decompensation (defined as the distance of C7 to the center sacral line) in 71 patients treated with the Wilmington brace. In this study, all patients had decompensation greater than 1 cm, with an average prebracing decompensation of 1.9 to 2.5 cm. At follow-up, the average distance improved to 1 to 1.4 cm, depending on curve pattern. Of 18 patients with decompensation greater than 3 cm, all had an average of 2.1 cm improvement. Based on these two well-documented studies, the authors suggest some cosmetic benefits to bracing that may be independent of the effect on Cobb angle measurements. On the other hand, two studies using stereoradiographic techniques or CT scans in patients treated with the Boston brace failed to demonstrate changes in rib hump, rotation, or spinal balance (60,100).

In summary, it is controversial whether bracing results in significant long-term improvements in posture as quantified by rib hump, spinal balance, or trunk shift. Although several well-documented studies have suggested improvement in spinal balance or trunk shift, it is likely that the effects are small. Additionally, one should keep in mind that reliability and variability testing for measurement error have not been performed and that the natural history of these parameters in untreated patients is unknown.

Results of Bracing on Curve Progression

To determine the effectiveness of bracing, it is important to have an abbreviated understanding of the fate of untreated curves in immature patients with AIS. Key factors that affect the natural history are curve magnitude and maturity. Lonstein and Carlson (63) documented progression of greater than 5 degrees in 68% of patients who have curves from 20 to 30 degrees and who are Risser grade 0 or 1. Others have documented progression of 52% to 79% in immature patients whose curves measured 20 to 30 degrees at presentation (19,39,85,89). Peterson and Nachemson (83) recently reported progression of 6 degrees in 50% of patients with curves from 25 to 35 degrees treated with electrical stimulation or observation. Higher rates of progression have been noted in curves with greater curve magnitude (19,39,76,83). In addition to these factors, differences in curve pattern are likely to affect different rates of progression in untreated patients. In general, lumbar or thoracolumbar curves are less likely to progress than are double or thoracic curves (19,29,63).

Part-time Brace Wear

Some physicians have recommended part-time brace wear to make bracing less invasive to normal adolescent life. The prescribed time for part-time brace wear may vary from nighttime-only wear (Charleston bending brace) to less than 22 hours per day (usually without having to wear the brace during school). In 1986, Green (45) reported 44 patients treated with either a Milwaukee or Boston brace for 16 hours per day. In this report, the average curve at bracing was 31 degrees; at a minimum follow-up of 5 months, the authors noted that 89% of their patients had no progression of their curves and that compliance was greater than 90% in patients. They concluded that part-time brace wear does decrease the risk for progression. Two other reports of patients treated with the full-time Boston brace were also unable to determine differences in results between compliant patients (full-time brace wear) and partially compliant patients (part-time brace wear) (33,82).

The Wilmington brace has also been prescribed on a part-time basis with good results (3,48). Allington and Bowen (3) compared the effectiveness of full-time versus part-time (12 to 16 hours/day) bracing and patients treated with electrical stimulation. All patients met contemporary indications for bracing and were followed to maturity. The rates of progression greater than 5 degrees were 36%, 41%, and 70% of patients treated with full-time bracing, part-time bracing, and electrical stimulation, respectively. No significant differences between full-time and part-time wear were detected.

As mentioned previously, the Charleston bending brace was designed for nighttime-only wear. After presentation of favorable preliminary results (35,86), longer-term follow-up on patients treated exclusively with the Charleston bending brace is available. Price and associates (87) presented results of a prospective multicenter trial of 98 patients treated for curves between 25 to 49 degrees who were Risser grade 2 or less at treatment onset. At minimal follow-up of 1 year, they reported no curve progression in 66% of patients, with acceptable results in 79% of patients who did not require surgery or change to a different orthosis. Similar to Katz and colleagues (56), better results were noted in single lumbar or thoracolumbar curves as opposed to double curves.

In summary, from these papers, it appears that part-time brace wear is at least as effective as full-time brace wear in the management of AIS. If this is true, patients who are prescribed full-time brace wear may not be fully compliant and are actually wearing the brace in a part-time manner (27). Alternatively, both protocols are meeting a minimal number of hours required to alter the natural history of AIS.

Full-time Brace Wear

Milwaukee Brace

The earliest and largest experience of bracing has been reported over the years from physicians in Minneapolis and St. Paul, Minnesota. In 1970, Moe and Kettleson (71) reported the results of 169 juvenile and adolescent scoliosis patients treated with the Milwaukee brace. With mean correction ranging from 10% to 23%, the authors conclude that the Milwaukee brace was effective in controlling mild to moderate scoliosis. In 1980, Carr and colleagues (23) continued studying 74 of 133 patients with greater than 5 years of follow-up. In this series, the overall correction in thoracic, lumbar, and high thoracic curves was 2, 4, and -1 degrees, respectively. Greater progression was noted in larger curves or curves that did not have substantial correction in the brace. A later separate review of 95 patients with only thoracic curves of 30 to 39 degrees also demonstrated effective control of curve progression in 84% of patients (102). In 1994, Lonstein and Winter (64) presented the cumulative experience of Milwaukee bracing in 1020 patients treated from 1954 to 1979. Twenty-two percent of patients required surgical intervention; in the remaining patients, the authors noted an average improvement of 1 to 4 degrees. The authors selected a subgroup of patients who would meet contemporary brace indications for comparison with natural history data. They concluded that the Milwaukee brace is effective in preventing curve progression in 20- to 29-degree curves at the time of brace cessation. However, significant differences could not be found at the time of follow-up; nor could significant differences be found in braced curves from 30 to 39 degrees at brace cessation or follow-up.

Other centers have also published good results of Milwaukee bracing, with average corrections at the time of follow-up from 1 to 6 degrees, depending on curve location (4,31,57,69,70,79). These authors concluded that the Milwaukee brace is effective in preventing curve progression. When looked at objectively, these studies have some shortcomings because of short or incomplete follow-up, exclusion of noncompliant or surgical patients, or inclusion of patients at low risk for progression. In 1991, Styblo (93) presented a well documented thesis of 290 patients treated with Milwaukee bracing. In a selected subgroup of 128 patients, he recorded no progression in 72% of patients. The patients who required surgery or had progression tended to be younger and skeletally immature with less correction in the brace. Cochran and Nachemson (26) reviewed 85 of 95 compliant patients treated with the Milwaukee brace. The average curve at bracing was 30 degrees, with 4 degrees of progression at follow-up. Based on their findings and the shortcomings of previously published papers, they concluded that the true effectiveness of bracing had yet to be determined.

In 1996, we reported our results in 111 patients treated with Milwaukee bracing (78). In an effort to eliminate some of the bias present in previous publications, we restricted our study to 88 patients who were considered at high risk for progression. At an average follow-up of 6.3 years, we documented progression of 5 degrees in 48% of patients. Forty-two percent of patients had or met radiographic indications for surgery. Patients who failed treatment tended to be younger and to have decreased maximal correction in the brace. Based on these findings, we questioned whether the Milwaukee brace significantly alters the natural history of progressive AIS.

Wilmington Brace

In 1980, Bunnell and coauthors (20) presented initial results of the Wilmington brace in 48 patients. After initial correction of 74% in the brace, progression of more than 5 degrees was noted in only 10%. Later follow-up in 79 patients with curves from 20 to 39 degrees in patients who were Risser grade 1 or less was published by Bassett and colleagues (10). In this paper, the mean initial correction was 50%; at an average follow-up of 2.5 years, only 28% had progression greater than 5 degrees. Thoracic and double major curve patterns were noted to have greater rates of progression. In 1990, the group was reexamined at an average follow-up of 8.1 years (84). Only 12% of patients required surgery, and 21% had progression after the brace was discontinued. This series of papers from Wilmington suggests a positive effect on the natural history and corroborates similar results on two later papers comparing full-time and part-time treatment with the Wilmington brace (3,48).

Boston Brace

After the Boston brace was introduced, several authors presented preliminary results of initial curve correction ranging from 40% to 65% (41,61,81,96,98,101). Greater initial correction with the Boston system has been appreciated with lumbar and thoracolumbar curves as opposed to double, thoracic, or high thoracic curves. In 1984, Jonasson-Rajala and associates (53) examined the efficacy of the Boston-Milwaukee, original Boston, and Boston-thoracic braces. In their study and in comparison with the literature, they found that the Boston-thoracic brace gave better initial correction than the other types. The only exception is in the lumbar region, where initial correction is better with the original Boston brace. This paper and that by Laurnen and coauthors (61) have examined the Boston-thoracic brace and documented potential success with apices up to T7.

In 1986, Emans and colleagues (33) presented follow-up data on 295 patients treated with the Boston or Boston-Milwaukee braces. At an average follow-up of 1.4 years, only 11% of patients required surgery, and progression of 5 degrees or more was documented in 7% of cases. Progression and need for surgery were more likely in patients younger than 13 years of age with curves greater than 30 degrees. The authors found no difference in results between the Boston and the Boston-Milwaukee brace in curves with apices at T7 or below. Katz and colleagues (56) recently published a comparative study between the Charleston bending brace and the Boston brace. In this study, the Boston brace significantly outperformed the Charleston bending brace. Thirty-four percent of patients treated with the Boston brace had progression greater than 5 degrees; surgery was required in

16% of patients. Both studies are limited because of short follow-up, although the report from Boston also includes some patients at lower risk for progression.

Despite the good results published, one study questioned the ability of the Boston brace to affect the natural history (43). In this study from two centers, 32 patients treated with bracing were compared with 32 patients matched by curve size, location, and age, and all were noted to be Risser grade 0. The authors did note a nonstatistical improvement in braced patients; however, there was no significant difference in regard to curve progression greater than 10 degrees or progression beyond 45 degrees. Although provocative, the results should be viewed in light of possible selection bias.

Other publications have compared the results of the Boston brace or similar TLSOs with those of the Milwaukee brace. In these studies, the Milwaukee brace has been inferior in regard to initial correction and final outcome (72,97). In 1998, Howard and coauthors (52) compared 35 patients treated with the Milwaukee brace with 45 and 95 patients treated with a TLSO and the Charleston bending brace, respectively. In this study, no differences in presenting age, curve magnitude, or Risser grade was noted. At follow-up, the TLSO demonstrated significantly decreased rates of progression of 6 and 10 degrees in comparison to the other two braces. Although these studies are convincing, one must keep in mind that selection bias may exist whereby patients with higher apical curves (and worse prognosis) are preferentially treated with a Milwaukee brace.

Scoliosis Research Society Study

In 1995, Nachemson and Peterson (76) presented the results of a prospective multicenter trial of 286 female patients with thoracic or thoracolumbar curves from 25 to 35 degrees at presentation. Three treatment protocols included a TLSO, electrical stimulation, and observation. In this landmark article, the percentages of curve progression greater than 5 degrees were 26%, 66%, and 67%, respectively. These findings demonstrate a statistically significant effect of bracing in this population over observation and electrical stimulation—both correlating closely with previous published natural history studies. These patients, however, were followed to the end of bracing only, and it remains to be seen whether differences in curve magnitude will continue to exist between the groups after 5 years of follow-up.

Complications of Brace Wear

Although bracing is considered nonoperative treatment, it should not be considered conservative treatment because complications are possible and have been reported. Potential complications include pain, alterations in renal and pulmonary function, skin irritation or pressure sores (up to 16% [71]), nerve irritation (meralgia paresthetica [45] or axillary nerve pressure [86]), and psychosocial impairment.

Renal testing of patients treated with the Boston brace has demonstrated that transient changes in the glomerular filtration rate, renal plasma flow, and urinary excretion of sodium return to normal after prolonged brace wear (1,13). Pulmonary function testing has also been performed by multiple investigators. Various parameters in pulmonary function testing have been altered by up to 80% of normal values after immediate bracing with both the Milwaukee brace and various TLSOs (20,88,91). It is theorized that these changes may be due to cephalad displacement of abdominal contents (58) or restriction of the chest wall. With time, however, most parameters return to normal, and no significantly deleterious effects of bracing on lung function have been recorded (59,88,91).

Normally, significant stresses are already present in adolescents because of rapid physical change and emerging concept of self and secondary sexual characteristics. In patients to be braced, it is important to recognize these issues because compliance and possible family and personal stress are directly related. Clayson and associates (25) compared 23 braced and 23 surgically treated patients with 23 age-matched controls. The scoliosis patients were found to have lower self-esteem and body image than controls; the surgical patients had slightly higher self-esteem than braced patients. In a detailed retrospective review by Fallstrom and colleagues (34), 157 treated patients (92 with arthrodesis; 65 with Milwaukee bracing) were evaluated at a minimal 5-year follow-up. In this study, surgical patients had less anxiety, were more satisfied with their treatment, and had higher body image. The authors concluded that although braced patients were getting on fairly well, they felt that the brace led to a lesser body image that may complicate identity development.

In 1997, we examined the psychosocial characteristics of 95 patients treated for scoliosis with bracing or with both bracing and surgery (77). Although there were no significant long-term signs of depression, the scoliosis patients who were between 13 and 21 years of age felt that they were more frequently discriminated against than did a group of age-matched controls. Fortunately, as they aged, this difference became insignificant. The results of this study are encouraging in that we found relatively few differences between the patient and control samples. These findings correlate with previous literature on the psychosocial effects of bracing. In such patients, a fairly standard initial psychological effect is present and includes anxiety, fear, and withdrawal. Fortunately, these problems usually improve with time (7,32,34,44,50,68,75).

Future Directions for Nonoperative Treatment

At this time, it appears that bracing is the only nonoperative modality that has been shown to affect progression in the immature patient with AIS. Further efforts need to be continued in the areas of optimizing brace design and to develop ways to improve the assessment of compliance. After an accurate means of documenting compliance is in place, we will be able to determine how much time is needed to alter the natural history. It is hard to evaluate the current literature when we are not sure how often and how well the treatment is applied.

Bracing as a treatment in AIS is still a controversial topic. Some physicians who treat AIS are convinced that bracing either is or is not effective. Most physicians who continue to prescribe braces may not be completely convinced of their practical effectiveness. This situation stems from differences and flaws in the older literature in comparison to more recent articles. Historically, older reports of bracing often included patients at low risk for progression because of small curve magnitude or increased skeletal maturity. Additionally, some publications exclude surgical patients from their follow-up analysis, which biases results in a favorable manner. Other studies exclude noncompliant patients, and one should also question the practicality of a treatment that cannot be effectively used because of poor patient acceptance. Further hindrances include grouping of adolescent and juvenile patients; poor documentation of risk factors; short-term or inadequate follow-up; and a failure to compare results with natural history controls.

It is true that bracing alters the natural history in smaller curves (20 to 35 degrees) by significantly lowering the rate of progression of 5 to 6 degrees in selected curves (76). However, it is not known whether similar effects are present in larger curves (35 to 45 degrees). It is well known that the risk for progression is much greater in this group (38,73). If one assumes a minimal magnitude (45 to 50 degrees) to be an indication for surgery in immature patients, perhaps we should reexamine the natural history and the results of bracing in more practical terms.

In the recent Scoliosis Research Society study, significant improvements in rates of curve progression are noted with bracing, yet it is unknown whether differences in surgical treatment also exist (76). In other words, a 30-degree curve that is braced would currently be considered a failure if it progressed to 38 degrees at maturity. On the other hand, this patient could be considered to have had a successful treatment because he or she is unlikely to require a spine fusion. Possibly, we should reanalyze the natural history in untreated patients and determine the incidence of progression to a surgical range for patients grouped according to presenting curve magnitude and maturity. Subsequently, braced patients should be similarly evaluated for the incidence of surgical indications according to their magnitude and maturity at treatment onset. Only when this information is readily available will we be able to determine whether bracing decreases surgical indications and to what degree. Perhaps only a minority of patients will practically benefit from bracing, and therefore the cost effectiveness of this treatment would need to be critically evaluated. With further genetic and biochemical research, we may be able to identify which patients are likely to progress to a surgical range and thus be more selective in the nonoperative treatment of patients with AIS.

Adolescent Idiopathic Scoliosis: Surgery

Keith H. Bridwell

K. H. Bridwell, M.D.: Washington University School of Medicine, St. Louis, MO.

Surgical treatment of idiopathic adolescent scoliosis continues to evolve. In the 1960s, Harrington instrumentation was introduced (29,49,50,82). In the late 1970s, sublaminar wires were introduced principally for paralytic deformities (85) but were also applied to idiopathic scoliosis, as were intraspinous Wisconsin wires (31,42,56,57). In the mid-1980s, instrumentation was further segmentalized into the use of two-rod multiple-hook configurations (1,2,26,58,75,78,113,117,119), which have now been expanded to the use of pedicle screws (4,20,47). Most commonly pedicle screws are applied at the thoracolumbar junction and the lumbar spine (4,47), although some authors also favor its use in the thoracic spine (124).

The goal of surgery in idiopathic scoliosis remains the same. It is desirable to obtain a solid fusion and to have the top and the bottom of the fusion balanced within the stable zone (63,67) (Fig. 1). It is desirable in most instances for the top and the bottom of the fusion to be neutral (Fig. 2) and level to the sacrum and pelvis (14,63,67). Autogenous bone works as a source of bone graft (13,51). Some authors have suggested that allograft may work (10,30). Others have suggested that bone graft may not be necessary if a complete facet excision is performed and the spine is immobilized with segmental fixation (37).

Investigators are exploring the role of anterior instrumentation for thoracic curves (9,53,62) as well as lumbar and thoracolumbar curves. Thoracoscopic and other endoscopic techniques for thoracic curves are also being considered (107).

Consideration for Surgical Treatment

Indications for surgical treatment of idiopathic adolescent scoliosis are relative. In terms of a specific Cobb number, the usual “tide mark” that is considered by most surgeons is 50 degrees (67). At 50 degrees, deformities are usually cosmetically noticeable, and natural history studies such as those by Edgar (34) and Weinstein (133,134) suggest that progression into adulthood is more likely in curves that exceed 50 degrees. We have to remember that idiopathic scoliosis is a three-dimensional deformity; hence, considerations regarding the axial and sagittal planes play a role in decision making. If conservative or active daytime brace treatment fails and the curve progresses beyond 40 degrees with a substantial amount of growth remaining, recommendation for surgical treatment may be appropriate (13).

The curve pattern is a factor. The tide mark for considering surgery for balanced double major curves is somewhat higher than for a single curve (13). “True” double major curves require long fusions, and most surgeons think twice about fusing both the thoracic and the lumbar curve unless the deformity is more substantial (15,67). Remember that just because the designated tide mark may be 50 degrees, this does not mean that all curves of more than 50 degrees have to be fused and instrumented. It simply means that at 50 degrees, one should consider the pros and cons of surgical treatment.

Preoperative Workup

Idiopathic scoliosis is still a diagnosis of exclusion. We do not have a clear understanding of its etiology. Before defining a curve pattern as idiopathic, one must consider other etiologies, such as neoplasm, inflammation, neurologic disease, muscle disease, central nervous system disorders, and neural axis anomalies, such as syrinx, Chiari malformations, or tethered cords.

If the patient has a left thoracic curve or spinal cord or nerve root signs, appropriate magnetic resonance imaging (MRI) studies should be completed before definitive surgical plans are made (41). If the patient has a substantial thoracic curve, pulmonary function tests may enter into the decision-making process regarding whether it is being treated anteriorly or posteriorly or whether thoracoplasty should be considered (5,8,39,118,123).

Radiographic analysis should include long-cassette standing coronal and lateral radiographs of the spine. These radiographs should be long-cassette 3-foot films and not a series of 14- × 17-inch radiographs because these will not provide an adequate representation of the patient's coronal and sagittal balance. A set of flexibility films should also be performed. Potential flexibility films include right side-bending, left side-bending, push-prone (13,15), and fulcrum-bending radiographs (22). These represent assessments of the flexibility of curves. The purpose of the push-prone radiograph is to apply a maximal force on one curve to see how the other curves above and below respond (13,15). This helps the surgeon decide whether one curve or several curves should be fused and instrumented. Some authors suggest that fulcrum-bending films demonstrate more correction than side-bending radiographs (22). Opinion varies regarding whether a traction film or a supine or standing side-bending radiograph demonstrates more correction (108,127). There are no right or wrong answers regarding which flexibility radiographs should be obtained (Table 1).

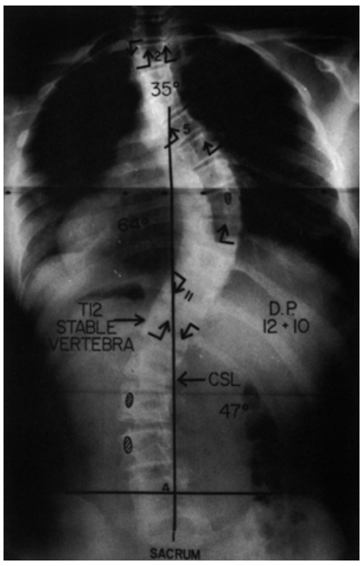

FIGURE 1. Identification of the stable zone, center sacral line, and stable vertebra: The determination is made on a standing coronal long cassette radiograph with the pelvis level. The center sacral line (CSL) is drawn through the midpoint of the sacrum perpendicular to the pelvis. The vertebra bisected by this line is the stable vertebra. Two vertical lines constructed perpendicular to the pelvis intersecting the S1 pedicles represent the stable zone. The center sacral line represents the center of the stable zone.

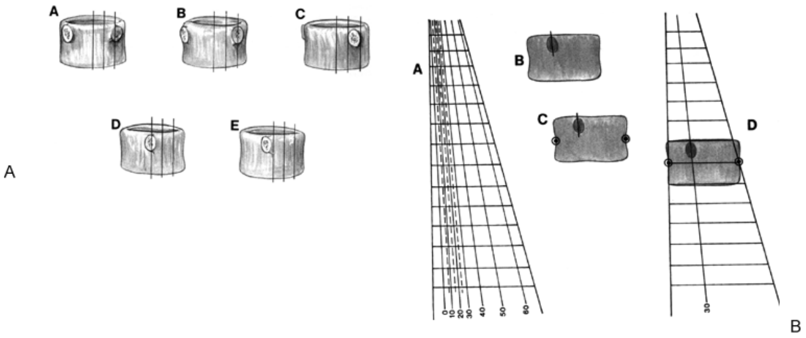

FIGURE 2. Vertebral body rotation, Nash-Moe method, Perdriolle method. **A:** Grade of rotation is determined by the location of the convex pedicle. As more rotation occurs, the concave pedicle disappears, and the convex pedicle moves in to the apparent midpoint of the vertebral body. **B:** Perdriolle method of measurement of vertebral rotation.

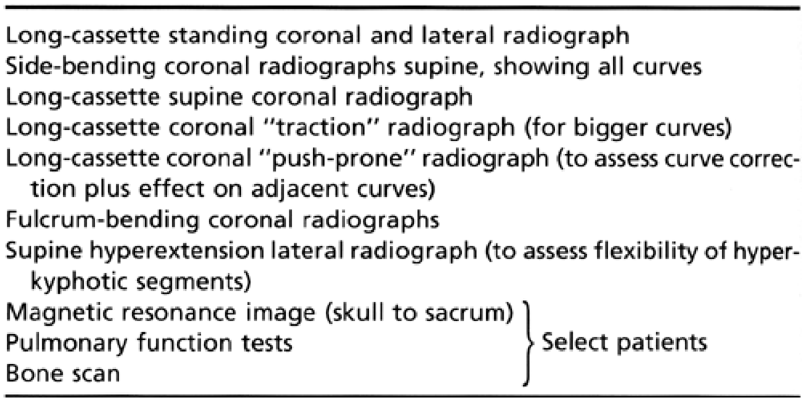

Long-cassette standing coronal and lateral radiograph

TABLE 1. Preoperative Workup

The additional value of side-bending radiographs relates to whether certain transitional discs bend two ways or one way, which may be a determinant of where a fusion stops if the fusion and instrumentation is being performed posteriorly. Within a curve, it is advisable to fix all levels within that curve down to the transitional and neutral vertebrae on the top and the bottom. There is some suggestion that with pedicle fixation, it may be possible to limit the fusion to those segments stopping at the neutral and transitional vertebrae both proximally and distally (4,47). With hook constructs, it has been recommended that the distal level be the "stable" vertebra, the one that is intersected or bisected by the center sacral line, which is a line drawn

through the center of the sacrum and perpendicular either to the top of the pelvis or the floor (63). To some extent, the appropriate level to fix proximally is determined by the sagittal plane as well. In the sagittal plane, the top and the bottom of the fusion should be transitional, in an area of relative lordosis, and within the weight-bearing line. Established teaching was that posterior fusion should stop two levels above and one level below the transitional segments (49,50), which was appropriate for Harrington instrumentation and systems employing only sublaminar wires or Wisconsin wires. Those levels can at times be shortened if fixation is achieved at every level with hooks or pedicle screws and if the "saving of levels" is compatible with the sagittal plane. Potentially, a disc space that points the opposite way on a standing film and points both ways on side-bending films can be excluded from the fusion (76) (Figs. 3 and 4 ; Table 2).

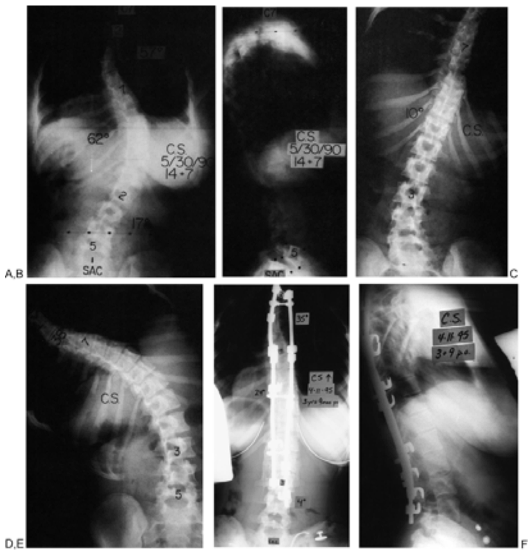

FIGURE 3. This patient presented with characteristics of both a type V and a type IV curve. Because the type IV curve was very flexible and the L3–L4 disc was out of the lower curve and bent both ways on the benders, it was possible to stop at L3. If Harrington instrumentation were used, the construct and fusion would have gone to L4. **A:** Standing coronal radiograph preoperatively. **B:** Standing sagittal radiograph preoperatively. **C:** Right side-bending radiograph preoperatively. **D:** Left side-bending radiograph preoperatively. **E:** Standing coronal radiograph postoperatively. **F:** Standing sagittal radiograph postoperatively.

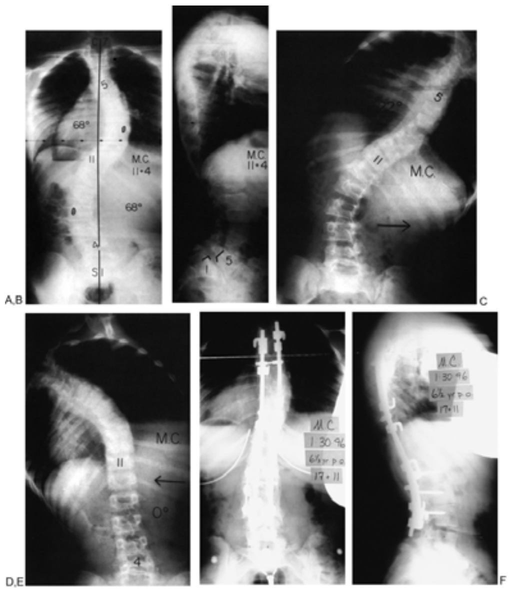

FIGURE 4. This was a double major curve pattern. The thoracic and lumbar curves had equal structural characteristics radiographically, although the lumbar curve was more flexible. Clinically, the thoracic and lumbar curves produced equal amounts of deformity. The L3–L4 segment was quite flexible. L3 was close to being neutral in rotation. It was, therefore, possible to stop at L3. With Harrington or Luque instrumentation, fusion would have been done to L4. **A:** Standing coronal radiograph preoperatively. **B:** Standing sagittal radiograph preoperatively. **C:** Right side-bending radiograph preoperatively. **D:** Left side-bending radiograph preoperatively. **E:** Standing coronal radiograph postoperatively. **F:** Standing sagittal radiograph postoperatively.

TABLE 2. When Can an Additional Lumbar Level Be Saved with Posterior Derotation Systems?[a]

1. L3 within 10° of neutral on standing coronal radiograph
2. The L3–L4 disc symmetrical or beginning to open up in the other direction on the standing coronal radiograph
3. The apex of the lumbar or thoracolumbar curve at the L1–L2 disc or higher
4. On the right side bending radiograph (assuming a left lumbar curve) the spine derotates, straightens out, and centralizes from L3 to the sacrum.
5. L4 must be bisected by the center sacral line and have less than 15° of tilt on the standing coronal radiograph.
6. Lumbar curve corrects to less than 30° on the flexibility films.
7. Control of distal lumbar segments is facilitated by either pedicle fixation on the convex side or the four-hook,[b] two-segment Shufflebarger technique at the last segment being fused.

---

[a] Stopping at L3 instead of L4.

[b] See accompanying diagram.

Determination of Fusion Levels: Anterior Approach

Anterior-only fusion and instrumentation is considered for thoracic and thoracolumbar-lumbar curves. It is not an option for double thoracic curves or for true double major curves. In considering selective anterior fusion of a right thoracic curve, the surgeon must exclude the structural upper thoracic curve (79). Likewise, if the surgeon is considering a selective anterior fusion of the lumbar or thoracolumbar curve, it is important to assess the structural characteristics of the thoracic curve above. If a patient has a right thoracic and left lumbar curve pattern and is particularly bothered by a high right shoulder, selective anterior instrumentation and fusion of the thoracolumbar-lumbar curve is unlikely to level the shoulders (13).

Otherwise, picking fusion levels anteriorly is straightforward. One should include all segments within the curve, fusing and instrumenting from the transitional and neutral vertebra above to transitional and neutral vertebra below (9,33,48). All discs that are concave into the curve should be included. Any discs that point the other direction or are symmetric do not need to be included. Anterior-only fixation traditionally has implied screw fixation of every segment (9,33,48).

Surgical Treatment of Type I, III, and IV Thoracic Curves

Recent articles (27,71) have suggested that there is an element of intrarater and interrater variability in assessment of the King classification (63), which is true of all classification systems. Nonetheless, the King classification system has been the most valuable one for classifying thoracic curves in the recent past and, therefore, is used in this chapter (Table 3).

Type I, III, and IV curves are single thoracic curves. A thoracic curve is one with an apex of T10 or higher. A type III curve is the most common pattern in which the stable vertebra is usually L2 (Fig. 5). A type IV curve is a longer thoracic curve in which the stable vertebra is L4 (Fig. 6). The stable vertebra is the one bisected by the center sacral line on the standing long-cassette coronal radiograph. With posterior fixation of these curves, a type III curve is usually stopped at L1 or L2, and a type IV curve is usually stopped at L3. With traditional Harrington instrumentation, a type IV curve would be stopped at L4. We know now that it is often possible to stop at L3 with more modern instrumentation in a type IV curve (1,76) (Fig. 3). Placement of hooks can be defined as either a compression mode or a distraction mode. Compression and distraction modes should be aligned according to the tilt of the disc at that particular segment. In other words, if the disc is convex to the left at a particular level, it makes the most sense to place the hooks in a compression mode on the left side and a distraction mode on the right side. For the most part, hooks are placed in a distraction mode on the concavity and a compression mode on the convexity, but with some reversal of hooks on both the top and the

bottom (13). For a type III curve, it is going to be advisable to preserve some lordosis from T12 to L1 or L2. For the type IV curve that is fused to L3 or L4, it is extremely important to preserve segmental lordosis, that is, the lordosis from T12 to the last instrumented vertebra.

TABLE 3. Curve Patterns

Thoracic	
Type I	Principal lumbar curve, secondary thoracic curve
Type II	Principal thoracic curve, secondary lumbar curve
Type III	Thoracic curve without structural lumbar curve
Type IV	Long thoracic curve with an apex at T10 but extending to L4
Type V	Double thoracic curve (rotation in the opposite direction from T2–T5 with incomplete correction on the side-bending film)
Double major	Equally structural thoracic and lumbar curves
Lumbar	Curve with apex in the lumbar spine
Thoracolumbar	Curve with apex at the thoracolumbar junction

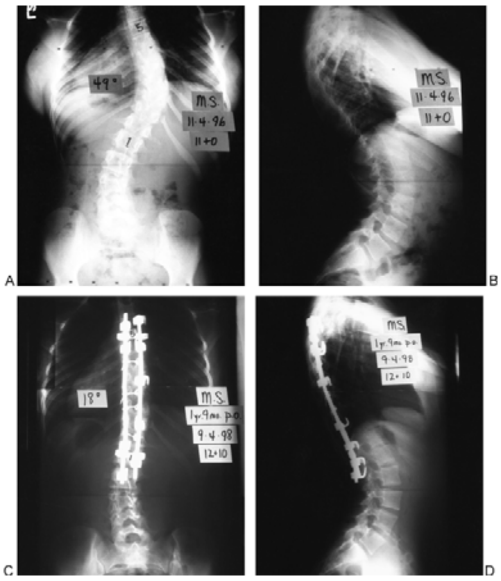

FIGURE 5. This was a moderate-sized right thoracic curve that was flexible. This case demonstrated treatment with posterior instrumentation. Correction was achieved by tightening Wisconsin wires and by in situ contouring of the rod on the left side. Correction was therefore achieved entirely through translation. No distraction was used, and no rod rotation maneuver was used. Initially, the hooks were engaged into the distal two-segment claw, which was then fixed in mild compression. The rod was engaged into the two-segment claw above but was not fixed at those levels. The Wisconsin wires were then sequentially tightened. This was followed by some in situ contouring of the rod, followed by more wire tightening and then a second set of in situ rod recontouring. When final correction was achieved, the proximal two-segment claw was fixed. Using this kind of correction, the incidence of junctional kyphosis and coronal decompensation problems appears to be substantially reduced. **A:** Standing coronal radiograph preoperatively. **B:** Standing sagittal radiograph preoperatively. **C:** Standing coronal radiograph postoperatively. **D:** Standing sagittal radiograph postoperatively.

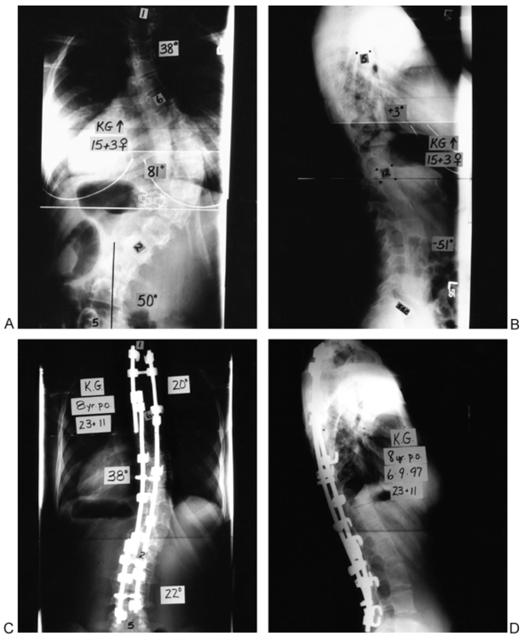

FIGURE 6. This was a type IV curve with an upper thoracic component as well. Fusion and instrumentation were performed down to L4. It is conceivable that the fusion and instrumentation really could have been stopped at L3. Note the hook patterns. Reversal of hooks was accomplished to correlate with reversal of the disc spaces and also with the desired sagittal correction. Note that there was an element of preoperative thoracolumbar kyphosis. With fusions and instrumentations to L3 and L4, it was particularly important to preserve and, in some cases, enhance segmental lordosis. **A:** Standing coronal radiograph preoperatively. **B:** Standing sagittal radiograph preoperatively. **C:** Standing coronal radiograph postoperatively. **D:** Standing sagittal radiograph postoperatively.

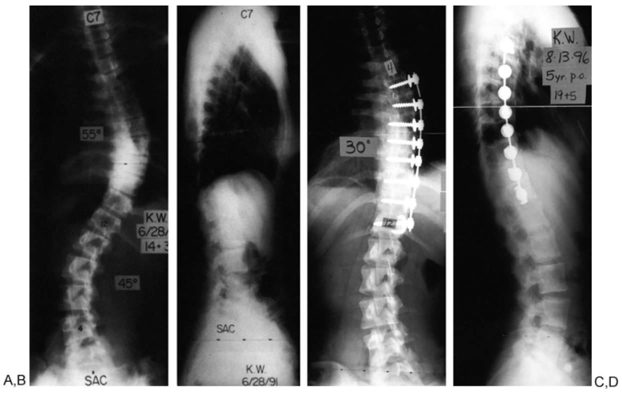

FIGURE 7. This patient presented with a curve pattern that was borderline between being a type II and a type III curve. She was treated with anterior instrumentation using a small flexible threaded rod (Zielke instrumentation). Note that the implant broke at one level. Despite that, she has had an excellent clinical and radiographic result. For idiopathic adolescent scoliosis, a more substantial rod is advisable than what was used in this case. **A:** Standing coronal radiograph preoperatively. **B:** Standing sagittal radiograph preoperatively. **C:** Standing coronal radiograph postoperatively. **D:** Standing sagittal radiograph postoperatively.

Type III and type IV curves are amenable to anterior-only instrumentation and fusion. Data for this approach are evolving (9,48,62). It has been suggested that the anterior approach can save one or two distal levels (9). The pseudarthrosis rate using threaded rods anteriorly is unacceptably high (9) (Fig. 7). However, data are evolving on the use of smooth solid rods anteriorly. In smaller patients, a single-screw, single-rod system may suffice. In larger patients, a double-screw, double-rod system may be more advisable (53,62) (Fig. 8). Fixation of a long thoracic curve may require a double thoracotomy. If a double thoracotomy is being strongly considered for a patient, pulmonary function assessment is crucial because some loss of pulmonary function occurs in the postoperative period (132). Fusions to T12 or L1 can be done above the diaphragm. Fusions to L2, as might be attempted in a type IV curve, may require severance of all or part of the peripheral portion of the diaphragm. Anterior convex instrumentation of thoracic curves tends to be kyphosing (9). Therefore, a kyphotic right thoracic curve is a relative contraindication to anterior instrumentation, as opposed to the more common hypokyphotic thoracic deformity. Instrumentation that crosses the thoracolumbar junction is best managed with structural grafting to the concavity of those disc spaces to preserve lordosis. Options of structural grafting include titanium mesh cages, fresh-frozen tricortical iliac grafts, and fibular allograft wedges supplemented with autogenous rib bone graft (15,125). Many articles discuss the result of fusion and instrumentation of thoracic curves on pulmonary function (64,74,122,130,131,132,138,139). There is not universal agreement, but most authors report a positive effect if there is not significant rib cage disruption associated with treatment.

A type I curve implies that the lumbar or thoracolumbar deformity is greater than the thoracic curve. In this circumstance, the structural component of the thoracic curve determine whether both curves are being fixed or fused or just the lumbar-thoracolumbar curve. Assessment factors include which shoulder is higher, the degree of shoulder asymmetry, and the size of the thoracic rib hump. When both curves are to be fused, a posterior approach is preferred. When only the thoracolumbar-lumbar curve is being addressed, either a posterior-only or an anterior-only approach may be considered. The more popular approach for fixing only the thoracolumbar-lumbar curve is the anterior approach, with a thoracoabdominal approach through the ninth or tenth rib (33,40,45,55,59,61,83,101,102,129). In this circumstance,

it is particularly important to preserve lordosis from T12 to the last instrumented vertebra. This is covered in more detail under the section entitled Thoracolumbar and Lumbar Curves.

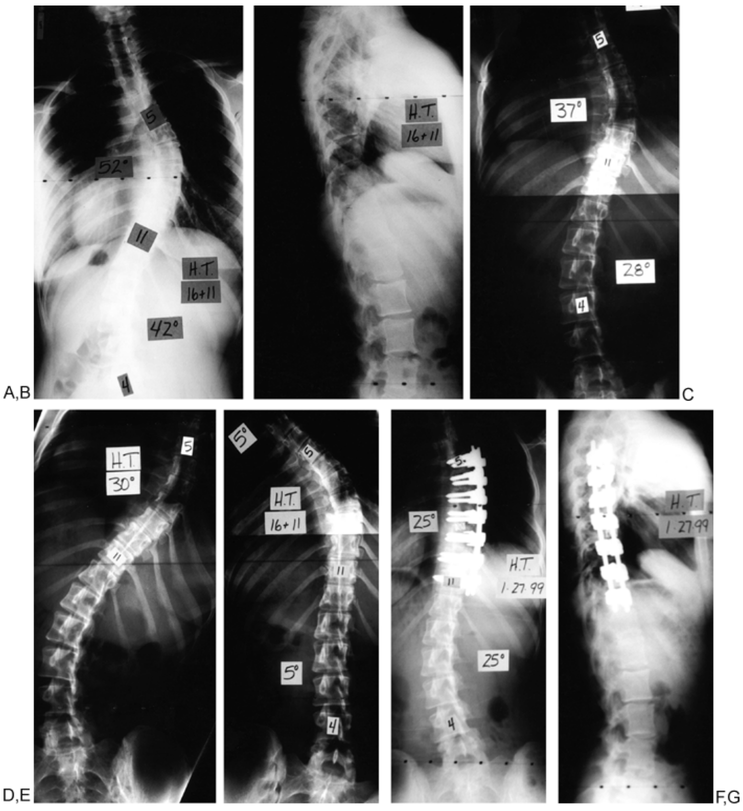

FIGURE 8. This was a skeletally mature teenager with a type II curve pattern. The thoracic curve was somewhat bigger than the lumbar curve. Clinically, the thoracic curve was much more noticeable than the lumbar curve. The patient and the patient's family were unhappy with the appearance of the thoracic deformity. This patient weighed about 175 pounds and was about 5 feet, 10 inches tall. She was treated with a double-screw, double-rod system (the Kaneda/KASS instrumentation). A selective fusion was done of just the thoracic curve. This produced acceptable coronal and sagittal correction as well as a clinical deformity correction that pleased the patient and her family. **A:** Standing coronal radiograph preoperatively. **B:** Standing sagittal radiograph preoperatively. **C:** Supine radiograph preoperatively. **D:** Right side-bending radiograph preoperatively. **E:** Left side-bending radiograph preoperatively. **F:** Standing coronal radiograph postoperatively. **G:** Standing sagittal radiograph postoperatively.

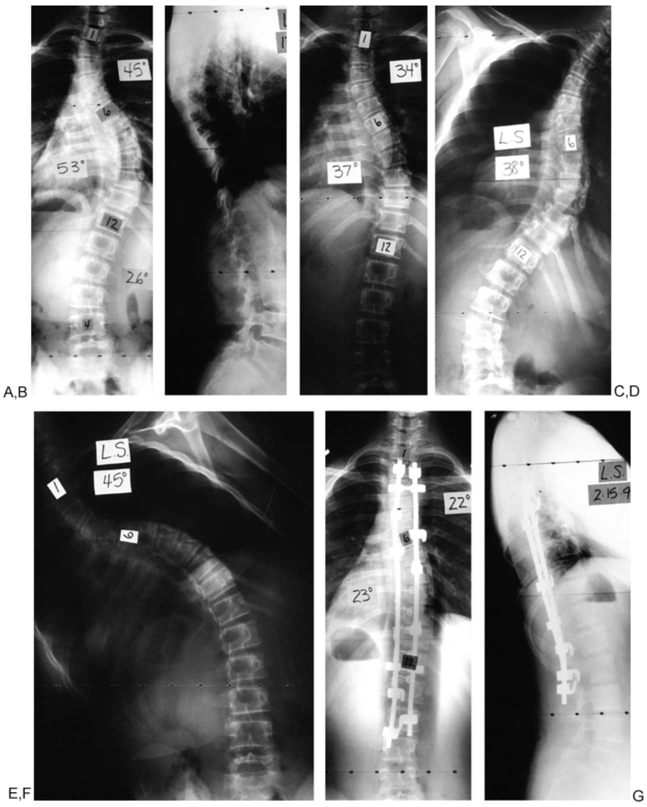

FIGURE 9. This was a double thoracic curve pattern. Note that there was some rotation and apical deviation from T2 to T5. Note that there was a slight junctional kyphosis between the two curves as well. The left first rib was slightly higher. Therefore, the hooks were reversed between the upper left thoracic and lower right thoracic curve. Correction of the lower thoracic curve was accomplished through translational forces applied through the Wisconsin wires as well as in situ contouring of the rod on the left side. Correction of the upper thoracic curve was accomplished through compression forces being applied. Most correction was achieved with the left-sided rod. Application of compression forces to the left side of the curve addressed the junctional kyphosis. **A:** Standing coronal radiograph preoperatively. **B:** Standing sagittal radiograph preoperatively. **C:** Supine radiograph preoperatively. **D:** Right side-bending radiograph preoperatively. **E:** Left side-bending radiograph preoperatively. **F:** Standing coronal radiograph postoperatively. **G:** Standing sagittal radiograph postoperatively.

Double Thoracic Curves

A double thoracic curve pattern implies a higher and lower thoracic curve, most commonly a high left thoracic, low right thoracic curve pattern (63,68,79). In this circumstance, the low right thoracic curve is more noticeable because it creates more apical deviation and a larger rib hump. However, the height of the shoulders is determined by the upper curve. In a single right thoracic curve pattern, the right shoulder is higher. In a double thoracic curve pattern, either the shoulders are level, or more commonly, the left shoulder is higher. If the left shoulder is higher, correction of only the lower right thoracic curve further unbalances the shoulders and creates an even higher left shoulder (68,79). With double thoracic curve patterns, the transitional vertebra is usually somewhat lower, that is, T6 rather than T4 to T5. Often, there is somewhat of a junctional kyphosis between the upper and lower curves as well. If the upper thoracic curve exceeds 35 degrees and does not bend out to less than 20 degrees on the opposite side-bending film, these coronal considerations, as well as the sagittal factors, may suggest inclusion of the upper thoracic curve (79). If the left shoulder is higher, the upper thoracic curve should always be included. As in any double curve pattern that is being treated posteriorly, the orientation of the hooks should be reversed as one goes from one curve to the next. If the upper thoracic curve is kyphotic, it is best to apply lordosing compression forces to the convexity first. If the upper thoracic curve is lordotic, it is better to apply forces along the concavity first. In most cases, the upper thoracic curve is kyphotic and the lower thoracic curve is hypokyphotic (13). Double thoracic curves are best treated posteriorly (Fig. 9). If one chooses to treat a double thoracic pattern anteriorly, it is important to limit the correction of the upper portion of the lower thoracic curve and to block correction of the transitional segments so that shoulder asymmetry is not worsened (Table 4).

Thoracolumbar and Lumbar Curves

Thoracolumbar and lumbar curves are defined as having an apex at T11 or below. When they are associated with a significantly structural thoracic component (a type I King curve), it may be advisable to fix both thoracic and lumbar curves posteriorly. In most cases, however, the lumbar curve can be treated selectively. This can be accomplished through either a posterior or an anterior approach. Although correction can be accomplished with a posterior approach, for lumbar and thoracolumbar curves, most surgeons today prefer the anterior approach (13,15,61) (Fig. 10).

TABLE 4. Characteristics of the High Left Thoracic Curve in a Double Thoracic Curve

High left shoulder
High left first rib
Rotation T2–T6
T6 transitional
Curve T2–T5/T6 > 35 degrees on standing radiograph
Curve T2–T5/T6 > 20 degrees on side-bending radiograph

At times, thoracolumbar curves in particular can be treated by a very short anterior approach if they are extremely flexible (45), the Hall-Millis concept. If the apex is a vertebral body, one segment above and below is included. If the apex is a disc, four vertebral bodies and three discs are included. In this situation, maximal correction or, in some instances, some overcorrection is desirable (Fig. 11).

In most cases, a thoracolumbar or lumbar curve is best treated by fixing and fusing from transitional-neutral to transitional-neutral. This usually entails a T10 or T11 to L3 anterior instrumentation and fusion. The principal advantages of the anterior approach are the abilities to obtain more correction and to stop at L2 or L3 rather than L3 or L4. The type of anterior instrumentation has evolved from Dwyer (33) to Zielke instrumentation (40) and now to solid-rod systems, either a single-screw, single-rod system or a double-screw, double-rod system (61,129). Problems with the Dwyer and Zielke approach include a significant incidence of pseudarthrosis and the kyphogenic nature of the systems (83). Kyphogenic instrumentation may be satisfactory for a hypokyphotic thoracic curve. For lumbar curves, however, one wants to preserve and, in some cases, enhance segmental lordosis. There are those who advocate a rod rotation maneuver anteriorly without application of any compression force to achieve correction but maintain segmental lordosis (129). Others advocate applying some compression, but against anterior structural grafts such as titanium mesh cages, fresh-frozen tricortical iliac grafts, or fresh-frozen or freeze-dried fibular grafts packed with autogenous rib bone (13,15). It has been shown that this approach of using anterior structural grafting or limiting the amount of compression force applied can preserve and, in some instances, even enhance segmental lumbar lordosis (125). With anterior instrumentation of curves, whether they are thoracic or thoracolumbar-lumbar curves, it is crucial that the screw purchase be bicortical at each level (60,61,125). The type of

staple or washer has not proved to be a critical component (Fig. 12).

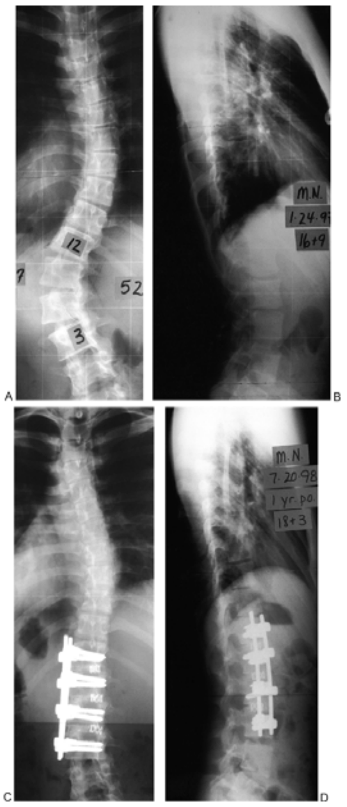

FIGURE 10. This patient presented with a substantial thoracolumbar curve. This boy was 6 feet, 2 inches tall and weighed 185 pounds. He was, therefore, treated with a double-screw, double-rod system (the Kaneda/KASS system) with an acceptable radiographic and clinical result. Note the use of structural cages to preserve segmental lordosis. Also note the residual deformity at the L3–L4 disc 1 year postoperatively. Will this predispose to early disc degeneration at this level? No answer exists in today's literature. **A:** Standing coronal radiograph preoperatively. **B:** Standing sagittal radiograph preoperatively. **C:** Standing coronal radiograph postoperatively. **D:** Standing sagittal radiograph postoperatively.

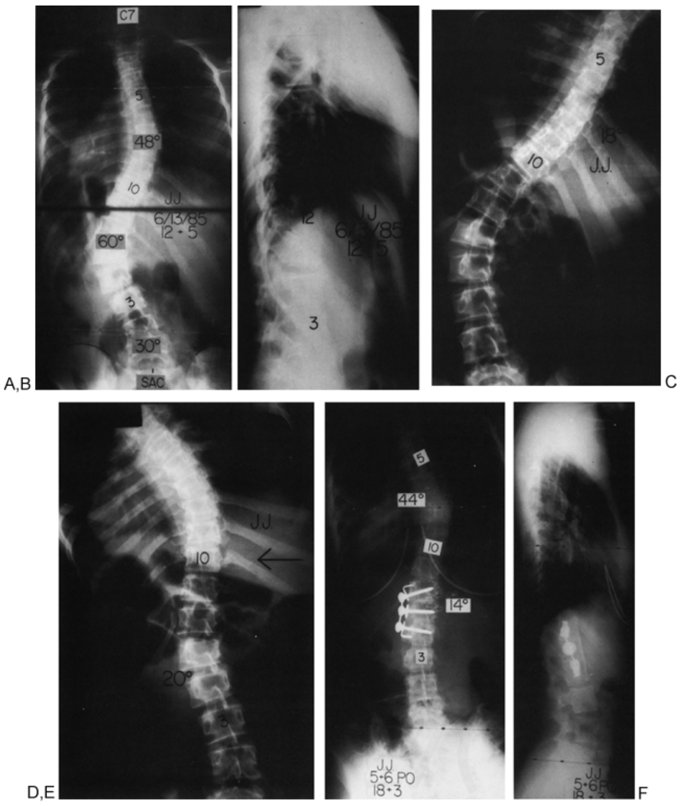

FIGURE 11. This patient presented with a type I curve pattern. The thoracolumbar curve produced substantially more clinical deformity than did the thoracic curve. This thoracolumbar curve was extremely flexible. This case was amenable to very short fixation with overcorrection of the thoracolumbar curve as described by Hall and Millis (45). See the excellent result achieved at 5-year follow-up. **A:** Standing coronal radiograph preoperatively. **B:** Standing sagittal radiograph preoperatively. **C:** Right side-bending radiograph preoperatively. **D:** Left side-bending radiograph preoperatively. **E:** Standing coronal radiograph postoperatively. **F:** Standing sagittal radiograph postoperatively.

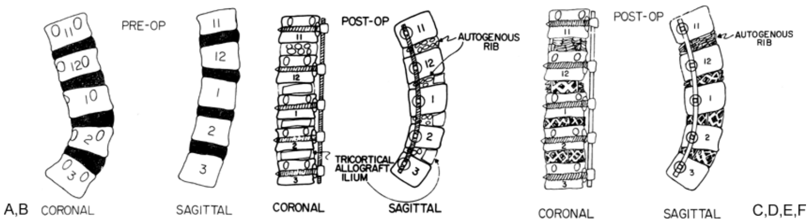

FIGURE 12. A and B: Preservation of lumbar lordosis with anterior VDS (Zielke instrumentation) and use of anterior allograft struts: a lumbar curve with rotation and some loss of lumbar lordosis. **C and D:** The disc spaces are opened with a laminar spreader, and the largest possible fresh-frozen tricortical allograft iliac graft is placed into each anterior disc space. The Zielke screws are placed in the posterior third of the vertebral body. After an element of derotation has been achieved with the Zielke derotator, the posterior disc space is compressed at each level. This serves to open the anterior disc space and close the posterior disc space, thereby allowing enhancement of lumbar lordosis. An autogenous rib graft is placed in the posterior disc space so that there is autogenous bone graft at each level. Large tricortical grafts must be placed in the anterior disc spaces to keep this column open; simply using rib graft does not provide enough structural support. After the instrumentation is complete, further osteogenesis can be promoted by raising osteal-periosteal flaps anteriorly with a curved osteotome. Additional autogenous rib graft is then placed inside these flaps. **E and F:** The same correction accomplished with a solid-rod system and cages packed with autogenous rib bone rather than structural allograft. , with permission.)

How to Distinguish a Type Ii From a Double Major Curve

The most important concept to evolve from the King paper (63) was that of the type II or false double major curve pattern (63), in which it is possible to fuse the thoracic curve selectively and to leave the lumbar curve alone. A typical type II curve has a stable vertebra at T12 or L1. The lumbar curve below has rotation to it, has some structural component, and crosses the midline. However, the thoracic curve is “bigger” than the lumbar curve, and the lumbar curve is more flexible. This definition of a false double major curve has lead to many interpretations (89). The critical point of interpretation is how to define “thoracic curve bigger than lumbar” (Fig. 13, Table 5). Some believe that rod rotation maneuvers are not advisable for false double major curves in which only the thoracic curve is being fused and the fusion is being stopped at T12 or L1, whereas others believe that too much correction of the thoracic curve in this situation is not desirable (18,73,110,112,128,140). Still others believe that anterior surgery for the thoracic curve is the ideal approach (72). Still others advocate fixing both curves and stopping the fusion at L3 if there is a substantial structural component to the lumbar curve (1).

My preference is to fix only the thoracic curve and to stay completely out of the lumbar curve. This is difficult to accomplish if there is a thoracolumbar kyphosis and not at least a 3:2 ratio of thoracic to lumbar apical vertebral rotation, apical translation, and Cobb measurement (15,73) (Figs. 8 and 14).

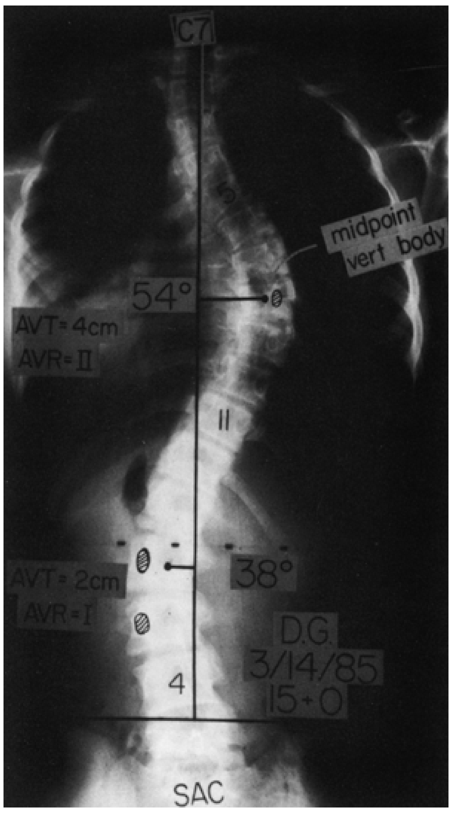

FIGURE 13. Determination of relative curve size: To determine the relative curve sizes (thoracic versus lumbar), one should consider not only the Cobb curve measurement but also the relative apical vertebral rotation (AVR) and the relative apical vertebral translation (AVT) or deviation from the midline.

If a true double major curve pattern exists, the fixation of the lumbar curve may be accomplished with hooks or pedicle screws. There is a growing body of literature that documents the safety of pedicle screws for the adolescent lumbar spine and suggests that pedicle screws may be used to position the last instrumented vertebra more horizontally and to enhance segmental lumbar lordosis (4,20,47). With modern systems, if L3 is relatively neutral (Nash-Moe I or less) on the standing coronal film, if the apex of the lumbar curve is L2 or higher, if the L3 to L4 disc is symmetric or swings the opposite way of the discs within the lumbar curve on the standing coronal film, and if the L3–L4 disc swings both ways on the bending film, the fusion and instrumentation may be stopped at L3 rather than L4 (47,76) (Fig. 4). Many articles discuss the aging of segments below a spinal fusion, with a wide spectrum of conclusions (24,25,36,84,93,96,105,126). Nonetheless, it is desirable in most cases to preserve mobile segments and to normalize segmental sagittal curves (7,16,28,52,120,136), especially in the lumbar segments. As distal segments age and lose anterior column height, flatback syndrome is disabling (11,38,65,66)

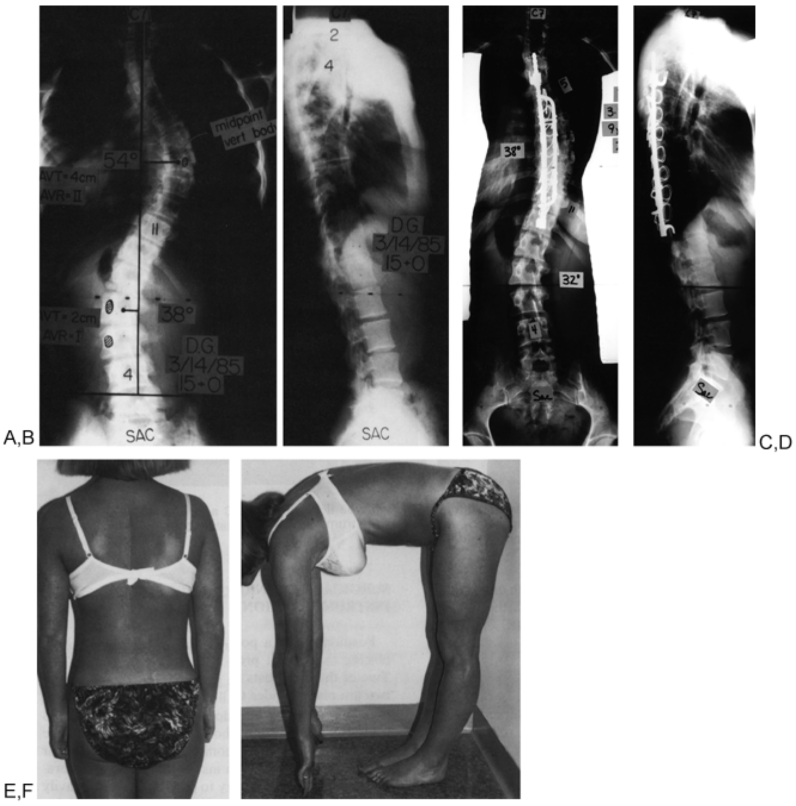

FIGURE 14. This was a classic type II false double major curve pattern. The thoracic curve was roughly 50% bigger than the lumbar curve in Cobb measurement, apical vertebral translation, and apical vertebral rotation. The lumbar curve had structural characteristics. It crossed the midline and had rotation to it and, therefore, a type II curve pattern and not a type III pattern. Note the excellent result 9 years after surgery. Also note how flexible the patient is. **A:** Standing coronal radiograph preoperatively. **B:** Standing sagittal radiograph preoperatively. **C:** Standing coronal radiograph postoperatively. **D:** Standing sagittal radiograph postoperatively. **E and F:** Clinical photographs postoperatively.

TABLE 5. Distinguishing Between a Type II (False Double Major) and True Double Major Curve Pattern

Radiographic Criteria
Standing film (long-cassette coronal)
Relative curve size by Cobb measurement
Relative apical deviation or translation from:
Plumb line
Center sacral line
Line connecting transitional vertebrae
Relative apical rotation of the thoracic curve versus the lumbar curve
Thoracolumbar junction sagittal plane based on standing sagittal radiograph
Flexibility of the curves (lumbar curve must be more flexible than thoracic curve to consider selective thoracic fusion)
Clinical Criteria
Standing examination: relative thoracic deformity to waistline asymmetry
Forward-bending examination: relative thoracic-to-lumbar hump

Decompensation Associated With Selective Curve Fusion

Treatment of type II curves with selective thoracic fusion is a potential cause for postoperative decompensation (18). There appears to be a higher incidence of decompensation if a rod rotation maneuver is performed (18). Also, if the thoracic and lumbar curves are close in Cobb measurement, apical vertebral rotation, and apical translation on the standing coronal radiograph, there is a significant incidence of decompensation even if the lumbar curve is more flexible than the thoracic (18). Frequently with true double major curve patterns, the lumbar curve is more flexible than the thoracic curve, even if it is clearly the more structural of the two curves (14,15).

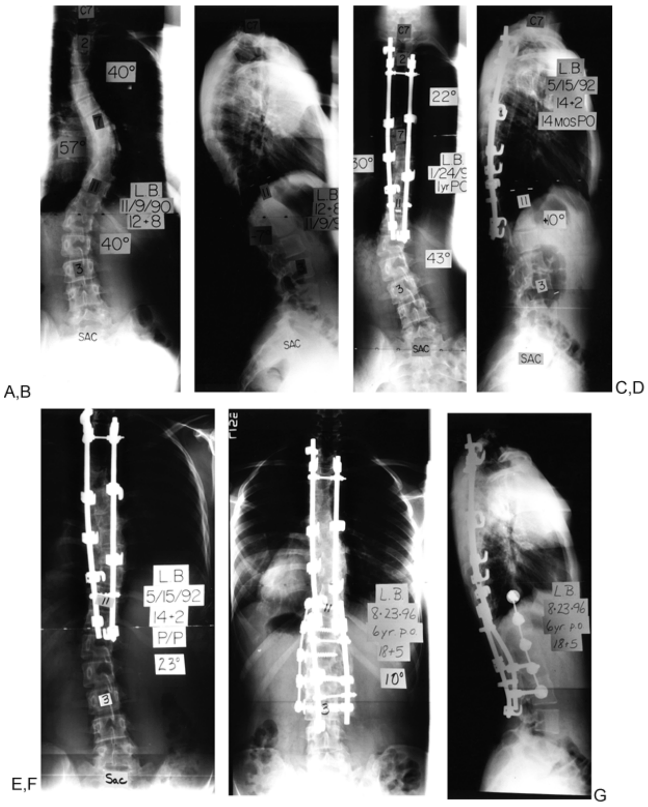

FIGURE 15. This patient initially presented with an upper thoracic, lower thoracic, and thoracolumbar curve pattern. She was initially fused and instrumented with a construct addressing the thoracic curves. This produced coronal decompensation and a junctional kyphosis. She then presented to our institution for revision surgery. She was revised by extending her fusion and instrumentation down to include the thoracolumbar curve. Fortunately, it was possible to stop at L3. Note the use of fresh-frozen tricortical iliac grafts in the anterior disc spaces to preserve segmental lordosis. The causes of the patient's initial decompensation were multifactorial. **A:** Standing coronal radiograph preoperatively. **B:** Standing sagittal radiograph preoperatively. **C:** Standing coronal radiograph 1 year postoperatively. **D:** Standing sagittal radiograph 14 months postoperatively. **E:** Push prone radiograph 14 months postoperatively. **F:** Standing coronal radiograph 6 years postoperatively. **G:** Standing sagittal radiograph 6 years postoperatively.

The other curve pattern with an associated incidence of decompensation is the double thoracic pattern. If the upper thoracic curve is not recognized, fusion and instrumentation of only the lower thoracic curve may lead to worsening of shoulder balance (79).

Junctional kyphosis is also an occasional complication of posterior segmental spinal instrumentation (13,15,18,70). The most common causes are (1) not fusing to the end vertebra of a curve, (2) applying an excessive amount of compression to the last instrumented segment, (3) inadvertently disrupting the ligaments at the adjacent segment, (4) applying an excessive cantilever force, and (5) stopping a fusion or instrumentation in an area of kyphosis that is posterior to the weight-bearing line of the spine. Often, junctional kyphosis is a radiographic finding of no apparent clinical significance in the short term. Other times, the junctional kyphosis is progressive and does become clinically significant. Junctional kyphosis of clinical significance usually requires extension of the fusion to a lordotic segment and frequently requires combined surgery.

If it is detected early, coronal plane decompensation, especially in association with type II and type V curves, may be treated by a revision of the instrumentation and applied forces. If it is not revised until the fusion is solid, the fusion should be extended to include the upper thoracic curve if it is a type V or to include the lumbar curve if it is a borderline type II or double major curve pattern (Fig. 15). Occasionally, if the coronal decompensation is mild, a short period of bracing or simply time resolves the problem.

Role of Halo Traction

Halo traction is not commonly used for idiopathic adolescent scoliosis. There are not clear guidelines for its use in the literature. If used, the most beneficial traction appears to be halo wheelchair traction. Halo bed, halo femoral, and halo walker traction are options (13). The potential role for traction is when a thoracic curve exceeds 90 degrees or in a patient who has several large curves and is not balanced in the coronal plane.

Halo traction in conjunction with anterior release can help to provide dramatic correction of thoracic curves. It is probably not advisable to start the traction the night after the anterior release procedure. There are significant dangers to halo traction that applies a distractive force to the spine. It is best to begin the halo traction roughly 48 hours after the anterior release when the patient is fully awake and capable of providing feedback about neurologic function and is hemodynamically stable. Although this is anecdotal information, I have been consulted about several cases throughout North America in which halo traction had been employed the night after an anterior release and a neurologic deficit developed. The halo traction should be applied slowly and gradually with small increments and frequent neurologic assessments. The addition of weights should always be performed during daytime waking hours when the patient can provide feedback regarding neurologic status.

The ideal ultimate weight and the time of halo traction have not been clearly established. One would expect that the longer the period of halo traction, the greater the potential for creep and relaxation of the spine.

Concerns About Crankshaft

The concept of the crankshaft phenomenon has been clearly described (32,97). *Crankshaft* refers to the continued growth of the anterior spine after the posterior spine is fused. With continued anterior growth, the spinal deformity progresses despite a solid posterior fusion. It has also been shown that if the triradiate cartilage is closed, the likelihood of a crankshaft phenomenon is extremely remote (46,69).

If the triradiate cartilage is open, there is some chance for crankshaft to occur after posterior fusion. A progression of 10 degrees or more has been described in roughly 35% of patients older than 10 years of age with idiopathic scoliosis and an open triradiate cartilage (46). Sanders and colleagues (115,116) have observed that the patient's proximity to the peak growth velocity is a factor. When patients are at or beyond their peak growth velocity, crankshaft appears not to occur. When they have not yet reached peak growth velocity, the risk is more significant.

A general consensus among most spine surgeons is that the risk for crankshaft in patients 10 to 12 years of age with adolescent idiopathic scoliosis is small. This certainly is a problem in patients younger than 10 years of age with a variety of juvenile deformities and for certain patients with congenital deformities, specifically failures of formation (46).

Indications for Circumferential Treatment

In most cases, idiopathic adolescent scoliosis curves can be treated with a one-stage approach. If a single curve exists, either an anterior or a posterior approach can be postulated. If structural double curves exist, a posterior approach is advisable. The only reasons for circumferential treatment are either very large curves or significant sagittal plane alterations.

There are no clear-cut tide marks in the literature. In general, thoracic curves between 75 and 100 degrees can benefit from thoracoscopic release anteriorly in order to accomplish more correction with posterior fusion and instrumentation (92,99) (Fig. 16). Thoracic and lumbar curves of more than 100 degrees benefit from formal anterior release and fusion along with posterior treatment (13) (Fig. 17). Patients with significant thoracic lordosis (not hypokyphosis but frank lordosis) benefit from the two-staged approach described by Bradford and colleagues (12) and Winter (137). In this situation, V-shaped kyphosing wedges are created through the disc spaces anteriorly. Posteriorly, the spine is translated to the prebent rods with sublaminar wires. Using two-segment “claws” at the top and bottom of the construct is preferred over Harrington instrumentation or sublaminar wires at the ends of the constructs.

In some patients with idiopathic scoliosis, a substantial thoracolumbar or upper lumbar kyphosis may warrant circumferential treatment. If a patient presents with this coexistent sagittal deformity, it is helpful to perform a supine long-cassette hyperextension lateral radiograph to see whether the sagittal deformity is flexible. If it is flexible, an anterior procedure is not needed. If it is inflexible, it often is advisable to “release” and graft anteriorly. The purpose in this circumstance is to recreate physiologic segmental lordosis.

Indications for Endoscopic and Thoracoscopic Techniques

It has been demonstrated that discs can be resected in the thoracic spine through a thoracoscopic approach (92,99) (Fig. 16). This may assist to “loosen up” curves that exceed 75 degrees (Cobb angle) or curves that are very hyperkyphotic. It has not been demonstrated whether there is an endoscopic role for the frankly lordotic thoracic spine.

Investigators are now performing endoscopic anterior instrumentation of the thoracic spine (107). The ultimate fusion and complication rates with this approach will not be fully determined for several years. Although desirable in terms of the short-term morbidity for the patient, the long-term results will only be acceptable if the technique provides as high a fusion rate and comparable correction with as few complications as open anterior or posterior techniques.

Surgical Techniques Excluding Instrumentation

Posterior Fusion

The technique of posterior fusion has not changed. Decortication from the spinous process to the tip of the transverse process is beneficial. Facet excision and decortication are part of the standard procedure. If segmental instrumentation is being used posteriorly, the fixation points have to be preserved. To some extent, this limits the surface area available for fusion. There are differing philosophies regarding the use of bone graft. The standard has been to use either an autogenous iliac or rib graft that is generated with a concomitant thoracoplasty. However, investigators have reported acceptable results using allograft (10,30) and also using no added bone graft (37). These studies had a minimal 2-year follow-up. A 3- to 5-year follow-up is needed with present-day implants to increase the confidence that spinal fusion is occurring.

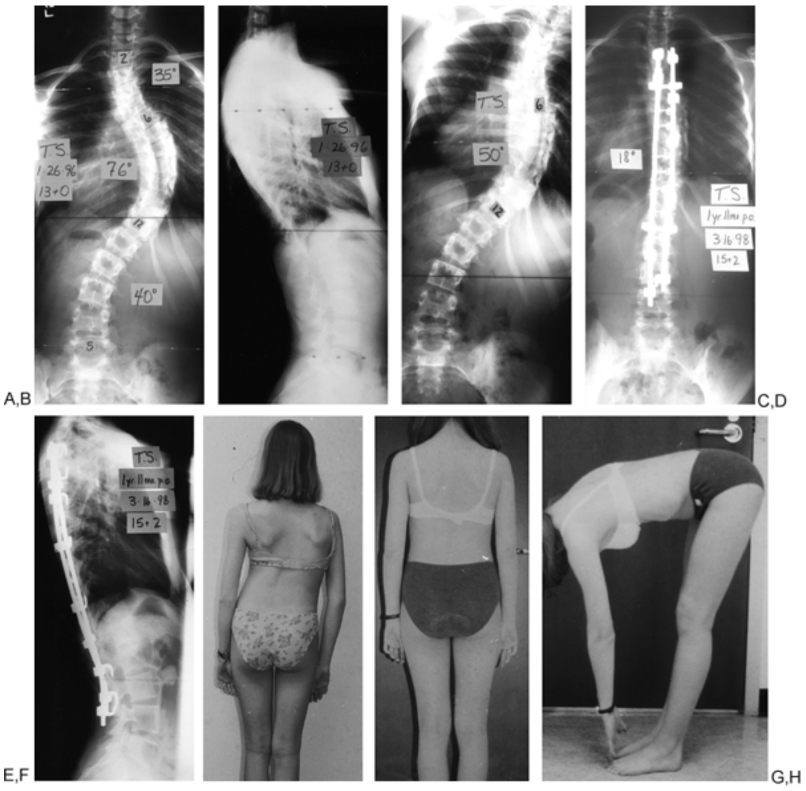

FIGURE 16. This patient presented with a fairly substantial thoracic curve that corrected only from 76 to 50 degrees on side bending. She was, therefore, initially treated with multiple thoracic releases done endoscopically through five portals. This mobilized the apical segments sufficiently that substantially more correction was achieved than what would have been possible without the anterior procedure. **A:** Standing coronal radiograph preoperatively. **B:** Standing sagittal radiograph preoperatively. **C:** Right side-bending radiograph preoperatively. **D:** Standing coronal radiograph postoperatively. **E:** Standing sagittal radiograph postoperatively. **F:** Clinical coronal appearance preoperatively. **G:** Clinical coronal appearance postoperatively. **H:** Patient is still able to touch her toes despite fusion to L3.

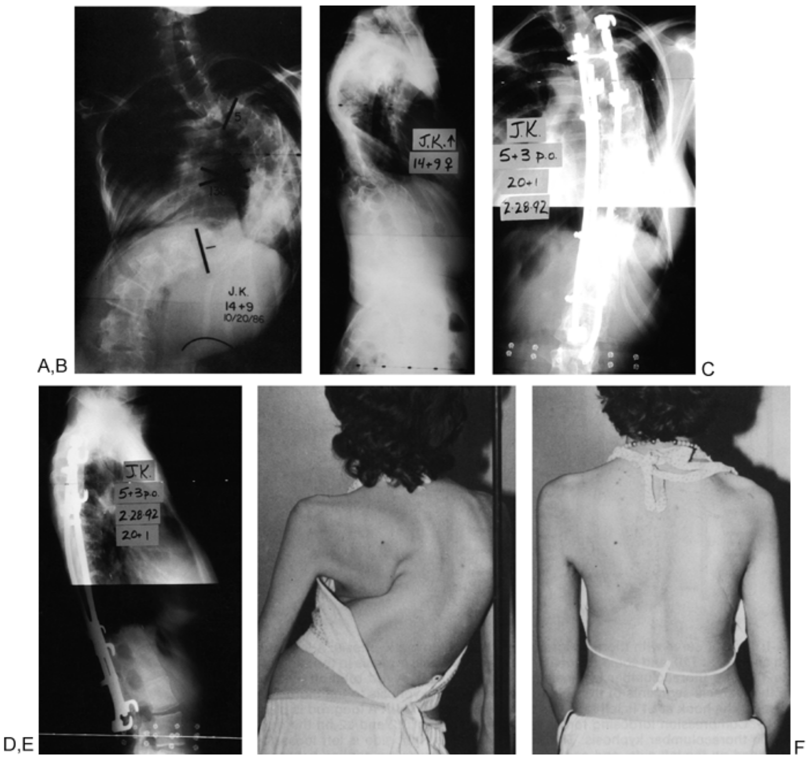

FIGURE 17. This patient presented with a 140-degree right thoracic scoliosis. She was treated with a thoracotomy and open anterior releases at multiple segments, followed by halo traction for 2 weeks, and then by the definitive posterior instrumentation. The patient gained 5 inches in height, and her forced vital capacity improved by nearly 2 liters. **A:** Standing coronal radiograph preoperatively. **B:** Standing sagittal radiograph preoperatively. **C:** Standing coronal radiograph postoperatively. **D:** Standing sagittal radiograph postoperatively. **E and F:** Preoperative and postoperative clinical appearance.

Anterior Fusion

The technique of discectomy and anterior fusion is a standard. It is helpful to excise the disc thoroughly with all of its cartilaginous components back to bony end plate. The most common bone graft placed in the disc space to facilitate fusion is autogenous rib bone, usually harvested during the anterior approach. If the anterior fusion is being performed at the thoracolumbar junction or the upper lumbar spine, there is added benefit to structural grafting anteriorly to maintain lordosis (15). Rib is not the ideal structural graft. Allograft tricortical iliac bone, allograft fibular chunks, and titanium cages filled with autogenous bone are better alternatives to serve that function (125).

Thoracoplasty

If the patient has a substantial rib hump, an anterior or posterior instrumented correction may not significantly improve the axial or tangential deformity. Resection of the prominent ribs can therein improve the cosmetic results (Fig. 18). There are several ways to accomplish this goal. Thoracoplasty can be performed from a posterior (8) or an anterior approach (open or endoscopic) (92,118). From the posterior approach, it is best to expose the rib cage from the midline rather than to make a separate incision over the rib hump. Large sections of the ribs can be resected from the apex of the rib deformity all the way to the transverse processes medially. It is important to resect the medial portions of the ribs as well. Failure to do so results in a noncosmetic ridge. The other posterior option is to resect the ribs medially close to their vertebral attachments and to suture the cut edge to the transverse process or convex rod. This provides some immediate stability to the rib cage (see Chap. 71).

Thoracoplasty does improve the deformity and therein may improve patient satisfaction (39). However, any chest cage disruption at least temporarily reduces pulmonary function and hence should only be considered in patients with excellent pulmonary function and low pulmonary demands (77,131,132).

Adjuncts

Blood loss during surgery for idiopathic adolescent scoliosis is rarely excessive but may amount to 1 to 3 units of blood if intraoperative losses are combined with losses the first 2 postoperative days. Hypotensive anesthesia, preoperative autologous donations, intraoperative cell-saver, and preoperative use of erythropoietin are all potential means of reducing the need for allogenic blood transfusion in patients with idiopathic adolescent scoliosis (3,87,91,95,98,106,114,121).

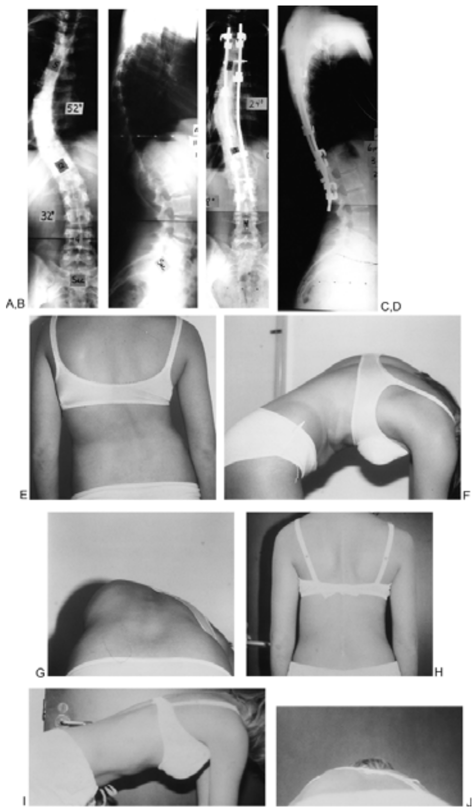

FIGURE 18. This was a left thoracic curve that was somewhat hyperkyphotic. Most right thoracic curves are hypokyphotic. The patient's magnetic resonance imaging study was normal. Instrumented forces were applied to the convexity first to correct the sagittal deformity. The correction of the deformity in the coronal plane and sagittal plane was achieved with the instrumentation. The correction in the axial plane was achieved by the thoracoplasty. **A:** Standing coronal radiograph preoperatively. **B:** Standing sagittal radiograph preoperatively. **C:** Standing coronal radiograph postoperatively. **D:** Standing sagittal radiograph postoperatively. Clinical photographs (coronal, sagittal, and axial) preoperatively and postoperatively.

Postoperative Management and Complications

The average hospital stay for an idiopathic scoliosis patient at our institution in 1999 is 4 to 6 days. We usually stand the patient at the bedside the day after surgery. In most cases, no external protection is used. A brace may be advisable if the patient is very small or judged to be unreliable. This is the exception and not the rule. Recovery from the surgery can be represented as a bell-shaped curve. At the middle of the bell-shaped curve is to be off of all pain medications by 4 to 6 weeks after surgery. During the hospital stay, intravenous narcotics are used during the first 3 days and then the patient is transitioned to oral pain medications.

All patients develop inappropriate antidiuretic hormone syndrome postoperatively (6,88). This usually resolves on the second or third postoperative day without any specific treatment. The tendency is for the patient to retain fluid and have somewhat limited urine output for the first 48 hours and then to have a significant diuresis between 48 and 72 hours after surgery. Most patients develop an ileus, in part from the surgery itself, in part from the anesthesia, and in part from the postoperative pain medication. Uncommonly, a very thin patient, especially with a component of hyperkyphosis, may develop a frank supermesenteric cautery syndrome, which requires several days of a nasogastric tube and intravenous fluids (13).

Postoperative regimens within the first year after the surgery are arbitrary and have not been tested scientifically. I generally tell patients to avoid bending, stooping, twisting, and heavy lifting for the first 4 months after surgery. At 4 postoperative months, some bicycling and swimming is allowed. After 7 months, patients can hit a tennis ball over the net. Running and jumping are restricted until 12 months after surgery. At that time, I generally allow patients to return to noncontact competitive sports, such as soccer and baseball and usually advise against contact sports either indefinitely or until 2 years after surgery. These are all arbitrary guidelines and are not necessarily substantiated by a specific peer-review publication.

The most commonly feared complications with surgical treatment of idiopathic scoliosis include pseudarthrosis, implant failure, decompensation, and neurologic deficit. The exact incidence of pseudarthrosis is not clear and probably can only be determined with present-day instrumentation after a minimal 5-year follow-up. The pseudarthrosis rate with anterior-only constructs may be higher than what it is for posterior-only constructs (9,14).

Wound infections, although uncommon, occur occasionally. If a deep wound infection occurs, it is advisable to return the patient to the operating room, thoroughly irrigate and débride the wound, and close over tubes with an additional period of intravenous antibiotics. The number of days that drainage tubes are used and the length of time that intravenous antibiotics are given has to be individualized to the particular case and offending organism. In virtually all cases, it is advisable to retain the bone graft and instrumentation until the fusion is solid. Anterior infections, especially in idiopathic scoliosis, are uncommon (90,135). At my institution, we have never had a deep anterior infection in a teenage idiopathic scoliosis patient.

There is an incidence of late infection. Some investigators have referred to this as “fretting corrosion,” but most believe this is a low-grade infection (23,111). In some instances, this represents a low-grade infection that was present since the time of the surgery. In other instances, it may represent a late hematogenous seeding of the implants. In both instances, the organism is usually of low virulence, and removal of the implants when the fusion is solid appears to eradicate the infection without the need for long-term antibiotics.

Minor neurologic deficits may occur with surgical treatment of idiopathic scoliosis. There is an incidence of brachial plexus irritation associated with positioning for anterior or posterior approaches (100). These plexopathies usually resolve with time. At my institution, spinal cord monitoring usually includes monitoring of the upper extremities to avoid postoperative deficit of the upper extremities from brachial plexus compression (100). If pedicle screws are being used, there is some potential for irritation of a nerve root. If pedicle screws are used frequently in the lumbar spine, one has to anticipate an occasional, although small, incidence of nerve root irritation (80).

The most dreaded complication with idiopathic scoliosis is a major paraparesis or paraplegia. This is extremely uncommon with idiopathic adolescent scoliosis (17,67,86). Patients at greatest risk are those with either large or hyperkyphotic curves and curves that are treated in a circumferential manner (17). The consequences of a major neurologic deficit in an otherwise healthy idiopathic scoliosis patient are devastating from the social, ethical, medico-legal, and financial perspectives. Therefore, some form of spinal cord monitoring is mandatory during idiopathic scoliosis surgery. Options for monitoring include the Stagnara wake-up test (44), the Hoppenfeld clonus test (54), somatosensory potential monitoring of upper and lower extremities, and motor potential monitoring of lower extremities (21,35,94,103,109). Which combination is most cost-effective is open for debate.

After an instrumented correction of an idiopathic scoliosis deformity, however, it is wise to establish some form of feedback regarding the patient's neurologic function before the wound is closed and the patient is awakened. Our institutional preference is to perform somatosensory and motor evoked potential monitoring. If these tracings are reliable and reproducible throughout the case, we rely on them exclusively (104). If there are any inconsistencies or limitation to the data, we perform a Stagnara wake-up test. In all instances, we rehearse the Stagnara wake-up test with the patient preoperatively to facilitate its performance if it is needed. If a major neurologic deficit does occur after spinal instrumentation for idiopathic scoliosis, advisable considerations include raising the patient's mean blood pressure, removing or revising the instrumentation, and in some cases, transfusing the patient to normalize the oxygen-carrying capacity of the blood (Table 6).

TABLE 6. Complications of Surgery

Imbalance (coronal or sagittal)

Junctional kyphosis (proximal or distal)

Pseudarthrosis

Pain at spine and graft sites

Paralysis (spinal cord or nerve root etiology: major or minor)

Lateral femoral cutaneous nerve palsy (from prone positioning on the frame)

Wound infection (superficial or deep)

Superior mesenteric artery syndrome

Scapulothoracic pain

Loss of segmental lumbar lordosis

Evolution of Spinal Instrumentation

From the 1960s to the 1990s, techniques of spinal fusion remained constant; however, instrumentation evolved into greater segmentalization. This provides improved correction in the coronal and sagittal planes, although in most instances, not dramatic correction in the axial plane. On balance, there is no evidence to suggest that greater segmentalization of the instrumentation reduces the fusion rate. When using new technologies, there is always a learning curve. The most commonly used posterior implants are somewhat lower profile today than they were several years ago. There are relative merits to anterior versus posterior instrumentation.

As stated earlier, thoracoscopic fusions and instrumentations are being performed by some investigators. Various methods of spinal deformity correction of lumbar segments, without fusion, are also being investigated (81).

Summary and the Future

The goals of surgery for idiopathic scoliosis are to achieve acceptable correction, maintain coronal and sagittal balance, fuse as few segments as possible, and return the patient to function as quickly as possible. Are patients and their families happier if they get 70% versus 50% correction? The answer is probably yes (43), but only if additional correction can be achieved without added complications or morbidity (19). Also, whenever a surgeon recommends a surgical procedure for an adolescent patient, it behooves the surgeon to consider the effect of the surgery on the patient 5, 10, 20, 30, and 50 years after the procedure is completed. Obviously, we do not have all of the answers regarding the effects of scoliosis surgery on aging of the spine.

Scheuermann Kyphosis

Elio Ascani

Guido La Rosa

Claudio Ascani

E. Ascani and G. La Rosa: Ospedale Bambino Gesu, Cemntro Cura Delle Deformita, Della Colonna, Roma 1 00050, Italy.

C. Ascani: Clinica San Giuseppe, Roma, Italy.

In 1921, Holger Scheuermann described a typically juvenile kyphotic vertebral disorder that could be distinguished from asthenic (postural) kyphosis on the basis of a peculiar rigidity (94). This condition, known as Scheuermann kyphosis, is radiographically characterized by vertebral wedging and causes a growth disturbance of the vertebral end plates (8,55). Scheuermann kyphosis affects 0.5% to 8% of healthy subjects (4,5,78), with a prevalence in the male population.

Etiologic Factors

The cause of Scheuermann disease has been a matter of controversy and is essentially still unknown. Scheuermann himself described it as a form of aseptic necrosis of the ring apophyses. The observations of Schmorl and Junghans (95) regarding the presence of intraspongy hernias as being typical of the disease led to the hypothesis of a weakening in the consistency of the cartilaginous end plate, with a consequent penetration of disc material and subsequent alteration of the endochondral ossification process, leading to kyphosis. The presence of Schmorl hernias (nodules) in vertebrae located outside the kyphotic areas as well as in patients not affected by Scheuermann kyphosis has challenged the credibility of this theory. Nevertheless, this mechanical theory has been endorsed by some authors who have observed greater tension in the anterior longitudinal ligament and a partial reduction of wedging through the use of corrective braces at a prepubertal age (27,103). Sorensen (98) observed a high familial incidence of the disease. Halal et al. (50) studied the genetic transmission pattern in five families having a high incidence of Scheuermann kyphosis and suggested an autosomal dominant hereditary mode of transmission with a high degree of penetrance and variable expressivity (43). Bradford (24) considers Scheuermann kyphosis to be a form of osteochondrosis. The association of juvenile dorsal kyphosis with dural cysts (1), Legg-Calvé-Perthes disease, hypertonia, hypotonia, polio, infectious processes, hypovitaminosis, and endocrine disorders has been suggested as the cause of Scheuermann kyphosis, but with a lower correlation index.

Hormone Studies

Investigations conducted in our department revealed a growth hormone hyperincretion (elevated levels of growth hormone) in Scheuermann kyphosis–affected patients (6,9). Although the kyphotic deformity was not corrected in these subjects, they were found to be taller than the percentile mean for their ages (97), and their bone age was more advanced than normal for their chronological age. The role of the growth hormone hyperincretion in the etiologic process of Scheuermann disease is still unclear. The increase in height recorded in these patients may be related to growth hormone hyperincretion (at least during the active stage of the disease). Earlier bone aging may be correlated with a qualitative rather than a quantitative alteration (early pubertal spurt) of sexual steroid secretion (6).

It remains to be shown whether the growth hormone hyperincretion is the primary cause of the disease or an attempt at compensation. In a study of 61 adult patients, Murray et al. (78) reported a mean height of 179 cm in men and 162 cm in women. These values are not considered significant in terms of subject height. However, it should be noted that these are real height values; the correction factor due to the severe kyphotic curve (mean Cobb angle for this series is 71 degrees) has not been taken into account.

According to Buckler's height diagrams for the Anglo-Saxon population, the mean values reported by Murray et al. were above the fiftieth percentile for both sexes (28).

It is possible to postulate that the growth hormone hyperincretion is limited to the pubertal period and then returns to normal. Unfortunately, no study has been conducted to assess growth hormone hyperincretion increase over the years. It is widely known that growth cartilage hypertrophy is the physiologic response of bone to growth hormone secretion. Hypertrophic areas have been reported in vertebral growth cartilage in histologic studies of vertebrae in persons with Scheuermann kyphosis.

Other hypotheses have been suggested by Bradford et al. (22), who have considered Scheuermann kyphosis as forms of juvenile osteoporosis and secondary to malabsorption (20,22,29,30). Lopez et al. (71) have confirmed this hypothesis by using dual-photon absorptiometry. Recently, however, Gillsanz et al. (46) studied vertebral bone density in Scheuermann kyphosis–affected patients by using quantitative computed tomography and observed normal ossification in all patients.

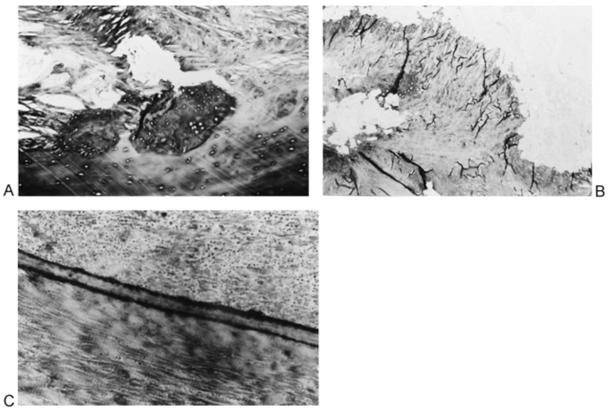

FIGURE 1. A: Vertebral cartilaginous end plate. Two strongly Alcian blue–positive pathologic areas, with many cells assembled in groups. These areas are clearly demarcated from the adjacent mainly period acid-Schiff–positive vertebral plate. **B:** Pathologic growth cartilage with a mosaic-like pattern—on the left, areas of hypertrophy; on the right, interruptions and areas where no cartilage is present. **C:** Matrix of pathologic areas: net reduction in the collagen fibers and an increase in the proteoglycans *(top)* close to the normal area.

Histologic Findings

Histologic studies of affected vertebrae demonstrate vertebral end plate and growth cartilage abnormalities, suggesting that the cause of the juvenile kyphosis may be an alteration of endochondral ossification. Aufdermaur (10,11) and Ippolito and Ponseti (56) have shown the presence of alterations in growth cartilage and in vertebral end plates in the absence of osteoporosis and without evidence of ring apophysis necrosis. The authors (8,9) carried out histologic, histochemical, and ultrastructural studies of vertebrae affected by Scheuermann kyphosis. The findings of these studies may be summarized as follows:

1. In Scheuermann kyphosis, the primary pathologic process is localized to altered areas of the growth cartilage and vertebral end plates according to a mosaic-like pattern (Fig. 1).
2. The alterations probably occur not only in the matrix but in the cells as well.
3. The matrix exhibits a lower number of collagen fibers and a greater proteoglycan content. The collagen fibers are also thinner.
4. The endochondral ossification process is altered: It is slowed down in the altered cartilage growth areas. In some areas it is absent, and direct bone formation on cartilage is seen without the deposition of bone on a necrotic and calcified cartilage model.
5. The longitudinal growth of the vertebra varies according to the variations in different regions.
6. The radiographic appearance of Scheuermann kyphosis should be interpreted as an “absence of growth” rather than a destructive process (7).

On the basis of recent investigations, the authors believe that Scheuermann kyphosis is caused by disruption of endochondral ossification, which causes a severe alteration in the longitudinal growth of the vertebral end plate. The areas that appear as erosions on radiographs are actually areas of altered ossification, where bone is directly formed from cartilage. The areas that appear “normal” have accelerated growth rates (Fig. 2), as shown by the hyperplasia of conjugation cartilage. The influence of mechanical factors on this growth disturbance produces increasingly unfavorable effects that lead to a progressive increase in the wedging of vertebral bodies and kyphosis. Genetic factors surely play a role in the etiology of the disorder but are yet to be defined.

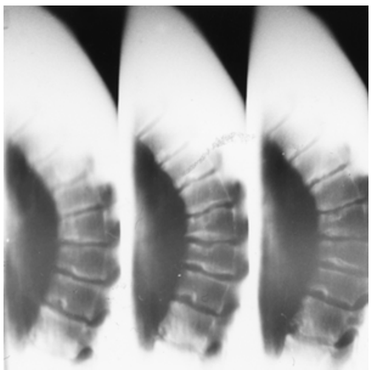

FIGURE 2. Typical radiographic alterations of Scheuermann kyphosis with vertebral end plate erosions, vertebral wedging, Schmorl hernias (nodules), and dorsal hyperkyphosis.

According to the studies obtained thus far, growth hormone hyperincretion has not yet been proved to be a primary etiologic factor; rather, it may occur in response to an unidentified metabolic condition. It is difficult to provide unequivocal data on the cause of this condition because the evaluation criteria used in case studies of Scheuermann kyphosis have not always been uniform.

Incidence

Sorensen (98) reported a 0.4% to 8% incidence of Scheuermann kyphosis. Ascani et al. (5) reported a 1% incidence in 19,650 school-aged children (between age 10 and 14 years). Bradford et al. (18) reported an incidence of up to 10% in different levels of severity. Scheuermann reported a predominance in males, with 88% of his cases involving males (male/female ratio of 7.3:1). Murray et al. (78) also reported a male predominance, although the ratio was lower (2.2:1). Montgomery and Erwin (77), Sorensen (98), and Travaglini and Conte (104) reported an equal male/female ratio, and Bradford et al. (18) reported a greater female incidence (2:1). The male/female incidence ratio varies in the literature because of variable inclusion criteria for the studied populations.

Clinical Picture

The disease onset occurs in the prepubertal phase, at around age 10 years (23). No radiographic evidence of Scheuermann kyphosis has been reported in the literature in any patient younger than 10. In particular, vertebral body wedging has not been identified before age 10 because of the absence of ring apophysis ossification (13), making the vertebral plate profile curvilinear rather than rectilinear. Many forms of Scheuermann kyphosis are probably neglected in the early stages, as they are often labeled asthenic (postural) kyphoses (78). The main clinical difference between asthenic kyphosis and Scheuermann kyphosis is in the rigidity of the kyphotic curve, which in Scheuermann kyphosis makes the voluntary or forced correction of the deformity impossible (Fig. 3). There is also an increase in dorsal kyphosis in the forward flexion of the trunk in Scheuermann kyphosis, compared with a normalization of the lateral spine profile in asthenic kyphosis. Furthermore, patients with Scheuermann kyphosis often have a more athletic body habitus than asthenic patients affected by nonstructural kyphoses. Scheuermann kyphosis patients also frequently present with a contracture of pectoral muscles and hamstrings.

Curve Location

There are two major forms of Scheuermann kyphosis: the more common thoracic type, with the apex localized between T7 and T9, and the so-called thoracolumbar form, with the apex between T10 and T12.

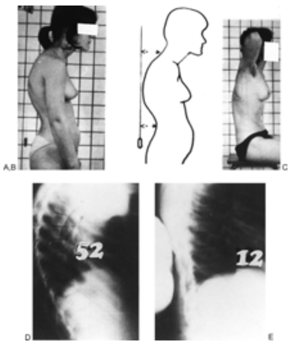

FIGURE 3. Asthenic (postural) kyphosis **(A)**. The clinical attitude may be corrected actively due to the flexibility of the spine **(C)**. The measurement parameters for kyphosis suggested by Stagnara **(B)** (see details in the text). The corresponding radiographs show the absence of lesions typical of Scheuermann kyphosis and the complete reducibility of the hyperkyphosis when the hyperextension test is performed **(D, E)**.

Thoracic Form

Clinical examination reveals an increased dorsal kyphosis. Affected patients develop a compensatory lumbar and cervical lordosis. Stagnara stresses the importance of conducting the clinical examination with the patient flexed forward, with the chest resting on the examination table and the knees slightly flexed. This position makes it possible to better appreciate structural deformities and the sites of pain. Murray et al. (78) conducted an accurate clinical examination in Scheuermann kyphosis patients in which about 30% of patients had significantly greater bilateral hamstring tension in the thoracic form as opposed to the thoracolumbar form.

Murray et al. (78) also observed a slight reduction in the strength of the trunk muscles in extension, with normal trunk strength during flexion. They reported a 90-degree mean trunk flexion (range 45 to 130 degrees) and a 20-degree mean extension (range 0 to 35 degrees). Comparative analysis of the flexibility range compared at the various stages of disease severity demonstrated that increasing curve magnitude is not accompanied by a greater limitation in articular elasticity during flexion and extension (78).

Scheuermann kyphosis is often associated with a moderate scoliosis (2). The scoliosis usually presents as an angular severity ranging between 10 and 20 degrees in 20% to 30% of affected subjects. Agostini et al. (2) found that the apices of the kyphosis and the scoliosis are the same. There is modest rotation of the vertebra and the gibbus in terms of the lateral deviation. These curves are structural but have a relatively benign natural history (2).

Thoracolumbar Form

The lower curve apex of this form of Scheuermann kyphosis may paradoxically reduce the upper dorsal kyphosis and may actually initiate a thoracic lordosis. This form is characterized by a greater degree of palpable tenderness of the spine. However, Murray et al. (78) have not reported this correlation between the level of kyphosis and increased vertebral tenderness. They found that there was a greater reduction in physical exercise and working activity over time in patients with the thoracolumbar form.

Lumbar Form

Over the past decade, there have been increasing reports of lumbar alterations simulating those typically reported in Scheuermann kyphosis. The peculiarities of this third form are an ever present backache, which causes the patient to present for medical treatment, and the absence of lumbar vertebrae deformations similar to those occurring at a dorsal level (74).

This form seems to occur mostly in male patients who do hard labor or are athletically active. Radiographically, this form is characterized by irregular vertebral end plates, Schmorl nodules, and a reduction in disc space height that is not associated with wedging (15). At times the lesion appears to be preferentially localized to the anterior rim of the vertebral body and resembles the so-called anterior marginal detachment (Fig. 4).

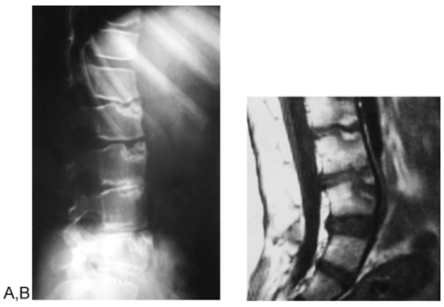

FIGURE 4. A: Tomography of a lumbar Scheuermann kyphosis. **B:** Magnetic resonance imaging demonstrates the anterior marginal detachment.

Pain

In addition to the cosmetic aspects of Scheuermann kyphosis, pain is the predominant clinical symptom of the disease (31). Its distribution and intensity vary according to age, stage of disease, site of kyphosis, and severity of the lesions.

Age

During the growth spurt, pain is uncommon (22% patients), but it reaches maximum incidence (60% of patients) as bone maturity progresses. Some authors believe that pain recedes completely when growth is completed (48,52). At this point, the pain is generally circumscribed and present only in the periapical region of the deformity, with upward or, more often, downward paravertebral radiation (Fig. 5).

By accurately and thoroughly palpating the skin and paravertebral muscle masses in patients presenting without pain symptoms, the physician can trace a latent tenderness map around the apex of the kyphosis and at the upper levels (65). According to our experience, this can be done in about 70% of patients presenting without any subjective painful symptoms. Pain is most frequently localized at the cervicothoracic border and in the interscapular region (9).

In adults, the pain takes the form of a backache, and the previously described periapical pain is not always reported. The pain seems to be localized to the iliac crest region, as evidenced by manually mobilizing T11 and T12. The sensory innervation of the dorsolumbar region presents a typical distribution; the dermatome pattern in the iliac crest region originates from T11 and T12 (Fig. 5B). The loss of mobility of the facet joints and the onset of arthritic degeneration may explain the prevalence of such symptoms in adults (9).

Stage of the Disease

The period of rapid growth, which generally coincides with the time of diagnosis, is when the greatest incidence of symptoms is reported (the so-called florid stage of the disease). Symptoms tend to decrease as vertebral ossification progresses.

Apex Level

Murray et al. (78) did not report any significant correlations between pain incidence and apex level. However, they did note that in patients with high-apex curves, the pain interfered more with day-to-day living than in those with the thoracolumbar form.

Degree of Kyphosis

It would seem logical to expect an increase in painful symptoms proportional to an increase in the angle of the kyphosis. However, Murray et al. (78) found a greater interference with everyday life (attributed to backache or sciatica) in patients affected by kyphosis with average angles (65 to 85 degrees) than those with lesser or greater angles (less than 65 and greater than 85 degrees, respectively). If the degree of the curve is correlated with the apex level, no significant differences in symptoms are observed. Patients with thoracolumbar Scheuermann kyphosis were found to decrease their activity as the curve magnitude increased (78).

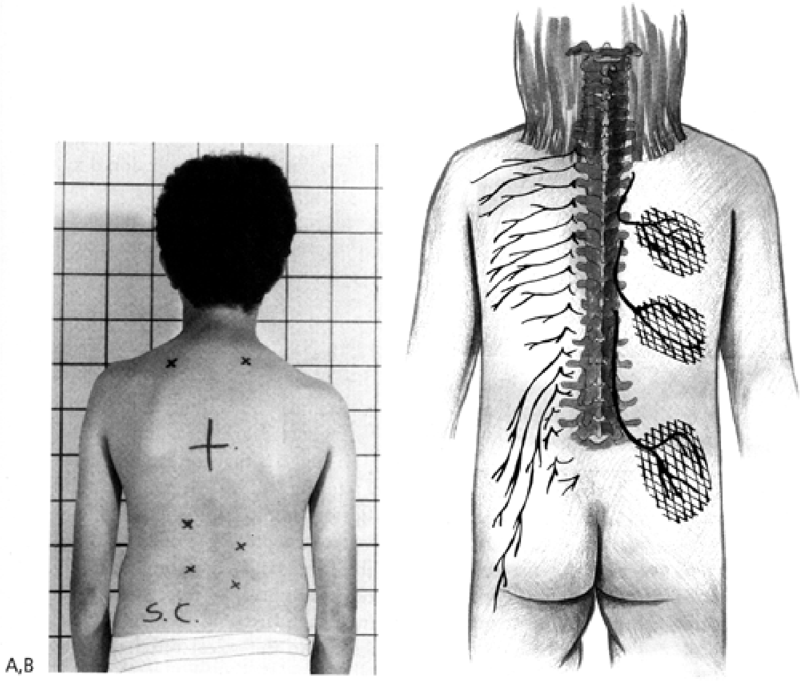

FIGURE 5. A: Typical pain distribution of a Scheuermann patient at a young age. The marker (+) identifies the apex of the kyphosis; the markers (X) show the pattern of pain distribution above and below the apex. **B:** Sensory area supplied by posterior primary division *(left)*. The nerve branches, after having supplied sensitive endings to the facet joints and the dorsal and sacrolumbar muscles, cross the fascia and split into an internal branch and an external branch that leads laterally downward and reaches the cutaneous area at a more caudal level (from three to five levels down) *(right)*. This accounts for the pain manifestation patterns at the level of the iliac crest that are typical in the adult patient.

Neurologic Symptoms

Neurologic symptoms are generally absent during the adolescent growth period but may become manifest sporadically in adulthood in the form of backaches and ischialgias (27). Paraparesis has been rarely reported in adolescence due to disc compression, generally at the apex of the kyphosis (107). Thoracic disc herniations in adults are seldom found to be the cause of paraparesis. Bouchez et al. (16) observed that hernia-induced neurologic symptoms in Scheuermann kyphosis patients occur in only 1% of the paralyzing disc hernia cases studied. A vascular pathogenesis, resulting from compression exerted on the spinal artery of Adamkiewicz, seems to be responsible for the onset of acute paraparesis.

Selective spinal arteriography is useful in all cases of a sudden onset of acute paraparesis (66,67). The magnetic resonance scan provides a clear illustration of the cause being investigated. In addition to disc herniation, a compression fracture in a relatively osteoporotic spine (at an adult or senile age) may cause paraparesis. This may lead to an acute paraparesis in patients affected by mildly severe Scheuermann kyphosis (17). Both conditions (dorsal disc hernia and compression fracture) act on spines that have experienced progressive angulation increases over time but in which the spinal cord has previously adapted. However, in these instances, the spinal cord cannot compensate for these changes and is sensitive to even 1- or 2-degree angle variations (63). One other possible cause of paraparesis has been reported by Lonstein et al. (70). It is typical of wide-angle kyphoses, in which the somatic and vascular compression mechanisms have a role identical to that of congenital curves.

In conclusion, it should be kept in mind that there is a slight possibility that by various pathogenic mechanisms Scheuermann kyphosis may lead to paraparesis in patients who were previously neurologically normal. Paraparesis should not be thought of as occurring exclusively in patients with a severe form of Scheuermann kyphosis (as might seem obvious) or only in adults.

Radiographic Studies

The Scoliosis Research Society has established that the normal thoracic kyphosis ranges from 20 to 40 degrees, based on the Cobb method (72). According to many authors, these figures are controversial. For example, Stagnara et al. claim that there is no such thing as a physiologic thoracic kyphosis; rather, each subject has his or her own “spinal profile.” Fon et al. (44) studied 316 normal subjects aged 27 years, finding a maximum limit of 45 degrees for a physiologic kyphosis.

Scheuermann kyphosis is diagnosed on the basis of radiographs performed in a left lateral projection. Bradford (23) suggests the following as some of the most accurate criteria for the diagnosis of Scheuermann kyphosis (Fig. 2):

1. Irregular upper and lower vertebral end plates
2. The apparent loss of disc space height
3. Wedging of more than 5 degrees in one or more vertebrae
4. The presence of a hyperkyphosis greater than 40 degrees

It is important to emphasize that the diagnosis of Scheuermann kyphosis does not require the presence of all of the typical radiographic findings associated with the disease. For example, a rigid hyperkyphosis, though it may not have any wedging, may be consistent with the diagnosis of Scheuermann kyphosis. Also, the isolated presence of vertebral end plate irregularities, not accompanied by wedging or hyperkyphosis, could also be indicative of Scheuermann kyphosis. There may be many variants or formes fruste of the disease. According to De Mauroy and Stagnara (36), these forms converge in a separate pathologic picture, which they refer to as idiopathic kyphosis.

The irregular nature of the vertebral end plates is the direct radiographic expression of the previously reported histologic features. Therefore, those areas affected by a longitudinal growth defect look like irregularities and grooves along the rectilinear profile of the vertebral end plate. The thickening and sclerosing of the spongy areas underneath the vertebral end plates are common and typical observations (76). Vertebral wedging is measured by drawing one line along the upper rim of the end vertebrae and another line along the lower rim and measuring the angle at which the lines intersect (105).

Sorensen (98) suggested a widely accepted criterion for the diagnosis of Scheuermann kyphosis that calls for the presence of at least three adjacent vertebrae with a wedging exceeding 5 degrees. Measuring vertebral wedging may be especially complex in patients who have not manifested ring apophyses. In this case, the lateral profile of the vertebra has a curvilinear rather than a rectilinear shape.

Stagnara (102) classifies the ossification stages of the vertebral end plate into six phases, ranging from puberty to bone maturity. In the most advanced stages of growth, the affected vertebra acquires a wedgelike shape, with a greater posterior height and a tendency toward platyspondylisis in both the anteroposterior and the lateral planes (49). The presence of Schmorl nodules, characterized by a depression of the vertebral end plate, is a result of the penetration of nuclear material into the spongy region. This finding is common but is not typical of the disease; it has also been observed in normal subjects (89). The marginal anterior bony detachment that is typical of lumbar localizations may be attributed to the same pathogenetic mechanism (15). The narrowing of the intervertebral space is a typical aspect of the advanced stages of the process. Bradford et al. (26) compare this picture to that of a marshmallow that is compressed between two smooth plates. The metaphor explains the apparently excessive thickness of the intervertebral disc, which seems to exceed that of adjacent vertebrae in the anterior rim.

Reduction of intervertebral disc space seems to be the only persisting radiographic evidence of the lumbar variant of Scheuermann kyphosis. In this form there is no vertebral wedging and kyphosis is constant because the lumbar segment is in lordosis, which maintains the posterior transference of the load-bearing axis (15,33).

A thorough and accurate radiographic investigation should be performed on patients affected by Scheuermann kyphosis and should include the following:

1. *Left-standing lateral radiographic projection of the entire spine.* According to some authors, it is advisable to position the patient so that his or her arms are resting on a support placed in an anterior position with respect to the body at a height not exceeding that of the heart so as to prevent the muscle contraction required to keep the arms suspended from altering the examination. This projection helps evaluate the degree of dorsal kyphosis and lumbar lordosis.
2. *Standing anteroposterior radiographic projection of the entire spine.* This projection helps determine the presence of associated scoliosis (in the various forms previously described) and the bone maturation of the iliac crest according to Risser's sign.
3. *Passive hyperextension test*, which is performed by positioning a wedge of plastic material just below the apex of the kyphosis. The patient is asked to lie in a supine position and release the weight of the head and shoulders in a reclining position. To avoid correction of kyphosis by increasing the compensatory lumbar lordosis, Stagnara (102) suggests that the radiograph be performed with the patient lying down with legs, pelvis, and lumbar spine in maximum flexion. Radiographic investigations performed in this fashion give an estimate of the degree of flexibility of the kyphosis and the percentage correction that may be obtained with standard corrective measures. Special emphasis should be given to positioning of the wedge. The wedge profile should be controlled with respect to the apical vertebra of the kyphotic curve. Incorrect positioning above the apex of the kyphosis will be misleading, giving the appearance of curve rigidity or even a paradoxical curve increase (Fig. 6).
4. *Lateral tomography.* The performance of three to four tomographic cuts at 4-mm intervals at the apical area of the kyphosis reveals in greater detail the irregular nature of the vertebral end plates (Fig. 6C). With this investigation, it is easier to measure the wedging and assess the state of development of the ring apophysis.
5. *Magnetic resonance imaging* (MRI).

Differential Diagnosis

The radiographic differentiation of a postural kyphotic curve is made by the total absence of wedging and vertebral end plate irregularities and the complete reduction of hyperkyphosis with the passive hyperextension test, using wedges as described above. In the clinical entity termed idiopathic kyphosis (35,36), which is probably completely different from Scheuermann kyphosis, the normal vertebral profile is accompanied by rigidity of the hyperkyphotic curve.

Specific or nonspecific spondylitis disorders initially become manifest by an irregular vertebral margin adjacent to the affected disc, and unlike the lesions typical of Scheuermann kyphosis, they do not present sclerotic rims surrounding the eroded areas (Fig. 6). The differentiation from spondyloepiphyseal dysplasias or other forms of osteochondral dystrophies is generally made by the general epiphyseal-metaphyseal involvement of other joints and the fact that the platyspondylisis typical of these conditions is not accompanied by vertebral irregularity or wedging. It may be more difficult to differentiate some forms of type II (failure of segmentation) congenital kyphosis from Scheuermann kyphosis. Kharrat and Dubousset (57) reported some forms of congenital kyphosis that achieve interbody fusion during the same time that patients typically present with Scheuermann kyphosis. Scheuermann kyphosis rarely exhibits a tendency to interbody fusion, but if fusion does occur it takes place through osteophyte bone bridges that always spare the intervertebral disc.

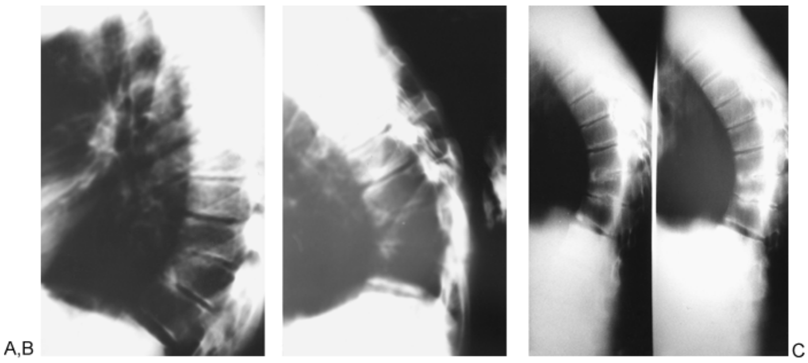

FIGURE 6. A: Vertebral kyphosis localized to few disc spaces. **B:** The supine hyperextension test shows that incorrect positioning of the wedge above the apex leads to worsening of the kyphosis. **C:** Tomography shows an apparent intersegment fusion, possibly as a result of spondylitis. No wedging or erosion is observed at other levels.

Natural History

The natural evolution of Scheuermann kyphosis during the growth spurt is quite variable (59). Bradford et al. (21) noted that 96 of 168 patients treated with a Milwaukee brace experienced progression of their deformity prior to the initiation of treatment. Lowe (74) maintains that if the residual kyphotic deformity at skeletal maturity remains under 60 degrees, the patient has an excellent possibility of experiencing little if any discomfort in adult life (74).

Travaglini and Conte (104) studied 50 patients affected by Scheuermann kyphosis with a minimum follow-up of 25 years and noted significant morphologic and structural evolution but insignificant clinical and functional problems. The incidence of pain was moderate in adult life, regardless of the severity of the curve and of the patient's type of work.

Murray et al. (78) observed 61 patients affected by Scheuermann kyphosis with a 31.7-year follow-up and compared them with 34 normal controls. This thorough investigation considered factors such as pain, work, social history, restriction of activities, cardiopulmonary function, vertebral function, and cosmetic aspects. Twenty-eight percent of the affected patients (62% of controls) reported that they had never suffered from vertebral pain. Sixty-four percent of the affected patients (15% of controls) reported that they had suffered from variable forms of backache, which could not be statistically correlated with the apex of the curve or its magnitude. In the group of Scheuermann kyphosis patients, 6.6% had had spinal surgery, compared with 2.9% of controls. No statistical difference was found between the two groups in terms of the interference of pain with everyday life, lower limb hypoesthesia, fatigue, self-esteem, psychological disorders, type of job chosen, or amount of sick leave required for backache or sciatica. Statistically significant differences were recorded only in the case of pain localization and intensity. A greater incidence of back pain and tenderness was reported in the group of patients affected by Scheuermann kyphosis. The levels of tenderness, however, were not great. No correlation was found with cardiopulmonary insufficiency, except for the most severe cases (curves greater than 110 degrees).

These findings suggest that the clinical and functional natural history of the disease tends to be benign. This is in spite of the morphologic and structural exacerbations that, beyond a certain angle (65 degrees), have to be taken into account even in adult life because of biomechanical imbalances that can lead to curve progression, such as occurs with scoliosis.

One aspect that needs to be addressed is cosmetic appearance and self-esteem, which cannot be easily or adequately quantified on the basis of questionnaires (75a,99).

Treatment

According to Stagnara (102), there are four pathologic evolutions or scenarios requiring either nonoperative or surgical treatment:

1. Rapid increase in the curvature of the kyphosis
2. Exacerbation of vertebral lesions and increase of wedging, leading to a progressive kyphosis

3. Pain related to a severe dorsal kyphosis that does not respond to any type of nonoperative treatment
4. Alteration of respiratory function related to the vertebral deformation

Infrequently, these four treatment indications may be accompanied by rapid- or slow-onset spinal cord compromise as a result of dorsal disc hernias and/or compression fractures (90). Generally, adolescents with a slightly increased thoracic kyphosis—between 40 and 50 degrees—with no evidence of progression require only exercise and periodic follow-up. As adults, these patients have an excellent chance of being problem-free.

Nonsurgical Therapy

Physical Therapy

Physical therapy may be helpful, but it should be used only in the early stages of the disease as a complement to more aggressive treatments (Milwaukee brace, casts, and surgery). Physical therapy alone cannot obtain more than improved muscle tone and correction of bad posture. Extension sports, such as swimming, basketball, and volleyball, are advised. Aerobic exercise is an essential adjunct throughout the entire treatment period.

The goals of exercise are to maintain flexibility, correct lumbar hyperlordosis, and strengthen the extensor muscles of the spine. Exercises for stretching the hamstrings should be reserved for patients with clinical evidence of tension in these muscles.

Braces

Scheuermann kyphosis responds positively to treatment with braces, provided the therapy is begun before skeletal maturity is achieved, ideally in the first stages of the disease (at the early diagnosis stage). In general, this approach is indicated for patients with satisfactory back flexibility, with no less than 40% passive correctability in a curvature between 50 and 75 degrees. Flexibility is the crucial factor in making the choice between an active correction system (Milwaukee brace) and a passive correction system (antigravity cast). The reconstitution of the vertebral end plate is possible only if the vertebra maintains its active growth potential for a sufficient time (12).

In spite of good immediate results, if the anterior vertebral height has not been thoroughly reconstituted, considerable loss of correction will be observed in the follow-up period. The most widely used type of brace is the Milwaukee brace (14), which acts as a three-point dynamic orthosis and promotes extension of the thoracic spine. The pelvic girdle stabilizes the lumbar spine, thus reducing the lordosis, while the posterior pads apply corrective pressure at the apex of the kyphosis. Use of this type of brace is indicated predominantly in kyphoses with an apex between T6 and T9. The brace is initially worn on a full-time basis (22 out of 24 hours) for an average of 12 to 18 months. After that, it is usually possible (based on both the correction achieved and the progression of bone maturity) to wear the brace for maintenance purposes on a part-time basis (usually at night) until complete skeletal maturity has been achieved (38).

Generally, brace wear is gradually reduced by progressive 2- to 4-hour daily increments as skeletal maturity approaches. It is difficult to establish in general terms when weaning from the brace should begin. Sachs et al. (91,92) observed that there is no statistical difference between the results of patients who wore the brace on a full-time basis for 11 months and those who wore it for 8 to 10 months. Therefore, they prefer this shorter duration, at least in statistical terms.

The Milwaukee brace's occipital chin ring has often been the cause of psychological problems, which may decrease compliance. For this reason, some authors suggest the use of low-profile braces for thoracic kyphoses with a curve apex below T9 and for thoracolumbar kyphoses. Several types of braces have been suggested. Zielke suggested an orthosis with four valves that act as a double-torque force at the lumbar and thoracic levels (83). At the lumbar level, it provides a pair of opposite thrusts on the sacral promontory and on the anterior part of the iliac crests; at the thoracic level, it provides a couple of thrusts exerted just below the apex of the kyphosis and in the opposite direction on the manubrium sterni.

The lumbar form of Scheuermann disease, characterized by more irregular vertebral end plates, responds well to the application of a lumbar orthosis in which correction of the lordosis is not necessarily complete, as occurs with the Boston brace.

Montgomery and Erwin (77) reported long-term results in 21 patients treated with a Milwaukee brace (full time for 18 months and part time for 6 months). After an initial mean 21-degree improvement at the end of treatment, they observed a mean correction loss of 15 degrees over time. The mean wedging correction amounted to 1.1 degrees. Sachs et al. (91) reported data on 132 patients treated according to this approach with a 5-year minimum follow-up period. The mean full-time wearing period was 14 months, and the part-time mean was 18 months. There was an initial mean correction of about 50% in all curve classes, followed by a constant loss of correction at follow-up of 20 degrees for each group of curves. Sixty-nine percent of the patients who wore the brace faithfully reported improvement of 3 degrees with respect to the initial curvature—an improvement over the natural history of the disease.

There was a trend toward wedging improvement (ranging between 8 and 10 degrees among the various classes), with a reduction in the number of wedged vertebrae from 432 at the beginning of treatment to 266 at the end of treatment. The apical wedging was 8.4 degrees prior to treatment, 7.6 degrees at the end of treatment, and 8.1 degrees at 5-year follow-up. Thirty-two of the patients underwent surgery. The mean apical wedging in these patients amounted to 9.4 degrees, and the mean curvature was greater than 60 degrees.

According to Bradford et al. (21), the indications for brace treatment are initial curves of less than 70 degrees with a Risser sign lower than grade 3 and minimal vertebral wedging in fewer than three vertebrae.

It may thus be concluded, at least from a statistical point of view, that if the goal of brace treatment is to achieve a curvature as close as possible to 50 degrees at maturity in affected patients, there is a good chance of obtaining this goal in immature flexible patients with an initial curvature not exceeding 60 degrees (50% correction = 30 degrees + 20-degree loss at follow-up = 50 degrees).

Casts

When vertebral rigidity is considerable, it is advisable to resort to the preliminary use of corrective casts. De Mauroy and Stagnara (37) developed a therapeutic regime (Lyon method) organized as follows:

1. Physiotherapy in preparation for the cast
2. Application of three antigravity casts
3. Plexidur maintenance braces until skeletal maturity

The plaster casts, changed twice at 45-day intervals, are applied in two stages.

A multicenter trial conducted in France among the members of the Groupe d'Etude de la Scoliose on a total of 255 patients treated with this method showed a 19-degree mean angular correction at the end of the treatment (from an initial 50 degrees to 31 degrees—a 40% correction—with a mean loss of 7 degrees of correction at 2-year follow-up) (83). These findings seem to indicate that although it achieves a lower initial mean correction, the Lyon method guarantees a lower loss of angular correction over time than the Milwaukee brace treatment method.

These studies lead to two conclusions: First, as happens following the treatment of other disorders (e.g., scoliosis), the long-term return to angular values similar to those recorded initially is considered to be a therapeutic success. Second, the goal of treatment is to end up with a curvature in the physiologic range (40 to 50 degrees) at the completion of growth. It is crucial to preserve the correction achieved initially with casts by continuing treatment with the Lyon method or a Milwaukee brace.

Ponte et al. (84,86) treated 3,064 patients affected by kyphosis of various causes, 2,604 of whom presented with wedging greater than 5 degrees in at least one vertebral body, and 1,043 of whom presented with irregular vertebral bodies that were consistent with a diagnosis of Scheuermann kyphosis. Treatment involved the application of antigravity or localizer-type casts for a mean period of 8 months (83% of cases), 12 months (16%), or 16 months (1%). The mean initial curvature was 57 degrees. Forty percent angular improvement was obtained with the antigravity cast and 42% with the localizer cast. This was followed by the application of a Milwaukee brace at night and intense physiotherapy up to maturity. With this therapeutic regime, the authors reported a mean loss of 4 degrees correction at a 3-year mean follow-up. On average, a 62% mean wedging improvement was obtained (from 9 degrees at the beginning of treatment to 3.5 degrees at the end).

This treatment experience with casts confirms that although the initial angular improvement was less, deterioration over time was lessened by use of the brace. There was no correlation between the beginning of treatment, stage of puberty, and degree of wedging. The later the treatment is begun, however, the smaller the chances of reconstituting the vertebral end plates. As a result, even considerable initial angular corrections will not last indefinitely.

Conclusions on Nonsurgical Treatment Methods

The Milwaukee brace is effective in the treatment of Scheuermann kyphosis, provided that treatment is begun in the initial stages of the disorder, with an angle between 45 and 60 degrees, in a skeletally immature patient with at least 40% flexibility.

More rigid kyphoses should be treated with a corrective cast followed by a plexidur or Milwaukee brace to maintain correction. It is not advisable to undertake this treatment at a postpubertal stage, when high loss-of-correction rates are reported. Therefore, in these cases, it may be preferable to resort to surgery, especially in the case of sudden curve increases.

Surgery

Preoperative Techniques

In order to make a decision about the surgical technique to adopt and especially the approach sequence, it is advisable to perform preoperative correction, which will give some idea of the flexibility of the curve and the extent to which it may be improved by surgery.

Lowe (74) suggests analyzing the supine hyperextension lateral radiograph with a wedge. If the kyphosis is not corrected to values under 50 degrees, the procedure should be performed in two stages (anterior-posterior). In patients in which the hyperextension test leads to a decrease in angular values under 50 degrees, a single-stage posterior arthrodesis with instrumentation is advised. Stagnara and Perdriolle (101) recommend a preoperative correction with cast or halo traction to avoid rapid intraoperative correction, which may pose some risk to the spinal cord or a gastrointestinal complication, such as ileus (see Fig. 15). They also suggest the preoperative relaxation of the contracted ligamentous structures in the concavity of the kyphosis. This correction may be achieved according to the flexibility and severity of the kyphosis with either corrective casts or halo traction. These methods are rarely needed in most cases, but will be described for completeness.

Elongation Cast

A pelvic belt resting on the iliac crests is connected to a cervicothoracic belt by means of two Donaldson and Engh elongation screws. The progressive elongation of the screws (1 mm per day) reduces the deformity over an average of 20 to 30 days.

The elongation cast allows for much greater correction than that obtained with the hyperextension test. It is also possible to perform posterior arthrodesis—when this is the only approach planned—without removing the cast for surgery.

Great care should be taken to avoid pressure sores on the iliac crests or chin rests, which must be appropriately padded with soft material.

Halo Traction

The halo system allows for adequate preoperative correction (82). Stagnara (102) suggested a variation of the halo bed or halo wheelchair treatment, which has been found to be effective. This system is rarely used in the curves treated only with a posterior approach. It greatly increases the possibility for correction in combined procedures, in the interval between anterior release and posterior arthrodesis.

Posterior Operative Techniques

According to Stagnara, the general aims of any type of surgical intervention are to shorten the convexity and elongate the concavity (102). The reduction of the convexity may be facilitated by a complete resection of the facet joints in the kyphotic area and may be obtained with the application of surgical instruments.

On the operating table, the patient may have cephalic traction applied, with possible pelvic countertraction. Traction is rarely used in North American centers. Resection of the facet joints must be complete to obtain maximum mobility of the curve. The instrumentation is then positioned, and autologous bone from the iliac crest is added to the joints and lateral transverse process gutter.

The advent of Cotrel and Dubousset's systems and deriving instruments (e.g., Isola), completely supplanted the instruments used up to the early 1980s (Harrington, Cotrel, Luque).

Therefore, we shall illustrate only the advantages and disadvantages of this last type of instrument, which is still in use today.

Cotrel-Dubousset System

The Cotrel-Dubousset system was introduced in 1983 for the treatment of scoliosis. It is currently the most frequently employed system to treat Scheuermann kyphosis (all posterior derotation systems can be used to treat Scheuermann kyphosis). Generally, in Scheuermann kyphosis it is suggested that three or four double pedicular transverse or laminar hook configurations be used on the spine above the apex of the kyphosis; this gives an excellent hold on the posterior arch and minimizes the risk of neurologic impairment. Through an initial levering maneuver (similar to that used with the Luque rod), it is possible to obtain correction of the kyphosis. This allows for the introduction of the rods into the inferior hooks, which are positioned under the lamina of the vertebrae below the apex of the kyphosis and mounted in compression.

Correction is further improved by segmental compression of the hooks. The use of open hooks toward the cranial surface allows for easy positioning of the rod, much more so than with Harrington compression instrumentation. The diameter of the rods (7 mm) is such that lasting correction over time can ensue and postoperative immobilization is unnecessary (Fig. 7). The stability of this system is further enhanced by the application of two transverse interlocks (Cotrel's Device Transverse Traction [DTT]), which convert the instrumentation to a square configuration that cannot be deformed, similar to that proposed by Dove.

All systems similar to the Cotrel-Dubousset system (Isola, Colorado, USS, TSRH) may be used effectively.

The use of a transpeduncular screw in the first two lumbar levels increases the stability of the assembly, provided that the general criteria for the selection of the fusion area are respected. Otherwise, a screw may pull out. The use of sublaminar site at all levels, combined with limited laminectomy of the adjacent vertebral borders, seems to be the most stable assembly scheme.

Biomechanics of Posterior Instrumentation Systems

As for the Cotrel-Dubousset system, biomechanical studies are lacking. However, it appears that the mechanical resistance of the rod increases according to its diameter and that the double hook-claw anchorage system is better biomechanically with regard to the arthrodesis area. The entire curve must be fused (60,61). Shorter fusion areas are subjected to a greater lever arm, created by the weight of the neck and trunk, and are not subjected to arthrodesis (Fig. 8).

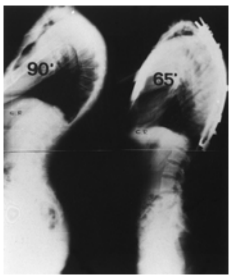

FIGURE 7. Severe 90-degree kyphosis treated with a posterior arthrodesis and Cotrel-Dubousset instrumentation. The curve was corrected to 65 degrees. The rigidity of the system obviates the need for anterior arthrodesis.

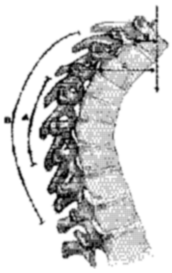

FIGURE 8. The mechanical advantage of a longer fusion (to the upper vertebra) over a shorter one. With the short fusion, there is an effectively longer lever arm *(A)* as opposed to the relatively shorter moment arm *(B)* when the entire kyphotic area is included in the fusion. Reprinted with permission from White AA III, Panjobi MM (1978): *Clinical biomechanics of the spine.* Philadelphia: J.B. Lippincott.

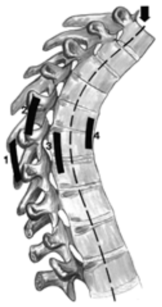

FIGURE 9. In the spine, the graft in position *(1)* is well away from the neutral axis *(dotted line)*. When biologically healed, it can offer tensile resistance against progressive kyphosis. The graft at position *(2)* can do the same but is less effective because it is closer to the neutral axis. The graft at position *(3)* is not likely to be as effective as *(1)* or *(2)* in preventing progression of deformity because it is even closer to the neutral axis. Graft *(4)* is effective because it can immediately begin to resist compression forces. The graft is also some distance away from the neutral axis. (Reprinted with permission from White AA III, Panjobi MM (1978): *Clinical biomechanics of the spine.* Philadelphia: J.B. Lippincott.)

In the most severe cases of kyphosis, which involve angles greater than 45 degrees after correction, the spine is exposed to greater stress in the arthrodesed area, which is under tension. This explains the occurrence of pseudarthrosis when the posterior fusion is not accompanied by an anterior arthrodesis.

With regard to the positioning of bone grafts, their resistance to stress increases with their distance from the neutral axis (Fig. 9). Increase in the kyphotic curvature is accompanied by an increase in the lever arm. Therefore, if reduction of kyphosis is insufficient, the residual tension will bring about such stress that posterior instrumentation may fail and the bone grafts may suffer fatigue fracture.

Bradford et al. observed that patients with vertebral wedging greater than 10 degrees tend to lose the operative correction obtained with posterior approaches more than patients with a wedging less than 10 degrees. The wedging seems to increase angulation and flexion, which in turn increases the eccentric load on the vertebral end plate.

Anterior Operative Techniques

When an anterior arthrodesis is indicated, it is performed by means of an intrathoracic approach for curves with a middorsal apex and by a thoracoabdominal retroperitoneal approach in thoracolumbar curves (54). The technique makes it possible to resect the anterior longitudinal ligament and to perform multiple discectomies at apical vertebral levels (Fig. 10).

Stagnara (102) suggests that the area arthrodesed be extended to at least two levels above and below the apex of the kyphosis (five to six disc spaces in total). He suggests creating an osteoligamentous flap starting from the anterior and lateral surface of the vertebral bodies within which a fibular strut graft is placed, along with fragments of the rib removed for surgical access (Fig. 11). Other bone fragments, taken from the iliac crest, are positioned in the disc spaces to allow for an interbody fusion. The angular correction obtained is maintained by the fibular strut graft, which is fixed in the apical vertebrae, acting as a mechanical support against flexion forces, until the arthrodesis is achieved. In this case too, the greater the distance from the neutral load axis, the greater the reduction of the lever arm and the better the structural support (60) (Fig. 12A).

Winter (106) described another technique using the rib as an inlay graft, positioning it in a groove excavated on the lateral surface of the vertebral bodies, encasing it in the apical vertebral bodies (26) (Fig. 10).

In cases of extreme vertebral rigidity, there are several distraction devices that may be used intraoperatively that allow for angular reduction when the procedure is performed by an anterior approach. This instrument may be used temporarily and removed following application of the supporting strut grafts (fibula or rib) (Fig. 12B). The use of distraction devices (temporary or permanent) may improve intraoperative correction, which is otherwise reduced because of the integrity of the posterior spine, which promotes maintenance of rigidity.

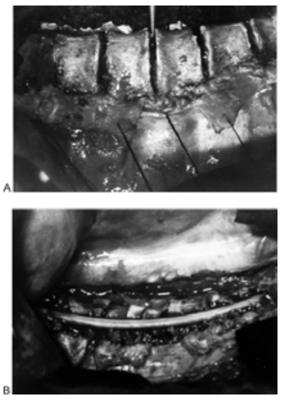

FIGURE 10. A: Complete discectomy and obliteration of the vertebral end plates is the best guarantee for successful interbody arthrodesis. **B:** Positioning of the graft in a trench excavated on the lateral aspect of the vertebral bodies; the graft is fitted into the vertebrae at the limits of the arthrodesis area. Other grafts are inserted into the interbody spaces.

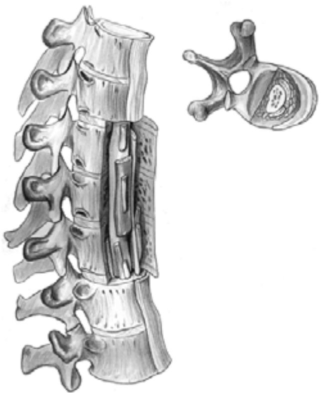

FIGURE 11. The osteoligamentous flap technique of Stagnara (102).

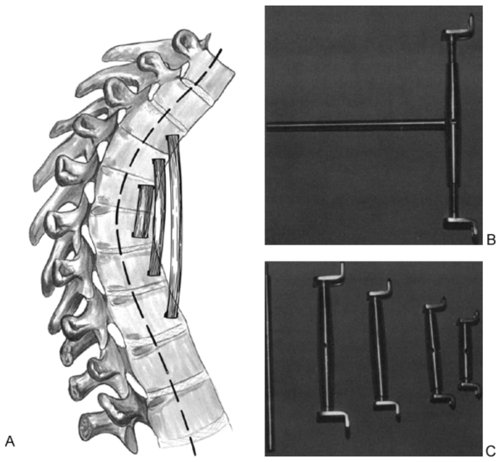

FIGURE 12. A: Various locations of anterior bone grafts for kyphotic deformity. The further one moves away from the neutral axis *(dotted line)*, the more the moments are reduced and the more effective the bony support. (Reprinted with permission from White AA III, Panjobi MM (1978): *Clinical biomechanics of the spine.* Philadelphia: J.B. Lippincott.) **B:** Pinto distractor used in kyphosis. (Courtesy of S. I. Weinstein, M.D., Department of Orthopaedic Surgery, University of Iowa, Ames, Iowa.)

Various other types of systems have been devised and, according to Dunn (41), may be broken down into two major groups. The first type of system acts by means of two transvertebral body screws connected to a metal bar; the no. 1 Dunn, the Kostuick-Harrington, and the Gardner systems are examples of this type (Fig. 13). This type of system provides no resistance to twisting forces and little resistance to lateral flexion forces. The second type of system acts with the addition of load forces transverse to the apex of the curve and improves the correction capacity that may be obtained with the first type of instrument, which acts according to isolated stretching (Fig. 13).

Planning Surgery

If, in assessing the flexibility of the kyphosis by means of hypercorrection tests or preoperative radiographic techniques, it is possible to correct the curve to values around 50 degrees, it is advisable to plan a single posterior procedure (3,47). If, however, the preoperative assessment of correction reveals a curvature of more than 50 degrees, it is suggested that an anterior procedure be performed first, followed by a posterior arthrodesis and instrumentation (25,53).

Some authors suggest performing the combined procedures (anterior-posterior) at a single operative session; others prefer a 7- to 10-day interval between the two procedures. Concomitant performance of the procedures affords a better control of the angular correction and a shorter hospital stay for the patient. However, it may increase the complexity of surgical interventions and related risks.

Treatment of Paraparesis with a Subacute Onset

The onset of paraparesis has seldom been reported in patients with Scheuermann kyphosis. When it occurs, it may be due to a disc herniation at the apex of the kyphosis or, less frequently, a compression fracture (42,58). In such cases, and especially when a centrally located hernia is present (89), it is advisable to perform a transpedicular decompression to obtain tangential access to the disc space, and to then perform an accurate discectomy, thus avoiding neurologic damage (80).

It is advisable to perform an associated partial osteotomy of the vertebral rims above and below the involved disc in order to broaden the diameter of the vertebral channel. To avoid iatrogenic instability, it is wise to complement this procedure by stabilization of the adjacent levels by means of plates and transpedicular screws. Lesoin et al. (67) suggest that stabilization be achieved by means of a Harrington rod. Bradford (17,25) again advises anterior decompression with circumferential arthrodesis by means of a Harrington compression system (81,88,96). Logroscino et al. (69) prefer to do a costotransversectomy two levels above the lesion and remove the head and neck of the rib and the transverse process at the lesion level. This makes it possible to effectively visualize the area and perform the discectomy. This anterior costotransversectomy causes less instability and is sufficient to perform a limited arthrodesis in the affected area by means of rib grafts removed to gain surgical access.

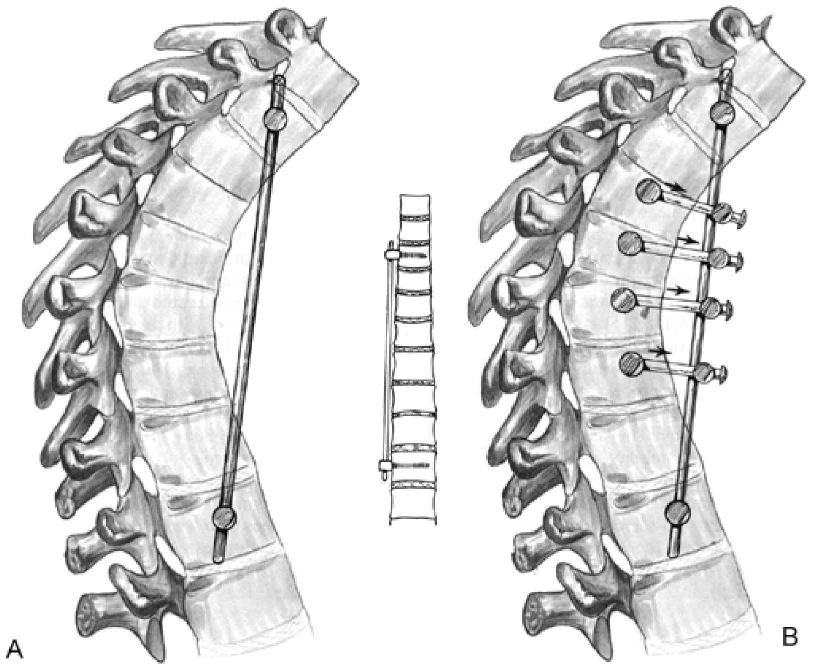

FIGURE 13. In the area of kyphosis there are two generic types of anterior implants. **A:** This implant gives no resistance to torsion and little or no resistance to lateral bending. **B:** This device applies transverse loading to the apex of the curve. The loading mode is more effective than distraction, as the kyphotic deformity is brought within the normal range. (Reprinted with permission from White AA III, Panjobi MM (1978): *Clinical biomechanics of the spine.* Philadelphia: J.B. Lippincott.)

It is advisable to perform selective arteriography to localize the emergence of the anterior spinal artery (branch of Adamkiewicz's artery) (39). According to Lazorthes et al. (64), in 75% of cases it is localized between T9 and T12, in 15% it is localized between T7 and T8, and in 10% it is localized between L1 and L2. In 80% of cases, it is localized on the left side (64). Knowing the exact origin of this artery is crucial to avoid cord damage because the anterior spinal artery supplies blood to two thirds of the dorsal medulla.

Results of Surgical Instrumentation

Anterior Arthrodesis and Combined Arthrodeses

Kostuick (62) analyzed the results of 12 patients treated with Kostuick-Harrington anterior instruments. One year after surgery, he reported no cases of pseudarthrosis, one intraoperative vertebral fracture, and one rupture of a transvertebral screw. Using circumferential arthrodesis in 12 cases, Savini et al. (93) obtained a mean correction of 34 degrees, with a 3-degree loss of correction at follow-up.

In 23 cases treated with combined anterior-posterior arthrodeses, Bradford et al. (25) reported excellent results in 80% of the subjects (correction loss less than 6 degrees), and a 15-degree mean loss in the remaining 20%. They observed the total relief of painful symptoms. Herndon et al. (53) evaluated 13 cases treated with anterior and posterior arthrodeses and reported excellent results in 69% (correction loss less than 6 degrees); 11 of these cases had a follow-up period of 3 to 5 years, with a loss of correction of less than 6 degrees in 80%.

Cotrel-Dubousset System

Lowe (73) and Clark and Shufflebarger (32) report results with this system, stressing the low incidence of negative side effects, especially with regard to neurologic problems. Donald et al. (40) compared the ability of the Harrington and Cotrel-Dubousset systems to correct the superior, middle, and inferior segments in the kyphosis. Both systems were found to effectively correct the middorsal section of the kyphosis but were relatively ineffective in correcting the superior section. The Cotrel-Dubousset system achieves a much greater correction on the inferior segment.

Lowe and Kasten (75) analyzed the behavior of sagittal curves subjected to correction with the Cotrel and Dubousset's system in 32 patients affected by Scheuermann disease of more than 75 degrees (range 75 to 105 degrees). The mean correction was 43 degrees (range 26 to 65 degrees). The mean magnitude of the lordosis was 75 degrees (range 58 to 100 degrees), and the mean correction was 20 degrees (range 16 to 35 degrees). Maintenance of the correction was excellent, with a mean loss lower than 5 degrees and a spontaneous reduction of the lordosis following correction of the kyphosis.

The authors observed the appearance of a junctional proximal kyphosis associated with an overcorrection (more than 50%) or a short instrumentation compared with the proximal apical vertebra. When the same situation was observed distally, the authors recommended that overcorrection be avoided (no more than 50% and no less than 40%) to prevent the onset of a proximal junctional kyphosis.

For this purpose, the proximal apical vertebra must always be included in the fusion; distally, the arthrodesis area must include all of the vertebrae included in the kyphotic area plus the transitional area (one or two lordotic vertebrae).

Sagittal balance was measured radiographically by dropping a plumb line from the center of the C7 vertebral body and measuring the distance from this line to the sacral promontory, with a positive value indicating when the plumb line lies anterior to the promontory of the sacrum.

The data indicate that the patients with Scheuermann disease were normally in negative balance and became somewhat more negatively balanced after surgery.

These studies show that the Cotrel-Dubousset system has improved the ease of assembly, in contrast to Harrington's instrument, which has now been abandoned. The larger size of the bars should not lead one to believe that the arthrodesis area may be reduced. The tensions that develop in an excessively short arthrodesis area are not great enough to break the instrument (as used to happen with the Harrington device), but they may cause a loosening of the lamina, as a result of which the hook may become unfastened from the site of the implant. The basic rules must thus be met.

The Cotrel-Dubousset instrument allows for an easier resumption of treatment with an easier extension of fusion area (domino). Therefore, the Cotrel-Dubousset system and its derivatives (Isola, TSRH, and so forth) prove over time to be easier to apply and easier to manage in case of failure, but the basic golden rules (i.e., selection of the fusion area, arthrodesis technique) must not be neglected, as serious problems may ensue if they are not applied (see Figs. 14, 15, 16).

This system is the best because of its corrective efficacy, its ability to maintain correction, the absence of neurologic complications associated with its use, and the fact that it does not require postoperative immobilization. Another positive aspect of the Cotrel-Dubousset system is the relatively easy handling of possible complications (such as inferior hook pullout) (Fig. 14).

Complications of Surgery

The complications related to this type of surgery are similar to those observed in major spinal surgery. For posterior procedures, the most frequently occurring complication is pseudarthrosis, followed by hardware failure and secondary loss of the correction. These complications seem to be related to technical defects. It is, however, crucial to perform the arthrodesis of articular processes with great precision (79).

Other complications reported in this type of surgery include pneumothorax, gastrointestinal obstruction, and the onset of postoperative backache or sciatica due to canal encroachment by synthesis devices (e.g., screws, hooks, sublaminar wires). Dural lacerations, infected dural fistulae, and postoperative meningitis and encephalitis may occur sporadically. In their series of 51 patients subjected to various types of corrective procedures, Speck and Chopin (100) reported one Brown-Séquard syndrome, seven vertebral fractures, four deep infections, and one instrument breakage.

In their series of 13 patients treated with combined anterior-posterior arthrodesis, Herndon et al. (53) reported one death, one intraoperative vertebral fracture, one deep venous thrombosis, one transient motor muscle weakness, and one postoperative onset of backache.

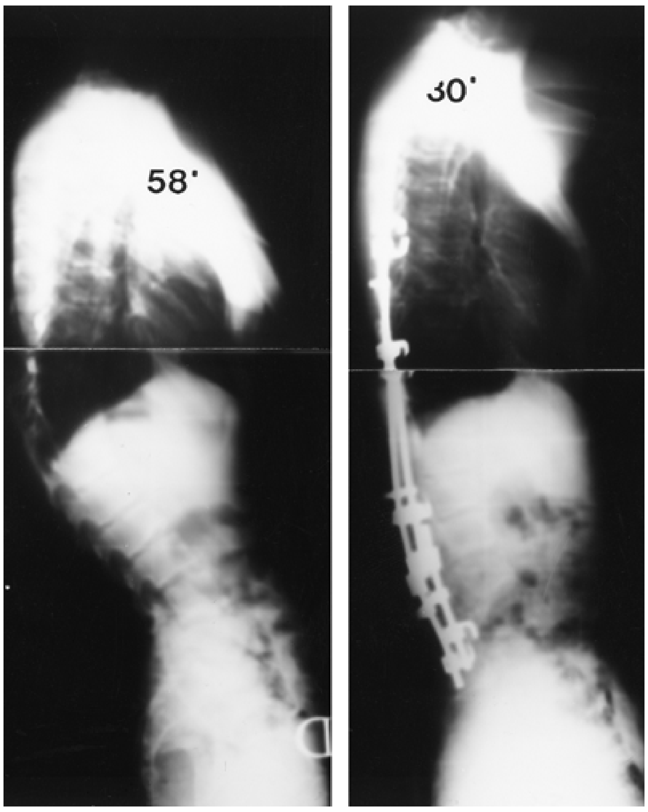

FIGURE 14. Thoracolumbar kyphosis of 58 degrees corrected with the Cotrel-Dubousset system. Perioperative dislodgement of the inferior hook was managed by means of a domino and extension of the fusion distally.

As an intraoperative complication, Stagnara (102) reported massive hemorrhage from vertebral venous sinuses and suggested the abundant use of surgical bone wax to avoid such a problem. He also reported frequent pulmonary complications resulting from the ablation of pleural drainage (late postoperative pleuritis and atelectasis). An excessively rapid correction of the kyphotic curve (only posterior) or over-correction may determine the onset of paralytic ileum due the closing of the so-called aortomesenteric compass (cast syndrome) (Fig. 15).

Whatever the instrumentation system used, it is crucial to perform the arthrodesis technique correctly, especially in cases in which the instruments used are cumbersome and hamper implementation of this important part of the procedure.

To avoid progression of kyphosis below the fusion region, it is advisable to extend the procedure one additional level into the area of the inferior neutral vertebra and always include L1 in the arthrodesis. To avoid the onset of a kyphosis above the arthrodesis, fusion and instrumentation should not be discontinued at the lower thoracic region, especially in a thoracolumbar kyphosis; it should be extended well proximal to additional segments.

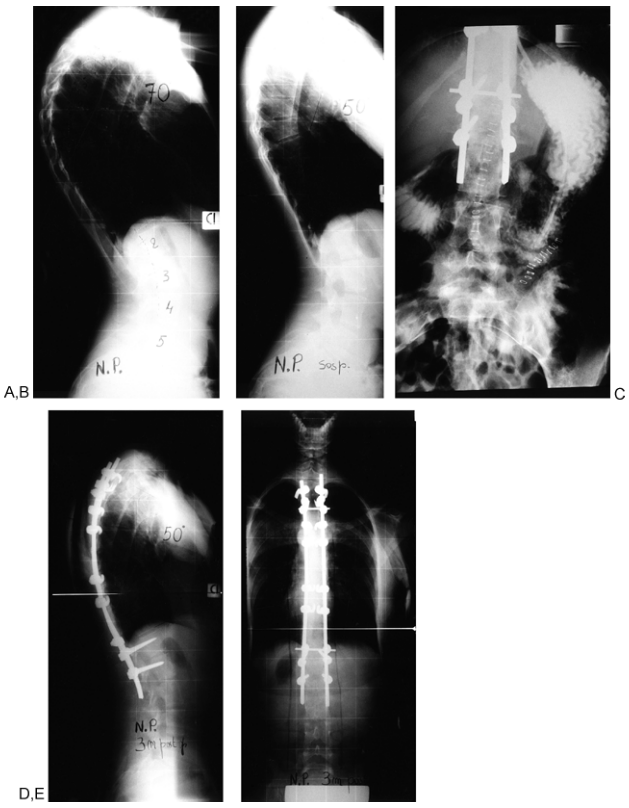

FIGURE 15. Thoracolumbar kyphosis treated with a compression double bar with hooks at T3–L1 and transpeduncular screws in L1 and D2. The use of the posterior approach alone determined a satisfactory correction with a good reshaping of the thoracolumbar junction. In the postoperative period, there was onset of paralytic ileum (cast syndrome–like), which was resolved by maintenance of the nasogastric tube over the following 2 weeks.

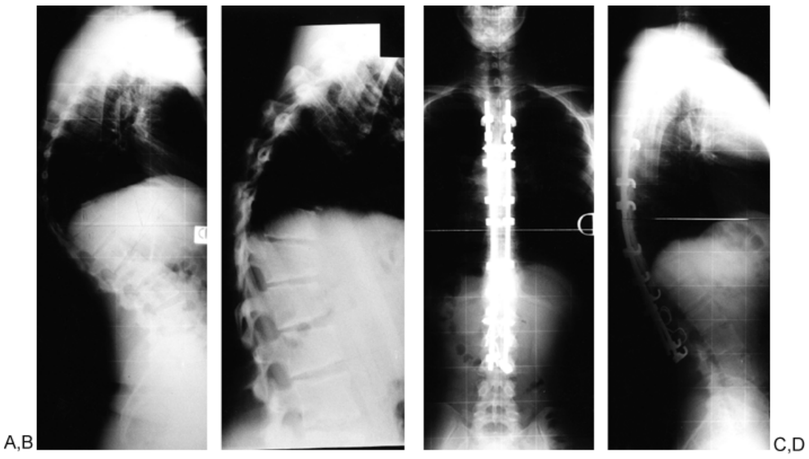

FIGURE 16. Thoracolumbar kyphosis with severe sagittal decompensation. Figure shows marked apical rigidity at the wedge hypertension test; anterior release and posterior T3–L2 instruments; sublaminar hooks and L1–2 sublaminar loops. At the end of correction, a sagittal decompensation condition remains.

Conclusions

About 5% of the Scheuermann kyphosis patients observed and subjected to treatment require a surgical correction and stabilization procedure. According to conventional concepts, surgery should be reserved for adolescents with curvatures exceeding 75 degrees, children with rapidly progressive kyphoses despite treatment with braces or casts (45), and adults with curves greater than 65 degrees.

Our experimental work has shown that it is possible to reconstitute the morphology of a vertebral body affected by Scheuermann kyphosis, depending on the age of the subject, the extent of the lesions, their distribution on the surface of the vertebral end plate, and the extent of wedging. Therefore, it is important to evaluate all of these factors, in addition to the angular level of the kyphosis, to determine the most suitable type of treatment. Surgical treatment for adults with Scheuermann kyphosis must be considered with great caution due to the disorder's benign natural history. The influence of surgical treatment on painful symptoms must also be considered. The rare case of paraparesis with an acute onset in adults requires surgical treatment.

In order to establish the correct approach to treatment, several questions should be addressed:

1. Does the natural history of Scheuermann kyphosis warrant the adoption of some form of preventive treatment? Travaglini and Conte (104) followed 50 cases for more than 25 years, observing that 80% of curves greater than 50 degrees increased in severity in adult life. Murray et al. (78) concluded a long-term clinical study on 62 patients and found that the disease does not bring about a progressive disability at a functional level in relation to pain or pulmonary dysfunction or in cosmetic terms.
2. Will the incidence of pain and its severity be significantly reduced by the treatment? Due to the variability with which pain is manifested (according to age and not in relation to severity of the curvature or the vertebral lesions), there are no proven correlations between a given radiographic or clinical picture and forecasts in terms of therapeutic outcome. Pratelli et al. (87) found that patients suffering from painful symptoms prior to treatment with casts had an 82% chance of suffering from low back pain as adults. In contrast, Murray et al. (78) stated that pain, though present, is never a debilitating symptom in the natural evolution of the disease.

   It seems that the presence of pain should not be considered an absolute indication for treatment in view of the disease's benign natural evolution. Thus, the only true indication for treatment is the severity of the angle of the curvature, which has been shown to progress over time.

3. Is it possible to obtain a significant correction of the deformities and maintain that correction over time? It is possible to obtain satisfactory and lasting results both with conservative treatment consisting of a Milwaukee brace associated with casts

and with surgical treatment performed with Cotrel-Dubousset instrumentation (associated with anterior arthrodesis in rigid forms with little preoperative correction).

The authors of this chapter agree with Stagnara (102) in terms of the danger of falling prey to the Procrustes complex (Procrustes was a bandit from Ancient Greece who forced his victims to fit into his own bed by stretching the excessively short and cutting off the legs of the excessively tall). Subjects who enjoy relatively good health and have a relatively benign prospect for adult life must not be "normalized" from a morphologic point of view.

Acknowledgments

I thank Dr. Sabrina Inciocchi, who contributed substantially to the preparation of this chapter by revising and sharing case photos and case materials.

Spondylolysis and Spondylolisthesis

Serena S. Hu

David S. Bradford

S. S. Hu and D. S. Bradford: Department of Orthopaedic Surgery, University of California School of Medicine, San Francisco, California 94143.

Spondylolisthesis is the slipping forward of one vertebra upon another. It is derived from the Greek words *spondylos*, or "vertebra," and *olisthesis*, meaning "to slip." Spondylolysis is the condition of a bony defect at the pars interarticularis, which may be unilateral or bilateral. Spondylolysis can result in forward slippage, or spondylolisthesis. In the child or adolescent, pars defects are most common at L5, with resultant slippage of L5 on S1.

Spondylolisthesis was first described by the Belgian obstetrician Herbinaux (82) in 1782. He noted on occasion a bony prominence in front of the sacrum that could cause problems during delivery. The presence of a defect at the pars interarticularis was recognized by Robert (156) and then Lambl (101).

There are two types of spondylolisthesis commonly found in children and adolescents. According to the classification system originated by Wiltse in 1969, these are type I (dysplastic) and type II (isthmic) (Fig. 1). Type I, or dysplastic, spondylolisthesis is a congenital deficiency of the superior sacral facets, the inferior fifth lumbar facets, or both, which permits forward slippage of L5 on the sacrum. Isthmic spondylolisthesis is caused by a defect in the pars interarticularis. Type II is further classified as IIA if there is a fatigue fracture of the pars, IIB if there is an elongated but intact pars, and IIC if an acute fracture exists.

More recently, Marchetti and Bartolozzi suggested a new classification system for spondylolisthesis. Their major groups being developmental and acquired types, they divided the developmental type, which encompasses types I and II of Wiltse's classification as well as traumatic, into high dysplastic and low dysplastic, and each of these types could be subdivided to include lysis or elongation of the pars. They felt that their classification was useful with regard to prognosis and treatment (116).

Etiologic Factors

There have been several theories on the cause of spondylolisthesis. Early reports suggested a separate ossification center in the neural arch, with failure to unite, resulting in a defect at the pars interarticularis (128,136). Morphologic studies (29,62,83,160,163) failed to support this; in fact, there is only one report of this condition in a newborn (15). (This should not be confused with congenital lumbosacral kyphosis.)

The role of upright posture and ambulation in the etiologic process has been suggested, as there are no known cases of spondylolysis or spondylolisthesis in nonambulatory patients (160). Also, although spondylolysis in newborns is virtually nonexistent, the incidence reaches 5% by age 6 years (6), nearing the 6% incidence found in the general population (57).

Repetitive microtrauma has been cited as a likely cause or a contributing factor. This theory is consistent with the belief that upright posture and ambulation are necessary in the development of the spondylolytic defect. Several authors (34,71,86,88,108,121,132,161,192) have noted an association between loads placed on the lumbar spine in hyperlordosis and the subsequent appearance of a lysis. This occurs specifically in such sports as diving, weight lifting, wrestling, and gymnastics. In 1963, Newman (137) noted the association of spondylolysis with the onset of ambulation in toddlers. The increased incidence (50%) of asymptomatic spondylolysis reported in patients with Scheuermann disease suggests that the compensatory increase in lumbar lordosis is a factor in the development of spondylolysis (144). Biomechanical (45,108,169) and structural studies (99,163) suggest that the pars interarticularis is under the greatest stress in extension. Shear stresses at the pars are greatest in lordosis; this mechanism also may lead to pars fractures (54).

Wiltse (209,211,212,215) and others (3,62,104,178,194,218) noted the familial incidence of spondylolysis and spondylolisthesis as well as the development of the condition after trauma. These authors believed that there was a congenital defect or dysplasia that when exposed to the stresses of upright posture and lumbar lordosis resulted in development of a pars defect, sometimes with elongation or slippage. The association of spondylolysis and spina bifida occulta also suggests the presence of congenital factors (8,26,57,143). The progressive development of a pars defect has been noted by other authors as well (35,98,127,207).

There is a significantly higher incidence of these conditions in certain populations. Alaskans are reported to have an increased incidence of neural arch defects, ranging from 5% in 6-year-olds to 34% in 40-year-olds (191). Examination of Eskimo skeletons reveals an incidence of spondylolysis in 13% of younger subjects and 54% of adults (183).

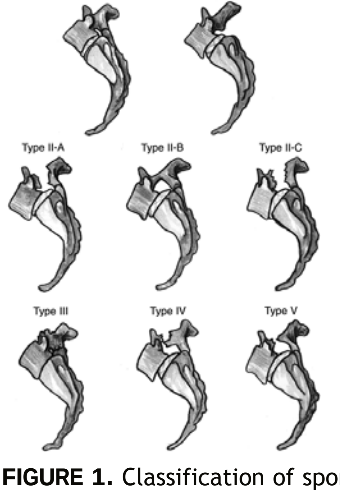

FIGURE 1. Classification of spondylolisthesis according to Wiltse (191). *Type I:* Dysplastic—congenital deficiency of the superior sacral and/or inferior fifth lumbar facets with gradual slipping of the fifth lumbar vertebra. *Type II:* Isthmic—*A:* lytic (fatigue fracture of pars); *B:* elongated but intact pars; *C:* acute fracture. *Type III:* Degenerative—degeneration of joints allowing forward displacement, usually L4 on L5. *Type IV:* Traumatic—acute fracture in areas other than the pars interarticularis. *Type V:* Pathologic—attenuation of the pedicle secondary to structural weakness of the bone. Children and adolescents most commonly demonstrate type I or type II spondylolisthesis.

Clinical Findings

Spondylolysis and spondylolisthesis may be completely asymptomatic or present with varying degrees of low back pain (73,115,130,146,180). The patient may note a recent injury or an association with a specific activity. Although the condition probably develops over the first two decades of life, symptoms most commonly present during the preadolescent growth spurt, between the ages of 10 and 15 years (7,37,62,75,80,151,198). The degree of slippage may not correlate with the severity of pain (180). However, some have noted, when comparing supine and standing radiographs, an association between a greater change in the percent of slippage and an increased likelihood of pain (63,114,145).

As noted, the incidence in the population is approximately 6% (57,62). Most reports note a higher incidence of spondylolysis in males, by a ratio of up to 2:1, but females have a higher risk of progression (4,130,174,180). Rowe and Roche (162) noted an overall incidence of 4.2%: 6.4% in white males, 2.8% in black males, 2.3% in white females, and 1.1% in black females.

Athletes participating in certain sports such as gymnastics, wrestling, or football (especially interior linemen) may note low back pain with the activity. The pain may last for varying amounts of time after the activity ceases and may be relieved by avoidance of the particular sport (31,176). Many patients present with acute symptoms related to a specific trauma. These patients may show pathology ranging from normal radiographs with positive bone scans, to a stress fracture, to a pars defect with sclerosis of the fracture edges suggestive of a longstanding process.

Radicular symptoms, bowel or bladder impairment, or both are rare but can occur, particularly with higher degrees of slippage (77). Regardless of the degree of slippage, tight hamstrings and the classic knees-bent, hips-flexed gait—the Phalen-Dickson sign (150)—may be observed. The exact mechanism that causes tight hamstrings is not entirely clear. It is believed by some to be secondary to the vertical position assumed by the sacrum in higher grades of slippage, with resultant flexing of the pelvis, so that the hips cannot extend sufficiently. This results in knees flexed to permit the patient to stand upright (Fig. 2). Such a patient cannot stand upright with his or her knees straight, has limited forward flexion of the spine, and exhibits a characteristic waddling or short-stepped gait (138,187). Tight hamstrings may be caused by nerve root irritation from instability and nerve entrapment (7,42,150).

In patients with spondylolisthesis, careful palpation of the spine may reveal a step-off with a prominent spinous process of L5. With higher degrees of slippage, as the pelvis becomes more flexed and the lumbosacral junction more kyphotic, the trunk appears shortened. The rib cage approaches the iliac crests. Straight leg raising is often limited as well (7).

There are reports that associate scoliosis with spondylolisthesis. It may be secondary to the associated conditions (109) of a rotatory slippage (28,118) or hamstring spasm (155), or it may be a separate condition. The association is reported to exist in 13% to 60% of patients (18,105,109,110,121), with the greater incidences in symptomatic populations.

Radiologic Evaluation

Identification of a pars defect is easily done on oblique radiographs of the lumbar spine, with observation of the “collar” on the “Scotty dog” (Fig. 3). Spot lateral views of the lumbosacral junction usually show the defect, particularly with bilateral defects. Isthmic and dysplastic spondylolisthesis are most common at the lumbosacral junction (4), although there are reports of their occurrence in the upper lumbar spine (112,154). Unilateral defects may show sclerosis of the pars or lamina on the contralateral side.

In patients who have a recent onset of pain and in whom no defects are seen on routine radiographs, bone scans may be useful in detecting early stress fractures at the pars interarticularis

(Fig. 4) or in determining the acuity of the fracture (66,113,199). Single photon emission computed tomography (SPECT) provides more detail and may be more sensitive (10,33).

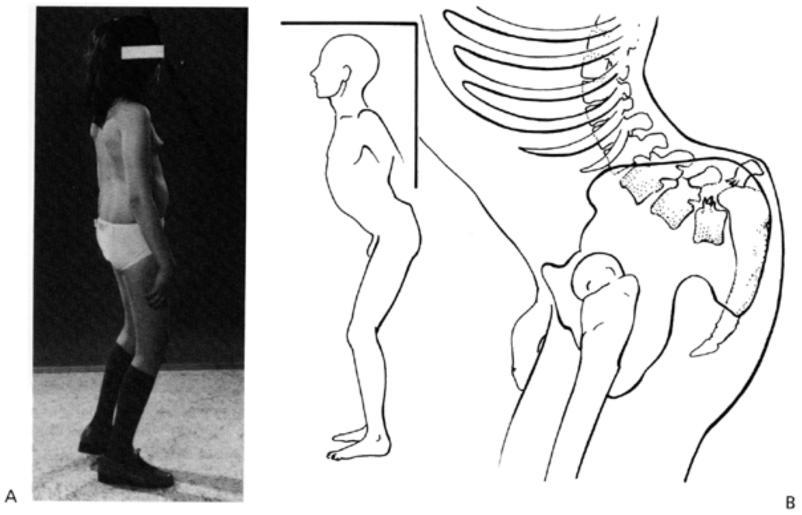

FIGURE 2. A: Clinical photograph of a patient with spondylolisthesis exhibiting a short trunk, flattening of lumbosacral lordosis, and flexed hips and knees. **B:** Schematic diagram demonstrating lumbosacral kyphosis. The pelvic tilt results in the inability of the hips to extend sufficiently to permit the patient to stand upright.

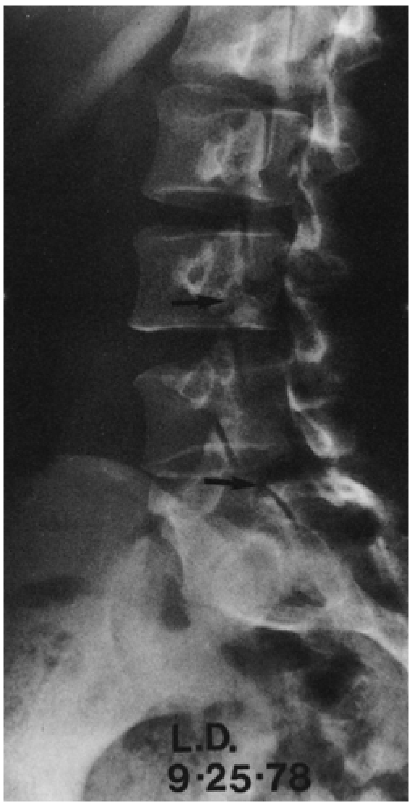

FIGURE 3. Oblique radiograph demonstrating pars defects at L5 and L3, which correspond to the “collar” on the “Scotty dog.”

A pars defect can be seen on computed tomography (CT) as an incomplete ring; it is occasionally unilateral but more frequently bilateral (103,195) (Fig. 5). If the CT gantry is not tilted to the plane of the L5–S1 disc space, the scan may be difficult to interpret. The pars defect can also be mistaken for a facet joint by the inexperienced observer. Unilateral cases may show sclerosis of the opposite pars, facet degeneration, or contralateral posterior element or pedicle fractures secondary to the increased stresses (2,141).

The actual slippage, or listhesis, can be measured by various parameters. Most commonly, Meyerding's (129) grading system is used: No slippage is grade 0, 1% to 25% slippage is grade I, 26% to 50% is grade II, 51% to 75% is grade III, and 76% to 100% is grade IV; grade V denotes spondyloptosis, or complete slippage past the anterior border of the sacrum (Fig. 6). Slippage is measured as a percentage of the anteroposterior diameter of the sacrum (Fig. 7). Some authors measure percent slippage relative to the inferior aspect of L5 (105). The sacrum may show secondary rounding of its anterosuperior aspect. For accurate and comparable measurements of percent slippage or lumbosacral kyphosis (i.e., slip angle), it is preferable to take radiographs in the standing or loaded position. There can be differences in slippage depending on the loading situation (94,97,114,148). Progression of less than 10% is difficult to detect (38).

In a skeletally immature patient, *slip angle* has been found to be the most useful measure in determining the likelihood of progression to higher grades of slippage (18). Slip angle provides a measure of several radiographic risk factors and the associated compensatory mechanisms. It is determined by drawing a line along the posterior cortex of the sacrum and measuring the angle between its perpendicular and a line drawn along the inferior border of L5 (Fig. 8). Normal angles should be from 0 to -10 degrees. Values greater than 55 degrees correlate with a higher likelihood of progression. Remodeling at the inferior border of L5 may make this measurement difficult; however, most studies that have used slip angle have used the inferior aspect of L5.

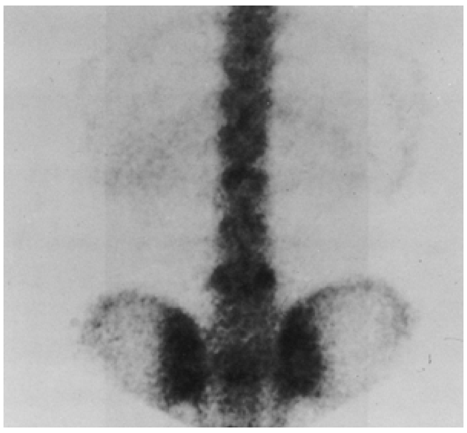

FIGURE 4. Bone scan demonstrating increased uptake—more prevalent on the right than on the left side of L4—corresponding to the patient seen in Fig. 5 with a pars defect on the left and a stress reaction on the right.

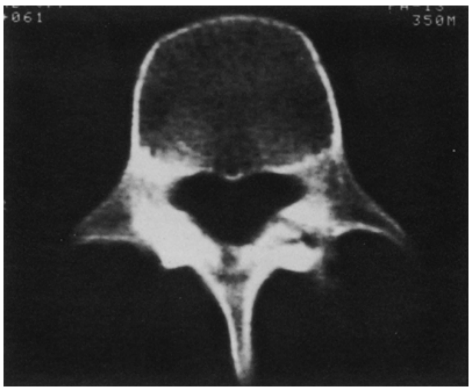

FIGURE 5. CT scan through left pars defect. Note sclerosis on the contralateral pars. (Courtesy of William Carr, M.D.)

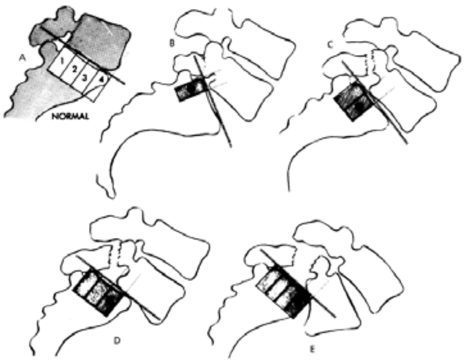

FIGURE 6. Meyerding's classification of spondylolisthesis. **A:** Normal or grade 0. **B:** 1% to 25% slippage is grade I. **C:** Up to 50% is grade II. **D:** Up to 75% is grade III. **E:** 76% to 100% slippage is grade IV.

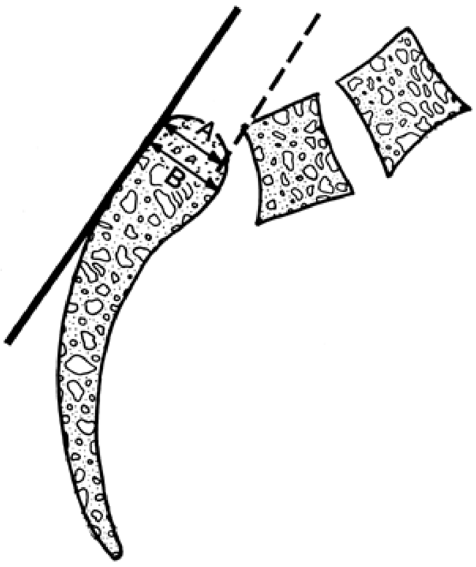

FIGURE 7. Percent slippage is measured relative to the anteroposterior diameter of the sacrum. As shown, *A*/*B* × 100 = 72%.

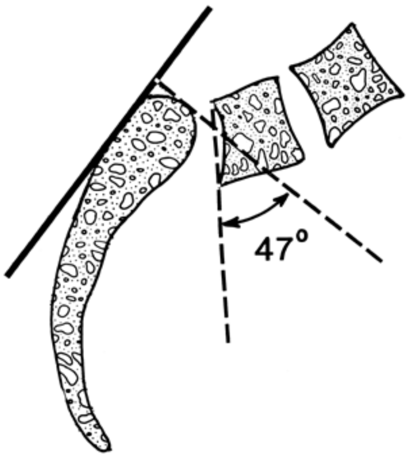

FIGURE 8. The slip angle (47 degrees as shown) is determined by drawing a line along the posterior cortex of the sacrum and measuring the angle between its perpendicular and a line drawn along the inferior border of L5.

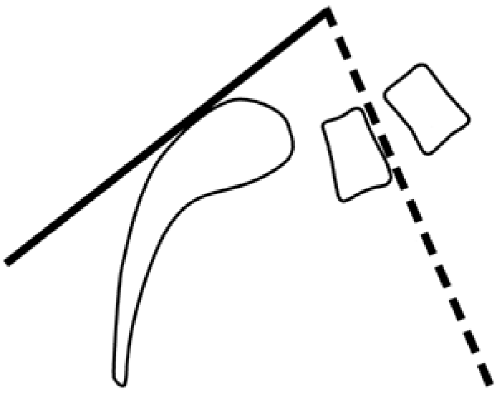

FIGURE 9. The lumbosacral angle is the angle between the posterior wall of the sacrum and the superior end plate of L5.

The *lumbosacral angle* is the angle measured between the superior end plate of L5 and the posterior border of the sacrum (Fig. 9) (46). Dubousset felt that a lumbosacral angle of less than 100 degrees (vertical sacrum) signified a spondylolisthesis that would always progress.

The *angle of kyphosis* can be measured between the cranial surface of L5 and the caudal surface of S1 (186). Normally, with physiologic lordosis, the value is positive. With spondylolisthesis and lumbosacral kyphosis, this value becomes increasingly negative.

The *lumbar index* is described as the height of the anterior aspect of the L5 vertebra, expressed as a percentage of the height of the posterior aspect of L5. Greater slippages tend to demonstrate lower lumbar indices, and progression of slippage appears to correlate with decreasing index (57,165).

Sagittal rotation is the angle between the posterior surface of the sacrum and the anterior cortex of L5 (Fig. 10). It is also known as *sagittal roll.*

Sacral inclination is determined by drawing a line along the posterior surface of the sacrum and measuring the angle between it and a vertical line from the floor. Normal sacral inclination is greater than 30 degrees, but with higher degrees of slippage the sacrum becomes more vertical and sacral inclination decreases (Fig. 11).

Recently, Schwab et al. (170) described the sagittal pelvic tilt index (SPTI) as a means of quantification of the relationship between S2, the center of the hip, and L5. This measurement is determined from a standing lateral radiograph of the lumbar spine that includes the hip joint. A horizontal line is drawn through the center of S2. A vertical line is drawn from the center of the L5 vertebral body. A second vertical line is drawn through the center of the femoral heads. The distance from the center of S2 to the projection of L5 on the horizontal line is *a* and the distance from the center of S2 to the projection of the femoral head is *b.* Their SPTI is defined as *a/b.* They found that a decreasing SPTI correlated with slip progression and also that those presenting with a lower SPTI (less than 0.7) were more likely to require surgical intervention for their symptoms or progression.

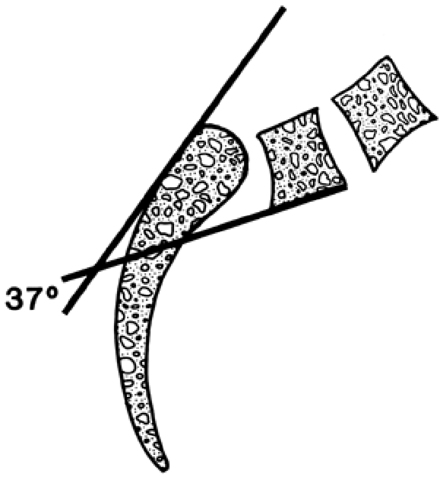

FIGURE 10. Sagittal rotation is the angle measured between the posterior cortex of the sacrum and the anterior cortex of the L5 vertebral body.

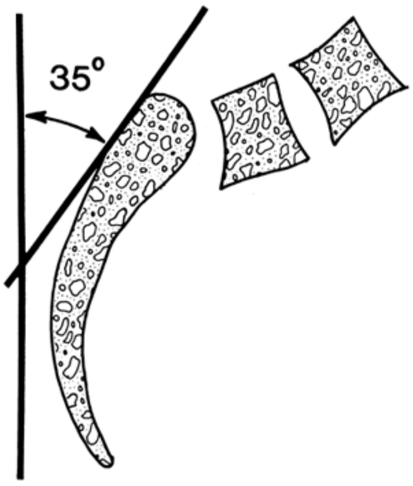

FIGURE 11. Sacral inclination is the angle between the posterior surface of the sacrum and a vertical line drawn from the floor. Normal sacral inclination is greater than 30 degrees.

CT scans and magnetic resonance imaging (MRI) studies are used with increasing frequency, particularly in patients whose symptoms suggest cauda equina or nerve root compression. It should be noted that other abnormalities, such as tethered cord, should be sought in such patients (120). It has also been noted that spondylolysis may retard the growth of the facet joints and affect the characteristics of the joint surfaces (131).

Both CT/myelography and operative findings suggest that nerve root compression may occur by one mechanism or by a combination of mechanisms. The L5 arch has been found by some surgeons to pinch the dura. This, as well as compression from the posterior aspect of the upper sacrum, may be seen on CT/myelography or found at the time of surgical exploration (26,68,150).

With significant slippage of the L5 forward on the sacrum, the intervening disc may remain with the sacrum but may appear split or bulging on CT or MRI images, suggesting canal narrowing (11,195).

Risk Factors

There is general agreement that low-grade spondylolisthesis can usually be successfully managed with conservative measures (60,171). Progression of spondylolisthesis is more likely in younger or skeletally immature patients because it usually occurs during the preadolescent years or in higher grades of slippage (79,105,125,173,174). Reports indicate that dysplastic spondylo-listhesis is more likely to progress than isthmic spondylolisthesis. Although spondylolysis and spondylolisthesis are more common in young males, progression and advanced slippage are more common in young females (172,174).

Most surgeons agree that spondylolisthesis with slippage greater than 30% to 50% in an adolescent or child is likely to progress and should be fused (105,106,115,125,202). Patients presenting at a younger age appear to be at increased risk for progression.

Patients with greater than 100 degrees of lumbosacral kyphosis (46), decreasing sagittal pelvic tilt indices (170), or higher slip angles also appear to be at risk for progression.

Conservative Treatment

In patients who have inciting repetitive trauma, such as gymnasts or divers, restriction of the aggravating activity or bed rest often relieves the symptoms of spondylolysis or spondylolisthesis (31). Bracing in neutral lordosis renders good to excellent results in up to 80% of patients with grade 0 or I spondylolisthesis (9,152,190). Brace wear is recommended for 3 to 6 months full time, with gradual weaning as symptoms permit. Occasionally, this treatment regimen permits healing of the stress fracture, particularly with more acute clinical presentations (31,190) (Fig. 12). Physical therapy should emphasize stretching of the lumbodorsal fascia and abdominal strengthening (70,187). Patients with grade I or II spondylolisthesis are more likely to respond to conservative measures, with only 1 of 12 patients with higher grade slips responding to nonoperative measures (60,152).

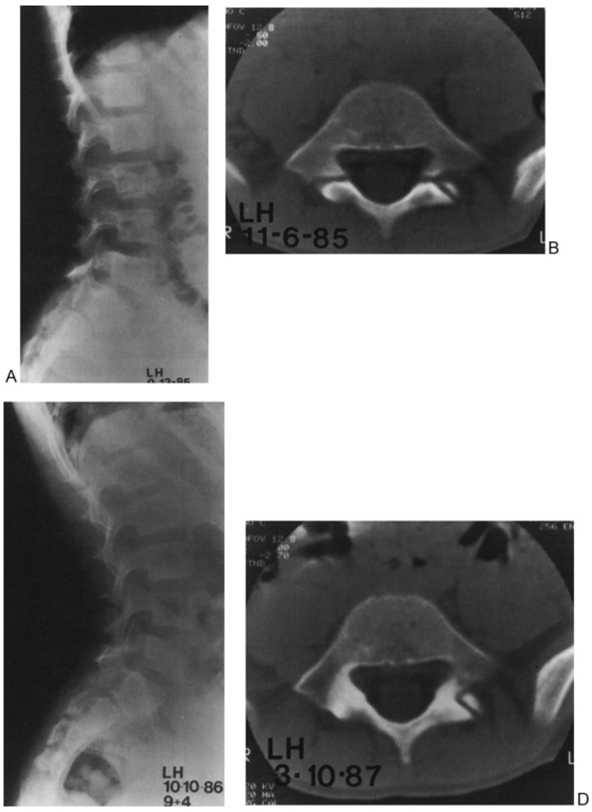

FIGURE 12. A: Lateral radiograph of an 8-year-old patient with symptomatic spondylolysis. **B:** Computed tomography (CT) scan showing bilateral pars defects. **C:** This patient was treated with a cast for 3 months, resulting in healing of the pars defects, as evident on this lateral radiograph. **D:** CT scan showing healed bilateral pars defects after casting.

Many surgeons allow patients who improve after conservative treatment to resume all activities once they are asymptomatic.

Others do so only if the patient has less than 25% slippage and restrict activities to those who do not load or hyperextend the spine if there is greater than 25% but less than 50% slippage (31,134,210). As will be discussed, fusion is indicated for skeletally immature patients with greater than 50% spondylolisthesis.

Reports tracing the natural history of patients who have spondylolysis or mild to moderate spondylolisthesis note a generally benign course. In one study from Germany (134), competitive athletes from a special school were followed for several years. Although small degrees of progression occurred in some patients, no patient developed any symptoms during the period of study. Most patients who have been managed conservatively as youngsters are satisfied as adults. Progression is rare after adolescence. In fact, progression is rare for those with less than 20% to 30% slippage (57,60,171,173,174).

Pars defects are seen less frequently at L4 and are even more rare in the upper lumbar spine. Male predominance, inciting trauma, and prevalence in young adults compared with adolescents have been noted. Significant slippage at L4 is more uncommon than at the lumbosacral junction. However, neurologic symptoms and spinal stenosis appear to be more common (87,164).

Posterior Fusion

Patients whose symptoms do not resolve with conservative measures, who show progression of their spondylolisthesis, who have greater than 50% slippage, or who have gait or postural abnormalities are candidates for surgical intervention (76,80). For low-grade (less than 50%) slippage, in situ fusion is the treatment of choice. Early reports of interlaminar fusion noted fusion rates of 83% to 84% and improvement of symptoms in 79% to 95% of patients (18,76,78,198). The advent of intertransverse or bilateral lateral fusion has improved fusion rates to 83% to 95% and the clinical outcome to 75% to 100% excellent or good results (37,61,66,73,202).

The need for decompression should be evaluated in patients who have neurologic findings (1,91,102,159,203). Gill (67,69) described good results with his technique of removing the loose lamina as well as the fibrocartilaginous scar at the site of the pars defect. Most surgeons currently recommend removing the residual pars to the base of the pedicle to complete the decompression. It should be noted that for young patients isolated decompression without fusion is contraindicated because it will increase the likelihood of progression (5,100). Several authors (18,39,172) reported an increased probability of slip progression in patients who had L5 laminectomy combined with fusion compared with those who underwent a fusion alone. Nevertheless, patients who undergo fusion without removal of the posterior elements of L5 may also demonstrate progression, particularly prior to consolidation of the fusion mass (16,76,80,104,173,193).

Some surgeons have found that signs of nerve root irritation often resolve with fusion of the spondylolisthetic level, making a formal decompression unnecessary. The time frame for resolution of these signs, including hamstring tightness and sciatic pain, averages 6 to 18 months; however, occasionally these signs do not resolve (80,91,215).

With higher grades of spondylolisthesis, fusion from L5 to the sacrum does not have as high a success rate. This is because the fusion mass is placed on tension and is more likely to fail. Therefore, inclusion of L4 in the intended fusion bed is recommended (153).

Because of the increased cosmetic deformity and gait disturbances that can occur with higher grades of slippage, reduction is recommended by some (this is discussed below). However, Hensinger et al. (80) and others (18,59,76,90) reported satisfactory treatment outcomes in such patients without reduction. Only an occasional patient had residual hamstring tightness or nerve root irritation—three of 16 in the Hensinger et al. (80) series—or complaints related to appearance—two of 14 patients in Freeman and Donati's (59) series, two of 17 in Johnson and Kirwan's study (90), and eight (all females) of 52 in Seitsalo's series (171). Progression may occur after fusion; this phenomenon is more common in higher grades of slippage (17,18,19,20,22,104,153,172,188). Related to these factors, Newton and Johnston (139) specifically found that poor outcome after in situ fusion was correlated with poor fusion mass and that patients with the greater slip angles had a greater chance of a poor result.

The technique of intertransverse process fusion has been extensively described (122,206,213,214) (Fig. 13). Originally, one transverse incision or two parallel paraspinal skin incisions were described. We prefer a midline skin incision with paraspinal fascial incisions, approximately two fingerbreadths off the midline. Blunt dissection with the index finger can direct one to the transverse processes, and the fibers of the sacrospinalis can be split, or divided, where needed. Curved self-retaining retractors, such as Gelpis, are often useful to facilitate exposure. The transverse processes, pars interarticularis, and facets of the levels to be fused are exposed using elevators and cautery. If desired, the facet joints may be exposed as well. One should not violate the facet joint at the highest transverse process exposed because its damage may accelerate degenerative changes at this higher level. Iliac crest bone graft is harvested, prepared in corticocancellous strips, and placed over the decorticated bony surface for fusion. Some surgeons advocate the creation of a window or trough in the sacral ala for placement of a larger piece of graft from the sacrum to the upper transverse process to be fused (80).

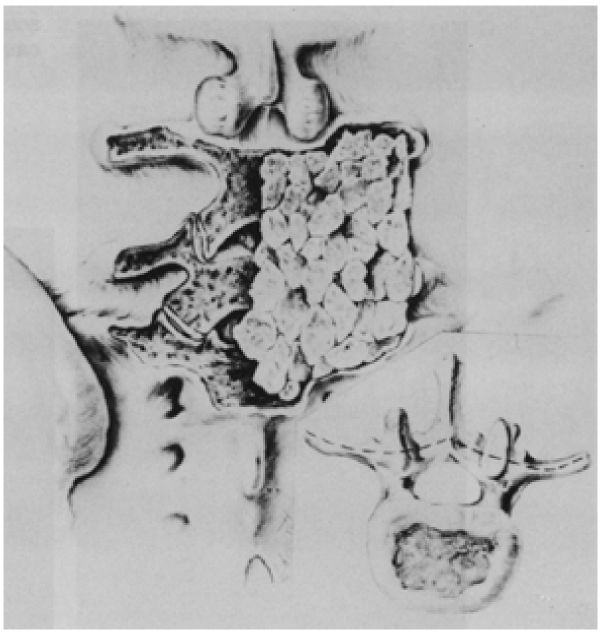

FIGURE 13. Technique of intertransverse process fusion. In this illustration, both midline and lateral bone grafts have been placed.

If decompression is desired, a midline fascial incision should be used to permit removal of the loose posterior elements and exploration and decompression, as described by Gill et al. (69). Not only the loose lamina but also the fibrocartilaginous scar at the site of the defect should be removed.

Postoperative care varies depending on the surgeon's preference. It can range from bed rest for 1 to 2 weeks with application of a pantaloon spica cast (76,80,186) to the use of lumbar corsets (16,66,73), thoracolumbar orthoses (73), or thoracolumbosacral orthoses with leg extensions. After achievement of a solid posterolateral fusion, patients are permitted to return to activities as desired.

A: Diagram showing transverse process to spinous process wiring, for direct repair of the pars defect. **B:** Computed tomography (CT) scan and sagittal reconstruction showing bilateral pars defects at L4. **C:** Anteroposterior radiograph after repair and wiring. **D:** Lateral radiograph after repair and wiring. **E:** Oblique view of direct repair with wiring. **F:** CT scan demonstrating healing of pars defect after direct repair and bone grafting of pars defect.

Direct Repair

Direct repair of the pars defect was originally described by Buck (25) in 1970. Screw fixation was used to fix internally the two fragments of the involved vertebra. Since his report, several authors have described their results with this technique (147,157,200,216). Bradford and Iza (23) described their results with transverse process to spinous process wiring, a technique suggested by James Scott (Figs. 14 and 15). Eighty percent of their patients had good to excellent results, with 90% achieving healing of the defect. Kakiuchi (94) described his results in 16 patients with grade I or II spondylolisthesis using a variable-angle Danek screw in the pedicle and a laminar hook, bridging and compressing across the pars defect. He removed all implants and gave radiographic evidence of osseous union in all patients, with all patients noting either complete relief or major improvement of symptoms; 90% obtained healing of their defects. Others have had comparable results with wiring (50,65,72,140) and rigid fixation (111,133), noting 67% to 92% good to excellent results. Pars repair is best considered for L1 to L4 defects in patients younger than 25, with no evidence of disc or facet pathology and no more than 1 to 2 mm of slippage (23). The technique may also be useful for patients with multiple-level pars defects (50).

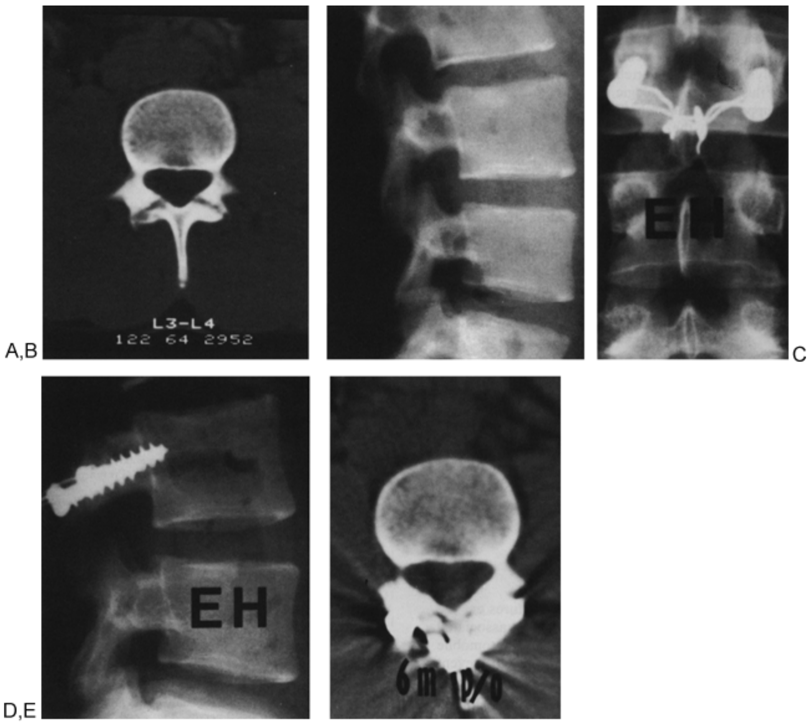

FIGURE 15. A 19-year-old college wrestler with gradually increasing activity-related low back pain over the course of several months. **A:** Computed tomography (CT) scanning confirmed bilateral pars interarticularis pseudarthrosis at L3. **B:** The lateral radiograph shows no evidence of spondylolisthesis. **C,D:** A modified Scott repair of the pars defects was performed using pedicle screws rather than the transverse processes to anchor the tension wires. **E:** Six-month postoperative CT scan shows healing of the pars pseudarthrosis. The patient returned to unrestricted activities. (Courtesy of Bruce van Dam, M.D.)

Biomechanical studies comparing the bending stiffness of the intact spine, the spine with pars defects, and the spine after transverse process–spinous process wiring indicate that this technique restores the spine to normal stiffness values (72,218).

Anterior Fusion

The anterior approach for spinal fusion as treatment of spondylolisthesis was first proposed by Capener (28) in 1932. Shortly thereafter, Burns (27) reported on his cases with an anterior fusion technique that included placement of a tibial or fibular graft through a drill hole from the L5 vertebral body to the sacrum (Fig. 16A). This technique and that of disc space grafting with tricortical iliac crest have been applied successfully (30,40,51,58,84). Adolescents, however, constitute only a small minority of each series. Studies of adolescents who underwent anterior spinal fusion with iliac crest bone grafting reported solid fusion in all patients and complete symptomatic relief in virtually all patients (110,177,201). One of these studies noted gait improvement in all patients; another study did not mention this clinical outcome.

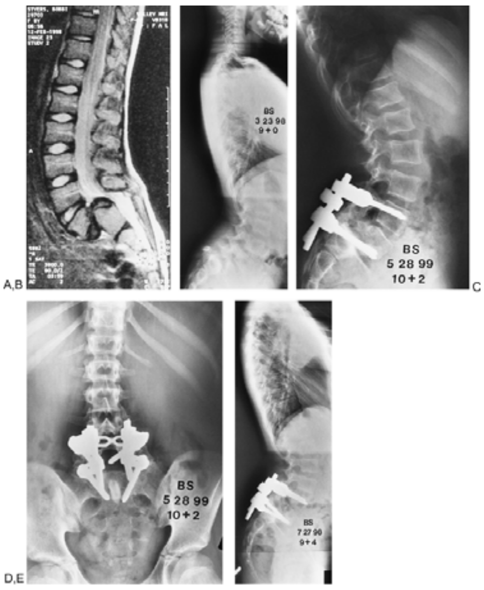

FIGURE 16. A: Preoperative standing lateral radiograph of 8-year-old female with grade V spondylolysis. **B:** Lateral MRI view. **C,D:** Postoperative anteroposterior and lateral radiographs after partial reduction, placement of transacral fibular graft, pedicle screw instrumentation, and posterolateral fusion. Note placement of S1 pedicle screws into the body of L5. **E:** Standing lateral radiograph demonstrating improved sagittal balance.

The procedure can be done via either a retroperitoneal or a transperitoneal approach, depending on the surgeon's preference. It has been suggested that for higher grade slips, an anterior fusion places the graft in compression, which is a more biomechanically sound construct (43). The risk of the anterior approach in males has been described, although the actual incidence of postoperative sterility secondary to retrograde ejaculation appears to be low (47,56,92).

Anterior spinal fusion with fibular or other structural graft may also be useful in cases of failed posterolateral arthrodesis (22,93,208).

Combined Approaches

With variable results from fusion in situ or anterior fusion alone for high-grade spondylolisthesis, some surgeons have advocated combined anterior and posterior approaches for these more challenging cases.

Muschik et al. (135) compared their results of anterior fusion versus anterior fusion combined with posterior instrumented reduction for high-grade spondylolisthesis. They found the pseudarthrosis rate, residual degree of slippage, and residual lumbosacral kyphosis to be lower in patients who had combined approaches rather than anterior fusion alone. However, the clinical outcomes were equivalent and the non-pseudarthrosis-related complications were higher for the patients with combined surgery. A similar study that also compared anterior interbody fusion with combined surgery for high-grade slippages found equivalent results with respect to subjective clinical, functional, and radiographic outcomes, except with respect to progression of sagittal rotation, which occurred in the anterior fusion group (196). The investigators noted that the long-term effect of this improved radiographic result was not known.

Posterior Dowel Graft/Posterior Interbody Fusion

Bohlman and associates (13,186) have described a technique, also utilized by others (52,158), for single-stage posterior decompression and interbody fusion in the management of spondyloptosis. After wide decompression and foraminotomy (as needed) and removal of the posterior-superior aspect of the first sacral vertebral body, a drill hole is prepared between the L5 and S1 nerve roots on each side. This hole traverses S1 to the displaced L5 vertebral body, not penetrating the anterior cortex of L5, and is checked with fluoroscopic control. Autograft fibula is then inserted and countersunk longitudinally to avoid dural impingement.

We have successfully used the interbody dowel technique combined with posterior interpedicular instrumentation in patients who have had partial reduction of a high-grade slippage (Fig. 16) (185).

Posterior lumbar interbody fusion has been successfully applied to young patients with spondylolisthesis (32). However, because of problems with graft resorption and collapse (181), as well as the dangers of perineural scarring, other surgical options are usually preferable.

Harms et al. have promoted the concept of performing an interbody fusion (either via a combined approach or via a transforaminal interbody fusion) in all cases of spondylolisthesis to reduce the shear forces seen at the intervertebral disc and reduce the lumbosacral kyphosis (74). Although we and others (184) have been encouraged by early results of instrumented posterior fusions combined with transforaminal interbody fusion, the selection of young patients for whom this approach is preferable to other techniques available has not been determined.

Reduction

Reduction of high-grade spondylolisthesis has received increasing attention in recent years. Reduction of the slip angle is particularly important in the maintenance of correction because those with higher slip angles are more likely to exhibit progression after fusion (18). Residual gait abnormalities in patients fused in situ for high-grade spondylolisthesis, though minor in the young patient (179), may have consequences with maturity, perhaps analogous to flat-back syndrome (205). Spondylolisthesis reduction also appears to improve sagittal alignment, resulting in a more normal gait and trunk appearance.

The technique of closed reduction and fusion was first reported by Jenkins (89) in 1936 and later refined by others (19,21,55,123,193). Preoperative halofemoral or halopelvic traction is applied. Distraction is applied along the axis of the spine; rotation of the pelvis brings the sacrum back to a more normal inclination. Direct pressure is applied to the posterior portion of the sacrum (166) (Fig. 17). This permits gradual reduction with less risk to the neural elements. Careful neurologic assessment is recommended every 4 to 6 hours. A posterior decompression may improve the correction attained, particularly if an elongated pars is present (166). Posterolateral fusion is performed after a period of traction or at the time of decompression. After the additional period of reduction is completed, anterior spinal fusion may be performed if desired. Dubousset recommended anterior interbody fusion if the lumbosacral angle, measured from the superior end plate of L5 and the posterior border of the sacrum, could not be improved to 100 degrees after reduction (46). Casting is performed after acceptable reduction has been attained.

The technique of anterior spinal fusion after reduction is similar to that described previously (43). In addition, the placement of a curved retractor, such as a Homan, within the L5–S1 disc space and the application of a distraction and posterior translation force may permit additional reduction to be achieved. If desired, a structural graft, such as fibula, can be placed through a drill hole from the L5 vertebral body into the sacrum to stabilize the reduction (89).

A period of bed rest after anterior fusion is recommended, followed by corrective casting in a pantaloon cast for at least 3 months (43).

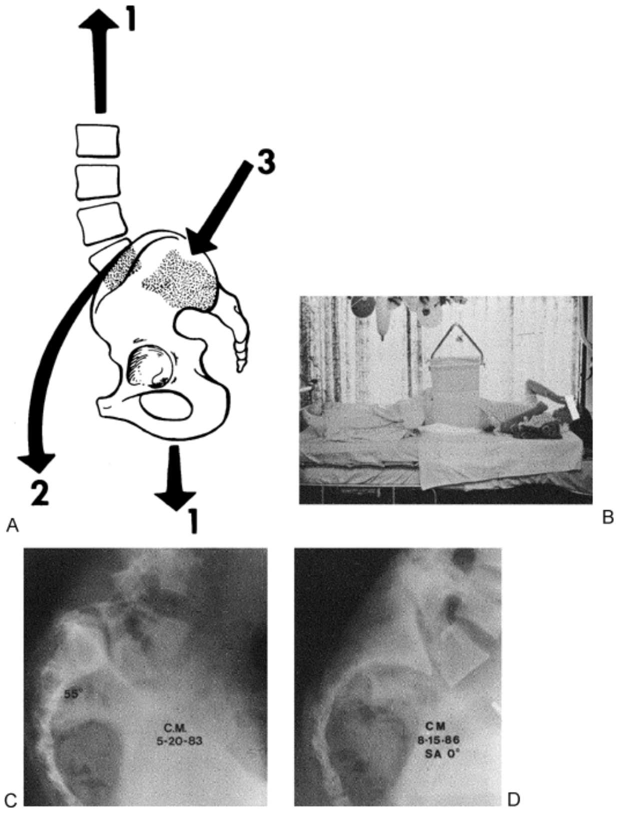

FIGURE 17. A: Illustration of the forces that should be applied during reduction of spondylolisthesis with traction. Axial traction is applied, the pelvis is rotated, and direct pressure is applied to the posterior portion of the scarum. **B:** Photograph of a young girl in traction to reduce her high-grade spondylolisthesis. **C:** Preoperative lateral radiograph demonstrating grade IV spondylolisthesis. **D:** Radiograph after preoperative traction, posterolateral fusion of L4 to the sacrum, and postoperative cast reduction and immobilization.

Previously, posterior distraction instrumentation from L2 to the sacrum has been used to provide the forces needed for reduction (41,43,75,96,182,204). Because distraction is now understood to flatten the patient's lumbar lordosis and to be a less biomechanically stable construct compared with pedicular screws (181), distraction instrumentation is no longer recommended in the treatment of spondylolisthesis. However, a temporary distraction rod may be used to facilitate reduction.

Interpedicular screws have been applied by several authors (14,44,53,117,126,142,168,182,189). Edwards (48,49) reported on the reduction of high-grade spondylolisthesis via a pedicle screw system that permits gradual distraction, flexion of the sacrum, and posterior translation of the upper lumbar spine. He reported satisfactory results in his patient series, averaging age 25 years, with an average preoperative slip angle of 33 degrees corrected to 4 degrees postoperatively, with only one neurologic deficit and one pseudarthrosis. However, his experience with spondyloptosis demonstrated a 25% rate of neurologic complications despite the fact that overall improvement of back and leg pain was quite high (36). We have also applied a similar technique to young patients who have failed previous treatment and in skeletally mature but young patients with advanced slippage and a significant cosmetic deformity, tight hamstrings, and the inability to stand erect with the knees straight (85). In this study, preoperative slippage averaged 89%; postoperatively this was improved to 29%. Slip angle averaged 50 degrees preoperatively and was improved to 24 degrees postoperatively. Hardware failure occurred in 25% of patients, all early in the series, and was successfully revised. Later, patients in the series and subsequently have had fibular interbody fusion performed if their slip angle was not adequately reduced. Neurologic complications, occurring in four of the 16 patients, resolved in all but one patient.

A variation of the reduction technique is an L5 vertebrectomy with reduction of L4 onto S1 (64). Surgeons applying this technique believed that it had decreased neurologic risk because the spine is, in effect, shortened. However, their follow-up, larger series (107) demonstrated that despite spinal shortening, the neurologic risk is considerable, with 75% of their 16 patients having early neurologic deficits (seven had preoperative deficits). All of the patients with permanent deficits had had preoperative deficits. Overall, five patients with preoperative deficits improved, six had a worsened neurologic deficit postoperatively, but only one had a permanent worsening of the neurologic deficit. The investigators also noted that the technique restores spinal alignment without the necessity of traction and postoperative casting. Detractors of this method note that the trunk remains shortened and neurologic risks are not avoided.

Results after reduction of high-grade slips have generally been satisfactory, although there have been complications. DeWald et al. (43) performed staged posterior fusion (L4-sacrum) and reduction with Harrington rod instrumentation (L1-sacrum), followed by anterior spinal fusion (L5-sacrum) on 14 young patients with greater than 50% slips. Instrumentation was removed after 6 to 12 months. Only one patient, who had a preoperative 100% slip, developed neurologic problems. This resolved after removal of rods, permitting the patient's spine to fuse in situ. All others went on to solid fusion with normal spinal alignment and gait. The patient who had fusion in situ continued to demonstrate abnormal posture and gait. Muschik's series (135) comparing anterior spinal fusion in situ with combined anterior fusion and posterior instrumented reduction, the fusion rate was greater and better reduction was achieved in patients with combined surgery; however, one neurologic injury (bilateral foot drop) and one vascular injury occurred in the group who underwent reduction.

In Harrington and Tullos's (75) series of nine adolescent patients with grade IV and V slippage treated with Harrington rod reduction, one patient developed cauda equina symptoms, which partially resolved. This patient had preoperative slippage of 90%, which was corrected to 5% at surgery. Some correction was lost in the first year, and the slippage increased to 30% at 3-year follow-up. This was the only patient who lost more than 5 degrees of correction. In Bradford's (21) series of 22 patients who underwent posterolateral fusion and cast reduction, two of six treated in skeletal traction developed unilateral transient L5 weakness. One patient had significant loss of correction secondary to infection and loosening of pelvic fixator pins. Correction of slip angle was well maintained, and only two patients noted mild low back symptoms at follow-up.

Up to a 20% incidence of postoperative sensory deficits and up to a 30% incidence of motor deficits have been noted in some series, although the majority of these have been transient (14,19,44,85,117,142,168). Transient bladder dysfunction was also noted in up to 28% of these patients (55,126). One case report noted paresis of the L2, L3, and L4 nerve roots after reduction of a grade IV spondylolisthesis. This was believed to have occurred because the reduction required posterior and proximal displacement of the proximal spine, with resultant traction on these proximal nerve roots (197). This improved but did not return to normal after reoperation and allowance for a partial loss of reduction.

The extent of L5 nerve stretch in spondylolisthesis reduction has been nicely demonstrated anatomically by Petraco and colleagues (149). They found that the mean nerve strain was 4% for the first 50% of reduction but increased to 10% for the second half of the reduction. With high grades of slippage, rotation of the L5 vertebral body (i.e., decreasing the lumbosacral kyphosis) resulted in nerve slackening.

Complications

Although fusion in situ is considered a safe and reliable operation for the treatment of spondylolisthesis, cauda equina syndrome has been reported to occur after fusion for grade III or IV spondylolisthesis (61,119,167). This may be related to mechanical factors secondary to impingement at the dome of the sacrum or lamina of L5, as direct iatrogenic injury to the cauda equina was not demonstrated. Early decompression, including removal of the dome of the sacrum and adjacent disc, appears to improve the likelihood of neurologic recovery. The neurologic risk with reduction maneuvers has been delineated above.

It has been suggested that because the lumbar segments above a spinal fusion may be required to bear additional stresses, they are susceptible to disc damage or even spondylolysis (12,24,73,81). However, when comparing patients who had had L5–S1 fusions for spondylolisthesis with those who had been treated conservatively, Seitsalo and co-workers did not find the rate of disc degeneration at L4–5 to be significantly increased by fusion (175).

Management of patients with significant complaints after surgery for spondylolisthesis is difficult. Jones et al. (93) reported on four patients with grade III or IV slippage who had severe low back pain, gait abnormalities, and neurologic deficit after previous surgery. These patients were then treated by anterior spinal fusion and stabilization using a fibular strut graft, supplemented in two cases by posterolateral fusion. All of the patients in this small series went on to fusion, with improvement of symptoms and gait.

Bradford and Gotfried (22) reviewed 16 patients with grade IV or V spondylolisthesis, all of whom had progressed after previous surgery. These patients presented with severe pain, often with symptoms of neurogenic claudication, and crouched gait. They underwent two- or three-stage surgery, including posterior osteotomy and posterolateral fusion, followed by anterior fusion, partial correction, and grafting. Several patients were treated in traction between stages. When it was deemed indicated, a third stage for application of Harrington compression rods was performed. Three patients in the series had resection of L5 with reduction of L4 onto the sacrum, with the anterior procedure performed first. There were six delayed unions; these were explored and the fusion was augmented, instrumentation was added, or both. There were five neuropathies, three of which resolved, and only one patient with transient difficulty voiding. All patients had excellent or good results and improvement of their deformities. There was marked improvement of percent slippage and slip angle in all patients, which was maintained at follow-up. Although this is a difficult procedure requiring prolonged treatment and with significant associated risks, it is believed to be feasible for patients with significant disability. Note that high rates of pseudarthrosis occurred in series prior to use of transpedicular instrumentation, which would now be considered the instrumentation of choice for these patients.

Conclusion

Spondylolysis and spondylolisthesis are common problems. The majority of patients presenting with symptoms can be managed nonoperatively. Continuing back pain, with or without radiculopathy, that is unresponsive to conservative management can usually be managed by posterolateral spinal fusion.

Reduction should be considered only if loss of sagittal alignment is significantly compromising function or if a decompression for a high-grade slippage is believed likely to result in progressive deformity even with arthrodesis in situ. Anatomical reduction is not necessary, and reduction of slip angle rather than complete reduction of the slippage appears less neurologically risky and yields satisfactory results in children, adolescents, and young adults for whom this procedure is indicated.

Herniated Nucleus Pulposus and Slipped Vertebral Apophysis

Vincent Arlet

François Fassier

V. Arlet and F. Fassier: Division of Orthopaedic Surgery, McGill University Health Center, Montreal, Quebec, H3H 1P3 Canada.

The symptoms and clinical signs of herniation of the nucleus pulposus (HNP) and slipped vertebral apophysis (SVA) are very similar in pediatric patients. Hashimoto et al. (41) showed no statistically significant differences in the average age, history of trauma, or symptoms and signs between SVA and HNP. Such differences are the result of a mechanical and or chemical conflict (as recently reported by Olmarker and Myers [66] and Kawakami et al. [47]) between the migration of material inside the spinal canal and the neural structures. For this reason, they should be considered as a consequence of a pathologic entity occurring during the growing years, this being the result of a genetic predisposition, traumatic event, or other causative factors.

A few authors (5,28,32,65,91) have stated that there is little or no difference between adult and pediatric herniations of the nucleus pulposus; this does not correspond to our clinical experience. We therefore reviewed the literature illustrated in Table 1 and summarized the differences between adult and pediatric HNP and SVA. In the sections that follow, the subject will be limited to the aforementioned pathologies. Therefore, problems related to Sheuermann disease, osteochondrodysplasia, and calcification of the intervertebral disc will not be discussed. By “pediatric” we mean patients who are younger than 18 years at the onset of first symptoms.

Epidemiologic Factors

Wahren in 1945 (90) was the first to report on the surgical treatment of a herniated nucleus pulposus in a 12-year-old child. In 1954, Begg (4) first reported ring apophyseal fracture associated with a central disc herniation. In 1973, Lowrey (54) first reported a cartilaginous and bony ridge protruding in the spinal canal.

If lumbar disc herniation is common in adults, with a 1.6% of sciatica prevalent in the adult population as reported by Deoyo et al. (23), its incidence in children is exceptional. The incidence of low back pain leading to hospitalization rises sharply from the age 19, according to Zitting et al. (95). Large series of surgically treated patients with disc herniation report an incidence of only 0.2% to 3.2% occurring in the young patient (27,33,37,73,75,91). In the study by Ramirez et al. (74), only two of 2,442 patients with back pain and scoliosis had disc herniation. However, the incidence of HNP in the Japanese seems higher, with an incidence of 15.4% in one series (49). However, if one considers patients younger than 15 years, the true incidence drops to 4.6%. This was confirmed by Ishihara (44), who reported an incidence of 3% for children younger than 16 years. The age of onset is observed in the second decade, at a mean age of 14.5 years. However, we observed a case in a patient as young as 5 years (Fig. 1), and one can find case reports on patients younger than 12 years (12,13,16,18,91). For most studies, the incidence in males is greater than in females (13,18,22,37,41,49) by a ratio of 2:1 or 3:1. However, two studies (28,46) found no differences. The sex ratio between girls and boys may vary depending on the age range considered. Girls mature faster than boys and are therefore more likely to have more disc herniations at an earlier age. In the adults likewise, one finds a male preponderance (92).

Etiologic Factors

Several factors can lead to migration of intervertebral contents into the spinal canal.

Trauma

Trauma is reported by patients in most instances (5,14,21,25,37,38). The reported incidence ranges between 30% and 70% of cases. Trauma may be responsible for an acute disc or ring apophysis migration. On the other hand, repetitive trauma or microtrauma encountered in sports (gymnastics, football, weight lifting) definitely has a role in the etiology of intervertebral materiel migration (Fig. 2).

TABLE 1. Pediatric Versus Adult HNP & SVA

	Pediatric	Adult
Etiology and Epidemiology		
Overall incidence	Exceptional	Between 1.5 and 5% (23)
% of operated cases	0.8–3.8% (25,27,37,65,67,75)	92–99%
	Japan: 3–15.4% (44,49)	
Male/female ratio	Variable (12,22,27,46,49,67)	2 for 1 (15,48,95)
Trauma history	Acute or repeated microtrauma: 50% (14,21,25,37)	Precipitating factor event on DDD
	No trauma history (75)	
DDD	Classically no. Yes recently (55,72,78)	Yes+++
Genetics	Identical twins (39,57,64)	
	Family predisposition (50,88,89,94)	Family predisposition for DDD (70,71,82)
Associated Conditions		
Spinal stenosis	Congenital: 12.5% (67)	Acquired and degenerative
Sheuermann	Juvenile discogenic disease (43)	Yes (43)
Transitionnal anomaly	Yes 30% (12,13,28,49,65)	No; only observed in less than 10%

Spondylo	Rare	Yes (degenerative or isthmic)
Clinical Findings		
Time for diagnosis	Delayed (mean delay is 11 months (37,49,50))	Rapid (less than few weeks)
Symptoms	Functional signs less than physical signs (56,75)	Functional signs more than physical signs
Back pain	Less than adult, and less than leg pain	More intense & frequent
Leg pain	Always present (often isolated leg pain) (37), Leg pain often outweights back pain	Intense but rarely isolated leg pain
Physical signs	Spine syndrome takes first place	Less impressive than symptoms
Lumbar lordosis	Decreased+++	Decrease less obvious
Back stiffness	(++++) (37)	Less pronounced
Gait anomaly	Frequent (21)	Rare
Sciatic scoliosis	Antalgic scoliosis: 55–72% (20,38)	Less frequent
Valsava	(+++) in 30%–76% (22)	Less pronounced
SLR	Very limited and present in 85–95% (33,37,21)	Not as limited. Very frequent but not constant despite HNP
	Bilateral SLR more often observed in SVA (41)	
Positive neuro signs	Rare: (34,35,37,50,65)	More frequent
Motor weakness	Classically rare. More frequent in ring #	More frequent (32%) (48)
Sensory deficit	Minor sensory changes	More frequent
Reflexes changes	Rare (possible mild ankle assymmetry)	More frequent
Cauda equina	Exceptional (possible in SVA) (2,50)	Frequence 1.2–2.4%
Imaging		
Plain x-rays	Often normal (in 50% of cases (21))	Often normal or disc space narrowing
	Antalgic scol., ring #, malformations (13,21,22,49)	Signs of spondylolysis
CAT scan	Better for ring #. Tanaka classification. Spinal stenosis	Inferior to MRI
Myelo CT	Rarely indicated	Prior surgery or stenosis or cauda equina syndrome
Discogram	Rarely indicated	Far lateral disc herniation (with CT) or discogenic back pain
MRI	Best for HNP (45), but inferior to CT for ring #	Yes (best for HNP). Often multiple level DDD
	Assess state of disc (degenerated) in ring #, & HNP Disc can be normal in ring apohysis # (2,52).	MRI + gadolinium: for postoperative radiculopathy.
	MRI can show intact Sharpey's fibers in SVA (3)	
	Multilevel disease in 3/4 patients with HNP (36)	
Location HNP	L4-L5 & L5-S1 equally affected; 2 levels HNP: 3.2% (79)	L4-L5 and L5-S1 equally affected; 2 levels HNP: 5.1% (79)
Location ring #	L4-L5: 55% L3-L4: 24% and L5-S1: 21%	L4-L5 and L5-S1 (sup. aspect of S1) (30,31)
Differential Diagnosis	Clinical, x-rays, CT and MRI & bone scan	Clinical, x-rays, bone scan, CT, MRI
Neoplasms	Primary tumors: age<11, bilat. leg pain, neuro. findings (56)	Secondary tumors and nonback syndromes
Spondylolysis	Yes	Yes
Discitis	Yes	Rare
Spinal stenosis	Yes (congenital)	Yes (acquired)
Tethered cord	Yes (MRI)	No
Spinal tumors	Yes	Yes
Natural History		

Short-term	Conservative treatment fails in 75% of cases (21,46,49)	Resolution in 50–75% of cases within a month (15)
Recurrence	Frequent if conservative treatment successful	Recurrence in 8–15% (63)
Long term	May lead to restriction of activity (sports)	70% still report sciatica (63)
MRI changes	Spectrum of MRI changes same as adult (55)	Decrease size of HNP, migration of HNP, DDD at other levels (59,86)
Operative Findings		
Disc degeneration	35% of normal disc on microscopic exam (49)	Degeneration
Herniated disc	Often disc protrusion, extruded free fragment rare (25,46)	Disc more often extruded or even sequestred
	Fragment is larger than in adult.	
	Disc more hydrated	Disc with decreased water content
	Herniated disc often attached to PLL or Sharpey fibers	Bony compression often associated
# Ring	19–32% of fractured vertebral rim (3,55)	Rare, can be observed to the 40s (30,31)
	Sharpey's fibers intact	
	Pathogenesis is the fragility of the end plate (84)	
	Mostly Takata 1 and 2	Mostly Takata 3 (84)
	Mostly associated with central disc herniation (54,83,85)	
	May require extended uni. or bilat. laminotomy (2,29,30,31)	Same as pediatric
	Remove avulsed fragment only or further discectomy? (52)	Same as pediatric
Treatment (Mainstay)	Open discectomy (after trial of conserv. treatment)	Mostly conservative
	Epidural, nerve root block?	Epidural steroids not superior to placebo injections (17)
	Fusion not recommended (13,27,46,49,67)	Fusion rarely recommended.
	Only few authors advocate chemonucleolysis (11,53)	Open discectomy sup. to chemonucl. or percut. discectomy (61)
	Microdiscectomy or conventional open discectomy	Microdiscectomy or conventional open discectomy
Outcome of Surgery		
Initial	Excellent or good: 73–95% (9,21,22,25,33,37,78,81)	Guarded: (24,63)
Long-term	Poor result in 9–26% (21,22,25,32)	70% still complaining of LBP (24)
Recurrence	4–10% (9,22,32)	45% still have residual sciatica (24)
Reoperation	21–28% with a 28 or 34 years f.up (25,67)	12–17% (4–17 years f.up) (24,63,87)

DDD, Degenerative disc disease; HNP, Herniated nucleus pulposus; LBP, Low back pain; NP, Nucleus pulposus; SVA, Slipped vertebral apophysis; SLR, Straight leg raising; PLL, Posterior longitudinal ligament.

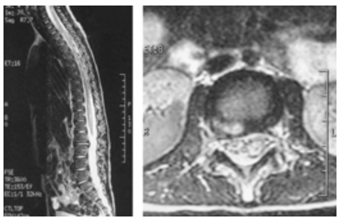

FIGURE 1. A 5-year-old patient with low back pain, right leg pain, and a decreased knee reflex. Her symptoms persisted despite one year of conservative treatment. The radiographs were read as normal. The magnetic resonance image showed a right posterolateral herniated L2–3 disc but with only partial dehydration (disc still white). At surgery, a large disc bulge contained by the posterior longitudinal ligament was identified. After incision of the disc, outer annulus disc material emerged under pressure "like toothpaste." The pathology report referred to "fragments of degenerated disc." (Courtesy of J. P. Farmer, M.D.)

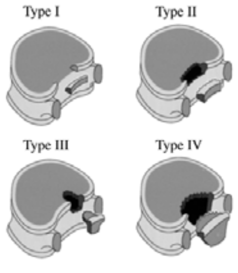

FIGURE 2. Classification of the ring apophysis fracture. Limbus vertebral fractures have been classified by Takata in type I, II, and III. Epstein later added the type IV. In children most of the ring apophysis fractures are type 1. (Redrawn from Takata et al. [84] and Epstein et al. [29]).

Disc Degeneration

Disc degeneration has always been thought to be one of the characteristics of the adult disc and its well-described degenerative disc disease (DDD). The advent of magnetic resonance imaging (MRI) has shown that early disc degeneration is observed at many other levels in teenagers complaining of sciatica or low back pain (36,55,72,76,78). At this age, as opposed to in adulthood, it is rare for asymptomatic individuals to show signs of disc degeneration on MRI (36). Poussa et al. (72) showed that after a 10-year follow-up patients operated before age 15 for an HNP had multiple level lumbar DDD on the MR image. This was further confirmed by Luukkonen et al. (55), who showed that 6 years after lumbar discectomy the MR images of 67% of patients indicated DDD at other lumbar levels. In this series, of nine patients with disc herniation, the intradiscal contents were normal in five and degenerated in four. Savini et al. (78) reported that early-onset disc degeneration was one of the most significant etiologic factors, along with trauma and lumbosacral malformation (Fig. 1). Gibson et al. (36) compared a control group of healthy asymptomatic teenagers with a matched group of patients with a disc herniation and found that there were multiple-level disc abnormalities in 75% of patients in the latter group. Heithoff (43) found a high incidence of lumbar DDD in patients with Sheuermann's disease. This suggests an underlying degenerative diathesis in patients with disc herniation. Salminen et al. (76), in a prospective 3-year follow-up study of low back pain in the young, found a causal relationship between degenerative process and frequent low back pain.

Congenital Malformation

Congenital anomaly or malformation of the lumbar spine has been recognized as a predisposing factor. This is observed in as many as 30% of young patients with lumbar disc herniation (13,22,27,28,49,65) and may consist of a transitional anomaly, such as 6 lumbar vertebrae, or complete or incomplete sacralization of the L5 vertebra. Spina bifida occulta has been reported in 15% of cases, an incidence higher than that of the general population. Congenital spinal stenosis has been recognized as a very important contributing factor in the clinical manifestations of HNP or SVA (69,8,10,26,28,42,67). The incidence of a congenital narrow canal was reported to be 12.5% (67). Small disc protrusions in a normal size canal may be little or mildly symptomatic, whereas their occurrence in a narrow canal may be a different situation entirely.

Genetic Predisposition

Gunzburg et al. (39), Matsui et al. (57), and Obukhov et al. (64) have separately reported on monozygote teenaged twins who developed at the same age a disc herniation. Varlotta et al. (88) in studying 63 patients younger than 21 years with sciatica found an incidence of 32% of first-degree relatives with sciatica. A control group had an incidence of only 7% of sciatica in first-degree relatives. This strong family predisposition has also been stressed by other authors (58,60) and in the adult population (70,71,82). The possibility of a congenital narrow canal as a predisposing factor and its genetic incidence must be kept in mind. Varughese and Quartey (89) reported on four brothers with such a condition.

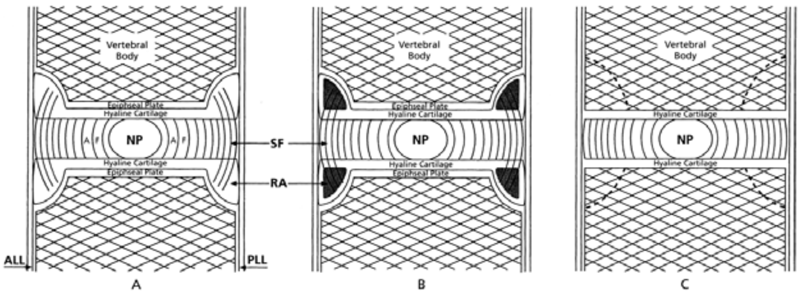

FIGURE 3. Drawing of the disc–vertebral end plate development, based on the original work of Bick and Copel (7,8). **A:** Age 6 years—The vertebral body grows longitudinally by enchondral ossification due to the growth plate. First foci of calcification determine the histology of the ring apophysis, which is separated from the vertebral body by the epiphyseal plate. The Sharpey fibers (which are the outer expansions of the annulus fibrosus) insert into the ring apophysis. The ring apophysis is a traction apophysis. **B:** Between ages 10 and 14 years—At age 10 there is a condensation of cartilage determining the triangular shape of the ring apophysis. At age 14 the ring apophysis starts to ossify. The Sharpey fibers become embedded in the bone of the ring apophysis. The ring, which is still separated from the vertebral body by the epiphyseal plate, appears on radiographs as a small triangular piece of bone separated from the vertebral body. **C:** At age 18 years—The ring apophysis fuses to the vertebral body when the epiphyseal plate disappears. *NP*, nucleus pulposus; *AF*, annulus fibrosus; *SF*, Sharpey's fibers; *ALL*, Anterior longitudinal ligament; *PLL*, Posterior longitudinal ligament; *RA*, ring apophysis.

Environmental Factors

Nutritional status, weight, and postural habits also have been suggested as causative factors.

Pathoanatomy

Intervertebral Disc and End Plate

The intervertebral disc space is occupied by the nucleus pulposus, the annulus fibrosis, and the cartilaginous end plates. The end plate of the immature spine consists of hyaline cartilage adjacent to the nucleus pulposus and a physeal cartilage adjacent to the bony vertebral body (Fig. 3). The physeal cartilage is further subdivided into a physeal plate (responsible for vertical growth) and a traction apophysis or ring apophysis. We refer the reader to the work of Bick and Copel (6,7) and to Fig. 3 for development of the end plate.The disc is constituted of the nucleus pulposus and the annulus fibrosis. The disc is attached to the ring apophysis (Fig. 4) by the curved Sharpey fibers. As the ring ossifies the Sharpey fibers insert into the vertebral bony end plate as the vertebra matures. The Sharpey fiber attachments to the ring are stronger than the junction between the ring and the vertebral body. Therefore, the osteocartilaginous junction is a weak point until it ossifies. As a result, in children one can observe migration into the spinal canal of disc material, cartilage, fibrous tissue, or bone, as opposed to the adult, in whom the pathology is almost exclusively migration of disc contents.

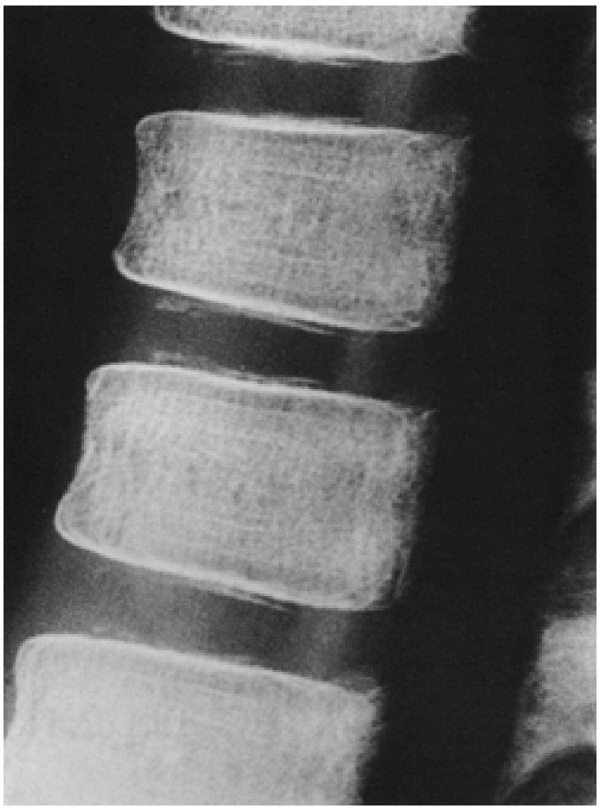

FIGURE 4. Ring apophysis at age 7 years (upper thoracic spine). (Reprinted from Ogden JA (1990): *Spine.* In: *Skeletal injury in the child.* Philadelphia: WB Saunders, with permission.)

Ring Apophysis Fracture

The advent of computed tomography (CT) has confirmed the higher incidence of ring apophysis migration into the spinal canal of what was thought to be a simple HNP. Likewise, careful review of the MR image and histologic examination of the excised disc will often reveal the presence of pieces of cartilage and/or bone. The pathology of slipped vertebral apophysis includes common histologic features: Part of the ring has displaced into the spinal canal with or without cancellous bone from the vertebral body. The classification of such lesions was described by Takata et al. (84). Epstein and colleagues (29,30,31) added a further subgroup (Fig. 2). Type 1 lesions occur more in the younger group. Most of these lesions seem to be located at the inferior aspect of L4 (40). Adjacent to it there is most often a central disc herniation (41). The fragment remains attached to the posterior longitudinal ligament by the outer expansions of the Sharpey fibers.

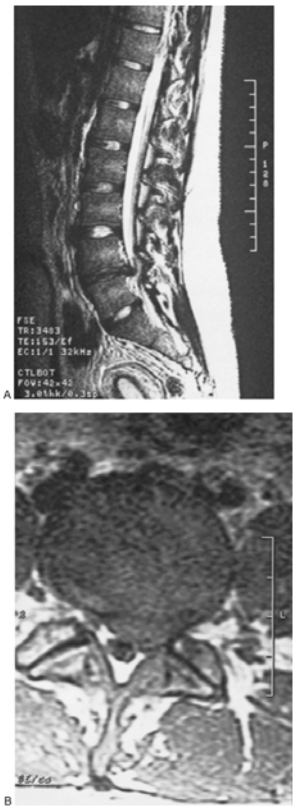

FIGURE 5. A 15-year-old girl with predominantly left leg pain for the last 9 months attributed to a hamstring pull. The magnetic resonance image shows the typical subligamentous L4–5 disc **(A and B)** herniation, which is posterolateral. At surgery, the herniated disc was subligamentous.

Herniation of the Nucleus Pulposus

According to Garrido (34), herniation of the nucleus pulposus rarely is completely extruded into the epidural space (free fragments) but rather is a disc protrusion in continuity with the rest of the nucleus pulposus and is covered by a thin membrane formed by the annulus and posterior longitudinal ligament. The herniation is mostly posterolateral (Fig. 5) (41). However, there is a clinical form wherein the disc protrusion is central and usually subligamentous too (79). These forms give more low back pain symptoms than true sciatica. The juvenile disc is quite moist, elastic, and gelatinous, and usually only a few pieces can be removed with the pituitary rongeur (34). The histologic evaluation of all excised specimens shows serious degeneration of the disc tissue (50) (Fig. 1). However, the degree of disc degeneration is not as great as that in the adult. Conversely, in the adult the hernia is more often extruded or even sequestered than in the juvenile. We think that this may be due to the stronger resistance of the outer fibers of the annulus fibrosus. The nucleus in the child is more gelatinous than the myxomatous nucleus observed in the older patient.

Chemical Factors Responsible for the Painful Radiculopathy

Recently, Olmarker and Myers (66), Kawakami et al. (47), and Yabuki et al. (93) have reported strong evidence of the role of chemical factors in the possible mechanism of painful radiculopathy. Mechanical factors were thought for a long time to be the only explanation for the pathogenesis of the radiculopathy. It seems that nucleus pulposus–related chemical substances sensitize the nerve root, producing pain even in the absence of compression. However, in children, because most of the hernia is subligamentous, chemical factors may not be as relevant to the pain pathogenesis as in the adult.

Clinical Presentation

Table 1 compares the pediatric disease to the adult version. We emphasize only the most striking features between pediatric and adult HNP and SVA: In children, the diagnosis is often delayed (33,37,49,50) because it is rare and the pain does not preclude functioning. Clinically, the radiculopathy (with Lasegue sign) is almost constant, the stiffness of the back is often impressive, and the patient may have sciatic scoliosis (Figs. 6 and 7). There is generally a lack of neurologic deficit. In contrast to the adult, the physical signs in children are usually more impressive than the clinical symptoms. However, in central disc protrusion the symptomatology may be limited to back pain, but without any sciatica (79). Neurologic complications in children seem to be more related to ring apophysis fractures (77).

Imaging Techniques

Imaging studies have recently emphasized the presence of slipped vertebral apophysis that was not recognized previously. It is now recognized that between 19% (55) and 32% (3) in the 13- to 14-year subgroup of what was thought to be a simple HNP are in fact an SVA. The presence of associated anomalies, such as spondylolysis (Fig. 8) and spinal stenosis (Fig. 9), is also a common feature. MRI will typically show a posterolateral subligamentous hernia for the HNP (Fig. 5) and a central disc herniation in SVA (16,41,83,85) (see Fig. 6). CT scanning is bested for SVA (1,3) and MRI best for HNP (45). MRI alone can fail to detect an SVA (68). It is the authors' opinion that when treating children one should request assessment of both the state of the discs and the possibility of a ring fracture (Figs. 10 and 11).

Differential Diagnosis

In children, sciatica is rare and one must rule out other causes of back and leg problems. In children before their teens the diagnosis of HNP or SVA remains unusual but possible (Fig. 1). One must rule out other conditions, such neoplasms, tethering of the cord, infections, discitis, and spondylolisthesis (74). In the teenager, spondylolysis typically does not produce a true radiculopathy. The diagnosis of these conditions may require a bone scan, MRI, and CT, but MRI is the examination of choice.

Natural History

Most authors recognize that conservative treatment is not very effective in children (94). According to DeLuca et al. (21), failure of conservative treatment was observed in 75% of cases. Kurihara and Kotaoka (49) reported that nonsurgical treatment was ineffective in 60% of cases. In a number of cases, conservative treatment that was at first successful is no longer effective once the child has resumed all sports activities. Some studies have focused on the state of the disc and the herniation by following the patients with sequential MRI (48,59). These studies have been done mostly in adults and have showed that the cases corresponding to protrusion showed little or no change on follow-up MRI. By contrast, migration of HNP frequently was associated with an obvious decrease in size and even disappearance. As to DDD, it seems to involve all age groups. Tullberg et al. (86) reported a 90% incidence of DDD at another level in the adult 1 year after lumbar discectomy. Luukkonen et al. (55) in his pediatric group found that with a mean follow-up of 6 years, 65% had disc degeneration at another lumbar level. The natural history as observed on MRI does not seem different from that of the adult. The natural history of SVA is more like a fracture type of pattern with callus forming at the fracture site, end plate irregularities, and possible late spinal stenosis as reported (41).

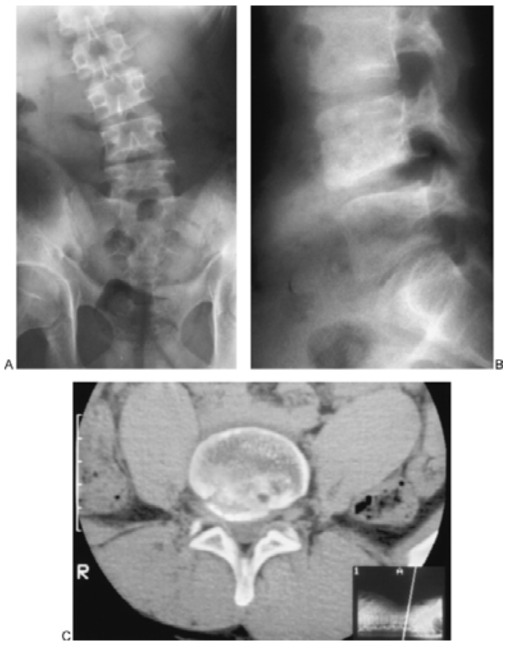

FIGURE 6. A 15-year-old patient complaining for several months of a severe right sciatica after having lifted a heavy weight. Radiographs show an impressive sciatic scoliosis without any rotation **(A)**. The spot lateral lumbar spine shows a localized kyphosis at L4–5 and an avulsed piece from the inferior border of L4 **(B)**. The CT scan demonstrates an arcuate avulsed fragment of the ring apophysis here classified as a type 1 in the Takata classification **(C)**. (At operation, removal of the fragment required an extended exposure, including a unilateral partial medial facetectomy.)

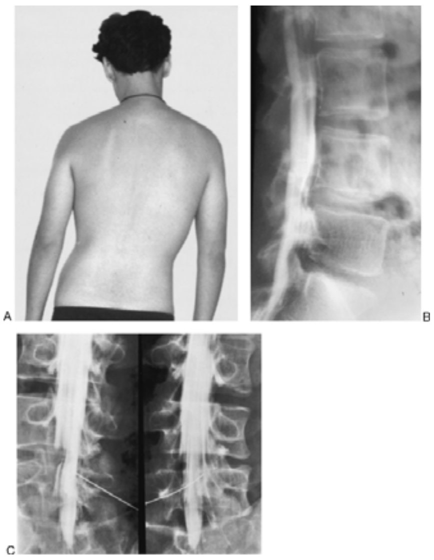

FIGURE 7. A 17-year-old boy with marked postural scoliosis and a left sciatica of 2 years duration **(A)**. Note that the patient is listing away from the sciatica. A myelogram was done at the time (old case). Lack of filling of the left L5 and S1 nerve root is evident with an extrinsic compression **(B and C)**. A two-level discectomy relieved the boy's symptoms.

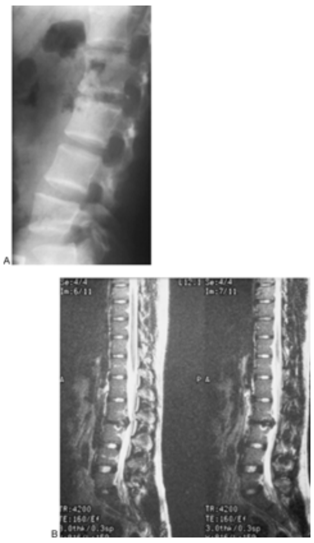

FIGURE 8. A 16-year-old patient with a longstanding history of low back pain after weight training. The lateral radiograph shows a sagittal malalignment of the lumbar spine with a spondylolysis L5–S1 and a triangular chip calcification in the canal at the L2–3 level **(A)**. The magnetic resonance image shows posterior Schmorl nodes and a black triangular shape corresponding to the avulsed ring apophysis still attached to the Sharpey fibers at the L2–3 level **(B)**. This case illustrates the possibility of a combined pathology and the question of the pain generator.

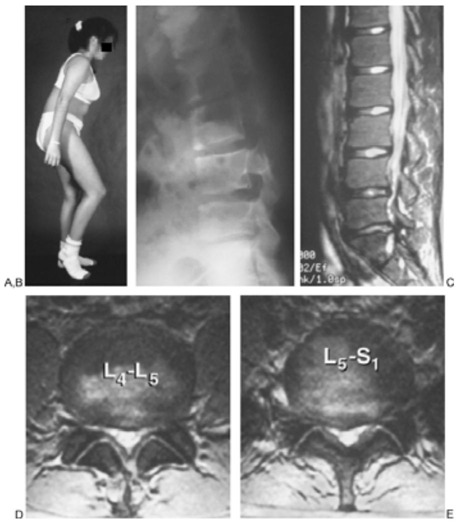

FIGURE 9. A 15-year-old girl with a longstanding history of leg pain and a marked postural anomaly without back pain **(A)**. The radiographs demonstrate a local kyphosis L4–5 and very short pedicles **(B)**. The magnetic resonance image shows L4–5 and L5–S1 disc herniation with severe spinal stenosis **(C–E)**. Her symptoms were relieved after L4–5 and L5–S1 discectomy.

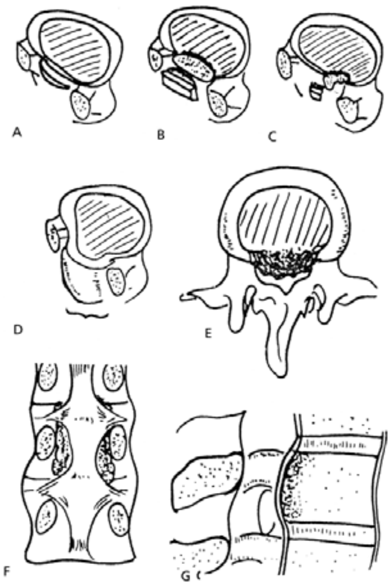

FIGURE 10. Schematic diagram of fractures of the vertebral limbus. **A:** Type I—simple separation of the entire posterior vertebral margin. **B:** Type II—avulsion fracture of some of the substance of the vertebral body, including the margin. **C:** Type III—more localized lateral fracture of the posterior margin of the vertebral body. **D–G:** Type IV—fracture that extends both beyond the margins of the disc and for the full length of the vertebral body between the end plates. The type IV fracture effectively displaces bone in the posterior direction, filling the floor of the spinal canal with a combination of reconstituted cortical and cancellous bone accompanied in part by scar formation. (Reprinted from Epstein NE, Epstein JA (1991): Limbus lumbar vertebral fractures in 27 adolescents and adults. *Spine* 16:962–966, with permission.)

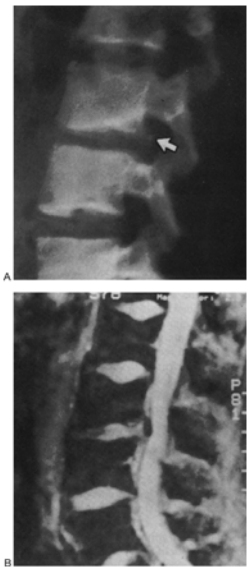

FIGURE 11. A 13-year-old boy scaled a high fence and jumped. He subsequently complained of back pain and presented with radicular symptoms with an L4–5 distribution. Removal of the large osteocartilaginous apophysis of the inferior aspect of L3 gave him immediate relief. **A:** A true lateral radiograph of the lumbar spine showing an ossific density in the spinal canal *(arrow)* posterior of the inferior margin L3. **B:** Magnetic resonance imaging illustrates the rim fracture of the posteroinferior end plate of the L3 vertebra with posterior displacement of the fragment into the spinal canal. The child underwent excision of the vertebral end plate apophysis and experienced complete relief. (Reprinted with permission from Crawford AH. (1990): Operative treatment of spine fractures in children. *Orthop Clin North Am* 21:325–339, with permission.)

Treatment

As disk problems are common in adults, conservative treatment is often advocated immediately without a proven diagnosis. In children and adolescents, disc problems are so rare that it is mandatory to make a diagnosis (and rule out other causes of back pain) before deciding which treatment is indicated.

Nonoperative Treatment

Conservative treatment is similar to that in the adult with a disc herniation. It includes the following:

- *Rest.* Complete bed rest in the acute phase or relative rest, with little or no physical activity in the rehabilitation period.
- *Medications.* Analgesics and muscle relaxants are indicated to help relieve the muscle spasms in the acute phase. Administration of local steroids by epidural injection has mostly been reported in adults (15). It remains an option in the acute phase if rest does not alleviate the symptoms and the patient has a contraindication for surgery. However, in a large prospective randomized study, Carette et al. (17) demonstrated that epidural steroids have not shown their superiority to a placebo-saline epidural injection.
- *Physiotherapy.* In the acute phase, massage, local heat, and transcutaneous electrical nerve stimulation can help reduce the muscle contracture. But it is in the rehabilitation period that these modalities are more helpful; the program may include strengthening muscles (including abdominal muscles), regaining motion (around the hips), and preventing bad postures and habits.
- *Bracing.* The use of thoracolumbosacral orthosis in HNP or SVA is not well documented and not advocated by the authors.
- *Chemonucleolysis.* Bradbury et al. (11) in a series of 60 pediatric patients reported 81% good or excellent results in his surgical group compared with 64% in his chymopapain group. However, they concluded that the patients were more likely to be employed after chemonucleolysis than after primary surgery. They favored chemonucleolysis as a first-line treatment, with surgery reserved for the failures. Lorenz and McCulloch (53) in a series of 55 pediatric cases had a failure of chemonucleolysis in 20% of the cases. However, most centers do not use chymopapain for adolescent disc protrusion. This may be due to the possible complications of treatment (mostly anaphylactic reaction) (62,63), the higher failure rate of chymopapain (19), and a lower success rate than open discectomy (63). In the authors' opinion, this is more true in the pediatric population, where surgery gives usually excellent result with little or no morbidity.

Conservative treatment must always be used first in the absence of neurologic deficit. However, results are controversial in the pediatric age group. Some authors report a satisfactory or good success rate in their conservatively treated group of patients (35,50,94), but a large majority agree that it is most often unsuccessful (21,37,46,49,56).

Operative Treatment

Before surgery is performed, the following questions have to be answered:

1. Does the compression involve one or two levels? (See Figs. 7 and 9 .)
2. Is the compression central? (This applies most often to an SVA.) In this case, the requirement of the decompression requires a bilateral approach and an extended laminotomy (Fig. 6). Is the compression posterolateral with a subligamentous HNP?
3. Is there a sequestered fragment? (This is rare in children.)
4. What is the size and shape of the canal when spinal stenosis is present?
5. Is there a fracture of the ring apophysis and is it old or new? (It will be easier to remove if new.)
6. What is the state of the disc (degenerated or not) and of the discs above and below it?
7. Is there an associated anomaly (spondylolysis, transitional anomaly, spina bifida occulta)?
8. Have other conditions, such as a tethered cord, been ruled out?

When all of these questions have been answered, the goal in treatment is to decompress the nerve root. In the absence of very clear scientific data regarding whether the discectomy should be complete or incomplete, the rationale for treatment is to perform a microdiscectomy that decompresses the nerve root. We believe that if MRI shows the disc to be not degenerated or only mildly degenerated, then removal of the hernia is sufficient. If, on the other hand, the disc is degenerated, a more complete removal of the disc on the side of the hernia should be done. In fracture of the ring apophysis this information is even more crucial because the disc may not be degenerated as mentioned (2,52). Therefore, removal of only the ring fracture is necessary if the disc is healthy on the preoperative MR image and adequate nerve decompression has been achieved.

Disc Excision

Whether the technique is a standard or a microsurgical approach, radiography is necessary to localize the proper level. The surgery then consists of opening of the ligamentum flavum, associated with a limited laminotomy if necessary to excise all compressing material. The herniation should be removed, but complete removal of the intervertebral disc is more difficult (and not necessary) than in the adult because the disc is not dehydrated and is more resistant (20). Cartilaginous fragments and bone fragments must be cut away, and if the diagnosis is delayed (as is often the case) local fibrous and remodeling make this part of the surgery harder and dangerous in terms of the dural sac and nerve roots. In the case of SVA, there is often a need to do a bilateral approach and an extended laminotomy (2,78) (Fig. 6). We have no experience with percutaneous nucleotomy or arthroscopic discectomy, both of which, in our opinion, are rarely indicated for treatment of HNP in children and are contraindicated in SVA or spinal stenosis.

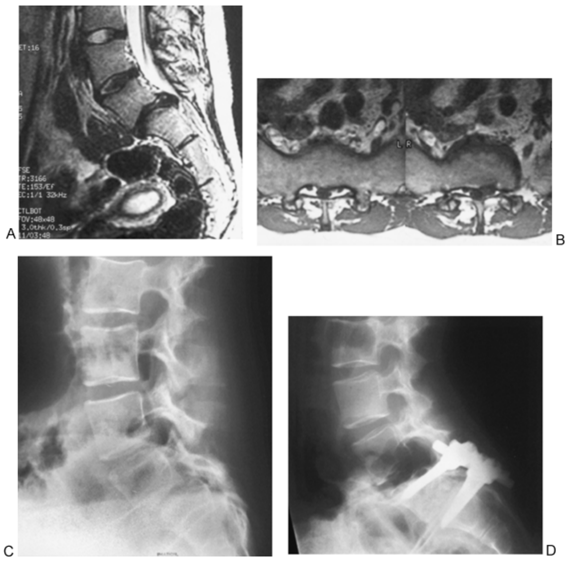

FIGURE 12. (A) Magnetic resonance image (MRI) from a 15-year-old girl who presented with left side sciatica of several months duration. MRI had confirmed the diagnosis of subligamentous disc herniation at L5–S1 **(B)**. A review of the magnetic resonance image and the radiograph **(C)** shows clearly a spondylolisthesis with a positive slip angle. At surgery, the hernia was subligamentous and compressing the left S1 nerve root. Because of the spondylolisthesis, an L5–S1 fusion was added **(D)**. This case illustrates the rare occurrence of a true herniation of the nucleus pulposus (HNP) and a spondylolisthesis. In our minds this is the only indication for a spine fusion in HNP in the pediatric spine.

Spinal Fusion

Most authors (12,13,27,28,46,49,81) (except Leong et al. [51] and Ishihara et al. [44] in selected cases) recommend that spinal fusion not be performed at the time of the discectomy. As the results of spinal fusion are not superior to those of simple discectomy, we do not advocate fusion. However, in the case of true sciatica due to HNP in a spondylolisthesis case, we strongly recommend that spinal fusion be performed at the time of the decompression (Fig. 12).

Results of Surgical Treatment

In contrast to adults, in whom the initial outcome is guarded (24,63), most authors agree that in the pediatric population surgical treatment gives good or excellent initial results in more than 85% of cases. The radicular pain and back pain disappear rapidly in the postoperative period (9,21,22,25,33,37,78,81).

Long-term results tend to endure but a certain number of reoperations are needed (78,81,72,22): In Ebersold and colleagues' (25) series of 74 patients, 16 patients (21%) had to undergo a second spine operation over a 34-year follow-up. For DeLuca et al. (21), there were poor results (9%) at 6.3 years follow-up. Fisher and Saunders (32) reported that 10% of patients required reoperation within 3 years. DeOrio and Bianco (22) reported 26.5% poor results at a mean of 19 years follow-up. Luukkonen et al. (55) had poor results in 10% of their cases.

Recommendations

In a child with symptomatic HNP or SVA one should rule out other causes of sciatica and obtain a CT scan and an MRI. A trial of conservative treatment consisting of rest, muscle relaxants, and anti-inflammatories should be started. Unfortunately, in the pediatric age group this treatment often is insufficient, and symptoms may persist. In more than 90% of such cases, surgical treatment can achieve a very satisfactory outcome. However, very long-term results may follow the spectrum of DDD.

Neurofibromatosis

Alvin H. Crawford

A. H. Crawford: Department of Pediatric Orthopaedic Surgery, Children's Hospital Medical Center, Cincinnati, Ohio 45229

Historical Review

Neurofibromatosis is a spectrum of multifaceted diseases involving not only neuroectoderm and mesoderm but also endoderm. It presents with a wide range of clinical manifestations that have in common the presence of schwannomas, neurofibromas, and/or café-au-lait spots (8). Clinically, this multisystemic, hereditary disease may manifest as abnormalities of the skin, nervous tissue, bones, and soft tissues. The primary pathologic process is believed to be a hamartomatous disorder of neural crest derivation. Common findings in pediatric neurofibromatosis type 1 (NF-1) are noted in Table 1 . Reports in the orthopaedics literature have dealt primarily with specific entities such as spinal deformity, pseudarthrosis of the tibia, paraplegia, hemihypertrophy, and neoplasia. Scoliosis is the most common musculoskeletal complication of NF-1 (2 ,31). This chapter deals with the primary and secondary effects of NF-1 on the pediatric spine.

Diagnostic Problems

Most investigators now accept four clinical forms of neurofibromatosis: peripheral (NF-1), central (NF-2), segmental, and mixed. A variety of eponyms have been used to describe all forms, although subsequent information has made these names technically inaccurate or incomplete. The most common type, NF-1, was previously known as von Recklinghausen disease and is an autosomal dominant disorder affecting about one in 4,000 persons; multiple hyperpigmented areas (café-au-lait macules) and neurofibromas are characteristic.

The 1987 Consensus Development Conference of the National Institutes of Health on NF-1 concluded that the diagnosis of NF-1 was established when two or more of the following diagnostic criteria were found: (a) six or more café-au-lait macules greater than 5 mm in widest diameter in prepubertal children and more than 15 mm in widest diameter in postpubertal individuals; (b) two or more neurofibromas of any type or one plexiform neurofibroma; (c) freckling in the axillary or inguinal regions; (d) optic glioma; (e) two or more Lisch nodules (iris hamartomas); (f) a distinctive osseous lesion, such as sphenoid dysplasia or thinning of a long bone cortex with or without pseudarthrosis; and (g) a first-degree relative (parent, sibling, or offspring) with NF-1 identified by the above criteria. Other disorders of pigmentation, such as McCune-Albright or Watson's syndrome, can be confused with NF-1 (49).

Genetics

NF-1 is the most common human single-gene disorder. It affects at least one million people throughout the world. It is seen in all racial and ethnic groups. It would be conservative to estimate that half of all people with NF-1 will suffer serious medical and social complications. The gene is fairly large (about 300,000 base pairs). (Most genes are several tens of thousands of base pairs, and the largest known, the gene for Duchenne muscular dystrophy, extends over 2.5 million base pairs.)

In 1990, the gene locus of NF-1 in humans was cloned and its protein product, neurofibromin, was identified (25). The gene is very large and has been linked to the long arm of chromosome 17. The NF-2 locus is probably linked to the long arm of chromosome 22; this genetic linkage is useful for the accurate diagnosis in families that have a high risk for NF-1. Given the fact that several hundred families with NF-1 have shown linkage to DNA markers on 17q (11 ,20), prenatal diagnosis for NF-1 is possible. For the time being, NF-1 prenatal diagnosis requires the genetic linkage approach, which means that only families in which two or more generations are already involved can use this exciting new aspect of health care (52). Continued rapid scientific progress is expected in molecular genetics for both NF-1 and NF-2. Such studies should lead to the development of a direct diagnostic test for NF-1, which would be especially helpful in establishing the diagnosis in uncertain cases, such as young children with only café-au-lait spots. This will directly influence classification, patient care, counseling of families, and research.

Clinical Findings

Café-au-lait Spots

Café-au-lait spots are present in well over 90% of all patients with NF-1. The pigmentation is tan, macular, and melanotic in origin and is located in and around the basal layer of the epidermis; the lesions may vary in shape, size, number, and location.

In NF-1, these spots are frequently found in areas of the skin not exposed to the sun (Fig. 1).

TABLE 1. Common Findings in Pediatric Neurofibromatosis Type 1

Finding	Percent
Cafe-au-lait (CAL) and cutaneous tumors by adolescent years	72–90
Positive family history	45–48
Central nervous system lesions	16–26
Scoliosis (as high as 60% in orthopaedic literature)	20–26
Skull and facial deformities	20
Significant CAL alone (not a true diagnosis of NF-1)	17
Failure to thrive in infancy	16
Aqueductal stenosis	16
Breast enlargement	13
Seizures	13
Hemihypertrophy	13
Tibial pseudarthrosis	12
Benign tumors alone	11
Extracranial malignancy (dramatic increase with age)	11–20
Vascular disease (dramatic increase with age)	10
Mediastinal tumors	8

Modified from Fienman NL (1981): Pediatric neurofibromatosis: review. *Compr Ther* 7:66–72.

Lisch Nodules

Lisch nodules, or iris-pigmented hamartomas, are present in 94% of patients with NF-1 who are 6 years of age or older; 28% of younger patients have them (42). They increase in number with age (39) but do not become symptomatic. The lesions appear to be specific for NF-1; they are not seen in non-NF-1 individuals.

Neurofibromas

Neurofibromas mostly involve the skin, but they may be seen in deeper peripheral nerves. They may be nodular and discrete, or diffuse with interdigitation with surrounding tissues. Highly vascular plexiform neurofibromas may cause segmental or localized hypertrophy. Puberty or pregnancy may cause an increase in the size and number of the lesions (12).

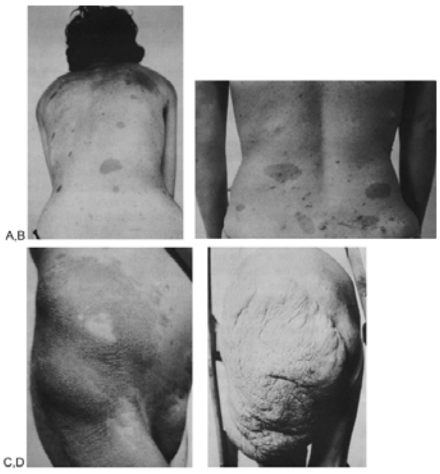

FIGURE 1. Cutaneous lesions of neurofibromatosis seen in children include café-au-lait spots, fibroma molluscum, pigmented nevi, and verrucous hyperplasia. **A:** Multiple café-au-lait spots in a young patient with scoliosis. Note the variation in size and shape of lesions. These lesions tend to increase in size and number as the child matures. **B:** Multiple café-au-lait spots in an older patient who also has subcutaneous nodules (fibroma molluscum), that is, pedunculated lesions that occur in the postpubescent adolescent. This patient also has several subcutaneous neurofibromas of the intercostal nerves, which are sessile. **C:** This large nevus, occurring on only one side of the trunk, is the nevus lateralis. It can be quite sensitive, and several patients who had spinal curvatures could not tolerate external corrective devices (e.g., Milwaukee brace or orthoplast jacket) because of this extreme sensitivity, which is believed to be related to an underlying plexiform neurofibroma. **D:** Verrucous hyperplasia of the skin over the left buttocks. This is the most grotesque of all cutaneous lesions. (Reprinted with permission from Crawford AH (1990): NF-1. In: Morrissy RT, ed. *Lovell and Winters pediatric orthopaedics*, 3rd ed. Philadelphia: JB Lippincott.)

Cutaneous Neurofibroma

Cutaneous neurofibromas, formerly called fibroma molluscum, are found in subcutaneous tissues after puberty. They are usually manifestations of longstanding or adult disease and do not occur with any frequency (12%) in childhood (53). Recent electron microscopy studies have demonstrated that axons and Schwann cells are present in these tumors; therefore, it is appropriate that they be called dermal neurofibroma (30).

Elephantiasis

Frequently, large soft-tissue masses are seen in NF-1. These masses have been termed *pachydermatocele* or *elephantiasis neuromatosa* and are characterized by a rough, raised, villous type of skin hypertrophy presenting an unmistakable appearance.

Pigmented Nevi

Eight percent of all patients presenting with NF-1 have pigmented nevi, some presenting with geographic descriptions (e.g., “nevus lateralus”). “Bathing trunk” nevi or hyperpigmentation may be present in up to 6% of children with NF-1 (53). Some nevi are quite sensitive, often the result of an underlying subcutaneous plexiform neurofibroma.

Plexiform Neurofibroma

Plexiform neurofibromas are subcutaneous neurofibromas that have a ropy, “bag of worms” feeling. Their cutaneous involvement may cause decreased sensation, causing sores to develop under a brace or cast without the patient's knowledge, or they may be hypersensitive. The plexiform neurofibroma has the potential for malignant degeneration (53).

Optic Gliomas

Although optic gliomas account for only 2% to 5% of all brain tumors in childhood, as many as 70% of cases are found in persons with NF-1. In many NF-1 patients these tumors change little in size over many years, but a small percentage of such tumors may enlarge rapidly, leading to exophthalmos and visual impairment.

Verrucous Hyperplasia

Verrucous hyperplasia is an uncommon, unsightly, extensive overgrowth of the skin, with thickening of a velvety-soft papillary quality. Many crevices form and tend to break down easily, with some weeping occurring in the skin folds.

Axillary and Inguinal Freckling

Freckles—diffuse, small, hyperpigmented spots up to 2 to 3 mm in diameter found in the armpits and inguinal region (areas not usually exposed to sunlight)—are helpful diagnostic criteria for NF-1.

Spinal Deformities

Spinal deformities have been noted to occur only in NF-1. The deformities include nondystrophic and dystrophic changes. The dystrophic changes may be intrinsic or associated with spinal canal anomalies secondary to abnormalities of the spinal cord dura mater.

The relative incidence of spinal deformities in NF-1 is unknown. Patients having some disorder of the spine will vary from 2% to 36% (3 ,60). Of the approximately 10,000 scoliosis patients seen by Winter et al. (73), only 102 were found to fit the traditional criteria for diagnosis of NF-1. Functional scoliosis resulting from limb hypertrophy or long-bone dysplasia must be ruled out in patients with NF-1. All preadolescent children with NF-1 should be evaluated by the scoliosis screening or Adam's “bend test” to rule out the presence of a spinal deformity, which usually occurs earlier in children with NF-1 (15). The characteristic deformity tends to a short segmented, sharply angulated curvature; it usually includes four to six vertebrae. It may be noticed in early childhood.

Recent investigators have suggested that there is no standard pattern of spinal deformity in NF-1; the types of curvature found are variable.

Radiology

Routine posteroanterior and lateral cervical, thoracolumbar, and sacral radiographs are necessary when studying the deformed spine because of the potential for occult deformity in each location. Careful attention is directed on plain radiographs to the sagittal plane for evidence of abnormal lordosis, kyphosis, or dystrophic changes.

Computed tomography (CT) has been used extensively to identify the occasional abnormal structure of the spine in NF-1; it allows one to assess the spinal canal, its contents, and the associated anatomy. Three-dimensional reconstruction enhances the explicitness of the bony detail. The addition of contrast myelography to CT has allowed the surgeon to identify lesions found in and about the spinal canal. Magnetic resonance imaging (MRI) has recently been utilized to determine the internal contents of the spinal canal and will show the presence of lesions within and about the spinal cord itself. There are occasional problems interpreting magnetic resonance image of severe deformities because of distortion brought on by the complex three-plane deformity of kyphoscoliosis (5).

Management of Deformities

Cervical Deformities

The cervical spine deformity is usually kyphosis. Until recently, only casual references to the cervical spine have been evident in studies of other manifestations of NF-1. Many patients with cervical spine deformities are asymptomatic and clinically not apparent. Even so, curves in this area are more frequently associated with dysplastic lesions than in other areas of the spine (37).

Yong-Hing et al. (76) reviewed 56 patients with NF-1 specifically for abnormalities of the cervical spine and found 17 to have lesions. Of 37 patients who had thoracic scoliosis or kyphosis, 15 (44%) had cervical spine lesions; many of these patients were asymptomatic. Adkins and Ratvich (1) reviewed 85 patients with NF-1 and found that head and neck masses were responsible for 22% of the patients' complaints. Five cases of atlantoaxial dislocation have been reported in patients with NF-1, two of whom were noted to have neurofibromas between the odontoid and anterior arch of C1 (57 ,68 ,76).

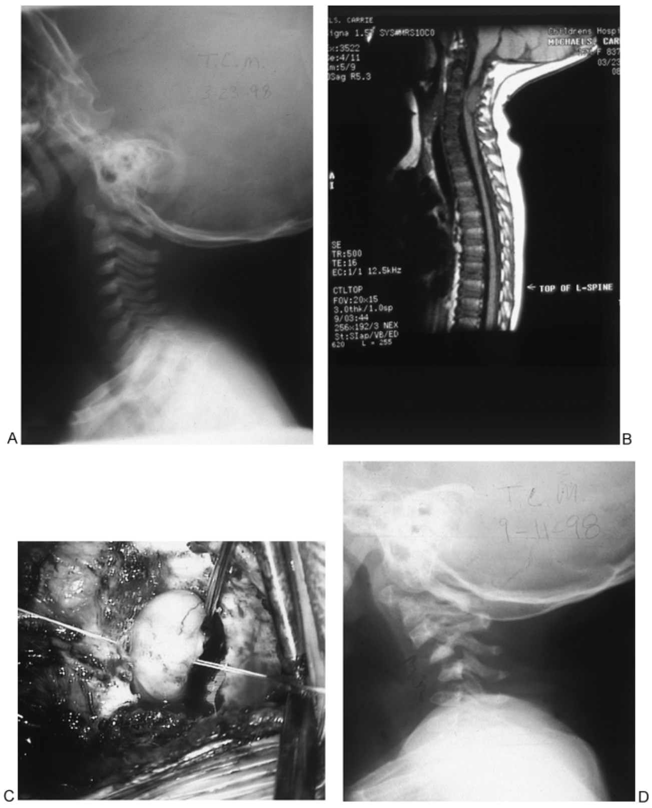

FIGURE 2. Spinal instability following laminectomy in a very young child who complained of neck pain and decreased range of motion. **A:** Presenting lateral cervical spine radiograph with slightly decreased lordosis. **B:** Magnetic resonance image illustrating extradural neurofibromatosis at C3–4 with spinal cord indentation. **C:** Operative view of neurofibroma excision. **D:** Lateral cervical spine radiograph 6 months following laminectomy and neurofibroma excision illustrating significant kyphosis of entire cervical spine.

The clinical consequences of cervical NF-1 tend to be less marked than in other regions because the cord versus canal diameter is commonly reported to be less critical. Because of its generally asymptomatic nature, the problem is probably underreported. However, these lesions should not be disregarded because the tendency of the disease to progress has led to severe neurologic deficits in several cases (24 ,28).

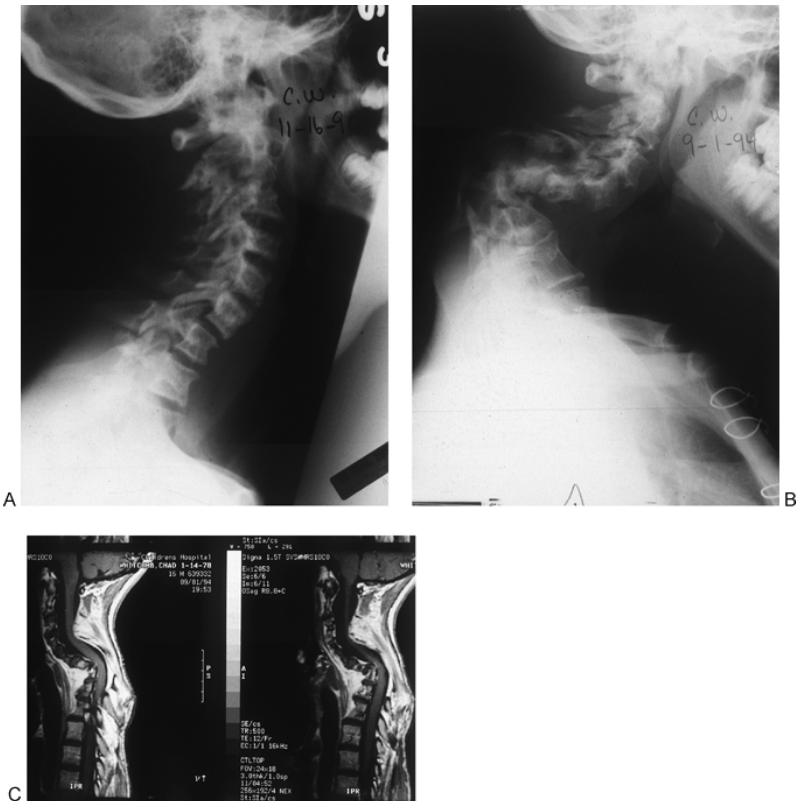

FIGURE 3. Spinal instability in 17-year-old following laminectomy for cervical neurofibrosarcoma. **A:** Lateral cervical spine x-ray taken prior to laminectomy. **B:** Lateral cervical spine radiograph taken 3 years following laminectomy illustrating significant (>90 degrees) kyphosis at time of referral to orthopaedic surgery. The child was neurologically intact. **C:** Preoperative magnetic resonance image illustrating dural sac expansion in area of kyphosis and absence of the posterior elements.

Most patients with cervical spine anomalies seen by the orthopaedist have already had excision of a neck mass by other surgical services (Fig. 2) The preceding workup has most likely included radiographs of the cervical spine showing considerable bony anomalies, but orthopaedic or neurosurgical consultations have not been obtained. Any evidence of bony deformity noted on cervical spine radiographs requires orthopaedic consultation (Fig. 3). Other reasons for consulting an orthopaedist and obtaining cervical spine radiographs in an NF-1 patient include torticollis and dysphagia. Both conditions may be related to intraspinal as well as extraspinal neurofibromas.

Anteroposterior and lateral radiographs of the cervical spine are recommended at the time of original evaluation of all spinal deformities in NF-1 patients. If dystrophic changes are noted, oblique radiographs to rule out dumbbell lesions (enlargement of neuroforamina due to intraspinal meningoceles, solitary tumors, or interstitial hypertrophic neuritis) and lateral flexion and extension radiographs to rule out instability should be obtained. One should be suspicious of scalloping of the vertebral bodies or an increase in the size of the neural foramina. If found, MRI should be performed to evaluate the intraspinal contents. All cases seen by the author following decompression laminectomies without fusion demonstrated instability with progressive kyphotic deformities.

Posterior spinal fusion is recommended for cervical spine deformity with instability. Autologous bone graft and halo immobilization are usually adequate, and a solid fusion can be expected. If there has been previous surgery, such as laminectomy, it may be necessary to perform anterior surgery as well. With the use of laser technology, neurofibromas in this region can be removed without compromise to the spinal cord. Because of the extent of bone removal required to completely excise the tumor and the resulting instability, posterior and anterior spinal fusion should always be carried out. The level of instability often requires an occipitocervical fusion. A halo-assisted orthosis may be utilized to stabilize the occipitocervicothoracic area until fusion takes place. Multiple view radiographs of the cervical spine are mandatory before general anesthesia or halo traction to rule out dystrophic deformity and possible instability.

Thoracic Scoliosis

Thoracic scoliosis is the most common osseous defect associated with NF-1. Gould (26) and Weiss (70) were the first to point out the associated spinal deformities in this disease; many authors have subsequently done so (5 ,13 ,32 ,64). The cause of spinal deformity is unknown, but it has been suggested to be secondary to osteomalacia, localized neurofibromatous tumor–related erosion and infiltration of bone, endocrine disturbances, or mesodermal dysplasia (7 ,26 ,29 ,64).

There have been relatively few clinical studies discussing the treatment of spinal deformities in patients with NF-1. Winter et al. (72) reviewed the natural history, associated anomalies, and responses to operative and nonoperative treatment in 102 patients with NF-1 and spinal deformity. Eighty patients were found to have curvature associated with dystrophic changes in vertebrae or ribs. The presence of dystrophic changes, such as rib rotation in the anteroposterior direction resulting in an abnormally thin appearance, spindling of the transverse processes, vertebral scalloping, severe apical vertebral rotation, foraminal enlargement, and adjacent soft-tissue neurofibromas, were found to be highly significant in terms of prognosis and management. Brace treatment has not been effective in the management of progressive dystrophic curves and should not be used, even in young children. Early fusion causes minimum stunting of truncal height because the curves are usually short, with poor growth potential in the involved vertebrae; therefore, one need not wait for the child to attain a certain physiologic or chronologic age (73).

Chaglassian et al. (10) reported a 6.5% incidence of pseudarthrosis following 23 operations in 15 patients; there was no separation of dystrophic and nondystrophic curves. Crawford (14) reported a 15% incidence of pseudarthrosis in 46 patients. Savini et al. (58) performed 56 operations on 26 patients. They recommended anterior fusion and complete disc excision in addition to repeat bone grafting for relapse after posterior fusion. Betz et al. (5) reported the results of surgery performed on 23 patients; 20 obtained solid fusion, but 13 required one or more posterior augmentations because of progressive deformity. Three patients with dystrophic kyphoscoliosis obtained solid fusion with no further progression following primary anterior-posterior fusion.

Shufflebarger (65) used Cotrel-Dubousset instrumentation on 12 patients with NF-1: ten with nondystrophic NF-1, one with dystrophic NF-1, and another following multiple laminectomies. Follow-up averaged 33 months. The fusion on the dystrophic deformity failed and required repeat anterior-posterior fusion. He advocated immobilization following Cotrel-Dubousset instrumentation in patients with poor bone stock. More importantly, he stressed the necessity of performing the anterior procedure from the concave side utilizing multiple strut grafts. Convex discectomies tend to further destabilize the spine, and it is technically difficult, if not impossible, to properly place struts from the convex approach.

Holt and Johnson (33) treated five patients with dystrophic scoliosis with Cotrel-Dubousset instrumentation; surgery included posterior, anterior-posterior, and multistaged fusion.

Hsu et al. (34) reported on 13 patients with dystrophic spinal deformities treated by anterior-posterior fusion. Anterior-posterior fusion achieved satisfactory results in patients with smooth kyphoscoliosis or scoliosis without excessive kyphosis, but it was unsatisfactory in patients with an angular kyphoscoliosis. Five patients had angular kyphoscoliosis; one had persistent pseudarthrosis after operation, and all had progression of the kyphosis despite the treatment.

Sirois and Drennan (66) reviewed 32 patients with NF-1 and spinal deformity, 23 (72%) of whom had dystrophic curve patterns. The incidence of pseudarthrosis was 38% for the dystrophic group undergoing isolated posterior fusion. Retrospective curve extension following surgery was noted in three patients; one required extension of the fusion mass. The average curve progression was 12.7 degrees and required an average of 1.7 procedures to achieve solid posterior fusion. They recommend treatment of kyphoscoliotic curves with anterior-posterior fusion.

The author agrees with others that spinal deformities in NF-1 should be divided into two groups: those with dystrophic changes and those with no apparent dystrophy. The most serious spinal deformity complicating NF-1 is dystrophy of the vertebral bodies, posterior arches, and spinal canal. The clinical problems associated with these deformities are most common in the thoracic area, possibly because the canal-to-cord-diameter ratio is more critical in the thoracic region.

Nondystrophic Scoliosis

The nondystrophic curvature is the most common spinal deformity in NF-1, and findings are believed to be similar to those of idiopathic scoliosis. The nonprogressive curvatures can usually be managed in the same manner as other idiopathic curvatures. When following patients with what appear to be nondystrophic spinal deformities over an extended period, there is a higher incidence of progressive deformity, including possible pseudarthrosis following instrumentation and fusion, than that found in idiopathic scoliosis. *There is the distinct possibility of modulation across a spectrum of nondystrophic to dystrophic curvatures, but this tendency shows no consistent pattern* (25). These patients are also subject to spinal canal neurofibromas that may grow and give rise to pressure-induced expansion of the canal, as well as dystrophy of the vertebral bodies.

The author's recommendations for managing nondystrophic scoliosis accompanying NF-1 are to treat the curvature as an idiopathic curvature (i.e., the patient should be observed for curvatures of less than 20 degrees). If there are no dystrophic changes, a brace is applied following progression of the deformity up to 35 degrees. For those deformities exceeding 35 to 45 degrees, a posterior spinal fusion of all articular facets and segmental spinal instrumentation is strongly recommended. Patients whose deformities exceed 60 degrees should routinely have anterior disc excision with bone grafting of the area of curvature followed by posterior spinal fusion of all articular facets, segmental spinal instrumentation, and autogenous iliac crest bone graft.

There is a definite tendency of nondystrophic curves to become dystrophic in some patients, with a coexistent higher incidence of pseudarthrosis and loss of correction following attempts at surgical stabilization.

Dystrophic Scoliosis

The short segmented, sharply angulated curvature is the most common identifiable spinal deformity associated with NF-1. Specific vertebral body changes, such as scalloping of the vertebral bodies, wedging of the vertebral margins (Fig. 4), severe rotation (Fig. 5), widening of the interpediculate distance, widening of the intervertebral foramina, “penciling” of the ribs, a spindled appearance of the transverse processes, and the presence of a paravertebral mass are characteristic.

Canal widening is believed to be the result of either an intraspinal tumor or dural ectasia, that is, an increase in the width of the thecal sac subsequent to an increase in hydrostatic pressure, causing expansive and erosive deformity to the surrounding spinal canal and vertebral bodies. Because of spinal canal widening and expansion, there may be tremendous angular deformity and distortion without spinal cord compromise or neurologic deficit.

There are no universally acceptable criteria for spinal dystrophy. We feel that there is a definite potential for what appears to be idiopathic deformities to become dystrophic (i.e., to modulate or transform to dystrophic). We studied the relationship of dystrophy to progression (18). Ninety-one patients were studied—48 male and 43 female—who presented at 2 months to 26 years of age, with an average follow-up of 6.5 years. There were 43 thoracic, 20 thoracolumbar, 14 cervicothoracic, and 14 double curves. There were 37 left convex and 32 right convex. We analyzed for dystrophic features (Table 2) and found 62% rib penciling, 51% vertebral rotation, 31% posterior vertebral scalloping, 36% vertebral wedging, 31% spindling of the transverse processes, 31% anterior wedging, 29% widened interpedicular distances, 25% enlarged intervertebral foraminae, and 13% lateral vertebral scalloping. We reviewed the natural history and described three types.

- Type I: No dystrophy at presentation or follow-up (N = 13).
- Type II: Dystrophy at presentation with (A) no progression (N = 18), (B) progression (N = 21), (C) progression and extension (N = 9).
- Type III: Acquired dystrophy not present when first seen (A), with no progression (N = 6), (B) progression (N = 14), (C) progression and extension (N = 10). A total of 31 patients showed no tendency to modulate.

We reviewed such risk factors as the patient's age, patient's sex, extent of curve (number of vertebral segments), location of curve, and side of curve for evidence of progression and dystrophy. Multiple regression analysis of radiographic dystrophy to progression was carried out. Our results revealed that 81% of patients diagnosed with deformity prior to 7 years showed modulation, whereas only 25% diagnosed after 7 years modulated. Age was the most significant finding of our series. The extent, number of vertebral segments greater or less than six, was not a predictor; neither was sex, location, or side. No other single dystrophic feature was significant; however, when three or more dystrophic features were present progression was significant in 85%. We concluded that spinal deformities in NF-1 are dynamic in terms of both modulation and progression. Deformities presenting before age 7 should be observed for modulation if no dystrophy is present initially because 81% did eventually modulate. Gender, location, side, and extent of deformity did not influence the propensity to modulate. Rib penciling was the only singular dystrophic feature statistically linked to progression. The presence of three or more dystrophic features statistically increases the risk of progression (18).

It is most important to recognize the dystrophic curve and to distinguish it from the nondystrophic one. It is equally important to determine the degree of kyphosis and/or lordosis. Brace treatment is not effective in the management of dystrophic curves, and an aggressive approach to management is recommended. There is no justification for passively observing the progression of the dystrophic spinal deformity of NF-1 (73). The dystrophic deformity has a strong tendency to progress even following fusion.

Those patients with a curvature of less than 20 degrees should be observed for progression at 6-month intervals. For patients with greater than 20 to 40 degrees of angulation, a posterior spinal fusion of all articular facets using autogenous iliac crest graft and segmental spinal instrumentation should be performed. The pernicious course of the dystrophic curve justifies early stabilization. Early aggressive surgical intervention, even in young children, is strongly recommended. Early fusion does not lead to significant trunkal height loss because the curves are usually short, with poor growth potential in the involved vertebra; therefore, one need not wait for the child to reach a certain physiologic or chronologic age. Thoracic lordosis is less often associated with intracanal lesions but should be treated as aggressively as kyphosis. Care should be taken during the exposure because some of the laminae may be extremely thin or eroded as a result of subjacent neurofibroma or dural ectasia, and the spinal cord could be injured directly. The fusion should be carried out from the neutral vertebra above to the neutral vertebra below. Postoperative orthotic immobilization is recommended, and the patient should be radiographed at 6 months post surgery; oblique views should be taken to assess the fusion of the facet joints and to rule out pseudarthrosis. Patients with dystrophic curvatures that exceed 40 degrees should undergo anterior discectomy, intervertebral fusion, and posterior fusion and stabilization with segmental instrumentation as a primary procedure. A postoperative Risser cast or thoracolumbosacral orthosis is recommended for all patients with dystrophic deformity following fusion.

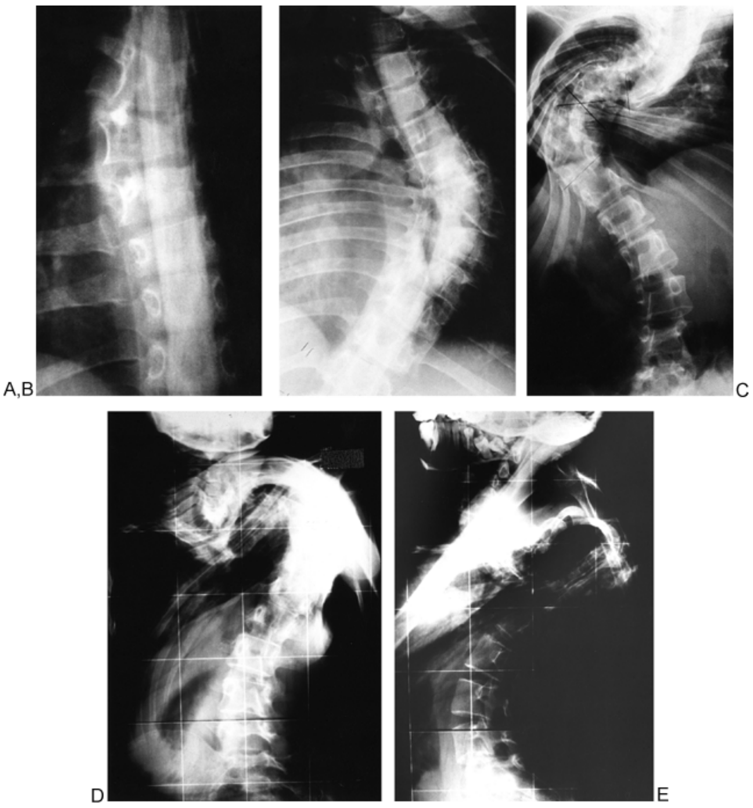

FIGURE 4. Examples of dystrophic scoliosis at ages 6, 9, 16, and 21 years. None of these patients had neurologic deficits when they presented to the orthopaedic surgeon. **A:** A left dorsal curvature in a 6-year-old with scalloping of the vertebral bodies and irregular sclerotic margins demonstrating dystrophic changes of neurofibromatosis scoliosis. Note the widening of the spinal canal that is not in conformity with scoliosis angulation. **B:** Right dorsal curve in a 9-year-old. Myelogram shows widening of the spinal canal and vertebral bodies rotating into the convexity. **C:** Left dorsal curve in a 16-year-old. The curvature is short segmented, sharply angulated, and kinky. Anteroposterior radiograph of the spine reveals scalloping of the vertebral margins, gross rotation of the apical vertebra, and penciling of the ribs in the concavity. Note proximity of the apical vertebrae to the ribs. The widening of the spinal canal is believed to be secondary to dural ectasia. (Courtesy of Dr. Michael Schaefer, Chicago, IL. Reprinted with permission of Crawford AH (1981): Neurofibromatosis in childhood. *Instr Course Lect* 30:56–74.) **D:** Anteroposterior radiograph of a 21-year-old with severe rotation and angulation. **E:** Lateral radiograph of the person shown in D. The kyphosis is striking in its severity, as is the scoliosis. (Courtesy of Dr. Klaus Zielke Badwildengen, West Germany.)

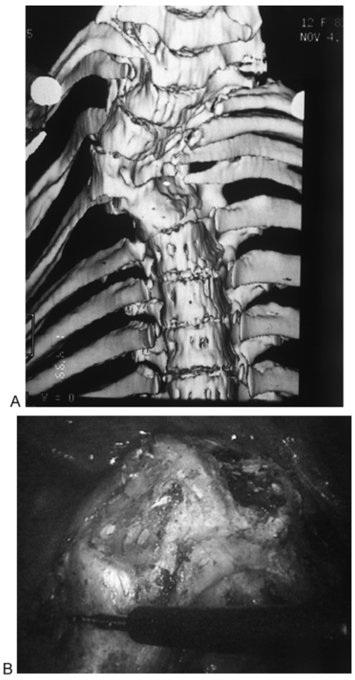

FIGURE 5. A 9-year-old child with dysplastic thoracic scoliosis who underwent anterior release and fusion by video-assisted thoracoscopic surgery. **A:** Three-dimensional reconstructed computed tomogram of a child with dysplastic scoliosis illustrating significant rotation of thoracic vertebra. **B:** Thoracoscopic view of anterior apical vertebrae. The anterior longitudinal ligament has rotated completely posterior and is attached to the concave rib heads. The vertebrae appear to have spun around toward the convex side.

TABLE 2. Dystrophic Features Noted in 91 Patients

Feature	Percent
Rib penciling	62
Vertebral rotation	51
Posterior vertebral scalloping	31
Vertebral wedging	36
Spindling of transverse processes	31
Anterior wedging	31
Widened interpedicular distances	29
Enlarged intervetebral forminae	25
Lateral vertebral scalloping	13

Modified from Durrani AA, Morley TR, Choudhary SN, et al. (2000): Modulation of spinal deformitive in NF. *Spine* 25(1):69–75.

Kyphoscoliosis

Kyphoscoliosis in NF-1 is distinguished by the predominance of kyphosis (more than 50 degrees on the lateral radiograph) associated with scoliosis; acute posterior angulation is a typical sign. The vertebral bodies are frequently so deformed and attenuated at the apex that it may be impossible to identify them on routine radiographs. Hsu et al. (34) described a progressive dystrophy of the apical vertebral body that led to an angular kyphosis and a sideways slip or subluxation of the spine such that the upper and lower limbs of the kyphosis were in bayonet apposition. Tredwell has theorized this deformity to be related to instability of the pedicle. Curtis et al. (17) believe that kyphosis contributed more to the production of paraplegia in their patients than did scoliosis. This view is supported by the biomechanical studies of Breig (6), which showed that flexion of the spine causes elongation of the spinal canal and deformation of the spinal cord. Pathologically increased spinal flexion, as by kyphotic deformity, leads to excessive axial tension of the spinal cord parenchyma and may result in neurologic impairment. Miller (47) found that among 20 patients with paraplegia associated with NF-1, severe angulation of the spine was responsible for the paraplegia in more than half of cases. Lonstein et al. (40) reviewed 45 patients with cord compression due to spinal curvature and found NF-1 to be second only to congenital kyphosis as the cause of spinal cord compression.

Winter et al. (72) reviewed 33 patients with NF-1 and kyphosis averaging 132 degrees. Six patients had paraparesis and six had respiratory distress; 27 patients had operative treatment. Laminectomy was useless for the treatment of paraparesis resulting from angulated spine deformity. Combined anterior and posterior spinal fusion, using abundant amounts of autogenous bone for both, coupled with a prolonged rigid immobilization gave the best results. Halo traction and halo casts were invaluable for the most severe deformities. Instrumentation was often impossible due to the severity of the deformity. All of the reported patients eventually achieved solid union.

Patients with dystrophic angular kyphosis respond poorly to posterior fusion alone. This is a potentially malignant deformity and should be aggressively pursued. Good results are consistently obtained only in those patients who have both anterior and posterior fusion; however, not every patient obtains solid fusion following these procedures (Fig. 6). Some patients require repeat operative procedures. Technically inadequate implementation of anterior procedures has been considered the usual reason for failure; however, pressure erosion from enlarging neurofibromas, dural ectasia, and meningoceles may play a role. Most important (Treatment A), the entire structural area of the deformity should be fused anteriorly with complete disc excision and strong strut grafting, preferably from the fibula, as well as rib and iliac crest graft. No soft tissue should be allowed to interpose between the grafts (Fig. 7), and all grafts should have contact with each other and with the spine. Those grafts surrounded by soft tissue tend to resorb in the midportion (73). Two of the author's patients with kyphoscoliosis have had a total of seven procedures each, both anterior and posterior, and have not obtained a stable spine as of this writing. Eight of 74 patients with kyphoscoliosis have had a total of 24 procedures to date. Only two of these eight patients have what appears to be a bona fide fusion and are asymptomatic, and only one patient has reached skeletal maturity; therefore, more problems can be expected.

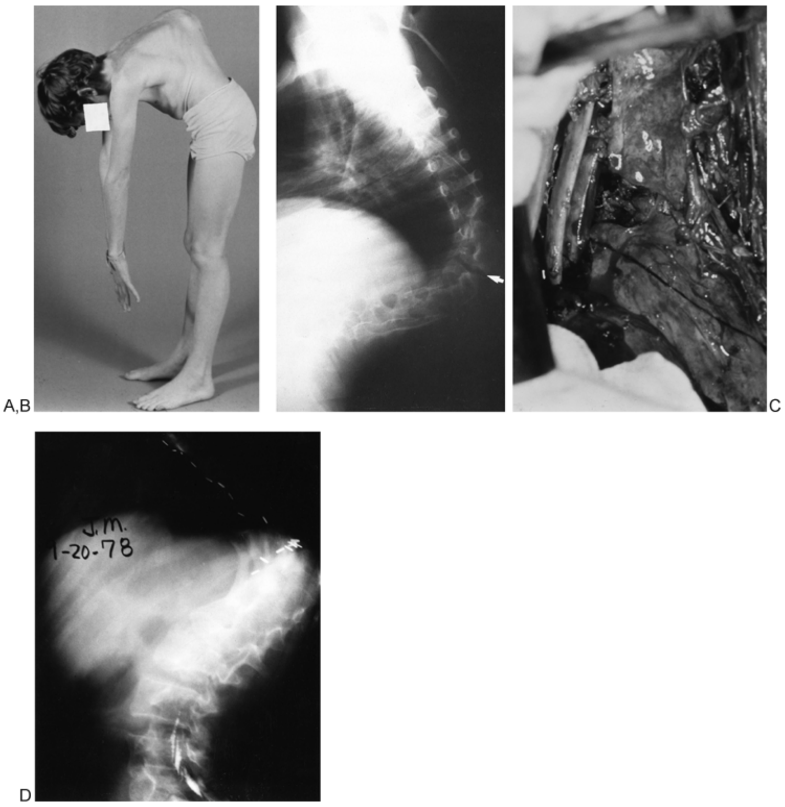

FIGURE 6. This boy presented with a severe kyphoscoliosis after having undergone three attempts at posterior spinal fusion. The kyphosis was in excess of 100 degrees. He underwent an anterior spinal fusion with fibular and rib strut grafts. The fusion subsequently failed, probably due to resorption of the grafts by neurofibromatous tissue. **A:** Clinical photographs of side view while the child is bending show severe gibbus or kyphotic deformity. The trunk is significantly foreshortened. **B:** Lateral radiographic view of thoracic spine showing one of the areas of pseudarthrosis *(arrow)*. **C:** An operative photograph at the time of thoracotomy demonstrating the nesting of the fibular and rib grafts across the apex of the kyphos. **D:** One-year postoperative radiograph showing incorporation of grafts with loss of correction and bending.

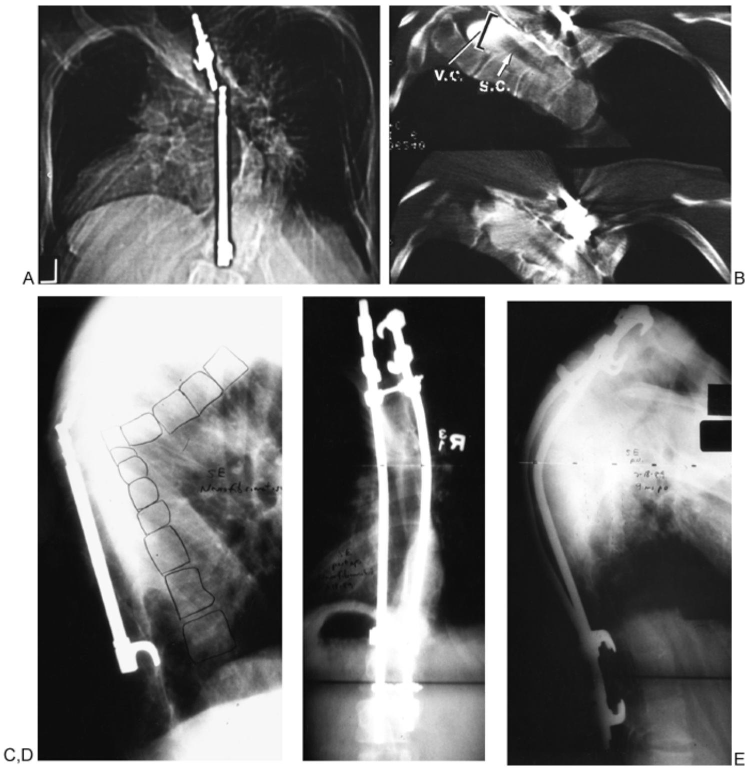

FIGURE 7. A 16-year-old patient with a dystrophic kyphoscoliotic curvature who encountered a pseudarthrosis following initial attempt at spinal fusion. He subsequently underwent anterior fusion with rib and fibular strut grafting followed by posterior spinal fusion with Cotrel-Dubousset instrumentation. **A:** Anteroposterior digital radiograph of the spine illustrating right dystrophic scoliosis with broken Harrington rod. **B:** Frontal computed tomogram illustrating the angular distortion of the spinal column. There is widening of the vertebral canal (V.C.). The myelographic dye outlines the scalloping of the posterior vertebral bodies as well as the shadow of the spinal cord (S.C.). Because of the widening of the canal, the cord is rarely injured even though there may be a severe angular deformity. **C:** Lateral thoracic spine radiograph revealing significant angular kyphosis at the site of the broken Harrington rod. Note the widening of the spinal canal at the level of the inferior hook purchase site. **D:** Anteroposterior thoracolumbar spine radiograph following anterior and posterior spinal fusion with Cotrel-Dubousset instrumentation. **E:** Lateral thoracic spine radiograph illustrating fibular and rib strut grafts used for anterior fusion. (Courtesy of Jame Lehner, M.D., Dayton, Ohio.)

Because of the association of paraplegia with kyphoscoliosis, there has been a tendency to perform laminectomies. Laminectomy alone for kyphoscoliosis cord compression is *absolutely contraindicated*; the inciting lesion is usually anterior, and the compression cannot be made visible from behind. Also, the removal of the posterior element predisposes the patient to unstable postlaminectomy kyphosis and removes valuable bone stock required for posterior spinal fusion. Because the majority of these patients with neurologic problems are seen first by neurosurgeons, orthopaedists should endeavor to inform them that spinal stability is critical following posterior decompression procedures; *all should undergo arthrodesis.* One of the benefits of the author's NF-1 clinic is the establishment of a multidisciplinary team approach to these problems in an attempt to eliminate subsequent problems (60).

Some authors have stratified dystrophic curves with kyphosis into two categories: type I kyphosis of less than 50 degrees; type II kyphosis of more than 50 degrees and recommended treatment (A). They recommended posterior fusion only for kyphosis less than 50 degrees and anterior posterior fusion for kyphosis greater than 50 degrees. This author strongly recommends anterior and posterior fusion for all dystrophic curvatures greater than 40 degrees coronal Cobb angle. If the kyphosis is greater than 50 degrees, a strong anterior strut graft (preferably fibula) should also be performed.

A complete spine MRI or a complete high-volume CT myelogram in the prone, lateral, and supine positions should be performed prior to surgical treatment. If there is spinal cord impingement, the problem should be approached directly—anteriorly with partial corpectomy for anterior lesions and a hemilaminectomy for posterior ones, both to be followed by anterior and posterior fusions. Finally, an anterior disc excision with tibial or fibular strut bone graft followed by posterior arthrodesis and instrumentation should be performed if the kyphotic angle is greater than 50 degrees; the anterior fusion should be extended one to two levels past both end vertebrae. The patient should be reexplored posteriorly at 6 months postsurgery, with augmentation of the fusion mass if polytomography or bone scan shows any evidence of weakness of the fusion mass. The curvature may be such that conventional or even hybrid instrumentation cannot be utilized, and prolonged halo casting may be necessary. Prolonged immobilization is required until the fusion is absolutely solid (possibly up to a year).

Lordoscoliosis

Lordoscoliosis has been reported in a small percentage of patients with NF-1. However, the lack of reporting should not be taken as proof that the problem is rare. Kyphoscoliosis has been closely observed and documented for some time in scoliosis evaluation, whereas lordosis has been well documented only over the last decade. It is well known that thoracic lordosis (hypokyphosis) predisposes to a significant decrease in pulmonary function and mitral valve prolapse (32 ,74).

The dystrophic thinning of the posterior elements and the possible presence of intracanal dural ectasia make planning instrumentation to correct the deformity a challenge. The author has used anterior intervertebral fusion and posterior spinous process wiring to a contoured Harrington rod to achieve correction of dystrophic scoliosis, a paravertebral mass, and thoracic lordosis.

Spondylolisthesis

Few cases of spondylolisthesis due to NF-1 have been reported (13 ,35 ,44 ,45 ,73 ,75). The deformity is usually the result of increased diameter of the spinal canal, with pathologic elongation and thinning of the pedicles giving rise to a pathologic forward progression of the anterior elements of the spinal column. Dural ectasia with meningoceles, or interstitial hypertrophic neurofibromas with involvement of the lumbosacral roots exiting the spinal canal through the neuroforaminae, is the cause of the problem (Fig. 8). MRI or large-volume CT myelography is necessary to identify the character of the soft tissue affecting and surrounding the vertebral elements before considering surgery. The vertebral bodies are secondarily affected and appear to be thin and dystrophic; the smaller vertebral bodies and narrower pedicles preclude reduction with pedicle screws. A posterior fusion may be inadequate because of the forward traction effect of the vertebral bodies, causing a tension field unsuitable for fusion. The author recommends a posterior fusion using autogenous bone and postoperative hyperextension pantaloon cast correction rather than instrumentation. The fusion mass should be evaluated for stability at 6 months and reinforced if necessary.

Paraplegia

Most articles on NF-1 and spinal deformities have included cases of paraplegia (17 ,40 ,47). It is possible that neurologic compromise may be related to tumor, structural instability of the vertebral column complex, dural ectasia, vertebral destruction, neurofibromas, neurosarcomas, fibrofatty tissue reaction, severe kyphosis, vertebral subluxation, dislocation, protrusion of ribs into the spinal canal, or progressive dystrophy of the bony elements of the spine. A neoplasm is usually responsible for paraplegia in older patients, whereas spinal malalignment or rib displacement into the spinal canal is the most common cause in younger individuals. Kyphosis contributes more than scoliosis to neurologic impairment. Rockower et al. (55) reported two patients who, because of vertebral body instability and displacement secondary to neurofibromatous tissue encroachment, developed paraplegia. The problem was solved by carefully monitored traction and spinal fusion. Traction should be used very rarely when the deformity is mostly kyphotic. Traction should be used only with *flexible* kyphosis—never if the kyphosis is rigid. If the kyphosis is rigid, an anterior release, disc excision, and fusion followed by posterior spinal fusion are recommended.

Using CT, Major and Huizenga (43) and Tredwell (69) were able to demonstrate that the rib heads had penetrated the enlarged neuroforamina, entered the spinal canal, and compressed the thoracic spinal cord directly (Fig. 9). Neither patient encountered permanent neurologic sequelae. It could be speculated that occult rib penetration into the spinal canal with spinal cord compromise could be a source of paraplegia that, prior to current imaging technology (CT, MRI), was thought to be the natural course of NF-1 with kyphoscoliosis.

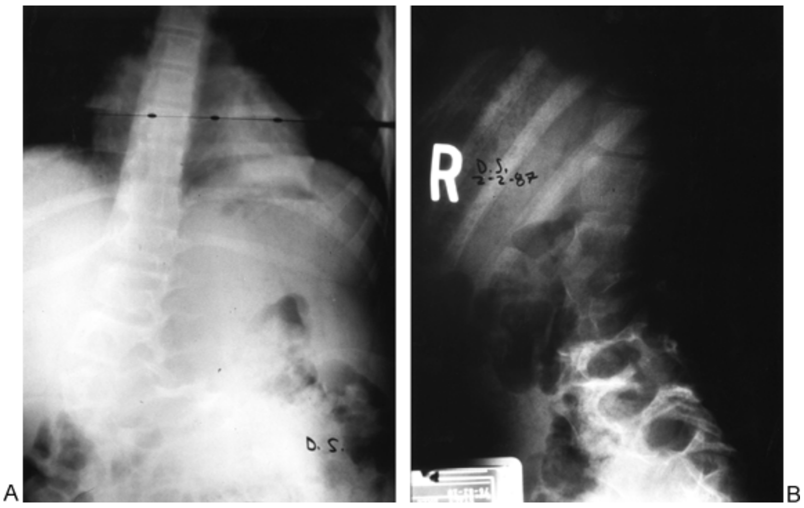

FIGURE 8. This child was noted to have hypertrophy of the left lower extremity, spondylolisthesis, and a right lumbar scoliosis. **A:** Anteroposterior thoracolumbar spine radiograph illustrating short segmented, sharply angulated, and rotated lumbosacral scoliosis. **B:** Lateral thoracolumbar spine radiograph showing dystrophic spondylolisthesis with elongation and thinning of the lumbar pedicles and widening of neuroforamina.

With the advent of hardware systems that can apply considerable force to the spine, there is a clear risk of neurologic injury in the presence of instability of the rib end and potential spinal canal protrusion. Preoperative high-volume CT or MRI should prevent this consequence.

For patients with paraplegia one must first rule out an intraspinal lesion (tumor, meningocele) as opposed to kyphotic angular cord compression (54). Those with severe spinal curvatures without significant kyphosis and with evidence of paraplegia should be assumed to have intraspinal lesions until proven otherwise. MRI or high-volume CT myelography is done in the prone, lateral, and supine positions. The author has not been able to perform adequate MRI studies in patients with severe deformities because of distortion. If the kyphosis is mobile and no intraspinal tumor is present, the patient should be placed in halo-assisted traction. This must be done with extreme caution and neurologic monitoring; it should definitely not be performed if the kyphosis is rigid. Even if the kyphosis is mobile and there is paraplegia, the author recommends somatosensory evoked potential monitoring during traction. If a tumor is anterior, immediate anterior excision, spinal cord decompression, and fusion should be carried out; if the lesion is posterior, a hemilaminectomy with tumor excision and posterior spinal fusion should be performed. If total laminectomy is required, posterior spinal fusion is mandatory. The posterior fusion should be performed with the addition of universal instrumentation if possible; if not, a halo cast should be applied. Deep hemovac drainage is necessary in all patients having spinal canal exploration because of the significant bleeding that may occur once the patient is normotensive. The patient should be observed for development of pseudarthrosis, and augmentation of the fusion mass should be carried out directly if such evidence is present.

Spinal instrumentation and fusion in the face of unrecognized intracanal neurofibroma or structural instability of the laminae due to dural ectasia can cause serious neurologic compromise.

Therefore, preoperative neuroradiographic evaluation of the spinal canal is warranted.

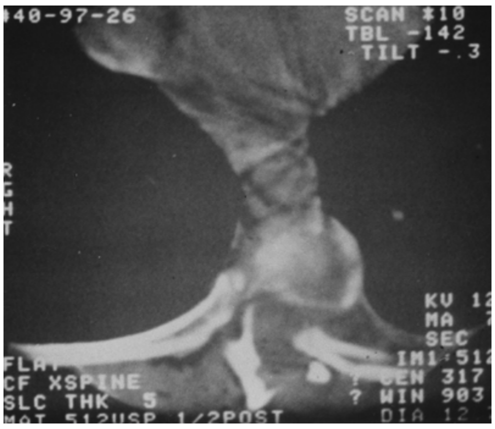

FIGURE 9. Thoracic cross-sectional computed tomogram of a patient with acute paraparesis. Computed tomography revealed that the head of a rib had entered the spinal canal through the neural foramina, with subsequent compression of the spinal cord. The paraparesis was transient and had resolved spontaneously prior to removal of the rib. (Courtesy of Drs. Huizenga and Major, Milwaukee, Wisconsin. )

Problems Related to Soft-Tissue Involvement

Dural Ectasia

A finding unique to NF-1 is an expansion of the dural sac, which often causes deformity of the adjacent spinal canal and vertebral bodies. It expands the spinal canal at the expense of the bony and ligamentous elements (Fig. 10). This wide expanse of the spinal canal may explain why, in spite of the severe progressive deformities of the spine seen in NF-1, the spinal cord is rarely injured (Fig. 11). The same does not hold true if a neurofibroma develops in the spinal canal, where it can provoke medullary compression, as can any space-occupying lesion. This expansion is responsible for the destabilization of the vertebra, giving rise to spontaneous dislocation (55) of the vertebra as well as penetration of the canal by ribs that have separated from the costotransverse ligaments (22 ,43). The continuation of this expanding dural sleeve more than likely gives rise to meningocele.

Intrathoracic Meningocele

Intrathoracic meningocele is relatively rare (19 ,38 ,46 ,50). A meningocele in this instance is a protrusion of the spinal meninges through an intervertebral foramen or bony defect of the vertebra; it contains an extension of the subarachnoid space filled with cerebrospinal fluid. Meningocele in association with NF-1 can occur at any level of the spine. A posterior mediastinal mass in a patient with NF-1, particularly if associated with kyphoscoliosis, is most likely a lateral meningocele. With contrast myelography, ultrasonography, or MRI, a well-demarcated soft-tissue cystic mass is seen protruding from the spinal canal into the posterior mediastinum (Fig. 12). Structural defects in the pedicles, enlargement of the intervertebral foramina, rib deformities including costotransverse dislocation, and scalloping of the vertebral bodies may accompany the mass. Several etiologies for the condition have been implicated, including nerve root sleeve elongation (63) (similar to a hernia of the meninges through the neuroforamina), cystic degeneration in a neurofibroma (48), trauma (16), dural dysplasia, bone dysplasia, regional dystrophy, and congenital derangement. The more likely explanation is that regional dysplasia affecting both bone and meninges is responsible for the formation of the meningocele (9 ,56).

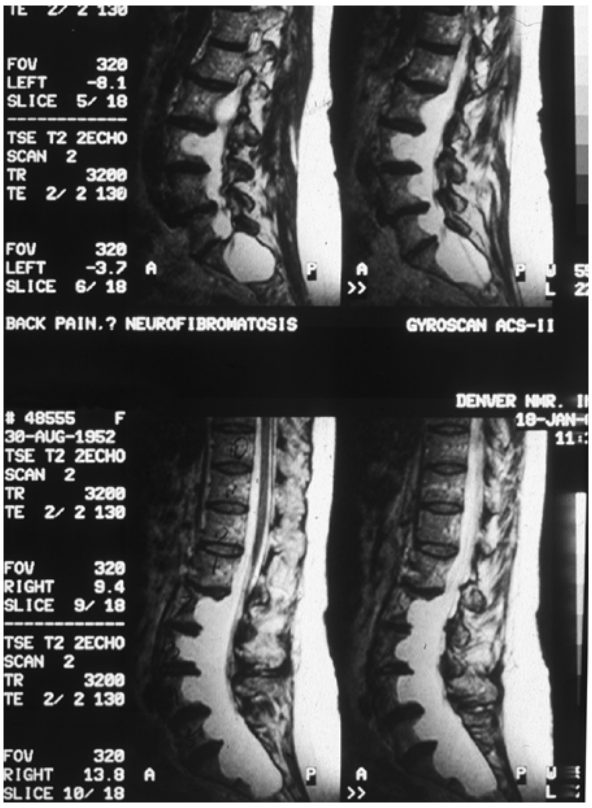

FIGURE 10. Four-level magnetic resonance image of a 47-year-old patient who complained of back pain. Image illustrates significant erosion of the lower lumbosacral spine from dural ectasia (Courtesy of Dr. Courtney Brown, Denver, Colorado.)

The posterior scalloping of the vertebral bodies, with deformities of the pedicle and widening of the intervertebral foramina, could be caused either by the presence of a dumbbell tumor (intraspinal neurofibroma) or by saccular dilatations of the dura (dural ectasia). There is a distinct potential spinal instability due to the loss of supporting bone structure when associated with kyphoscoliosis. It is possible that neurofibromatous meningoceles and dural ectasia are variations of the same phenomenon, with the meningocele being more localized and possibly related to its exit through the neuroforamina and the dural ectasia being more diffuse. Thoracic and sacral meningoceles in patients with NF-1 may develop secondary to the growth of ectatic dural outpouchings through preexisting bony deformities, such as enlarged neuroforamina, when exposed to changing cerebrospinal fluid pressures (4).

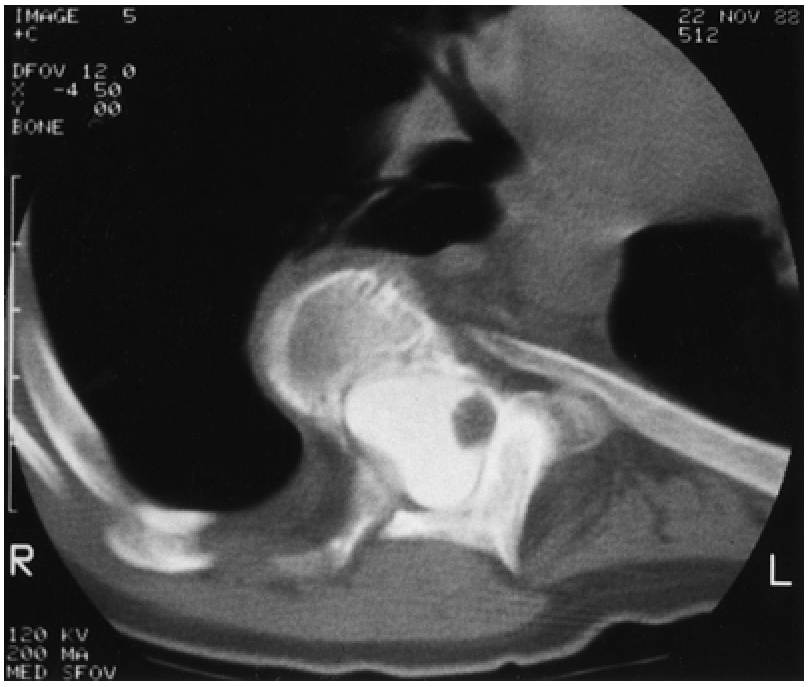

FIGURE 11. Cross-sectional computed tomography myelogram at the apex of a thoracic curve showing the deformity of the vertebral body with elongation of the pedicle on the concavity. There is a significant widening of the spinal canal from intrinsic pressure on the lamina, pedicles, and posterior vertebral body. The spinal cord is notched into the concavity of the spinal canal to the left. Neurofibromatous tissue has caused a widening of the spinal canal and is itself a tremendous space-occupying lesion. There is a paravertebral soft-tissue mass on the concavity. At surgery, the tissue from the neuroforamina proved to be fibrofatty, encapsulated material surrounding the spinal nerves. (Reprinted with permission from Crawford AH (1989): Pitfalls of spinal deformities associated with NF-1 in children. *Clin Orthop Rel Res* 245:29–42.)

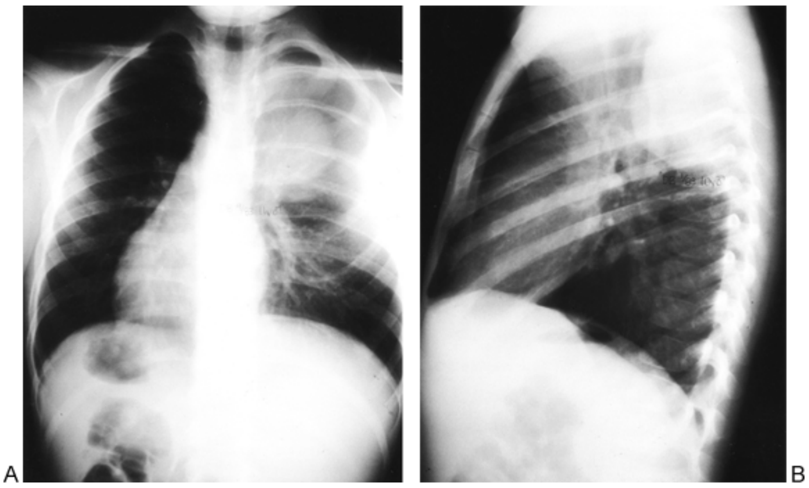

FIGURE 12. Intrathoracic meningocele associated with neurofibromatosis. **A:** Anteroposterior view showing increased shadow density in upper right chest cage. **B:** Lateral view illustrating superior posterior mediastinal mass. The lesion was removed by thoracotomy. (Courtesy of Anthony Herring, M.D., Dallas, Texas.)

Most meningoceles (60%) are discovered incidentally on routine radiologic examination of the chest. Pain, though not a characteristic feature, was noted by Miles et al. (46) in 23% of cases; in all but one case, kyphoscoliosis was noted.

Pulmonary symptoms (cough 10%, dyspnea 11%) have been associated only with massive intrathoracic lesions. Only two cases of pulmonary problems as a direct result of the lesion have been reported; one meningocele ruptured during a bout of coughing when it was penetrated by a previously fractured rib. The patient died from medullary coning due to leakage of cerebrospinal fluid into the pleural cavity. Another patient presented with spontaneous hemothorax originating from the very vascular wall of the meningocele; the patient survived.

Because intrathoracic meningoceles are often symptomless, the question of treatment is difficult. If it is a chance radiologic finding and causes no symptoms, the right course would be observation. If there is definite progressive enlargement, an initial attempt should be made to ligate the sac. It may be feasible to occlude the neck of the sac by plicating sutures via video-assisted thoracoscopy. Excision of the lesion is indicated for progressive excavation of the vertebra, neurologic injury, respiratory distress, or if there is evidence of rapid progression in size.

Dumbbell Lesions

The classic dumbbell lesion is one in which the neurofibroma is constricted as it exits the neuroforamina, giving it the appearance of a weight lifter's dumbbell (Fig. 13A). Love and Dodge (41) defined dumbbell neurofibroma of the spine as a benign neoplasm that arises from a nerve root and grows in such a way that two or more portions of the tumor are connected by a narrow stalk through an intervertebral foramen, through the interlaminar space of the vertebra, or through the dura mater. They may be intradural and extradural, intradural, extradural, or extradural and extraspinal. The tumors may occur at any level of the cord, but the cervical and thoracic levels are most often involved. The tumors may present as nodules arising from the sheath along the nerve, or they may actually invade the nerve. If the tumor invades the nerve with consequent interstitial hypertrophy, then “the nerve becomes the tumor and the tumor becomes the nerve” (Fig. 13B, C). In this case, resecting the tumor results in a neurologic deficit. The incidence of malignant degeneration of peripheral neurofibromas is unknown.

We recently reviewed 260 pediatric patients with NF-1 and noted that nine patients (3.5%) had extrapleural thoracic tumors. Ninety-five of these patients were primarily screened by chest radiographs, and many patients might have asymptomatic thoracic tumors that have yet to be diagnosed. All patients were 6 years of age or older, six were asymptomatic, and three presented with respiratory symptoms. A clue to thoracic involvement in two patients was the presence of a visible plexiform neurofibroma in the neck, which later was found to have extended into the chest. Focal scoliosis was a significant clue to an underlying tumor in four patients, and bony changes such as narrowing of ribs were often seen in the area of tumor involvement. Malignant transformation of a benign plexiform neurofibroma occurred in one patient. Signs on physical examination that should raise suspicion of an underlying thoracic tumor include a plexiform neurofibroma of the neck or a focal area of scoliosis. When reviewed retrospectively, eight of the nine patients had either a symptom or a sign on physical examination that was a clue to the underlying tumor. Surgical management of these tumors can be difficult because of frequent involvement of nerves and blood vessels (61).

Vertebral Column Dislocation

Complete dislocation of the spine in NF-1 is rare. In one review of 55 patients who had NF-1 and spinal deformity, only two had a lateral subluxation or dislocation of the spine (59); one of the dislocations involved a thoracic vertebra and posterior arch with destruction of the latter, and the other patient had destruction of the articular part of the apophysis. In another study of eight patients who had NF-1 and paraplegia, five patients had a vertebral subluxation or dislocation (17). Involvement of the cervical spine by NF-1 was noted in one study in which five patients had subluxation of a cervical vertebral body (31). In a second study of 56 patients, 17 had abnormal cervical spines; one patient had a fixed subluxation of the second cervical vertebra on the third, and another had an atlantoaxial rotatory instability (76). Isu et al. (36) reported on three patients (two with hemiparesis) who had atlantoaxial dislocation due to NF-1. They pointed out that laxity of capsular and ligamentous structures in patients with NF-1 may contribute to a predisposition to instability of the cervical spine. Scott's (62) study of scoliosis associated with NF-1 showed a cervical thoracic dislocation, but no details were provided of the history and physical findings. Rockower et al. (55) reported two cases of spinal dislocation after minor trauma in children who had NF-1. One patient had a dislocation of the fourth thoracic vertebra on the fifth and no neurologic deficit. At surgery, neurofibromatous tissue was found to envelop the vertebral bodies anteriorly but not posteriorly. The second patient had a dislocation of the sixth cervical vertebra on the seventh and was quadriparetic. Stone et al. (67) reported a 9-year-old child with NF-1 who had complete dislocation of the first thoracic vertebra on the second anteriorly, with the body of the seventh cervical vertebra situated completely anterior to that of the second thoracic vertebra following a 2-day history of pain in the lower neck. Complete reduction following traction and manipulation was not successful. Surgery resulted in the child having a solid union with no neurologic deficits. They believed that dural ectasia produced erosion of the middle column of the spine, with dissociation of the posterior elements from the body of the first thoracic vertebra and complete dislocation of the first thoracic vertebra on the second. They speculated that the child was spared neurologic damage by virtue of the pathologically enlarged spinal canal (67).

Significant subluxation or dislocation of the spine in patients who have NF-1 can occur with little radiographic or clinical warning because the osseous erosion is so extensive (Fig. 14). This diagnosis should be considered in any patient who has NF-1 and unexplained pain in the neck or back. The mechanism of dural expansion and osseous erosion is unknown. When seen at operation, the dura in the area of ectasia is extremely thin and fragile. Therefore, every effort should be made to avoid entry into the region of the dural ectasia. Aggressive surgical stabilization should be carried out when radiographic examination reveals instability of the spine, which may precede dislocation (71).

Plexiform Venous Channels

McCarroll (45) pointed out that a plexiform type of venous anomaly may be encountered in the soft tissues; these may surround the spine, impeding the operative approach to the vertebral bodies. In one of Hsu's patients with angular kyphosis, the venous anomalies were so dense that the anterior approach to the internal kyphos had to be abandoned due to excessive bleeding (34). Greene et al. (27) described vascular NF-1 in two categories according to the diameter of the vessel: the larger (greater than 1 mm, such as the aorta, carotid, and proximal renal arteries), which are surrounded by or involved with neurofibromatous tissue, reveal intimal hypertrophy, fragmentation of the medial and elastic laminae, and a fibrous adventitial reaction leading to stenosis or aneurysm formation. The author has not experienced excessive venous bleeding while performing anterior removal of neurofibromatous tissue and strut grafting, but warns the reader of the possibility. Wound hematomas following surgery have not been a problem; however, meticulous hemostasis and wound drainage should be carried out when performing surgery on patients with NF-1.

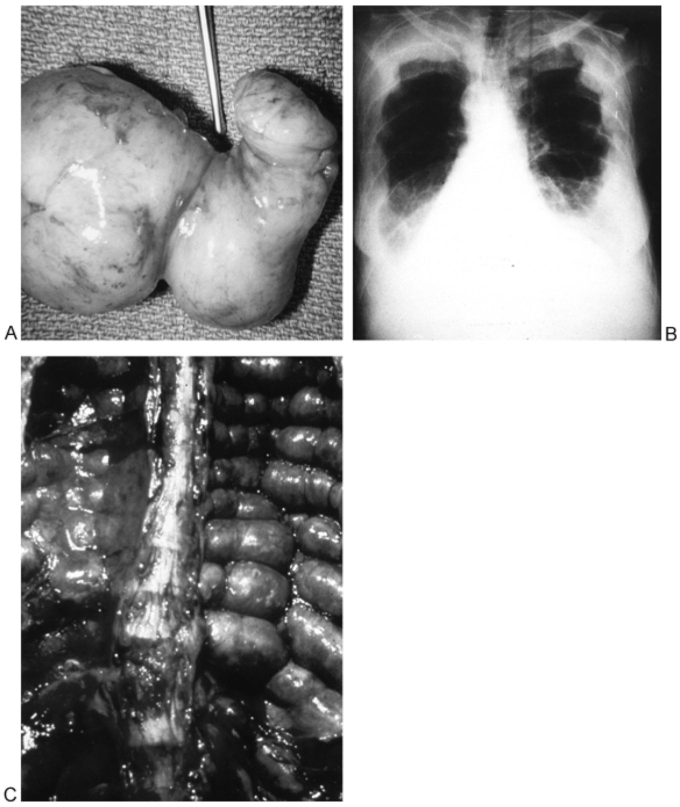

FIGURE 13. A: Example of a dumbbell-shaped tumor removed from the neuroforamina of a 17-year-old patient at time of exposure for posterior spinal fusion. The dumbbell appearance results from the constriction of the neurofibroma that occurs when the tumor exits the spinal canal. **B:** This 44-year-old woman was hospitalized for pneumonia and subsequently expired. The chest radiograph showed bony hypertrophy of the ribs in addition to increased soft-tissue densities in the intercostal spaces and surrounding the lung fields. **C:** At necropsy the intercostal spaces were found to be filled with neurofibromas that had infiltrated and replaced all of the intercostal nerves. (Courtesy of B. Van Damm, M.D., San Diego, California.)

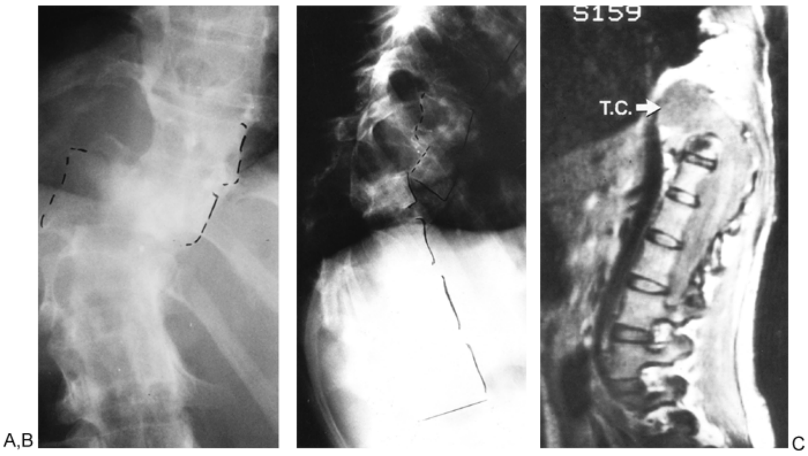

FIGURE 14. Example of a dislocation of the spine noted in a patient with neurofibromatosis. **A:** Note the sharply angulated deformity on anteroposterior radiograph, with some translation of the vertebral bodies. **B:** The lateral radiograph shows a short-segment kyphosis with anterior dislocation of the thoracic spine. **C:** The sagittal plane magnetic resonance image through the spine shows complete separation of the thoracic segment of the spine from the lumbar segment. The area of increased signal intensity just above and posterior to the lumbar segment *(arrow)* is a thoracic meningocele. The patient experienced a minor neurologic deficit. Philadelphia: JB Lippincott.)

Pseudarthrosis

Pseudarthrosis occurs more commonly following attempted spinal fusion for both dystrophic and nondystrophic curvatures than for idiopathic ones. The incidence is higher in those associated with kyphosis of greater than 50 degrees. Prior to the use of universal spinal instrumentation and anterior-posterior combined surgeries, reexploration was routine for patients with neurofibromatous spinal deformities. The best results are obtained by planning a double (anterior and posterior) arthrodesis from the start. Even the increased strength of the instrumentation is insufficient to obtain stability at the time of surgery when dealing with deformed dystrophic posterior elements.

Discussion

Careful attention should be paid to the vertebral body shapes on the posteroanterior and lateral spine radiographs. When one sees scalloping and indentation of vertebral bodies, a careful investigation should be carried out for intraspinal pathology, such as dural ectasia, meningocele, or dumbbell lesion. The scalloping has been associated with intraspinal NF-1 as well as with the expansion of the dural sac, suggesting dural ectasia or meningocele. Scalloping can exist only with one of the aforementioned eroding factors. The implication that the deformity is primarily a vertebral or developmental defect associated with NF-1 and not dependent on pressure erosion is incorrect. Because some intraspinal myelography studies have shown that the contrast material does not conform to the posterior scalloped surfaces of the vertebrae, there is a suggestion of an intervening intradural mass. These masses have been clearly elucidated by modern diagnostic technologies, such as CT, myelography, and especially MRI. The vertebral scalloping and dysplasia represent an indirect manifestation of a proximal tumor. Because of the possibility of an intraspinal tumor or dural ectasia being present, it is strongly recommended that contrast CT or MRI be performed on those patients with dystrophic vertebral bodies and curvatures requiring instrumentation and fusion (13). Angtuaco et al. (4) recommend CT myelography for patients with NF-1. Myelography alone can help differentiate between a mass lesion and the pseudomeningocele-like pattern of dural ectasia. With CT, additional details, such as displacement of the spinal cord and the extent of involvement of the subarachnoid compartment by tumor, can be assessed. Klatte et al. (38) attempted to elucidate the cause of posterior scalloping of the vertebrae in NF-1 with CT. They believe that eccentric unilateral scalloping favors a neurofibroma whereas central scalloping occurs more frequently in dural ectasia. The author recommends MRI assessment of any areas demonstrated by CT myelogram to be suspicious, as well as any areas that are poorly demonstrated.

Careful evaluation of the cervical spine is indicated prior to instrumentation of the thoracic or lumbar spine. The most dangerous situation for the neurologically intact NF-1 patient and the surgeon is the instrumentation and manipulation of the spine in the presence of unrecognized intraspinal lesions. More often than not, the patient presents to the spinal surgeon with a significant deformity with or without an intraspinal tumor or expansive dura, with no evidence of a neurologic disorder or paraplegia. This author currently utilizes four methods of spinal cord monitoring: SSEVP, NMEP, electromyography, and the gold standard, the “wake-up” test.

While correction is the goal of the spine surgeon in idiopathic scoliosis, halting the progression of the deformity, even with a small correction, can be considered a good result in the case of NF-1 spinal deformities. The surgeon's responsibility is to stabilize the spine in the most expedient, permanent, and safest way without causing permanent neurologic injury.

Definitions

Iatrogenic

From the Greek, *-genic* is "to produce," *iatro-* denotes a relation to a physician or to medicine. *Iatrogenic* may be anything resulting from the activity of physicians or medicine. More commonly it denotes any adverse condition caused by treatment given by a physician or surgeon. These adverse results do not imply improper management or technique but only that a certain percentage of cases can have an untoward outcome.

Spinal Deformity

Spinal deformity is abnormal coronal or sagittal curvature or imbalance of the spine in the coronal or sagittal plane. This includes scoliosis, kyphosis, and decompensation of the normal balance position of the head over the pelvis in the upright, standing position.

Introduction

Iatrogenic Spinal Deformities

An iatrogenic deformity can consist of scoliosis, kyphosis, or an imbalance in the sagittal or coronal plane that develops as the result of therapy for another condition that does not include the "new" deformity. By definition, this excludes residual deformity or progressing deformity believed to exist before treatment. Numerous causes of these iatrogenic deformities exist. Understanding the principles of production of deformity will assist physicians in understanding when a deformity may develop. With this knowledge, physicians may be able to reduce the incidence of deformity or minimize the severity of deformity to optimize patient outcomes. When a condition is encountered that may produce a deformity, it is incumbent on the physician to make certain that the child is observed for the development of the deformity. If a deformity develops, appropriate treatment should be instituted to minimize the consequences.

Information regarding iatrogenic spinal deformities usually deals with specific causes related to the diagnosis, such as postlaminectomy kyphosis. Information about specific causes of iatrogenic spinal deformities should help clinicians understand the risk of deformity and responses to previous treatments. This specific information, on top of the foundation of a good understanding of the principles of development of deformity, should help clinicians treating patients who are prone to iatrogenic spinal deformity.

Treatment
