Keywords: Uniform credit; Stackelberg model; Benefit analysis.

1 Introduction

In the business of supply chain finance, the third party logistics can provide not only basic inventory financing business, but also credit guarantee business which otherwise known as uniform credit financing. In this financing model, the banks give 3PLs a certain credit limit according to the enterprise scale, operating performance and credit rating of the 3PLs. Then the 3PLs break credit limit down to small businesses, and these small businesses use real documents and inventory as a counter guarantee. The uniform credit financing model allows 3PLs to have more choices in making decisions and simplifies the business process largely.

With the increasingly complex structure of supply chain, the income distribution mechanism among its members has brought to public attention. Cossin, Huang (2003) studied the determination of loan-to-value ratio of banks. Klapper(2004) analyzed the mechanism and function of inventory financing that used for the little and middle enterprises. Buzacott, Zhang (2004) who are the first put inventory financing mode into production decision. Li Yixue et al. (2007) gave a quantitative interest ratio decision model aimed at the pledge with random price. Wang Yong et al. (2010) discussed the 3PLs' incentive problems for banks in consider of fairness preferences. Zhou Xuenong(2010) stood in the perspective of supply chain financing and studied the contract design problem of inventory financing. Yi Xuehui et al. (2011) discussed the banks' pricing problem under the condition that the core enterprises provide repurchase guarantee. Ma Zhonghua et al. (2011) considered how 3PLs can maintain yield by adjusting the regulatory decisions at the time the banks increase the interest rate. The above research findings are significant for us to understand inventory financing business deeply and provide much beneficial reference in solving decision-making problems of all the participants. However, most of studies are based on the viewpoint that the banks dominate the market unilaterally, this paper will study the contract design problem in the framework that banks and the 3PLs have comprehensive cooperation.

2 The Model

2.1 Model Assumptions

There is no collusion between 3PLs and loan enterprises in the situation that banks develop comprehensive cooperative relations with 3PLs. Under uniform credit financing model, the 3PLs provide credit guarantee for loan enterprises according to the full understanding of pledge. So if loan enterprises can't repay the loan, the 3PLs should be responsible for pledge realization. And if the 3PLs do not provide credit guarantee, the banks will not choose to lend.

For easy analysis, the paper only considers two extreme cases: the loan enterprises repay the principal and interest fully and the loan enterprises do not repay any principal and interest. The model assumptions are as follows:

(1) The loan enterprises invest borrowings in projects, the probability of success is p . Assume that if the project is successful, the loan enterprises will be certain to repay the loan, and if the project is fail, the loan enterprises will default.

(2) The loan enterprises need B quantity of money to invest in a project, equity fund is $B\alpha$, α ($0<\alpha<1$) represents the proportion of equity fund, so the amount that the loan enterprises need to borrow is $(1-\alpha)B$.

(3) The amount of guarantee provided by 3PLs is equal to $(1-\alpha)B$, and the loan enterprises should provide $\frac{(1-\alpha)B}{\omega}$ pledge as a counter guarantee. ω is pledge rate, then the risk bearing ratio of 3PLs is $\Delta\beta=\frac{B(1-\alpha)-\frac{B(1-\alpha)}{\omega}\beta}{B(1-\alpha)}=1-\frac{\beta}{\omega}$, β ($0<\beta<1$) is the liquidity of pledge.

(4) Banks determine their optimal loan interest rate after observing the behavior of 3PLs.

(5) The 3PLs supervise pledge for banks, and the banks pay corresponding supervision fee at the same time. Assume the supervision fee is proportional to the value of pledge, and that proportion is φ.

(6) Assuming that the demand of the whole finance market is a function of the ratio of enterprises' own resources and loan interest rate, that is

$$D(\alpha, r) = \theta - \mu\alpha - \sigma r \quad (1)$$

Where θ is an intrinsic value of financing amount, μ represents the sensitivity of enterprises' own resources, and σ represents the sensitivity of interest rate.

2.2 Model Building

In this Stackelberg game model of uniform credit financing business, there are only 3PLs and banks who actually participate in the game, and the 3PLs' action profile is (guarantee, not guarantee), the banks' action profile is (lend, not lend). Banks will be reluctant to lend, if 3PLs do not provide guarantee, so in order to gain benefit, the 3PLs have to provide guarantee. In this situation, there are four income profile for 3PLs and banks, they are:

① （0,0）;

② （0,0）;

③ （$(\theta-\mu\alpha-\sigma r)\frac{B(1-\alpha)}{\omega}\varphi,\ (\theta-\mu\alpha-\sigma r)B(1-\alpha)(r-\frac{\varphi}{\omega})$）;

④ （$(\theta-\mu\alpha-\sigma r)B(1-\alpha)(\frac{\varphi}{\omega}-\Delta\beta),(\theta-\mu\alpha-\sigma r)B(1-\alpha)(\Delta\beta+\frac{\beta-\varphi}{\omega}-1)$）.

Thus the expected profits of banks and 3PLs are as follows:

$$\pi_1 = (\theta-\mu\alpha-\sigma r)B(1-\alpha)[p(r-\frac{\varphi}{\omega})+(1-p)(\Delta\beta+\frac{\beta-\varphi}{\omega}-1)] \quad (2)$$

$$\pi_2 = (\theta-\mu\alpha-\sigma r)B(1-\alpha)[p\frac{\varphi}{\omega}+(1-p)(\frac{\varphi}{\omega}-\Delta\beta)] \quad (3)$$

3 Model Solutions

We use backward induction method to gain the game's Nash equilibrium. Firstly, considering the case that $\Delta\beta$ is given, and the optimal loan interest of banks is r^*. Take π_1 partial respect to r, and make it equal to zero, then we can get banks' rules of action as follows:

$$r^*(\Delta\beta)=\frac{p[\theta-\mu\alpha+(\Delta\beta+\frac{\beta}{\omega}-1)\sigma]-(\Delta\beta+\frac{\beta-\varphi}{\omega}-1)\sigma}{2\sigma p} \quad (4)$$

Substituting the Eq.(4) value into Eq.(3) , and make Eq.(3) equal to zero, we can get:

$$\Delta\beta^*=\frac{p[\theta-\mu\alpha+(1-\frac{\beta}{\omega})\sigma]-(\frac{2\varphi-\beta}{\omega}+1)\sigma}{2(p-1)\sigma} \quad (5)$$

From model assumptions we can know that $\Delta\beta=1-\frac{\beta}{\omega}$, so

$$\omega^*=\frac{2\varphi\sigma-(p-1)\sigma\beta}{p(\theta-\mu\alpha)-(p-1)\sigma} \quad (6)$$

Then substituting the Eq.(5) value into Eq.(4) , can get:

$$r^*=\frac{p(3\theta-3\mu\alpha+\frac{\beta}{\omega^*}\sigma-\sigma)-\frac{\beta}{\omega^*}\sigma+\sigma}{4\sigma p} \quad (7)$$

Finally, substituting r^* and $\Delta\beta^*$ value into π_1 and π_2, we can get:

$$\max\pi_1=\frac{B(1-\alpha)}{16p\sigma}[p(\theta-\mu\alpha-\frac{\beta}{\omega^*}\sigma+\sigma)+\frac{\beta}{\omega^*}\sigma-\sigma]^2 \quad (8)$$

$$\max\pi_2=\frac{B(1-\alpha)}{8p\sigma}[p(\theta-\mu\alpha-\frac{\beta}{\omega^*}\sigma+\sigma)+\frac{\beta}{\omega^*}\sigma-\sigma]^2 \quad (9)$$

4 Equilibrium Analysis

4.1 The Equilibrium

In the above model, the 3PLs' risk bearing ratio is required to be less than the loan interest rate, and the market demand is greater than zero, so $0<\Delta\beta^*<r$, $D(\alpha,r^*)>0$. With the increase of loan enterprises' performance probability, the risk the banks and 3PLs faced will be decreasing, thus we can get $\beta<1$, $\mu\alpha+2\sigma\frac{\varphi}{\omega}<\theta$.

The interest rate should make not only banks' profit but also market demand to be greater than zero, that is

$$\begin{cases} p(r-\frac{\varphi}{\omega})+(1-p)(\Delta\beta+\frac{\beta-\varphi}{\omega}-1)\geq 0 \\ \theta-\mu\alpha-\sigma r\geq 0 \end{cases}$$

So we can get:

$$\frac{\varphi}{p\omega} \le r \le \frac{\theta-\mu\alpha}{\sigma} \tag{10}$$

While in the traditional pledge financing mode, the 3PLs do not provide financing guarantee, so $\Delta\beta = 0$, substitute it into Eq.(4), then we can get the banks' optimal interest rate.

$$\hat{r}^* = \frac{p[\theta-\mu\alpha+(1-\frac{\beta}{\omega})\sigma]+\sigma(\frac{\varphi-\beta}{\omega}+1)}{2p\sigma} \tag{11}$$

Substituting r^* and $\hat{r}^*$ into Eq.(1) respectively, and subtracting two $D(\alpha,r)$, then the difference value is as followed:

$$\Delta D = D(\alpha,r^*) - \hat{D}^*(\alpha,\hat{r}^*) = \sigma(\hat{r}^* - r^*)$$
$$= \frac{-p[\theta-\mu\alpha+3(\frac{\beta}{\omega}-1)\sigma]+\sigma(\frac{2\varphi-\beta}{\omega}+1)}{4p} \tag{12}$$

From Eq(5)and $\Delta\beta > 0$, so $p[\theta-\mu\alpha+3(\frac{\beta}{\omega}-1)\sigma] < p[\theta-\mu\alpha+(1-\frac{\beta}{\omega})\sigma] < \sigma(\frac{2\varphi-\beta}{\omega}+1)$, thus $\Delta D > 0$, and it shows that the market demand in two-sided market is greater than one-sided market dominated by banks.

4.2 Sensitivity Analysis

The following pages will focus on analyzing influence the loan enterprises' compliance rate p has on the equilibriums above. When analyzing 3PLs' risk bearing ratio, banks' interest rate, market demand and corporate profits, we set other parameters to fixed defaults, the results shown in figure 1-4 respectively.

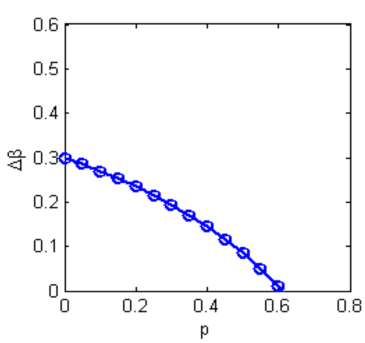

Fig.1 The influence of p on $\Delta\beta$
$(\theta=\mu=\sigma=1, \alpha=0.3, \beta=0.7, \varphi=0.15)$

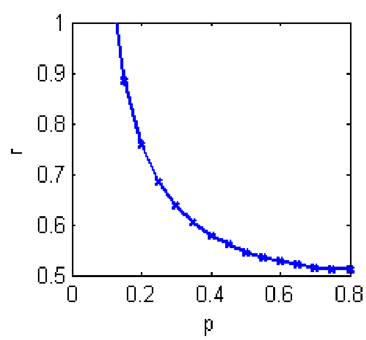

Fig.2 The influence of p on r
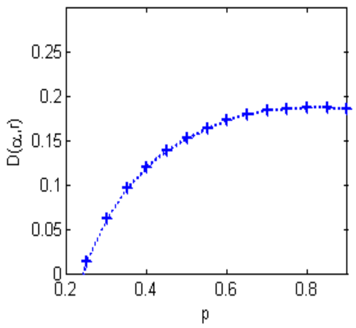
$(\theta=\mu=\sigma=1, \alpha=0.3, \beta=0.7, \varphi=0.15)$



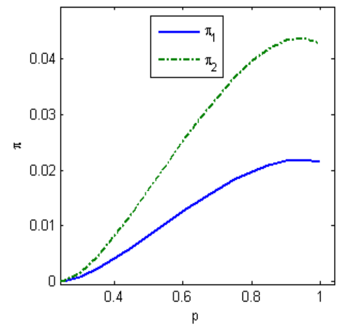


Fig.3 The influence of p on $D(\alpha,r)$ ($\theta=\mu=\sigma=1,\alpha=0.3,\beta=0.7,\varphi=0.15$)

Fig.4 The influence of p on π_1 and π_2 ($B=\theta=\mu=\sigma=1,\alpha=0.3,\beta=0.7,\varphi=0.15$)

These results indicate that the higher the loan enterprises' compliance rate p, the lower the 3PLs' risk bearing ratio and banks' interest rate. On the contrary, the market demand and corporate profits are in proportion to p.

5 Conclusions

Different from the former study, this paper puts forward a uniform credit financing mode in the two-sided framework that 3PLs decide risk bearing ratio first, then the banks decide interest rate accordingly. The result indicates that the two-sided mode can expand financing demand, flourish financing market and provide theory and practice support for the application of the uniform credit financing mode.

Analysis of International Logistics Demand in Sichuan

Rui Feng

School of Transportation and Logistics, Southwest Jiaotong University, Chengdu, Sichuan 610031, China. E-mail: 459106809@qq.com

Abstract: Under the background of development of international trade in Sichuan province, Sichuan province is actively developing international logistics to raise trade. International logistics demand, presents obvious growth in recent years. In this thesis, from both the macro (economic, policy, industrial, etc.) and micro (logistics, transportation operations, etc.) levels, using the method of gray correlation analyze the influencing factors of international logistics demand. Then, calculate the correlation between influencing factors and international logistics demand. Secondly, according to current situation of international logistics development of Sichuan province, analyze the trends and causes of international logistics demand change of Sichuan province and on the brief analysis of the future development trend of international logistics in Sichuan province.

Keywords: International logistics; Influencing factors; Grey correlation; Development trend.

1 Introduction

In recent years, China actively develop international trade, international logistics demand will get higher and higher. And one of the most impressive things is that China proposed building “the Silk road economic belt” and “the 21st Century Maritime Silk Road”, which means the international logistics is desperately in great demand. Thus, doing research on influencing factors of international logistics demand is contribute to promote international logistics development. In academia, Many experts and scholars study on logistics and its impact, more specifically, the relationship between regional economy and logistics. However, the study of international logistics demand and study on the affecting factors of international logistics demand is rare.

International logistics is formed on the basis of international trade development. Xiao Liang pointed out that international trade is the premise to promote the international logistics development and international logistics is a necessary condition of the development of international trade (Xiao Liang, 2013). Many scholars adopted the empirical studies on the relationship between international logistics and international trade. LI Ang used VAR model analysis the promoting function of international trade to the international logistics in different period (Li Ang, 2014). Zhang Xueliang use VECM model to explore the supply and demand equilibrium relationship between international trade and logistics (Zhang Xueliang, 2012). CHEN Yang, Button and other scholars studied on the relationship between logistics industry and international trade relations development (Chen Yang, 2013; Kenneth Button, 2003, etc.). The empirical analysis results show that there is a close relationship between international logistics and international trade, relying on each other and common development

There are obvious relationships among international logistics, international trade, regional economic development and comprehensive transportation. Wang Binyi discusses the two aspects of influence international logistics from positive factors such as the economic growth, technology development, deregulation, and barrier factors such as market competition, market barriers (Wang Binyi, 2006). Xue Bing using the grey correlation analysis of the Xinjiang international logistics demand influence factors, such as the economic development level, the freight turnover and so on (Xue Bing et al., 2013).Yang Yi using Panel–VAR and impulse response function analysis relationship between regional foreign direct investment and logistics (Yang Yi, 2014). Research results show that the more significant impact the international logistics has, the more different the Impact Angle and levels is. But the influence degree needs further research.

In conclusion, there are many studies of international logistics is more, but the researches about the specific international logistics index to measure international logistics demand levels are insufficient. This thesis will use the amount of import and export goods to measure international logistics demand levels, then discuss the influence degree of each index from regional macro-economic environment, the regional logistics development environment, and at last, give advice on regional international logistics development.

2 International logistics influence factor

In the thriving of modern logistics, under the effect of some external factors just like regional economic development, circulation trade present situation, the characteristics of industrial structure, the strength of fixed investment and logistics development environment, the regional logistics service would be obviously different. In view of the international logistics demand, it could be not only affected by the factors of regional domestic economy industry, but also the development of international trade. Therefore based on this thesis, we will combine the motivation of international logistics demand and the existing research results (Xiao Liang, 2013; Xue Bin et al., 2013; Wang Binyi, 2006), and the influence factors of international logistics demand be divided into five types, such as social economic, industrial structure, fixed investment, trade development, logistics development. The concrete impact factor analysis is as follows.

(1) Social economic

Social economy and logistic development have strong association. Social economy could have a great impact on the development of the logistics by some indexes such as GDP, PGDP, RCL (Resident Consumption Level), PCDI (per capita disposable income).

(2) Industrial structure

Industrial structure mainly performed through three times Industry increase, which reflect the status of different industries logistics demand.

(3) Fixed investment

Fixed investment intensity can reflect the investment of the construction of the regional economy, which can perfectly reflect regional future logistics development potential by using gross fixed asset formation and Transportation Investment of the whole society.

(4) Trade development

Trade development mainly includes domestic trade development and foreign economic development, which reflects the circulation situation in different extent and shows the demand for logistics.

(5)Logistics developing

Logistics developing environment mainly about Logistics infrastructure construction, which includes Logistics infrastructure and related logistics equipment, through highway, railway, aviation and other mileage and freight car ownership such and such.

3 International logistics impact analysis model

In this thesis, the grey correlation degree of each index is calculated by using the grey correlation model. Grey correlation model is a new method which can be used to study few data, poor information and uncertainty problems. Through generating, exploitation and extracting the part of the valuable information, we can achieve a correct description of system behavior, evolution and effective monitoring. The basic idea is according to the sequence curve geometry similarity to determine whether the contact closely first, and based on grey correlation space, we can use grey incidence coefficient, grey relational grade, grey incidence sequence analysis system advantage, then calculate the correlation coefficient of each scheme and ideal scheme. According to the correlation coefficient, the relational grade can be obtained. Finally, sorted according to the size of the relational grade and draw the conclusion. Grey relational grade calculating steps are:

(1) To establish the reference sequence and compared sequence

Assuming the system character as reference sequences, reference sequences is dependent variable sequences, denoted by $X_0 = \{x_0(k) \mid k = 1, 2, \ldots, n\}$;comparative sequences is variable sequences, denoted by $X_i = \{x_i(k) \mid k = 1, 2, \ldots, n\}$.

(2) Variables dimensionless

According to the grey theory, the sequence units and dimension is not unified, so, there need to use dimensionless method. The specific method is as follows:

Mean method:

$$X_i' = X_i / \overline{x_i} = (x_0 / \overline{x_0}, x_1 / \overline{x_1}, \ldots, x_m / \overline{x_m})$$

Initial value method:

$$X_i' = x_i / x_i(1) = (x_0 / x_0(1), x_1 / x_1(1), \ldots, x_m / x_m(1))$$

Standardization method:

$$X_i' = \frac{x_i(k) - \overline{x_i}}{\sqrt{var(x_i)}}$$

(3) Calculate absolute difference sequences

Absolute value of difference value between reference sequences $\Delta_0'(k)$ and comparative sequences $\Delta_i'(k)$ at the k point $(k = 1, 2, \ldots, n)$ is absolute difference sequences $\Delta_{0i}'(k)$. Calculation formula:

$$\Delta_{0i}(k) = \left| x_0'(k) - x_i'(k) \right|, \quad \Delta_i = (\Delta_{01}(k), \Delta_{02}(k), \ldots, \Delta_{0m}(k))$$

(4) Calculate maximum difference and minimum differential

$$M = \max_i \max_k \Delta_{0i}(k), \quad m = \min_i \min_k \Delta_{0i}(k)$$

(5) Calculate grey incidence coefficient

$$\gamma_{0i}(k) = (m + \varepsilon M) / [\Delta_{0i}(k) + \varepsilon M], \varepsilon \in (0.1); \quad k = 1, 2, \ldots, n; \quad i = 1, 2, \ldots, m$$

Among them, ε is resolution coefficient, which used to weaken distortion caused by the maximum value. In this thesis, the values is 0.5.

(6) Calculate grey correlation

$$\gamma_{0i} = \frac{1}{n} \sum_{k=1}^{n} \gamma_{0i}(k), i = 1, 2, 3, \ldots, m$$

4 Data Analysis

This thesis selects the indicators from 2008-2013 in Sichuan province logistics related data, comparing with the total import and export goods (Table 1).

Table 1. Sichuan province logistics related data

Type	Index	Unit	2008	2009	2010	2011	2012	2013
	international logistics freight volume	Tons	89	111	148	143	149	154

	EVA of the tertiary industry	0.9301		total export	0.8667
Fixed investment	FAI	0.8475		total retail sales of consumer goods	0.9342
	Transportation industry FAI	0.6783		FDI	0.7606

	--	--		Foreign economic turnover	0.8667

5 Discussion of Results

The results of calculations show that the correlation of the indicators are strong, and per capita disposable income has the highest correlation. The data shows that as the residents' income increase, the material demand will improve, so the logistics demand will increase, and will drive the international ascend through putting. The results show that the influence from big to small in turn is social economic, industrial structure, logistics developing, trade development and fixed investment.

The large correlation between the social economy and the international logistics quantity shows the high related degree between the local economic development and the local international logistics demand. With the regional economy development, regional logistics and international logistics demand will increase. Regional economic development reflects the social overall demand of logistics, which also affects the international logistics development. As regional social and economic growth, therefore, the international logistics will must be stronger.

In view of the index of industrial structure, the correlation degree of the third industry is the largest. With the transformation of economic development in Sichuan province and service industry development, to some extent, regional international logistics demand will increase. As a result, regional economic industrial structure adjustment will affect international logistics. These adjustments must be reasonable international logistics development level to adapt to economic development, and need to develop international logistics to adapt to changes in economic structure

In view of the logistics developing, construction of logistics infrastructure can promote the development of logistics. With the development of international logistics, international aviation logistics demand will increase, thus expanding airline mileage is a necessary condition for the promotion of international logistics development.

For trade development, domestic and international trade directly affect the level of development of regional logistics market demand. As the extent of the circulation of strengthening regional consumption, logistics demand will growth rapidly, and it will develop domestic trade and pull logistics. Therefore, with the development of foreign economic and trade, international logistics will further enhance the level of demand.

Fixed investment, to some extent, helps to stimulate economic growth, enhances regional logistics infrastructure service levels, while demand growth will help the logistics, but no significant change in the short term.

In summary, the international logistics is an important part of modern logistics. There is a close link with the various aspects of the regional social and economic. With the maturity of regional socio-economic development and logistics development environment, in improving the investment environment and trade, regional demand for external products will be further strengthened. Meanwhile, in the context of economic globalization and trade international background, international logistics will be the basis to promote international trade development support to enhance the protection of the regional economy. Therefore, enhancing the regional economic development, improving trade and investment environment, optimizing logistics and resource allocation will effectively promote the development of international logistics.

6 Conclusions

This thesis analyzes from multiple perspectives affect international demand for logistics. The comparative study of the international logistics by using grey correlation method shows that the influence of different indicators. Through the analysis we know that the regional economic, industrial and so on have a certain degree of influence on the international logistics development. By understanding their impact, we can effectively find the best way to develop international logistics. This thesis uses gray relational analysis as a research method. Among them, the reference sequence selection is yet to be further. Future research should be aimed at a number of international logistics and a number of regional social development, looking for more deep relationship, for logistics and economic development to provide good advice.

Abstract: The location selection of logistics distribution center is of important strategic significance to optimize modern logistics system. This kind of algorithm based on GIS and genetic algorithm is established on the basis of analysis of traditional location selection algorithm of logistics distribution center. First of all, the elementary logistics distribution center selection and its influence factors are determined. Then influence factors of location selection are analyzed by means of GIS spatial analysis techniques and a serial of candidate sites are obtained. Finally, the best logistics distribution center location was obtained on the basis of genetic algorithm. With the development of modern great sports event, it has been focused on the politics, economy and culture to great sports event. The sponsor takes importance on how to hold the great sports event successfully. So this paper studies on the location selection of great sports event logistics distribution center in combination with GIS and genetic algorithm by means of the method of theory model and example analysis. The conclusion is that the location selection of great sports event logistics distribution center based on GIS and genetic algorithm can benefit to the development of modern great sports event and provide some valuable reference theoretically and practically and shorten the cost of great sports event logistics.

Keywords: GIS; Genetic algorithm; Location selection of logistics distribution center; Spatial analysis; Great sports event.

1 Introduction

Logistics distribution center is a turning and conjunction spot of in the course of logistics distribution to those equipment and organization. It is very important strategic significance how to optimize the location selection of logistics distribution. Meanwhile, no matter what they want to construct, remake and hire distribution center. It will spend a lot of money and time to decide to select logistics distribution center location. So it is very important to location selection of logistics distribution center how to optimize the location selection of logistics distribution center. Of course, the better method of location selection of logistics distribution center is the best beneficial result from the logistics distribution center to requirement spot through assembly, transfer and distribution. However, once the location selection of logistics distribution center is improper, it will result the traffic jam, impact the normal operation of logistics distribution center and also the negative effect. In a way, it depends on the operative achievements of logistics distribution center to the advantage and disadvantage of logistics distribution center. In the fact, the location selection model of logistics distribution center is mainly divided into continuous model, dispersive model and comprehensive location selection model. To the continuous model, it might ignore the geographical feature, environmental condition and traffic status by the “centre of gravity” method. To the dispersive model, these location selection spots of logistics distribution center, they might be selected finally, are only limited to several spots and it will lose some key location selection spot. To the comprehensive location selection model, it will depend on the experience and knowledge of some experts by “Delphi” method. The subjective idea will impact the location selection of logistics distribution center and finally this kind of location selection model might be lack of the objective character. To the contrary, GIS can show relative data by the electronic map and it might eliminate improper location spot obviously. It can analyze some factors impacting location selection of logistics distribution center by quantified analysis method to reduce the subjective factor. So this paper will get some candidate location selection spots by GIS. Furthermore, it will get the best excellent spot of location selection of logistics distribution center by genetic algorithm.

On the other hand, with the development of modern society culture and economy everyone takes importance into the sports training and their own healthy, every country and department at all levels propel sports development and people healthy level to hold some great sports event (YUAN Jixue, LIU Jian, XU Fang, 2009). However, if the great sports event wants to be held successfully, it concerns a lot of factors, such as great sports event propaganda, great sports event organization and safety guarantee, especially location selection of great sports event logistics distribution center and so on. So this paper will discuss how to select the location of great sports event logistics distribution center in combination with GIS and genetic algorithm in order to propel the development of the great sports event.

2 Determination Object of Location Selection in Great Sports Event Logistics Distribution Center

The flow chart of location selection of great sports event logistics distribution center will be described in detail as follows:

Trough the flow chart of location selection of great sports event logistics distribution center in Figure 1, it might be made of seven phases. First is object of distribution center location selection. Second is data preparing by GIS mainly, such as spatial information of basic geography and dissertation information of logistics. Third is factors of impacting location selection including natural environmental factor, condition of basic facility, operational environmental factor and others. Fourth is GIS platform which is key point of spatial analysis. The main spatial analysis methods include spatial check, buffering district analysis, superimposing analysis and etc. Fifth is candidate spot of location selection and there are several possibilities to candidate spot of location selection. One is not candidate spot of location selection. Two is a series of non continuous candidate spots of location selection. Three is unique candidate spot of location selection. It might take advantage of genetic algorithm to optimize the selection of these non continuous candidate spots once it appears non continuous candidate spots of location selection. Finally the idea will be tested by investigation on the spot. So it will discuss how to optimize the location selection of logistics distribution center in modern great sports event according to above-mentioned steps (LIN Na, LI Zhi, 2010).

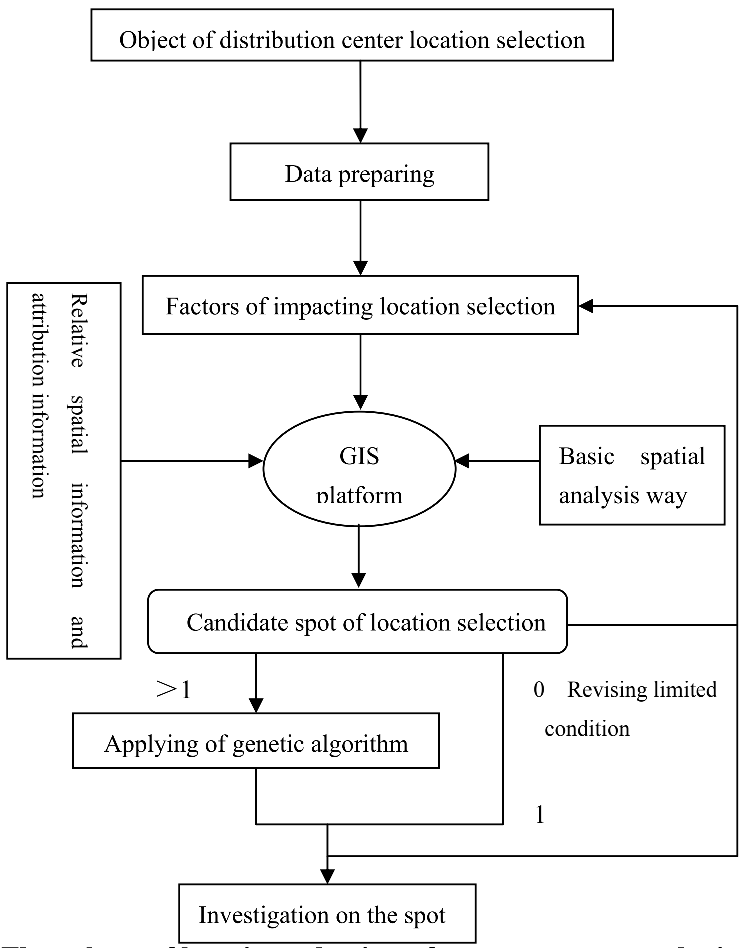

Figure 1. Flow chart of location selection of great sports event logistics distribution center

It should consider long range planning principle, basic requirement of location selection and lowest operative cost to determination object of location selection in great sports event logistics distribution center. The whole operative cost of distribution center should conclude governing cost, stock cost and transportation cost and others. In these cost, it is not close relation between the location selection of logistics distribution center in great sports event and governing and stock cost. In contrast, there are very close relation between the transportation cost and the location selection of logistics distribution center in great sports event. Of course, transportation cost includes the expense from commodity supplying base to distribution center and the expense from distribution center to requirement spots. So it is to get the lowest transportation cost to determination object of location selection in great sports event logistics distribution center.

3 Preparing Relative Data to Location Selection of Logistics Distribution Center in Great Sports Event

It needs to collect a lot of data information to location selection of logistics distribution center. Normally, it concerns some spatial information of basic geography and dissertation information of logistics in this paper. To the information, it might be figure, table and electric data information. Some data can be used immediately and the other must be converted into another formation to content GIS system (XU Fang, YUAN Jixue, JIANG Chaozhe, 2011). So it is very important to prepare relative data about location selection of logistics distribution center in great sports event and furthermore, it can also optimize the location selection of logistics distribution center.

4 Main Factors Impacting the Location Selection of Logistics Distribution Center in Great Sports Event

The location selection of logistics distribution center should consider natural environmental condition, basic equipment condition, operative environment factor and other factor according to the theory of modern logistics. In Table 1, they might also be divided into smaller index to above-mentioned four main impacting factors. Meanwhile, smaller index has own evaluation norm. Actually, there are some different traits to smaller index in different objects and it all depends on reality condition. It is hard to appear in the map to above-mentioned many factors and this paper will analyze those factors which is close relation between them and geography spatial condition by GIS.

Table 1. Main Factors Impacting the Location Selection of Logistics Distribution Center in Great Sports Event

Impacting factors	Evaluation norm
Natural environment	Meteorological condition: temperature, wind strength and direction, raining condition and etc
	Geologic condition: suitable for building requirement
	Hydrology condition: away from inundating river
	Topography condition: falling gradient placid, fitting building
Basic facilities	Traffic convenient, supplying water, electricity and gas which are content to the normal standard
Operative environment	Government policy: policy permission
	Enterprise condition around distribution center: suitable density
The others	Environment protection: protect natural and humanity environment
	Sustainable development

5 Candidate spot of location selection in great sports event logistics distribution center based on GIS

GIS platform is key point of spatial analysis. The main spatial analysis methods include spatial check, buffering district analysis, superimposing analysis and etc. Now GIS platform including ArcGIS, MapInfo has relative perfect spatial analysis function. Such as spatial check can find all enterprise around certain district to know their density, buffering district analysis can understand the condition of dweller spot, superimposing analysis can superimpose some buffering district. By these methods, there are several possibilities to candidate spot of location selection. One is not candidate spot of location selection. Two is a series of non continuous candidate spots of location selection. Three is unique candidate spot of location selection.

6 Draw the Best Location Selection of Great Sports Event Logistics Distribution Center by Genetic Algorithm

Genetic algorithm is a kind of simulating biological genetic and evolution phenomenon which the nature choice and adaptation existence are its basic principle. This kind of algorithm depends on biological evolution mechanism and genetic theory by advantage of simple encoding technology and reproducing mechanism to solve some complex problem. The steps in detail as follows: First is to determine the object function. Second is to choose encoding tactics. Third is to produce initial groups. Fourth is to set fitness function. Finally it should carry out genetic manipulation.

Mathematic model can be described as following to this question (YUAN Jixue, LIU Jian, KANG Lian, XU Fang, 2008):

$$MinC = \sum_{i=1}^{m} Fi \qquad i = 1,2,3,\cdots,m$$

Where:

F_1 means the total costs of transportation from supplying base to distribution center of great sports event logistics.

F_2 means the transportation distance from supplying base to distribution center of great sports event logistics.

F_3 means the total costs of transportation from distribution center of great sports event logistics to requirement spot.

F_4 means the transportation distance from distribution center of great sports event logistics to requirement spot.

Subject to:

It should be linear function to transportation cost from supplying base to distribution center and from distribution to requirement spot.

7 Conclusions

This paper analyzes impacting factors of great sports event logistics distribution center by GIS platform and genetic algorithm. By GIS platform some impacting factors will be analyzed and it also draws some candidate spots. Meanwhile, it also set up selection location of great sports event logistics distribution center in order to get lowest transportation cost. Finally, it might get the best location selection spots of great sports event logistics distribution center. In a long run, it will be useful of great sports event development.

Abstract: In order to clarify the relationship between port logistics and economic growth, based on data of port logistics and economic development in Ningbo from 1990 to 2013, the dynamic correlation and causality between Ningbo's port logistics and economic growth has been analyzed via co-integration and Granger test. The empirical results reveal that there is a long-run stationary relation between port logistics and economic growth in Ningbo; and a unidirectional causality between the both, namely, both cargo throughput and container throughput of Ningbo port are Granger causes of economic growth, and container throughput is Granger cause of cargo throughput, not vice versa. According to the experimental results, conclusions and suggestions are put forward from the sustainable level.
Keywords: Port logistics; Economic growth; Co-integration analysis; Granger causality test.

1 Introduction

The measure of "Invigorating the city through the port, which will, in turn, stimulates the port" has become an evolving rule of port city. The development of port logistics promotes economic prosperity of its city, and economic growth provides support and guarantee for port logistics development.

In recent years, the relationship between port logistics development and economy growth has become a research focus. In the aspect of theory research, main achievements have been made by using factor endowment theory, economies of scale theory, investment multiplier theory, growth pole theory and city economic growth theory, which qualitatively clarified the interactive effects of port logistics and economic growth (Zhang, 2007; Zhang, W.B., 2007); in the aspect of empirical analysis, the existing results mainly used correlation analysis, co-integration analysis, Granger causality test to quantitatively analyze the interactive relationship between the both(Huang, 2011; Li, 2009; Liang, 2011; Liu, 2014; Shan et al., 2014; Shen, 2013; Sui, 2012; Zhou et al., 2008). The results show that, in most studies, there is a strong correlation between port logistics and city economy, the development of port logistics bring opportunities for the economy growth of its city, and meanwhile, the latter can also provide powerful support for the former.

Port is Ningbo's strategic and leading resource, after years of development, Ningbo Port has become one of the world's busiest ports. Its cargo throughput and container throughput were 0.526 billion and 1.87 million TEU in 2014, ranked fourth and fifth respectively in the world (Yang, 2015). Port logistics in Ningbo plays an important role in promoting its economic growth. By the end of 2013, Ningbo's GDP ranked 17th among 52 cities nationally (Shan, 2014) and 10th among 35 major cities as for its headquarter economic development ability (Zhou, 2014).

Nowadays, the impact of Ningbo's port logistics on its economy has become increasingly prominent; however, relevant research is relatively rare. In order to clarify their relationship, based on data of port logistics and economic development of Ningbo over the period 1990-2013, the dynamic correlation and causality between the both has been analyzed via co-integration and Granger test. According to the results, relevant suggestions are put forward from the sustainable level.

2 Variables Selecting and Data Processing

Considering time scope, representation and availability of the data aimed for co-integration analysis, as well as the indexes of port logistics and city economy chose by existing research (Huang, 2011; Li, 2009; Liang, 2011; Liu, 2014; Shan et al., 2014; Shen, 2013; Sui, 2012; Zhou et al., 2008), this paper selects port cargo throughput (denoted by PT) and container throughput (denoted by CT) as Ningbo's port logistics indexes, adopts GDP as its economy index. Original data are obtained from "Ningbo Statistical Yearbook", as shown in table 1.

Table 1. Economy and port logistics indexes of Ningbo from 1990 to 2013

Year	PT (million tons)	CT (ten thousand TEU)	GDP(billion yuan)	CPI	RGDP(billion yuan)
1990	25.54	2.20	14.14	100.00	14.14
1991	33.90	3.60	16.99	106.80	15.91
1992	43.67	5.30	21.31	119.83	17.78
1993	53.21	7.90	31.51	150.99	20.87
1994	58.50	12.50	45.97	186.47	24.65
1995	68.53	16.00	60.27	222.08	27.14
1996	76.38	20.20	78.41	245.18	31.98
1997	82.20	25.70	87.91	254.74	34.51
1998	87.07	35.30	95.28	254.23	37.48
1999	96.60	60.10	101.71	254.49	39.97
2000	115.47	90.20	114.46	255.25	44.84
2001	128.52	121.30	127.88	253.46	50.45
2002	153.98	185.90	145.33	251.43	57.80

2003	185.43	277.20	174.93	254.45	68.75
2004	225.86	400.50	210.95	261.32	80.72
2005	268.81	520.81	244.73	266.55	91.82
2006	309.69	706.79	287.44	271.61	105.83
2007	345.19	935.00	341.86	282.21	121.14
2008	361.85	1084.63	394.65	296.32	133.19
2009	383.85	943.45	432.93	294.54	146.99
2010	412.17	1300.35	516.30	305.44	169.04
2011	433.39	1451.24	605.92	321.62	188.40
2012	453.03	1567.14	658.22	327.09	201.23
2013	495.92	1677.37	712.89	334.29	213.26

In order to eliminate the influence of price on GDP, set Consumer Price Index (denoted by CPI) as 100 in 1990 and use it to deflate annual GDP so that GDP is valuable, denoted by $RGDP$, as shown in table 1. The variation trend of $RGDP$, PT and CT are shown in Figure 1, which present a nonlinear growing trend.

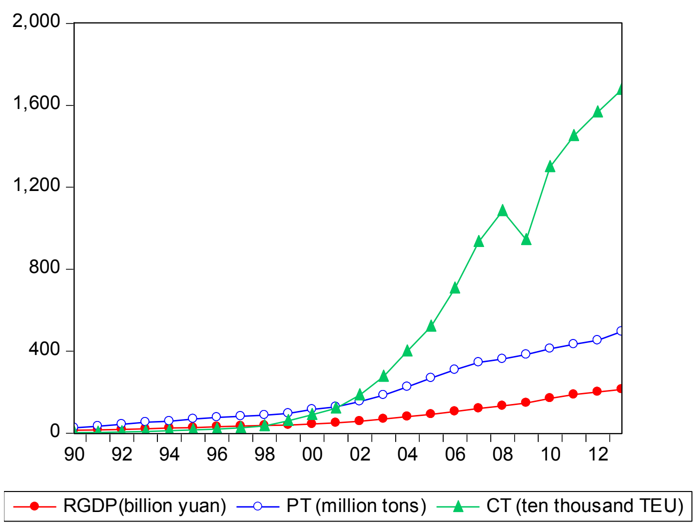

Figure 1. Time trends of three variables over 1990-2013

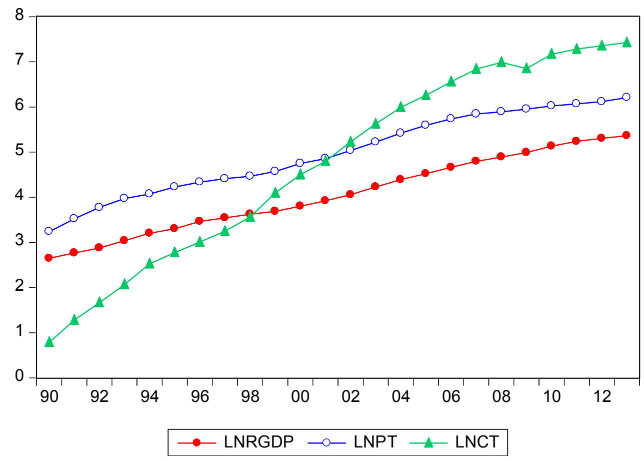

Figure 2. Time trends of natural logarithm of three variables over 1990-2013

Co-integration analysis requires all indexes perform a property of homogeneity, while economic and logistics indexes usually cannot meet the requirement. The natural logarithmic forms of these variables are used in the regressions to take into account the possibility of a nonlinear relationship between the two indexes, as well as ensure the estimated coefficients are robust to the co-integration of variables (Shan et al., 2014), therefore, this paper transformed the selected variables into natural logarithms, which denoted by $LNPT$, $LNCT$ and $LNRGDP$ respectively, and their variation trend are shown in figure 2.

3 An empirical analysis of the relationship between port logistics and economic growth in Ningbo

3.1 Stationarity test

Using econometric analysis software Eviews7.2 to test the correlation between $LNRGDP$, $LNCT$ and $LNPT$, the coefficient matrix are shown in table 2. The correlation coefficients between $LNRGDP$ and $LNPT$, $LNRGDP$ and $LNCT$ are 0.9941 and 0.9880 respectively, and the correlation coefficient between $LNPT$ and $LNCT$ is 0.9956, which means the three are closely related.

Table 2. Correlation coefficients of variables

	LNRGDP	LNPT	LNCT
LNRGDP	1	0.9941	0.9880
LNPT	0.9941	1	0.9956
LNCT	0.9880	0.9956	1

In order to avoid spurious regression caused by the nonstationarity of time series, unit root test is necessary before co-integration analysis (Cai et al., 2010). This paper adopts ADF test and the results are show in table 3. Where D is the first order difference, DD is the second order difference, and (c,t,k) are intercept term, time trend and lag terms respectively; intercept term and time trend are determined by sequence graphs, while lag terms determined by the software.

Table 3. Results of ADF test

Variables	Types(c, t, k)	ADF Statistics	Prob.*	Critical Value (5%)	Conclusion
LNRGDP	(c, t, 2)	-2.3500	0.3920	-3.6450	nonstationary
DLNRGDP	(c, 0, 0)	-2.7279	0.0854	-3.0049	nonstationary
DDLNRGDP	(0, 0, 0)	-6.6029	0.0000	-1.9581	stationary
LNPT	(c, t, 1)	-1.8820	0.6295	-3.63290	nonstationary
DLNPT	(c, 0, 0)	-2.7005	0.0898	-3.0049	nonstationary
DDLNPT	(0, 0, 0)	-4.8816	0.0000	-1.9581	stationary
LNCT	(c, t, 0)	0.5705	0.9988	-3.6220	nonstationary
DLNCT	(c, 0, 0)	-2.6398	0.1005	-3.0049	nonstationary
DDLNCT	(0, 0, 0)	-6.8430	0.0000	-1.9581	stationary

From table 3, we can know that all ADF statistics are greater than the critical value under the level test, it means that all the series are nonstationary; but all of them become stationary after second difference. Thus $LNRGDP$, $LNCT$ and $LNPT$ are second integrated series, namely $LNRGDP \sim I(2)$, $LNPT \sim I(2)$ and $LNCT \sim I(2)$. Therefore, it is necessary to conduct co-integration test.

3.2 Co-integration test

If two nonstationary time series are of the same difference, then there might be a long-term stable equilibrium relationship between them. This paper employs the E-G two-step-test to verify whether the residual series are stationary.

Firstly, regression analysis was conducted on $LNCT$ and $LNPT$, so that the long-term relationship between them can be determined, the results are as follow:

$$LNPT = 2.9929 + 0.4169 * LNCT + e1 \quad (1)$$

As can be seen, every 1% growth of container throughput devoted 0.416902% to cargo throughput growth, for container transport is one of main transport modes in Ningbo Port, thus the contribution of container throughput to GDP was covered by cargo throughput, so their contribution should be discussed respectively.

Secondly, regression analysis on $LNRGDP$, $LNCT$ and $LNPT$ was conducted, the results are as follow:

$$LNRGDP = -0.6151 + 0.9406 * LNPT + e2 \quad (2)$$

$$LNRGDP = 2.2032 + 0.3914 * LNCT + e3 \quad (3)$$

Thirdly, test stationary of the residual series. According to co-integration theory, if there exist co-integration relationship between dependent and independent variables, then residual series et that composed of the independent variable parts which cannot be explained by dependent variable are also required to be stable. There ADF is used to determine the stability of residual series and the results are shown in table 4.

Table 4. The stationary test of residual series

Variables	Difference	ADF Value	1%level	5% level	10% level	prob.*	Conclusion
e1	1	-4.1886	-2.6743	-1.9572	-1.6082	0.0002	stationary
e2	1	-3.8846	-2.6743	-1.9572	-1.6082	0.0005	stationary
e3	1	-3.1098	-2.6743	-1.9572	-1.6082	0.0035	stationary

From table 4, we can know that ADF values of residual series is less than the critical values of 1%, 5% and 10% level, therefore, it can be estimated that t residual series are stationary, and there are long-term equilibrium relationship between $LNCT$, $LNPT$ and $LNRGDP$. Besides, the results indicate a 1% increase in port cargo throughput is associated with a 0.9406% increase in per capita GDP growth; a 1% increase in container throughput devoted a 0.3914% increase to GDP. But it is not sure whether there exists causal relationship between $LNRGDP$, $LNCT$ and $LNPT$, therefore, it need to be verified by causal relationship test.

3.3 Granger causal relationship test

In this paper, using Granger test with Eviews7.2 to test whether there are causal relationship between $LNRGDP$, $LNCT$ and $LNPT$, and the lag value is 2, test results are shown in table 5.

Table 5. Results of granger casual test

Null Hypothesis:	Obs	F-Statistic	Prob.	Conclusion
LNPT does not Granger Cause LNRGDP	22	9.8366	0.0015	Accept
LNRGDP does not Granger Cause LNPT		0.3136	0.7349	Refuse
LNCT does not Granger Cause LNRGDP	22	3.8275	0.0424	Accept
LNRGDP does not Granger Cause LNCT		1.5371	0.2434	Refuse
LNCT does not Granger Cause LNPT	22	6.0816	0.0102	Accept
LNPT does not Granger Cause LNCT		1.6791	0.2160	Refuse

As is show in table 5, under the 5% of significance level, there is unidirectional causal relationship between port logistics and economic growth in Ningbo, namely cargo throughput and container throughput are Granger cause of economic growth, not vice versa. Thus port logistics has a positive effect on the host city's economic development, which is consistent with theoretical predictions, while economic growth has no direct effect on port logistics. In addition, container throughput is Granger cause of cargo throughput and not vice versa.

4 Conclusions and suggestions

As analyzed above, there is a strong association between port logistics and economic growth in Ningbo. On the one hand, the development of port logistics not only promotes the efficiency of economic operation, but also provide a guarantee for the healthy and ordered development of Ningbo's economy; on the other hand, as one of the composite industry with "linkage effect", port logistics forms a new growth pole and improves Ningbo's investment environment by multiplier effect, which directly propelled economic prosperity of Ningbo region.

However, the interaction coefficient of Ningbo's port cargo throughput to GDP is much greater than that of container throughput, which is a blow for Ningbo to construct deep pivot port and container ocean mainline port. Adding the competition from Zhoushan, Wenzhou, Shanghai and Xiamen, it is critical for Ningbo Port to focus on transformation and upgrading, enhance its container throughput status by combining ports, logistics and shipping lines as the leading part, speeding up the construction of port logistics infrastructure and promoting effective cohesion of logistics nodes, standardizing the development of port logistics industry to create a beneficial macro environment. Moreover, the government and relevant departments should take actions to guide industrial development and promote communication between the supplying and purchasing parties. In general, only policies, soft and hard environment are available and the government cooperates closely with enterprises, can port logistics benefits more for Ningbo's economic development.

Management System Implementations and Application Research of Supply Chain Enterprise Based on Multi-Agent Technology

Jingjiang Liu

School of Business Administration, Nanchang Institute of Technology, Nanchang, Jiangxi 330099, China. E-mail: 375427571@qq.com

Abstract: Following network popularization, many researchers paid more and more attention to the development of Electronic Commerce in twenty-first century. They hope make greatly development for goods flow and information flow which consist of factory, supplier, retailer and users which develops the management of the net information so as to make up an efficient supply chain management. The paper introduces the technique about J2EE and JADE which is needed in the system. The paper also described the mechanism of the Agents in detail.

The paper also described the mechanism of the Agents in detail. Moreover the paper describes the methods of the integration of the JADE and J2EE.The paper designs the logic design of between the J2EE and JADE and the way from the client to the Agent. Methods using JADE and J2EE technology of realizing the combination of supply chain management system of Agent technology based on the development work of chain enterprises.
Keywords: Agent; J2EE; JADE.

1 Introduction

The business model of B2B (Business to Business) in the next five years will account for more than 78% of the whole electronic commerce market. While the management of the supply chain is a key in the model of B2B. With the factors of production between each other the multiple companies can increase productivity and profits of the whole business activities. In the process of developing electronic commerce the problem about the management of the supply chain is becoming increasingly fierce. How to coordinate the relationship of manufactures, retails, supplies and customers has become a key issue for the success or failure of electronic commerce. While traditional simple management model obviously can't meet the needs of the big market. A series of complex factors, such as vast data amount, complex web of supply relationship and so on, are all affecting the benefits of every enterprise and every user. Therefore, the research on the relationship of the supply chain has a very high use value. At the same time, Multi-Agent technology is a hot topic discussed in the field of distributed artificial intelligence in recent years. Multiple Agents with autonomous and intelligent characteristics coordinate, negotiate, and collaborate together in hope of accomplishing all kinds of cooperation efficiently. It is said to be very effective. But we can't make the research on Agent technology only be stayed in the aspect of theory. We must make it be combined with modern advanced technology to solve many practical problems. The combination of Multi - Agent technology and electronic commerce is just such an attempt. We make the advanced Multi-Agent technology be limited to a specific application domain in order to do research on it. This way not only can enrich its academic value but also can solve practical problems better at the same time. It is also the purpose of academic research.

2 Implementation Technology

FIPA97 only has studied static Agent. FIPA98 begins to make specifications for Mobile Agent technology. At present the set of FIPA specifications has been already quite mature and stable. It is worth mentioning that FIPA is a specification which can be used publicly. It is not a specific application technology, but it is general technology with the aim of different application fields. It is not an independent technology, but it is a basic set of specifications. The set of specifications makes the developer be able to develop a complex system with highly cooperative ability. At present the latest public standard is FIPA 2000. By the integration of Language--Behavior (Speech Act) theory, predicate logic and common ontology, it provides a standard method for us to understand the communications between the Agents. Its basic content includes the following several aspects. The middleware supports include Agent registration, location service, communication service, mobility and security support. Agent communication languages include semantic, interaction protocol, responsibility and so on. The interactions with the local software will make enterprise legacy in system or database be wrapped up. The communication between agents with people defines the communication content and communication mode.

3 The Management System Implementations of the Supply Chain with Chain Enterprise Based on Multi-Agent Technology

3.1 Problem Description

As mentioned above, we can make the planning process in the supply chain of chain enterprise be divided into two levels, that is to say, the upper level is the preliminary planning and coordination, and the lower level is the local planning and scheduling. Next we simulate the preliminary planning process partially. We identify four Agents in the system, namely the Agent of inventory, the Agent of production, the Agent of order and the Agent of transportation. Figure 1 shows the coordination process which may appear in the coordination of preliminary planning. Among them, arc label is the coordination process, and the arrow points to the participants of the coordination from the direction of the initiators of the coordination. In addition, we introduce an intermediary Agent. Every function doesn't have the direct interaction between the Agents, and it has the direct interaction by the intermediary Agent.

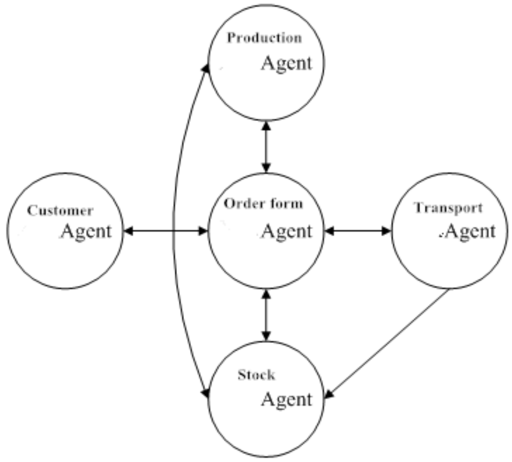

Figure 1. The Coordination Process which may appear in the Coordination of Preliminary Planning

3.2 The Implementation Mechanism of Agent

Because multiple Agents which constitute the supply chain of chain enterprise have the similar structure and implement mechanism, next we set up a general Agent model to describe its implementation process. After the Agent receives the message from other Agents in the outside, we should decide how to deal with according to the responded task list first, that is to say, we should determine which executable module. After we know how to deal with, we get the data which are needed in the process of dealing with the message from the public data area and make them be stored on the blackboard. Then we use our own knowledge to perform the current task. If it is executed successfully, we will send the executive results to the public data area. We will send a message with successful execution to the external Agent, or else we will send a message with failed execution to the external Agent, including the information with the failed reasons.

Algorithm: the message processing of the Agent.

Input: the message from external Agent.

Output: the message which is sent to the external Agent.

Methods: Step l The Agent receives the message from the external Agent. Step2 We analyzes the content of the message and determines the executable module and the needed data according to the responded task list. Step3 We extract data from public data area and make them be stored on the blackboard. Step4 With the guidance of knowledge, we perform the current task. Step5 If it needs collaboration with other Agent in the in the implementation process, then we will send the message about the requested collaboration to other Agents. Step6 If the executive task is finished. Step7 We will make the data on the blackboard be written into the public data area. Step8 We sends the task the external Agent and completes the message. Step9 If the executive task fails; we will send a message with failed execution to the external Agent.

3.3 The Management System Agent Implementations of the Supply Chain with Chain Enterprise Based on Multi-Agent Technology

3.3.1 The Technology Integration of Using J2EE and JADE

(1)The Dedicated JADE Application Server

Because JADE has become an application service project provided by the application server among the application servers which support JADE, so the support of JADE is more perfect. It can achieve seamless integration with J2EE application server. If we choose this plan, the project which is designed and developed can have high efficiency to realize the integration of design, development, and implementation. However, considering that JADE is still an open project and the standard is not entirely uniform, the first scheme refers to reducing the flexibility of the JADE to achieve its efficiency. In addition, the cost of dedicated application server is higher than the cost of general application server. And maintenance personnel must receive additional training.

(2)The Integrated JADE of General Application Server

The second scheme makes the application of JADE be combined with general application server. The application developers develop the interface of JADE and general application server so as to realize the integration of the two. In this way the developed project can be applied to the latest development environment of JADE, so the flexibility is improved. Contrary to the dedicated application server, because the build-in components which the application server has itself don't be adopted, the implementation efficiency with the application of JADE project is lower than the dedicated server. However, considering that the general application server has many technical supporters, making the integration JADE on the general application server doesn't need to spend a lot of time to train maintenance personnel again, at the same time the development of a network application system based on JADE doesn't need to make large-scale update and upgrade with the software and hardware of previous system and it also saves the costs to a certain extent. This paper adopts the second scheme to learning platform to realize the learning platform of the project.

3.3.2 The Way of the Client Access Agent

We use the client with the integrated JADE application to access Agent. Due to the openness of the J2EE platform, we can use the client with the integrated JADE application to access the Agent in the system. Because the two sides all conform to the JADE standard, in fact it is the communication model of different Agent platforms which meets the standard of JADE. This paper will not discuss deeply about this mode.

We use JSP/Servlets to access Agent. Because JADE becomes a component of the application server after it is compiled, JSP considers the Agent in the JADE to be JavaBean's access. At the same time, it gives the functions of the startup at the client side and closing Agent.

3.3.3 The Communication between Agent and EJB

Because the business logic is stored in the EJB container/server, we need the Agent of communication and EJB container server to communicate, and invoke the EJB object and accept the return results of business execution. Therefore, this paper develops corresponding communication interfaces, and respectively realizes the communication between the user and Agent and between Agent and EJB container server. The work process of communication interface can be seen as follows.

(1)The user client sends the application of invoking business logic to Agent in the web access page.

(2)The web page deals with Agent and accepts the application, and then it sends the invoking application to the Agent of communication.

(3)The Agent of communication creates a new EJB object by the Home interface of the EJB which is provided by the EJB container server.

(4)Home interface creates an EJB object and invokes the access business logic of the EJB object to perform related business operations.

(5)Home interface makes the results which the EJB object quotes be returned to the Agent of communication.

(6)The Agent of communication makes the return result with execution be given to the web page to deal with Agent.

(7)After the web page deals with Agent, it gives the return result with execution to the user.

3.4 The Deployment and Running Environment of the Supply Chain with Chain Enterprise Based on Multi-Agent Technology

The development and running environment of the supply chain with chain enterprise can be seen as follows.

Operating System: Microsoft Windows Server 2000.

Database: SQL SERVER 2000.

J2EE application server: WebLogic8.1.

The Web server: Tomcat5.0.

Java development tools: Eclipse3.1.

Among them, Eclipse is one of the best Java development tools at present. It makes the supports of J2EE and XML are go-ahead. WebLogic Server is by far the most excellent BEA application server. Tomcat is also a powerful free open source Servlet container.

As far as the deployment structure of supply chain management system is concerned, in the general situation the client only needs to install IE and doesn't need to employ other programs. Engine is deployed on the J2EE application server. The system also needs a Web server that supports JSP and Servlet. In the general situation J2EE application server and Web server can share a machine. Relational database server can be deployed on another server, and it can also share a single server with the J2EE application server or Web server.

5 Concluding

Research on traditional management system of the supply chain are often limited to a closed market environment and competitive environment. And we assume that there is a common goal between every enterprise or the entity in the supply chain so that we make the study of the management system of the supply chain be simplified into a simple hierarchical scheduling problem. However, the application environment of the actual supply chain system often conflicts with the assumptions above. First, each individual (enterprise) in the supply chain is driven by their own interests and each individual pursues to maximize their own interests.

When their own goals conflict with the overall goal of the supply chain, generally they will abandon the overall interests. Second, in the real supply chain environment, each entity in the supply chain decide to join or leave the supply-chain system at any time according to their own judgments. This paper makes Agent technology and Multi-Agent technology be introduced into the application of the management system about the supply chain to be more fit the actual operation of the supply chain. This way can make the supply chain software reflect the real status about the reality of supply chain.

This paper introduces the application and the adopted technology of the management system of the supply chain with chain enterprise based on multi-Agent technology and describes the implementation of the supply chain management system core. It analyzes FIP technology and JAD technology. It introduces the structure and function of J2EE platform. In addition, with the combination of FIP technology and AD technology, we make it be used to the application of Bokang mobile phone chain sales field.

Mile Mismatch Correction Method of Track Geometry Data and Its Application

Kun You; Haifeng Li; Wanqing Zhang; and Sihan Yan

The Key Laboratory of Road and Traffic Engineering of Ministry of Education, Tongji University, Shanghai 201804, China. E-mail: youkun_1989@126.com

Abstract: Track geometry state is one of the important indexes to measure the comfort and stability of train. However, large amount of field data analysis indicates that the mile mismatch exists in different measurement of track geometry data in the same track section, which may cause a great adverse impact on analysis and mastering the development rules of track geometry. To solve such problems, a mile mismatch correction method based on the identification of curve characteristic and track geometry data characteristic is proposed. First, according to curve characteristics and the corresponding response on track geometry data while train passes, the mile error between track geometry data and curve can be calibrated. Then, in association with the method of least-squares and dynamic programming, a mile match calculation model is built and used to match the miles of track geometry data inspected at different time in the same section. The mile match method is developed by MATLAB and tested by track geometric data from several railway lines. The practice results show that the method is accurate, efficient and reliable.

Keywords: Railway track; Track geometry; Mile mismatch; Correction method.

1 Introduction

Track geometry state is one of the important indexes to measure the comfort and stability of train. The present method to detect track geometry state includes manual inspection, static detector measurements and track geometry measurements. While the track geometry measurements hold dominant position with its detection speed and high efficiency. However, large amount of field data analysis indicates that the mile mismatch exists in different measurement of track geometry data in the same track section, which may cause a great adverse impact on analysis and mastering the development rules of track geometry. Thus, mile mismatch correction is necessary to eliminate the adverse effect brought by mile drift.

In response to this phenomenon, relevant works have been done extensively, and larger progress has been achieved. Based on the least-square method, SUI Guodong from Tongji University have calculated mileage offset for each unit section, which followed by monolithic translation to correct the mile mismatch. The formula is as follows:

$$\min U = \sum_{i=1}^{n}[Y_{1i} - Y_{2(i+x)}]^2$$
$$s.t. -200 \leq x \leq 200, x \in Z$$

XU Guiyang, a researcher at the China Academy of Railway Sciences, analyzed the mileage drift with correlation coefficient. The formula is as follows:

$$\rho(k) = \frac{\sum_{i=0}^{N-1} x_0(i) x_j(k+i-1)}{\sqrt{\sum_{i=0}^{N-1}(x_0(i))^2}\sqrt{\sum_{i=0}^{N-1}(x_j(k+i-1))^2}}$$
$$k = 1,2,\cdots,800$$

WANG Kui have made some progress in analyzing the similarity of track geometry measurements wave forms with grey theory.

Summarizing the results of the above stated three research, their shared assumption is that the mileage drift between different measurements in the same section (generally 1 km) is constant, while it's nonlinear with the increasing mileage actually. Thus, this article has presented a track geometry measurements correct method on the basis of massive measurement results.

2. The reason and characteristics of mileage drift

The mileage positioning and marking are realized through grating encoder fixed on the axle. As the rotation of wheel, grating encoder will constantly output pulse. Then position could be determined by calculating its number after the system receives the pulse. But deviation can't be eliminated because of wheel idle, slipping, wheel diameter size change caused by rail wear and random failure on grating encoder. The cumulative error may larger with increasing distance. Influences on sampling position by wheel idle and slipping will be showed in the figure below.

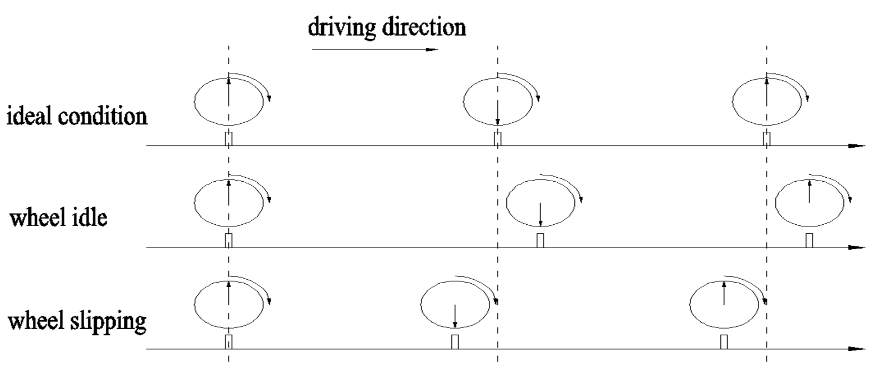

Fig.1 Influences on sampling position by wheel idle and slipping

The characteristics of mileage drift are as follows:

(1) Mileage deviation should not be neglected and the maximum deviation reaches 100m.

(2) In macroscopic view, mileage drift in the same direction as a whole while drift distance is similar for each mileage scatter within the same section.

(3) In microscopic view, the amount of drift distance is nonlinear with the increasing mileage, which means the drift distance is different in different points.

3. Mile mismatch correction method

The procedures of mileage correction include three steps: data pre-processing, mile correction based on the identification of curve characteristic and track geometry data characteristic.

3.1 Data pre-processing

Limited by test conditions, outliers, trends generally exist in test data. In order to ensure accuracy and reliability of the results, this article will eliminate outliers and trends at first.

3.2 Mile correction based on the identification of curve characteristic

Based on large data analysis, there is a one-to-one correspondence between curve and super-elevation waveform in track geometry data. The super-elevation waveform appears as trapezoid in curve section while digital fluctuations near 0 in the line section which shows in the figure below.(ZH, HY, YH and HZ respective the point of tangent to spiral, spiral to curve, curve to spiral, spiral to tangent in the picture)

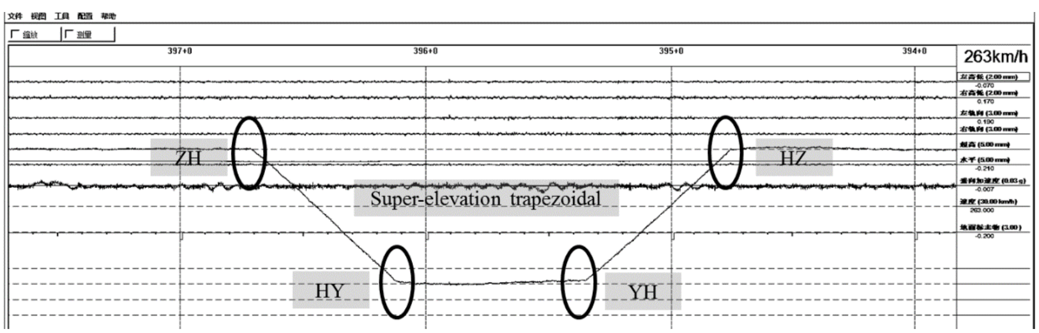

Fig.2 correspondence between curve and super-elevation trapezoidal

Based on the above analysis, super-elevation data could be used to identify the curve which followed by the mile match between identified curve and account. For the reason that mile drift with 100m which is far less than the length of the curve, adjacent curve won't be mismatched.

Name the ZH, HY, YH, HZ points as the characteristics of the curve. This four feature points can be extracted in the super-elevation wave for every curve and take the average of drift miles in ZH, HY, YH, HZ as mile correction amount. And then, based on the second characteristic of mileage drift, correct every points with this amount in this curve to establish the first match.

3.3 Mile correction based on track geometry data characteristic

Due to the deterioration on the state of track geometry is a very slow process, the change trend of track geometry state are basically identical without track maintenance or within two times of maintenance, and the mile correction based on track geometry data characteristic is feasible as a result. And railway engineer's experience and statistics showed that the gauge change smallest between several track geometry parameters in the same period. So gauge is preferred.

Based on the above analysis, in association with the method of least-squares and dynamic programming, a mile match calculation model is built and used to match the miles of track geometry data inspected at different time in the same section.

Take two adjacent track geometry data after the first match as the sample and divide the segment between adjacent feature points by number of unit section (generally 200m per section). Then the correction of every unit section will be calculated by least squares method and dynamic programming to establish the whole mile match.

Set the first track geometry measurements as the sequence $Y_1 = \{(x_1(i), y_1(i)) | i = 1,2,3,\cdots,n\}$, which is chosen as the standard sequence. Its length is the variable n. The sequence $x_1(i)$ means mileage. The sequence $y_1(i)$ means measurements. Set the second track geometry measurements as the sequence $Y_2 = \{(x_2(j), y_2(j)) | j = 1,2,3,\cdots,m\}$. Its length is the variable m. Sequences which length is n are chosen from the sequence Y_2. These sequences are set as $Y' = \{(x_2(j_g), y_2(j_g)) | j_g \in [1,m], j_g \in Z; g = 1,2,3,\cdots,n; x_2(j_{g+1}) > x_2(j_g)\}$. Find the best subsequence Y^* which has the highest similarity with Y_1 in Y' by the means of least-squares method, and Y^* should be considered as the matching result. The formula is as follows:

$$min\, U = \sum_{i,g=1}^{n} [y_2(j_g) - y_1(i)]^2 \tag{1}$$

$$Y' = \{(x_2(j_g), y_2(j_g)) | j_g \in [1,m], j_g \in Z; g = 1,2,3,\cdots,n\} \tag{2}$$

4. Instance analysis

To verify the reliability and validity of mileage correction method, a software is prepared according to the method and analysis is carried out based on a large number of measurements. Some of the results are chosen to be introduced.

Data source: measurements of Hangzhou-Changsha Line on July 31, 2014 and August 6, 2014.

In the first mileage correction, the mileage of the chosen measurements is K270~K272. Mileage drift is corrected using the super-high of the measurements, as shown in Fig.3 and Fig.4.

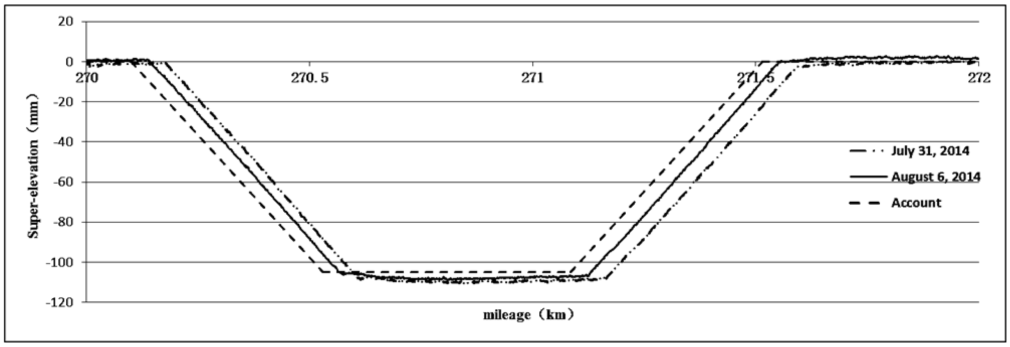

Fig.3 two measurements before the first correction

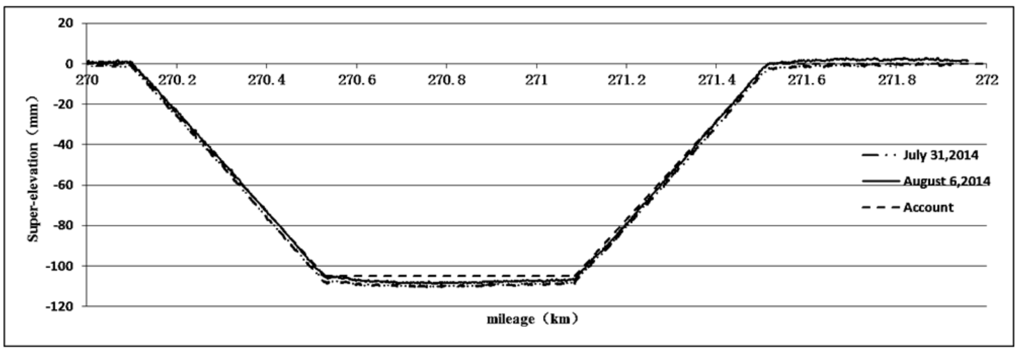

Fig.4 two measurements after the first correction

As shown in Fig.3, two measurements both have mileage drift. The mileage deviation of measurement on July 31, 2014 is 92m, while the other is 51m. Because of wheel slip and idling, the mileage deviations of different curves are different. As shown in Fig.4, two measurements match well with account after the first mileage correction.

In the second mileage correction, the mileage of the chosen measurements is K283+176~ K283+176. Mileage drift is corrected using the gauge of the measurements, as shown in Fig.5 and Fig.6.

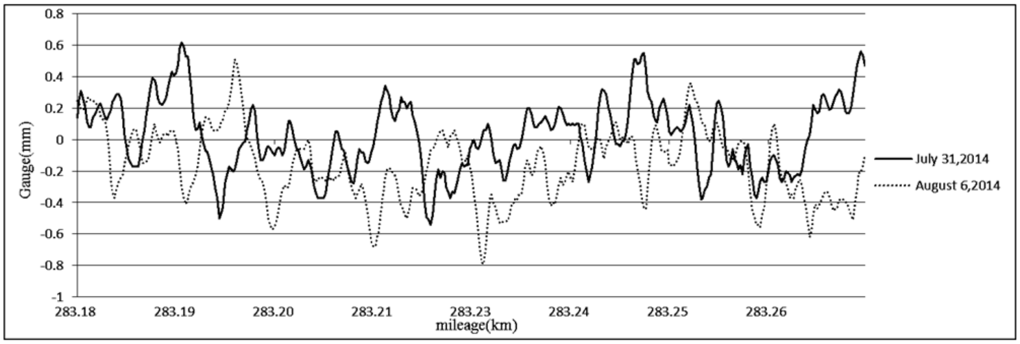

Fig.5 two measurements before the second correction

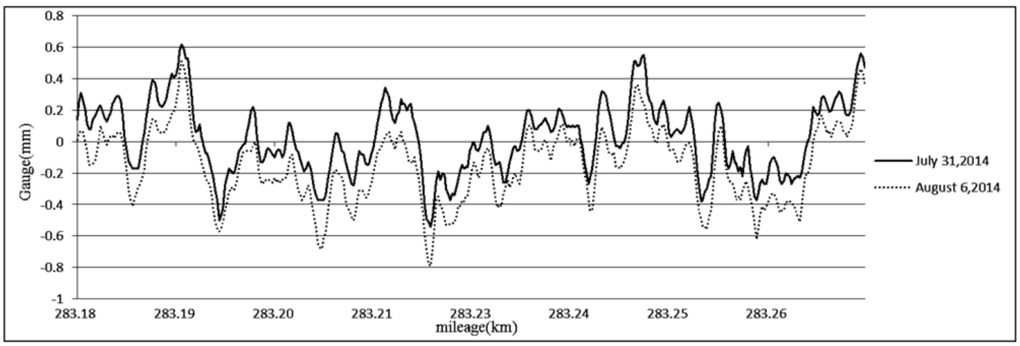

Fig.6 two measurements after the second correction

As shown in Fig.5 and Fig.6, two measurements match well after the second mileage correction, which ensures the accuracy of mileage when analyzing track geometry measurements.

5. Conclusion

For the mileage drift of track geometry measurements, a track geometry state data mileage deviation correction method is proposed. The method is based on curve characteristic parameters and identification of track geometry measurements characteristic parameters. According to several calculation results, a few times of track geometry measurements match better after mileage correction, which shows that the correction method is effective. Thus, this method will be very helpful to guide the maintenance operation, accurately analyze and grasp the development regular of track geometry measurements.

Turnout Geometry Linetype Design System Based on the Plane-Parameter Theory

Yang Cao[1]; Ping Wang[2]; and Peigui Wu[1]

[1]College of Civil Engineering, Fuzhou University, Fuzhou, China. E-mail: hnyccy@163.com
[2]MOE Key Laboratory of High-Speed Railway Engineering, Southwest Jiaotong University, Chengdu, China. E-mail: wping@home.swjtu.edu.cn

Abstract: Besides small radius curves and rail joints, railway turnout is one of the weak parts of railway track structure. Due to its complex geometry linetype, turnout becomes one of decisive factors to define the speed that is possible by means of the diverging route of the turnout. A sophisticated system was developed, which could effectively complete the turnout geometry linetype design and drawing. The foundational theory and the method applied in this system were described and illustrated respectively in this paper, the structure and the functions of this system were explained in detail. This system can achieve the calculation of turnout plane parameters and the drawing of its geometry linetype accurately and rapidly, so it improves the design quality and efficiency greatly.
Keywords: Turnout geometry linetype; Plane parameter theory; Design system; Structure and function.

1 Introduction

Turnout represents one of the important elements of railway infrastructures providing flexibility of the system by enabling railway trains to switch from one track to another at a railway junction. The rapid development of high-speed railway in China demands faster trains, which make turnouts sensitive to kinds of damages and increased maintenance services. Since turnout geometry linetype is the main factor influencing the speed of train passing through a turnout on the divergent route (Lichtberger B., 2005), great efforts should be made to optimize the design method of turnout geometry linetype. Many literatures have researched on the track geometry (Sadeghi J., and Askarinejad H., 2009; Shu X. G., and Wilson N., 2008) and the turnout geometry optimization (Burgarin M. R., Garcia J. M., and Diaz-de-Villegas, 1994; Burgarin M. R., Garcia J. M., and Diaz-de-Villegas, 2002). There are also some researches on track and turnout geometry measurements (Madejski J., 2005; Sadeghi J., Fathali M., and Boloukian N., 2009; Drozdziel J., and Sowinski B., 2002). However, all these studies above did not cover turnout geometry linetype design or provide automated tools to complete turnout geometry draw efficiently. In China the current calculation and draw of turnout geometry linetype depend on designer’s experiences, which is not a standard design method and leads to low efficiency and low precision especially when it is used to design a large number turnout of spiral segment. For these reasons, this paper use an appropriate method to develop the automatic design-draw system of turnout plane geometry, which makes the design work convenient and highly efficient for designers to fulfill.

2 Foundational theory and key technology

2.1 Turnout geometry linetype design

Turnout geometry linetype design includes the following steps: ①Select suitable geometry linetype, calculate the relevant parameters, and make the corresponding limiting value judgment; ②On the basis of information in ①, select a right cutting way for switch rail, a proper crossing type and a suitable sleeper distribution; ③Complete the drawing of the turnout parameters for geometry linetype, uncompensated lateral acceleration and its changing rate of the curve on the divergent track (Shi Y. J., 2001); ④Do the three steps above repeatedly before the geometry linetype design is preferable. The whole design process above provides a premise to realize a more detail design and the general draw of the turnout.

2.2 The geometry linetype selection and design method

Based on different design parameters, curve types of turnout branch can be classified into constant radius curves, clothoids and a combination of these types of curves. Small-size turnouts mainly with constant radius curve and partly with double radii curve can satisfy the safety and comfort when trains pass through turnouts. Compared with the constant radius curve, the spiral segment has some advantages: ①the curvature radius increases with the curve length increasing. Because of this, the uncompensated lateral acceleration and its changing rate descend; ②when train switches between the straight and the divergent track, the centrifugal force, the vertical and the lateral impact forces would not appear or disappear suddenly. In this situation, riding instability is avoided and the vibration is reduced, so the riding comfort is improved. As to large-size turnouts with the speed of 160km/h or more when train passes over turnout branch, the long closure rail makes it possible to apply the spiral segment. So turnouts with circle-spiral segment or spiral segment-circle-spiral segment curves are suggested in the paper.

The circle-spiral segment turnout with the spiral segment is taken as an example to describe its geometry linetype design method. One side of the turnout with circle-spiral segment curve is shown in Figure 1.

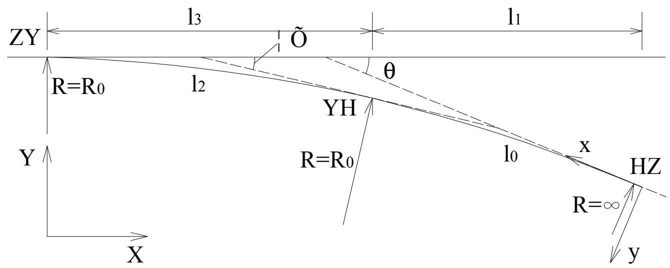

Figure 1. Geometry sketch of the turnout with circle-spiral segment curve

Where θ denotes crossing angle, which is the angle between stock rail and the tangent at point HZ, Φ is the angle between stock rail and the tangent of the constant radius curve at point YH, and is also the one between stock rail and the tangent of the spiral segment curve at the same point YH. R_0 is the radius of the constant radius curve, and is also the radius of the end of the spiral segment. As point ZY coordinate (X, Y) in the integral coordinate axis is (0, Y_0), the coordinate (X_{YH}, Y_{YH}) of point YH on the constant radius curve can be calculated as shown in formula (1).

$$\left.\begin{aligned} X_{YH} &= R_0 \sin\phi \\ Y_{YH} &= Y_0 - R_0\left(1-\cos\phi\right) \end{aligned}\right\} \quad (1)$$

If the length of the spiral segment curve is l_0, a local coordinate axis is established, of which the point HZ is the origin, the upswept direction of the tangent is x axis direction, and the downward direction being perpendicular to the x axis is y axis direction. For the cubic clothoid, the quintic and the septic spiral segment curves, the point coordinates (x_l, y_l) at the end of the spiral segment with the length l in the local coordinate axis are respectively expressed in formulas (2), (3) and (4).

$$\left.\begin{aligned} x_l &= l - \frac{l^5}{40R_0^2 l_0^2} \\ y_l &= \frac{l^3}{6R_0 l_0} \end{aligned}\right\} \quad (2)$$

$$\left.\begin{aligned} x_l &= l - \frac{l_0^3}{2R_0^2}\left(\frac{l^7}{7l_0^7} - \frac{l^8}{8l_0^8} + \frac{l^9}{36l_0^9}\right) \\ y_l &= \frac{l_0^2}{6R_0}\left(\frac{3l^4}{2l_0^4} - \frac{3l^5}{5l_0^5}\right) \end{aligned}\right\} \quad (3)$$

$$\left.\begin{aligned} x_l &= l - \frac{l_0^3}{2R_0^2}\left(\frac{25l^9}{36l_0^9} - \frac{3l^{10}}{2l_0^{10}} + \frac{14l^{11}}{11l_0^{11}} - \frac{l^{12}}{2l_0^{12}} + \frac{l^{13}}{13l_0^{13}}\right) \\ y_l &= \frac{l_0^2}{6R_0}\left(\frac{3l^5}{l_0^5} - \frac{3l^6}{l_0^6} + \frac{6l^7}{7l_0^7}\right) \end{aligned}\right\} \tag{4}$$

When $l=l_0$ in the formulas above, the (x_l, y_l) is equal to the (x_{YH}, y_{YH}), which is the local coordinate of the point YH on the spiral segment. Then by using the crossing angle θ, the (x_{YH}, y_{YH}) can be changed into the integral coordinate axis. Finally, based on the formulas (1) the coordinate of the point HZ is determined as shown in formulas (5). In the integral coordinate axis, the coordinates of all other points on the spiral segment curve can be obtained using the same method mentioned above.

$$\left.\begin{aligned} X_{HZ} &= X_{YH} + (x_{YH}\cos\theta + y_{YH}\sin\theta) \\ Y_{HZ} &= Y_{YH} - |\, y_{YH}\cos\theta - x_{YH}\sin\theta\,| \end{aligned}\right\} \tag{5}$$

The parameters of key points in the turnout geometry linetype are determined based on the formulas above, then select the right switch rail and crossing, and choose a proper layout for turnout sleepers. Finally, draw the foundational geometry linetype with the use of all the data calculated above.

2.3 Case analysis for the turnout geometry design system

Based on the design method, two cases are formulated with the premise whether the turnout number is known or not, the flowchart is shown in Figure 2.

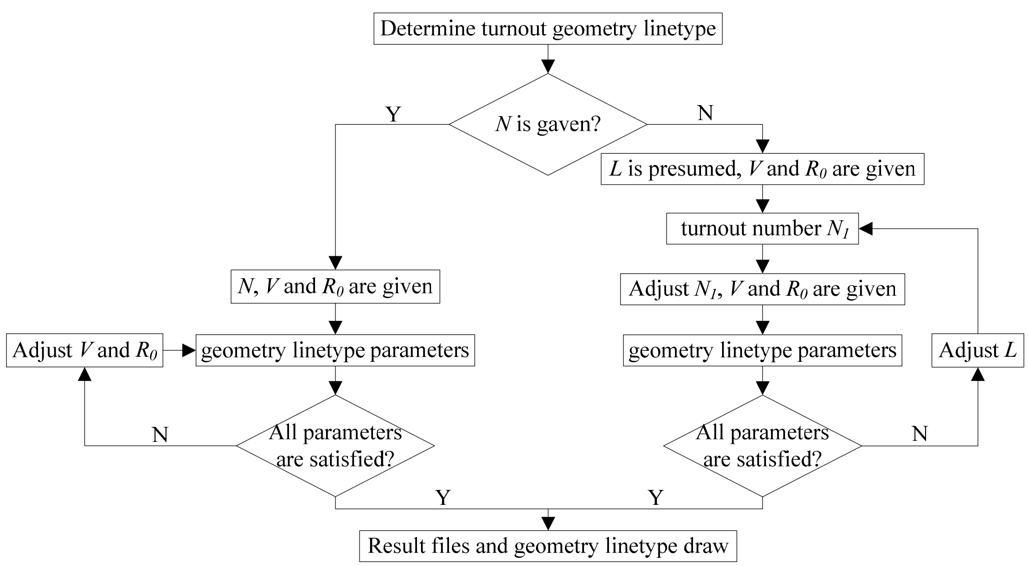

Figure 2. The flowchart for turnout geometry linetype design

(1) If the turnout number is given, the design steps are carried out according to the following steps. Step one: based on the plane-parameter method, all curve parameters involved are obtained on the basis of the speed *V* through turnout branch and the curve radius R_0. Step two: the optimal design could be obtained by evaluating all parameters from adjusting the curve radius, the cutting style of the switch rail, the crossing layout and the turnout sleeper layout. Step three: when all parameters can satisfy the stability, the geometry linetype should be draw in the end.

(2) If the turnout number is unknown, the steps are different from those in (1). Step one: the assumed curve length *L* is given, and then a turnout number is obtained with the consideration of the speed *V* through turnout branch. Step two: based on the turnout number, calculate the corresponding curve length. Step three: adjust the curve length in step two to match to the speed *V*, and then select a right curve radius to calculate a turnout number again. Don’t stop the three steps above until the design can satisfy all the requirements. Finally the geometry linetype is drawn.

3 The system function

The turnout geometry linetype design and draw system consists of the calculation module and the draw module. It can accomplish plane parameters calculation and the geometry draw for various geometries and design demands. The plane parameters are obtained by the calculation module and the results files by the draw module. Then use AutoCAD software to draw the geometry linetype. The details on the function are provided below.

Depending on whether turnout number is given or not, the system can provide geometry linetype designs for turnouts with four kinds of curves including constant radius curve, double radii curve, circle-spiral segment curve and spiral segment-circle-spiral segment curve. Some parameters including turnout geometry, number, or curve length, the radius of constant radius curve, speed through turnout branch, turnout sleeper layout, proper switch rail and nose rail, need be given by Users. According to given parameters and specific track conditions (track gauge, rail size, single crossover zone or not, and so on), the system can deal with the following five terms of work: calculate and check geometry parameters of turnout main and branch; determine switch rail cutting profile and make small-radius-curve track gauge widening design; display switch rail robust of its different parts, turnout sleeper layout; draw turnout plane geometry. The switch rail cutting profiles include five types which are semi-tangent, tangent, semi-secant, secant, and semi-tangent. The turnout sleeper layout involves three kinds which are the straight-line layout, the sector layout, and a layout being vertical to the crossing angle in the crossing zone. All the designs above show that the system provides a highly accurate tool to design and draw turnouts with various numbers and geometry fast and efficiently, which makes it convenient to fulfill turnout details design. The flowchart shown in Figure 3 outlines the steps taken in executing the system functions.

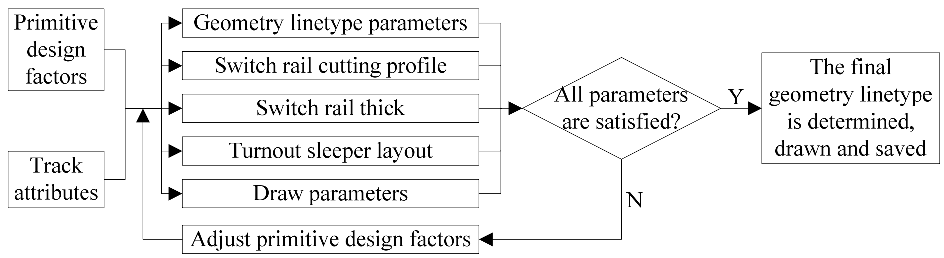

Figure 3. The flowchart of the system function operating

4 Conclusions

This system is an attempt to improve the efficiency of the current design of turnout geometry linetype. Based on plane parameters method, all analytic formulas for a variety of turnout geometry linetype are derived, and then they are solved via computer program according to two cases which are determined depending on whether turnout number is known or not. The plane parameter method is of clear derivation, easy to be grasped, and can meet the required precision of designs with all limiting values for stability design being satisfied. Due to all advantages above, this method is appropriate to be used in the initial design of turnouts.

The system interface is of great availability and high definition. The system involves most turnouts-design functions, of which the Auto draw module is quite useful to improve the efficiency and makes it possible to compare many design cases at the same time. Applied for many times, the system is greatly valuable and meaningful to turnouts design especially to the large-size turnouts with spiral segment curves. The system is a helpful tool to be widely used in turnouts design.

Abstract: In order to realize the transient analysis of track circuits, the general solution of current and voltage of each rail to earth are obtained from the Laplace transform of track circuits transmission equation. In the condition of sending end and receiving end of track circuits with arbitrary impedance, the receiving end current and voltage solution in time domain are obtained by the Laplace inverse transform. With difference of ballast resistance, frequency, transmission distance and signal resource type, the transient response of current and voltage in receiving end are simulated. It shows that the solution in time domain conform to the transmission characteristic of track circuits and provide a novel method to realize transient analysis of track circuits.
Keywords: Track circuits; Transmission equation; Solution in time domain; Laplace inverse transform.

1 Introduction

Most of studies frequently focus on the analysis of the electric quantity of track circuits receiving end in spatial domain, because track circuits operation modes are distinguished by the electric quantity of receiving end. However, when the surroundings of ballast is very bad, such as long tunnel,it is difficult to distinguish the operation modes of track circuits by the electric quantity. when the operation modes of track circuit have changed, actually , the electric quantity of track circuits receiving end transit from transient response to steady response.it is a interesting problem to study whether the operation of track circuits can be differentiated by the transient response. The key to solve this problem is how to get the transient solution of track circuits transmission line equation.

Usually, the transient solution of transmission line equation are got by analytical method and numerical method. Analytical method research is relatively less and most papers use numerical method to solve transmission line equation. Numerical methods is mainly divided into the time domain method and frequency domain method. By discreting spatial and time, the time domain method firstly gets difference equations or ordinary differential equations of transmission line partial differential equation, and the solution is obtained by iterative algorithm. According to complex frequency domain models of transmission line, the frequency domain method firstly gets the general solution of transmission line in complex frequency-domain, and the solution is obtained by inverse fast Fourier transform

(IFFT) or inverse Laplace transform (ILT) .Those methods have complex problem is that different zero and pole points with different load of track circuit make computatial difficult.

For the reason of leakage current existing between rail and earth, track circuits has a certain difference with power transmission line, so we can't adopt the general solution of power transmission line in time domain. As a result, firstly, the general solution of track circuits transmission line equation in complex frequency domain are got in this paper. Secondly, according to boundary conditions of track circuits in normal mode, propagation constant is approximately calculated with Taylor formula, and the solution of convolution type is obtained in time domain. Lastly, with difference initial parameters of track circuit, the simulation proves that this method conforms to transmission characteristic of track circuits. This method does not consider the zero and poles point and suitable for arbitrary loads of track circuit transient analysis.

2 Track circuit transmission equation

Rail line is uniform transmission line, which has two asymmetric leakage current branches. one current branch directly leaks into earth from one rail and the other flows into other rail through ballast. When the basic operation modes of track circuits are analyzed, rail line usually is regard as circuit which is consisted by three wires, two rails and earth. Rail can be regard as longitudinal impedance and mutual inductive reactance , and earth can be regard as wire with big sectional area and zero impedance. Rail line differential equivalent circuits is shown in Figure 1.

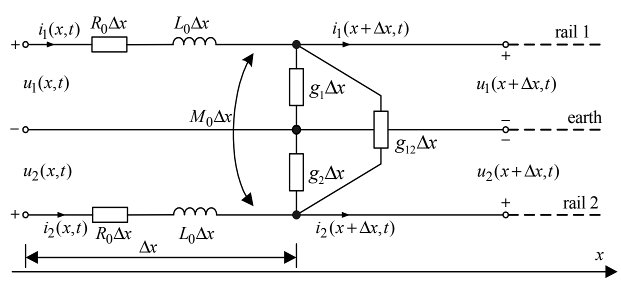

Figure 1. Differential equivalent circuits diagram of rail line

where: R_0 is singnle rail effective resistance, Ω/km ; L_0 is singnle rail internal inductance, H/km ; M_0 is mutual inductance between rail1 and rail 2, H/km ; g_1 is leakage conductance between rail1 and earth, $(\Omega\cdot\text{km})^{-1}$; g_2 is leakage conductance between rail2 and earth, $(\Omega\cdot\text{km})^{-1}$; g_{12} is leakage conductance between rail1 and rail2, $(\Omega\cdot\text{km})^{-1}$; x is the length of track circuit, km ; $i_1(x,t), i_2(x,t)$ are current of each rail to ground, A ; $u_1(x,t), u_2(x,t)$ are voltage of each rail to ground, V .

According to the KVL, the following equations are obtained:

$$u_1(x,t)-u_1(x+\Delta x,t)=\left[R_0 i_1(x,t)+L_0\frac{\partial i_1(x,t)}{\partial t}+M_0\frac{\partial i_2(x,t)}{\partial t}\right]\Delta x \tag{1}$$

$$u_2(x,t)-u_2(x+\Delta x,t)=\left[R_0 i_2(x,t)+L_0\frac{\partial i_2(x,t)}{\partial t}+M_0\frac{\partial i_1(x,t)}{\partial t}\right]\Delta x \tag{2}$$

$$i_1(x,t)-i_1(x+\Delta x,t)=\left\{g_1 u_1(x,t)+g_{12}\left[u_1(x,t)-u_2(x,t)\right]\right\}\Delta x \tag{3}$$

$$i_2(x,t)-i_2(x+\Delta x,t)=\left\{g_2 u_2(x,t)+g_{12}\left[u_2(x,t)-u_1(x,t)\right]\right\}\Delta x \tag{4}$$

Dividing both sides of Eq. 1-4 by Δx ,and when Δx approaches to zero, partial differential equations of track circuits transmission line can be expressed by:

$$\frac{-\partial u_1(x,t)}{\partial x}=R_0 i_1(x,t)+L_0\frac{\partial i_1(x,t)}{\partial t}+M_0\frac{\partial i_2(x,t)}{\partial t} \tag{5}$$

$$\frac{-\partial u_2(x,t)}{\partial x}=R_0 i_2(x,t)+L_0\frac{\partial i_2(x,t)}{\partial t}+M_0\frac{\partial i_1(x,t)}{\partial t} \tag{6}$$

$$\frac{-\partial i_1(x,t)}{\partial x}=g_1 u_1(x,t)+g_{12}\left[u_1(x,t)-u_2(x,t)\right] \tag{7}$$

$$\frac{-\partial i_2(x,t)}{\partial x}=g_2 u_2(x,t)+g_{12}\left[u_2(x,t)-u_1(x,t)\right] \tag{8}$$

Eq. 5-8 are partial differential equations with constant coefficient.Under the certain initial conditions and boundary conditions,the unique solution $u_1(x,t)$, $u_2(x,t)$, $i_1(x,t)$ and $i_2(x,t)$ can be determined. Eq. 5-8can be written to Eq. 9-12 in complex frequency domain:

$$\frac{-\mathrm{d}u_1(x,s)}{\mathrm{d}x}=\left(R_0+L_0 s\right)i_1(x,s)+M_0 s i_2(x,s) \tag{9}$$

$$\frac{-\mathrm{d}u_2(x,s)}{\mathrm{d}x}=\left(R_0+L_0 s\right)i_2(x,s)+M_0 s i_1(x,s) \tag{10}$$

$$\frac{-\mathrm{d}i_1(x,s)}{\mathrm{d}x}=u_1(x,s)\left(g_1+g_{12}\right)-u_2(x,s)g_{12} \tag{11}$$

$$\frac{-\mathrm{d}i_2(x,s)}{\mathrm{d}x}=u_2(x,s)\left(g_2+g_{12}\right)-u_1(x,s)g_{12} \tag{12}$$

The general solution of Eq. 9-12 are as follows:

$$u_1(x,s)=F_1(s)\mathrm{e}^{\gamma_1(s)x}+F_2(s)\mathrm{e}^{-\gamma_1(s)x}+F_3(s)\mathrm{e}^{\gamma_3(s)x}+F_4(s)\mathrm{e}^{-\gamma_3(s)x} \tag{13}$$

$$u_2(x,s)=F_1(s)\mathrm{e}^{\gamma_1(s)x}+F_2(s)\mathrm{e}^{-\gamma_1(s)x}-F_3(s)\mathrm{e}^{\gamma_3(s)x}-F_4(s)\mathrm{e}^{-\gamma_3(s)x} \tag{14}$$

$$\begin{aligned} i_1(x,s)=&\frac{-1}{ZB_1(s)}F_1(s)\mathrm{e}^{\gamma_1(s)x}+\frac{1}{ZB_1(s)}F_2(s)\mathrm{e}^{-\gamma_1(s)x}\\ &-\frac{1}{ZB_2(s)}F_3(s)\mathrm{e}^{\gamma_3(s)x}+\frac{1}{ZB_2(s)}F_4(s)\mathrm{e}^{-\gamma_3(s)x}\end{aligned} \tag{15}$$

$$i_2(x,s)=\frac{-1}{ZB_1(s)}F_1(s)e^{\gamma_1(s)x}+\frac{1}{ZB_1(s)}F_2(s)e^{-\gamma_1(s)x}+\frac{1}{ZB_2(s)}F_3(s)e^{\gamma_3(s)x}-\frac{1}{ZB_2(s)}F_4(s)e^{-\gamma_3(s)x} \tag{16}$$

where: $\gamma_1(s)=\sqrt{ks+b}$, $\gamma_2(s)=-\sqrt{ks+b}$, $\gamma_3(s)=\sqrt{ms+c}$, $\gamma_4(s)=-\sqrt{ms+c}$, $k=(M_0+L_0)g_1$

$b=R_0g_1$, $k=(M_0+L_0)g_1$, $m=(L_0-M_0)(g_1+g_{12})$, $c=R_0(g_1+g_{12})$, $ZB_1=\frac{\gamma_1(s)}{g_1}$, $ZB_2=\frac{\gamma_3(s)}{2g}$, $g=0.5(g_1+2g_{12})=r_d^{-1}$. g is leakage conductance of ballast, $(\Omega\cdot\text{km})^{-1}$; r_d is ballast resistance, $\Omega\cdot\text{km}$. Eq. 9-12 are the general solution of current and voltage of each rail to ground in complex frequency domain.Accoding to the boundary conditions of track circuits operation modes, $F_1(s)$, $F_2(s)$, $F_3(s)$ and $F_4(s)$ can be determined.

3 Complex frequency-domain solution of track Circuits in normal operation

Equivalent mode of track circuits in complx frequency-domain is shown in Figure 2. Two rail sections of length l with arbitrary terminal loads $Z_1(s)$ and $Z_L(s)$ and excited by the source $u_s(s)$.

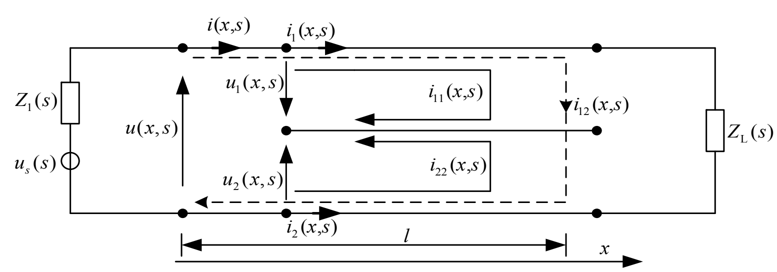

Figure 2. Equivalent mode of track circuits in complx frequency-domain

Based on loop circuit method,the following equation are appropriate for a symmetrical track circuits:

$i_{11}(x,s)=i_{22}(x,s)$; $i(x,s)=i_{12}(x,s)$; $i_1(x,s)=i_{11}(x,s)+i_{12}(x,s)$; $i_2(x,s)=i_{22}(x,s)\quad -i_{12}(x,s)$.

Thus,the $u(x,s)$ and $i(x,s)$ can be expressed as:

$$\begin{cases} u(x,s)=u_1(x,s)-u_2(x,s) \\ i(x,s)=\frac{1}{2}\left[i_1(x,s)-i_2(x,s)\right] \end{cases} \tag{17}$$

Substitution of Eq.13-16 into Eq. 17 yields:

$$\begin{cases} u(x,s) = 2F_3(s)e^{\gamma_3(s)x} + 2F_4(s)e^{-\gamma_3(s)x} \\ i(x,s) = \frac{1}{ZB_2(s)}\left[F_4(s)e^{-\gamma_3(s)x} - F_3(s)e^{\gamma_3(s)x}\right] \end{cases} \tag{18}$$

When $x = 0$,we have

$$\begin{cases} u(0,s) = 2F_3(s) + 2F_4(s) \\ i(0,s) = \frac{1}{ZB_2(s)}\left[F_4(s) - F_3(s)\right] \end{cases} \tag{19}$$

When $x = l$,we have

$$\begin{cases} u(l,s) = 2F_3(s)e^{\gamma_3(s)l} + 2F_4(s)e^{-\gamma_3(s)l} \\ i(l,s) = \frac{1}{ZB_2(s)}\left[F_4(s)e^{-\gamma_3(s)l} - F_3(s)e^{\gamma_3(s)l}\right] \end{cases} \tag{20}$$

According to Figure 2,the following expression are obtained based on KVL:

$$\begin{cases} u(0,s) = u_s(s) - i(0,s)Z_1(s) \\ u(l,s) = i(l,s)Z_L(s) \end{cases} \tag{21}$$

Substitution of Eq. 19 and 20 into Eq. 21 yields:

$$\begin{cases} 2F_3(s) + 2F_4(s) = u_s(s) - \frac{Z_1(s)}{ZB_2(s)}\left[F_4(s) - F_3(s)\right] \\ 2F_3(s)e^{\gamma_3(s)l} + 2F_4(s)e^{-\gamma_3(s)l} = \frac{Z_L(s)}{ZB_2(s)}\left[F_4(s)e^{-\gamma_3(s)l} - F_3(s)e^{\gamma_3(s)l}\right] \end{cases} \tag{22}$$

The solution of Eq. 22 is:

$$\begin{cases} F_3(s) = \frac{n_2(s)k(s)u_s(s)}{e^{2\gamma_3(s)l} - n_1(s)n_2(s)} \\ F_4(s) = \frac{k(s)u_s(s)e^{2\gamma_3(s)l}}{e^{2\gamma_3(s)l} - n_1(s)n_2(s)} \end{cases} \tag{23}$$

where $n_1(s)$ is the incidention coefficient, which is defined as:

$$n_1(s) = \frac{Z_1(s) - 2ZB_2(s)}{2ZB_2(s) + Z_1(s)}.$$

$n_2(s)$ is the reflection coefficient , which is defined as:

$$n_2(s) = \frac{Z_L(s) - 2ZB_2(s)}{2ZB_2(s) + Z_L(s)}.$$

$k(s)$ is defined as:

$$k(s) = \frac{ZB_2(s)}{2ZB_2(s) + Z_1(s)}.$$

Substituting Eq. 23 into Eq. 18 ,we get:

$$\begin{cases} u(x,s) = \dfrac{e^{-\gamma_3(s)x} + n_2(s)e^{-\gamma_3(s)(2l-x)}}{1 - n_1(s)n_2(s)e^{-2\gamma_3(s)l}} \cdot k(s) \cdot u_s(s) \\ i(x,s) = \dfrac{e^{-\gamma_3(s)x} - n_2(s)e^{-\gamma_3(s)(2l-x)}}{1 - n_1(s)n_2(s)e^{-2\gamma_3(s)l}} \cdot \dfrac{k(s) \cdot u_s(s)}{ZB_2(s)} \end{cases} \tag{24}$$

3 Transient Analysis of Track Circuits in Normal Operation

Based on Taylor formula, propagation function $\gamma_3(s)$ and surge impedance can be approximated as:

$$\gamma_3(s) = \sqrt{c}\sqrt{\frac{m}{c}s + 1} \approx \sqrt{c} + \frac{m}{2\sqrt{c}}s \tag{25}$$

$$ZB_2(s) \approx \frac{\sqrt{c}}{2g} + \frac{m}{4g\sqrt{c}}s \tag{26}$$

$Z_1(s)$ can be defined as:

$$Z_1(s) = a + bs \tag{27}$$

$Z_L(s)$ can be defined as:

$$Z_L(s) = a_1 + b_1 s \tag{28}$$

Substituting Eq.25-28 into $n_1(s)$ and $n_2(s)$,respectively, the following explicit formulas for $n_1(s)$ and $n_2(s)$ are obtained:

$$n_1(s) = k_0 \cdot \frac{1 + k_1 s}{1 + k_2 s} \tag{29}$$

$$n_2(s) = m_0 \cdot \frac{1 + m_1 s}{1 + m_2 s} \tag{30}$$

where the following definitions are used:

$$k_0 = \frac{ga - \sqrt{c}}{ga + \sqrt{c}}; k_1 = \frac{2gb\sqrt{c} - m}{2gb\sqrt{c} - 2c}; k_2 = \frac{2gb\sqrt{c} + m}{2gb\sqrt{c} + 2c}; m_0 = \frac{ga_1 - \sqrt{c}}{ga_1 + \sqrt{c}}; m_1 = \frac{2gb_1\sqrt{c} - m}{2gb_1\sqrt{c} - 2c};$$
$$m_2 = \frac{2gb_1\sqrt{c} + m}{2gb_1\sqrt{c} + 2c}.$$

For the convenience of calculation, Eq. 25 can be writed as:

$$\begin{cases} u(x,s) = \dfrac{P_1(s) + P_2(s)}{1 - P_3(s)P_4(s)} \cdot k(s) \cdot u_s(s) \\ i(x,s) = \dfrac{P_1(s) - P_2(s)}{1 - P_3(s)P_4(s)} \cdot k_i(s) \cdot u_s(s) \end{cases} \tag{31}$$

where $P_1(s)=\mathrm{e}^{-\gamma_3(s)x}$, $P_2(s)=n_2(s)\mathrm{e}^{-\gamma_3(s)(2l-x)}$, $P_3(s)=n_1(s)n_2(s)$, $P_4(s)=\mathrm{e}^{-2\gamma_3(s)l}$, $k_i(s)=k(s)/ZB_2(s)$.

When $|\xi|<1$, $(1-\xi)^{-1}=1+\xi+\xi^2+\ldots\xi^n=\sum_{n=0}^{\infty}\xi^n$,due to $P_3(s)P_4(s)<1$, Eq.25 can be expressed as:

$$\begin{cases} u(x,s)=[P_1(s)+P_2(s)]\cdot\left[1+P_3(s)P_4(s)+\left[P_3(s)P_4(s)\right]^2+\ldots+\left[P_3(s)P_4(s)\right]^n\right]k(s)u_s(s) \\ i(x,s)=[P_1(s)-P_2(s)]\cdot\left[1+P_3(s)P_4(s)+\left[P_3(s)P_4(s)\right]^2\ldots+\left[P_3(s)P_4(s)\right]^n\right]k_i(s)u_s(s) \end{cases} \quad (32)$$

According to ILT ,the following inverse Laplace transform pairs exist:

$$P_1(t)=L^{-1}\left[P_1(s)\right]=\frac{1}{2}x\sqrt{m}\pi^{-\frac{1}{2}}t^{-\frac{3}{2}}\exp\left(-\frac{mx^2}{4t}-\frac{ct}{m}\right);$$

$$P_4(t)=L^{-1}\left[P_4(s)\right]=\frac{1}{2}l\sqrt{m}\pi^{-\frac{1}{2}}t^{-\frac{3}{2}}\exp\left(-\frac{ml^2}{4t}-\frac{ct}{m}\right);$$

$$P_3(s)=k_0m_0\left[\frac{1}{(1+k_2s)(1+m_2s)}+\frac{(k_1+m_1)s}{(1+k_2s)(1+m_2s)}+\frac{k_1m_1s^2}{(1+k_2s)(1+m_2s)}\right],$$

$$P_3(t)=L^{-1}\left[P_3(s)\right]=\frac{k_0m_0}{k_2-m_2}\left[(1-\frac{k_1+m_1}{k_2}+\frac{k_1m_1}{k_2^{\,2}})e^{-\frac{1}{k_2}t}-(1-\frac{k_1+m_1}{m_2}+\frac{k_1m_1}{m_2^{\,2}})e^{-\frac{1}{m_2}t}\right];$$

$$n_2(t)=L^{-1}(m_0\cdot\frac{1+m_1s}{1+m_2s})=\frac{m_0m_1}{m_2}\delta(t)-\frac{m_0(m_2-m_1)}{m_2^{\,2}}\left[e^{-\frac{1}{m_2}t}\right];$$

$$P_2(t)=\left[\frac{m_0m_1}{m_2}\delta(t)-\frac{m_0(m_2-m_1)}{m_2^{\,2}}e^{-\frac{1}{m_2}t}\right]*\left[\frac{1}{2}(2l-x)\sqrt{m}\pi^{-\frac{1}{2}}t^{-\frac{3}{2}}\exp\left(-\frac{m(2l-x)^2}{4t}-\frac{ct}{m}\right)\right];$$

$$k(t)=L^{-1}\left[k(s)\right]=\frac{q_0q_1}{q_2}\delta(t)-\frac{q_0}{q_2^{\,2}}\left[(q_2-q_1)e^{-\frac{1}{q_2}t}\right];$$

$$k_i(t)=L^{-1}\left[k_i(s)\right]=\frac{2q_0g}{q_2\sqrt{c}}e^{-\frac{t}{q_2}}$$

Where:

$$q_0=\frac{\sqrt{c}/2g}{a\ +\sqrt{c/g}},\ q_1=\frac{m}{2c},\ q_2=\frac{2gb\sqrt{c}+m}{2ga\sqrt{c}+2c}.$$

As a result, transient solution of Eq.32 are given by the form of convolution:

$$\begin{cases} u(x,t)=[P_1(t)+P_2(t)]*\left[\delta(t)+P_3(t)*P_4(t)+\left[P_3(t)*P_4(t)\right]^2+\ldots\left[P_3(t)*P_4(t)\right]^n\right]*k(t)*u_s(t) \\ i(x,t)=[P_1(t)-P_2(t)]*\left[\delta(t)+P_3(t)*P_4(t)+\left[P_3(t)*P_4(t)\right]^2+\ldots\left[P_3(t)*P_4(t)\right]^n\right]*k_i(t)*u_s(t) \end{cases} \quad (33)$$

In this section, two examples are provides to illustrate the transient solution of track circuits meet the character of track circuits.

Example1:we assume following parameters for track circuits: rail type P_{60} ; $a = 1\Omega$; $n = 3$; $f = 1\text{kHz}$; $b = 1\times10^{-5}\,\text{H}$; $a_1 = 10\Omega$; $b_1 = 2\times10^{-5}\,\text{H}$; $l = 1\text{km}$; $u_s = 10\sin(\omega t)$. With different of ballast resistance, the transient response of current and voltage in receiving end are shown in Figure 3 and Figure 4. With different of frequency, the transient response of current and voltage in receiving end are shown in Figure 5 and Figure 6.

The attenuation constant α and phase constant β are defined as:

$$\begin{cases} \alpha = \sqrt{\dfrac{1}{2\cdot rd}\left(\sqrt{R_0{}^2 + \omega^2 L_0{}^2} + R_0\right)} \\ \beta = \sqrt{\dfrac{1}{2\cdot rd}\left(\sqrt{R_0{}^2 + \omega^2 L_0{}^2} - R_0\right)} \end{cases} \tag{34}$$

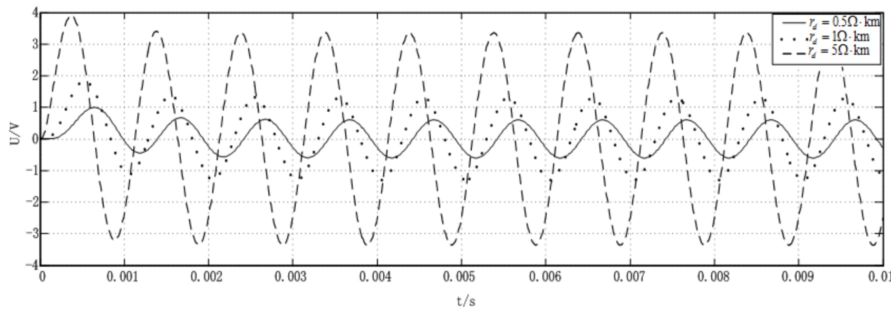

Figure 3. The transient response of voltage in receiving end with different ballast resistances

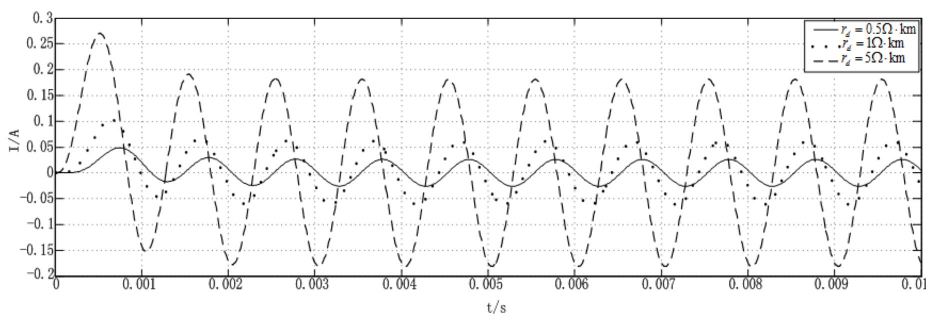

Figure 4. The transient response of current in receiving end with different ballast resistances

From the Eq.34 we know that, when the ballast resistance rd increases, the attenuation constant α and phase constant β decreased. According to wave velocity $v = \omega/\beta$, wave velocity increases with the ballast resistance. The results of Figure3 and Figure4 completely meet this law. Figure 3 and Figure 4 also show that ballast resistance is smaller, the waveform distortion is greater and the steady state response time is longer.

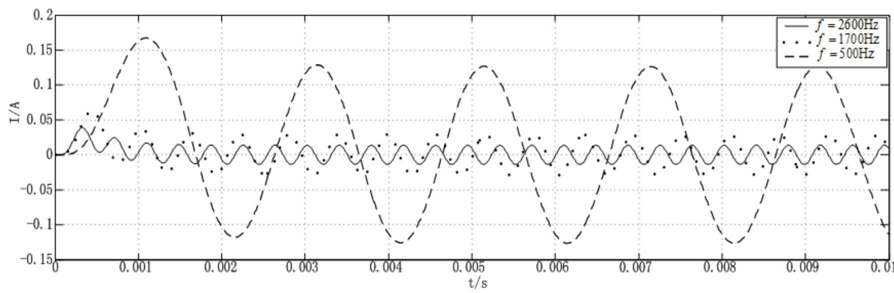

Figure 5. The transient response of voltage in receiving end with different of frequency

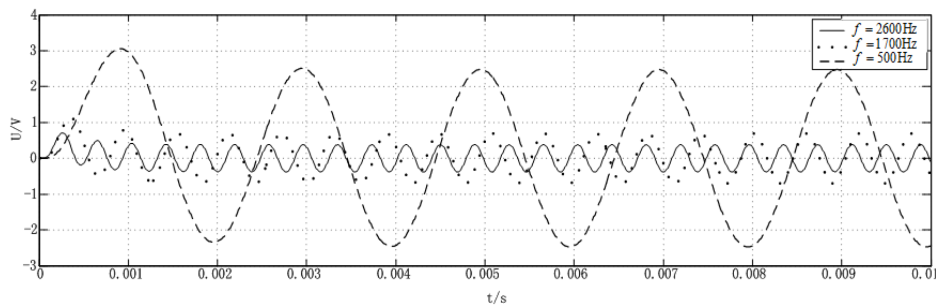

Figure 6. The transient response of current in receiving end with different of frequency

According to Eq.34 ,with the increasing of frequency, the attenuation constant α increase,and the results of Figure 5 and Figure 6 completely meet this law. Figure 5 and Figure 6 also show that frequency is higer, the waveform distortion is smaller and the steady state response time is longer.

Example2:we assume following parameters for track circuits: rail type: P_{60} ; $a = 1\Omega$; $n = 3$; $b = 1\times10^{-5}\,\mathrm{H}$; $a_1 = 10\Omega$; $b_1 = 2\times10^{-5}\,\mathrm{H}$; $l = 1\mathrm{km}$; $f = 1\mathrm{kHz}$; ballast resistance $1\Omega\cdot\mathrm{km}$.

The resouce is rectangular pulse signal shown as Figure 7 .With different of ballast resistance, the transient response of voltage in receiving end and middle are shown in Figure 8.

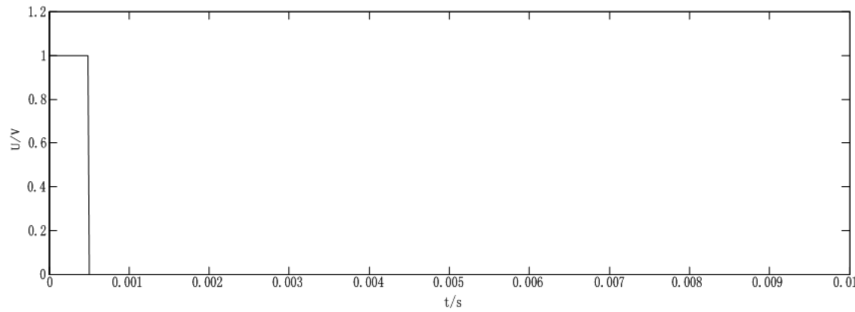

Figure 7. Rectangular pulse signal

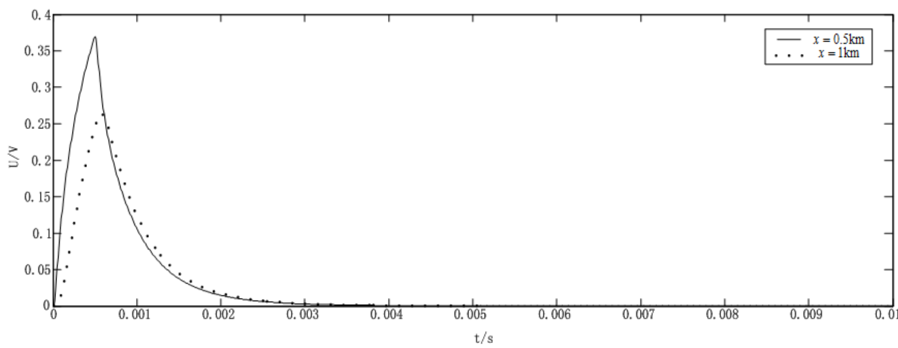

Figure 8. The transient response of rail surface voltage in different points

In the process of voltage wave transmission from middle of track circuits to receiving end, we note that the waveforms of voltage is distorted and attenuate by examining Figure 8.

Example1 and example2 prove that solution in time domain conform to the transmission characteristic of track circuits.

4 Conclusions

The general solution of current and voltage of each rail to ground are obtained from the Laplace transform of track circuits transmission equation，when sending end and receiving end of track circuits load arbitrary impedance,and the solution in time domain of current and voltage of rail surface in receiving end are obtained.At the same time,the following conclusion are valide:

(1) Wave velocity of current or voltage increases with the ballast resistance.

(2) If ballast resistance is smaller, the waveform distortion is greater and the steady state response time is longer.

(3) If frequency is higer, the waveform distortion is smaller and the steady state response time is longer.

(4) rectangular pulse signal has heavily distorted and attenuate.

(5)The simulation conform to the transmission characteristic of track circuits, which prove that this method is suitable to analyze trancient of track circuits.

Abstract: In accordance with the theory of accident cause and system safety, this paper systematically analyzes various risks in subway station construction and divides them into four categories. They are: (1) risks of construction environment (including architectural complex environment, hydro-geological environment, meteorological environment, traffic flow, etc.); (2) risks of construction technique (including deformation monitoring, special safety program, safety disclosure, etc.); (3) risks of construction organization (including personnel, safety system, safety mechanism, safety culture, etc.); (4) special risks (including template, scaffold, support, electricity, hoisting, towering machine, etc.). Moreover, the paper analyzes and determines the methods and standards to judge the severity level (including slight, great, serious, very serious, and disastrous) and probability level (including very likely, likely, occasional, unlikely, and very unlikely), to research the method of calculating every single risk value r_i through consequence rating a_i and probability rating f_i of each risk accident. On this basis, it considers using risk weight (w_{Ri}) and expert weight (w_{Ei}) for comprehensive evaluation of project risks. Additionally, the paper explores the method of applying the results of project risk evaluation and studies reasonable application of the project's single risk ranking management, dynamic management of risks, and integrated assessment value of risks. By taking People's Square Station of Metro Line 1 in Shijiazhuang City, Hebei Province, China for example, the paper applies expert scoring method and analytical calculation method to analyzing single risk and evaluating the project's comprehensive risks, which is of great significance to safety management and risk control in similar subway station constructions.
Keywords: Subway station; Construction risks; Fuzzy evaluation; Risk weight.

1 Research Background

With the rapid development of Chinese economy and society, traffic congestion and air pollution problems have become more and more serious. In order to improve the traffic environment, many cities have begun to develop subways since last ten years , among which subway stations are the key project. The stations are places where passengers take public vehicles and transfer, so they are generally located in a bustling center of the cities and many of them are constructed beside intersections. Normally, the stations are large-scale projects and the nearby buildings and underground utilities are complex and mixed. In addition, the engineering geology and hydrogeological conditions are unstable, and the constructions involve complex conditions and the schedules are usually tight. All these increase the safety risks. Therefore, it is of significant importance to monitor and detect the safety risk during construction process of subway stations.

2 Analysis of Risk Source

According to accident causation, the risks of transfer station with complex conditions are divided into four types: environment risk, technical risk, organization risk and special risk.

(1) Surrounding environment risks: including risks of neighboring building (structure) damage, adjacent utility damage, hydrogeological risks, weather conditions, traffic dynamic load risk and risks of interference. We can use quantitative analysis and expert assessment method to rank the risk consequence(Luo Furong,2011).

(2) Technical risk: including risks related to safety plans, monitoring and excavation. We can apply quantitative analysis and expert assessment method to rank the risk consequence(Liang Qinghuai et al.,2012).

(3) Organization risks: including risks related to personnel, security system, security organizations, security culture construction, security disclosure, supervision and implementation. We can adopt expert assessment method to rank the risk consequence.

(4) Special risks: include risks of special operations, special equipment and other possible risks, involving risks related to template, operations high above the ground, scaffolding, temporary power, crane operation, towering equipments, man-made digging and temporary projects. Analyses and evaluation made by experts can be used to rank the risk consequence.

3 Individual Risk Consequence Severity Rating and Hierarchical Control

3.1 Individual Risk Assessment Method

Severity of each risk factor is analyzed and scored by invited experts (slight, larger, serious, very serious or catastrophic),then the possibility of accident induced by each risk is given （very likely, likely, occasional, unlikely or impossible). For each risk, its risk value can be assessed according to accident result and occurrence ranking and added value of ranked risks and accident probability as follows:

$$r_i = a_i f_i + S_c(a_i) + S_P(f_i) \quad (1)$$

Where r_i ---- The evaluation vale of risk *i*.

a_i ----- The consequence grating of risk *i*; it is zero when there is no consequence.

f_i ----- The probability grating of risk *i*.

$S_c(a_i)$ -----The added value of risk *i* accident consequence, and this coefficient is the dependent variable of accident consequence grading.

$S_c(f_i)$ ------ The added value of risk *i* accident probability, and this coefficient is the dependent variable of accident probability grading.

3.2 Identification of Added Value of the risk

AHP method is used to identify the risk grating added-value of accident consequence and risk grating added-value of accident probability. Questionnaires were sent to 22 experts and 15 were returned and used for further analysis. Reconsidering all the risk values, the probability accident occurrence was rated by five levels: "slight", "large", "serious" and "very serious" and "catastrophic" and the corresponding value is 0, 0.97, 2.97, 6.07 and 9.97. Since the values of accident occurence and probability should be integer, which makes the calculation easier, the approximate value of risk grating added-value of accident consequence will be 0, 1, 3, 6 and 10 respectively. The accident probability grating consists of five levels: "impossible", "very unlikely", "accidental", "likely" and "very likely", and the corresponding added-value is 0, 0.93, 2.83, 5.87 and 9.8 and also the approximate value will be 0, 1, 3, 6 and 10, respectively.

3.3 Method to Identify the Weighted Average Value of Individual Risk

The risk evaluation values given by experts are different. When calculating one individual risk, therefore, expert weights (w_E) should be taken into consideration, and adopt weighted average valueis used here, as: :

$$R_i = \sum_{j=1}^{m} (w_{Ej} r_{ij}) \tag{2}$$

where, j ---the number of expert;

m ---the number of experts.

R_i --- weighted average value of risk *i*.

r_{ij} ---the evaluation value of risk *i* given by No. *j* expert.

w_{Ej} ---the importance of No. *j* expert in the comprehensive evaluation of project risk.

$$\sum_{j=1}^{m} w_{Ej} = 1$$

3.4 Hierarchical Control of Individual Risk

As obtaining the above mentioned results, risk values can be calculated, , as shown in Table 1.

In the Table 1, the oblique line (for the risk value 1 and 3) stands for low risk that can be ignored and no measures need to be taken. The dark graticule line (the risk value is 6 and 10) represents moderate risk that can be acceptable. Generally no measures need to be taken but risk control and monitoring is needed. The diagonal graticule line (the risk value is 15 and 21) indicates high risk that should be avoided. Monitoring measures must be taken to prevent this type of risk, and the risk-control cost should not be higher than the post-risk damage. The lower oblique line (the risk value is 28, 36 and 45) stands for an extremely high risk that is unacceptable. Effectivemeasure should be taken to avoid this type of risk. Otherwise, measure will have to be taken at all loss to reduce this type of risk to undesirable scale.

Table 1. Parameter for Risk Value Calculating

Consequence Rating / Probability Rating		Slight	Large	Serious	Severer	catastrophic	Added-value of Risk Probability
		1	**2**	**3**	**4**	**5**	
Very Likely	**5**	15	21	28	36	45	**10**
Likely	**4**	10	15	21	28	36	**6**
Occasional	**3**	6	10	15	21	28	**3**
Unlikely	**2**	3	6	10	15	21	**1**
Impossible	**1**	1	3	6	10	15	**0**
Comprenhensive risk level		**0**	**1**	**3**	**6**	**10**	

According to the risk value in Table 1, the following suggestions can be presented for safety consideration: when $R_i \le 3$, it is considered low risk; when $3 < R_i \le 10$, it is regarded as a moderate risk; when $10 < R_i \le 21$, it is considered high risk; when $R_i > 21$, it is regarded as high risk. In practical operation, when we evaluate the risk value, we can control the risk according to the standard in Table 1, thus enabling hierarchical management of individual risk.

4 Project Risk Comprehensive Evaluation and Dynamic Integrated Control

The stations, building structure, surroundings and construction technologies on the same subway line are often quite different from each other. For the sake of comprehensive evaluation of risk, unified evaluation method and indicators should be applied. This paper suggests using three indicators to have a comprehensive evaluation of the risks: average risk evaluation value $\overline{R}$, high risk rate P_{hr}, and extremely high risk rate P_{hrst}.

Average risk evaluation value:

$$\overline{R} = \frac{\sum_{i=1}^{N} R_i}{N} \tag{3}$$

where N—— The sum total of project risks.

i—— The serial number of risks.

R_i—— The weighted evaluation average of risk i.

High risk rate

$$P_{hr} = \frac{N_{hr}}{N} \quad \text{formula (4)}$$

where N—— The sum total of project risks.

N_{hr}—— The number of high risks.

Extremely high risk rate

$$P_{hrst} = \frac{N_{hrst}}{N} \quad \text{formula (5)}$$

where N—— The sum total of project risks.

N_{hrst}—— The number of extremely high risks.

The evaluation indicators above are for wholeness evaluation and can be used as the basis for strengthening security management. According to the three indicators, the employer and supervision unit can pay close attention to the examination and supervision of the items with higher risks. With the progress of the project, the risks are changing, so are the probability and severity. After effective risk management measures, the original risks can be controlled, but new risks may appear. Therefore, dynamic risk assessment and management is necessary during the construction process (Wang Fan,2013).

5 Case of Fuzzy Evaluation

As one of major stations of Subway Line 1, the Remin Square Station, is located at the intersection of East Zhongshan Road and Jianshe Road in Shijiazhuang, China. Passengers from Subway Line 1 can transfer to Subway Line 2 at this station. The layout of this station is the shape of "L" and the underground structure is shape of rectangle. A commercial area lies to the northeast of the crossroad and there is a two-layer frame structure underground. The main structure is underground and adopts cover-excavation method. This stations is located on loess-like silty clay, loess-like silt and sand bed. The underground water level is lower below the baseboard, so no lowering of watertable. The East Zhongshan Road and Jianshe Road are located at the heart of the city, where there is huge traffic flow and traffic jam and the bounding wall may influence the traffic. The layouts of the neighboring facilities are complicated and the foundation trench may cause deformation of the neighboring buildings. There are underground structures, pipelines, rain rills, sewers, water pipes, communication pipes and heat distribution pipelines in the construction area. So any improper operation may cause damage to these facilities. As for the special conditions mentioned above, expert survey (involving 24 sources of risk) was designed and five experts were invited to evaluate the risks. The evaluation results were averaged, as shown in Figure 1.

Figure 1 shows that the weighted average of the hydrogeological risk evaluation is 1.4, within the range between 0 and 3, indicating a low risk; the weighted average evaluation values of the risks of weather conditions, damage of neighboring pipelines, safety tests, and special security programs, nearby road surface, personnel safety and safety organization are 5.4、8.0、8.0、8.8、9.0、9.0、9.2 respectively, within the range (3,10], suggesting moderate risk; the weighted average evaluation values of the risks of traffic dynamic load, temporary electricity utilization, safety culture construction, aerial operation, scaffold utilization, temporary project, damage of neighboring buildings (structures), construction interference and implementation are 10.6,11.0,11.7,17.0 , 17.0,18.0,19.2,21.0 and 21.0 respectively, within the range (10, 21], suggesting high risk; the weighted average evaluation values of the risks of security system risk, project supervision, templates, excavation of foundation pit and supporting techniques, lifting operation, deformation supervision and aerial equipments are 21.5,22.7,22.7,25.5,26.9,32.0 and 38.9 respectively, which are greater than 21, suggesting high risk. According to the evaluation results above, the construction unit can carry out level-to-level management of each individual on the basis of its risk rating.

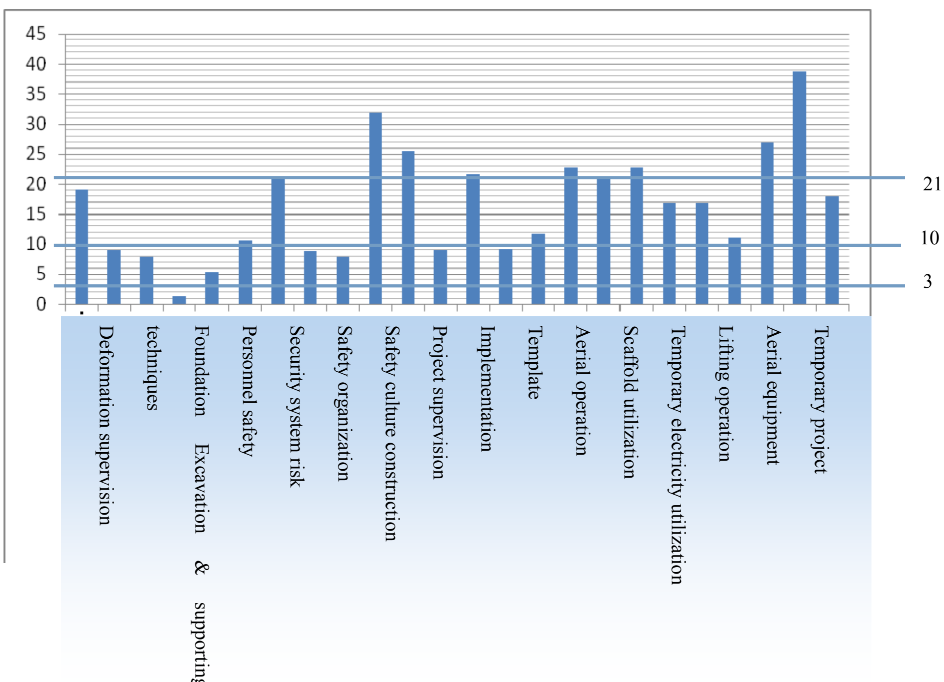

Figure 1. Bar Chart of Average Value of Individual Risk Evaluation at Renmin Square Station

4 Conclusions

This paper has proposed the concept of added value of consequences of the accident risk and the concept of added value of accident probability risk for the first time in the world, and that its calculation method are discussed in this paper.

The above method was used to risk assessment and management in construction of People's Square Station of Metro Line 1 in Shijiazhuang City, Hebei Province, China. It realizes that risk is always controllable, and that accidents always can be prevented, which is of great significance to safety management and risk control in similar subway station constructions.

Influence of Shield Tunnel Construction beneath a Railway on a Culvert-Embankment Transition Zone

Yao Shan; Shunhua Zhou; Quanmei Gong; Binglong Wang; Yao Shu; and Zhiguo Zhao

Key Laboratory of Road and Traffic Engineering, Ministry of Education, Department of Urban Rail Transit and Railway Engineering, Tongji University, Shanghai, China.

Abstract: Since the uneven settlement and the variation of the track stiffness are inherent problems of transition zones, the construction of the shield tunnel in the vicinity of the transition zone may aggravate the track geometry deterioration, maintenance demand and poor ride quality. In view of the importance of the problem, the influence of the shield tunnel construction on the subgrade uneven settlement is investigated. Results show that the reinforce treatment of the foundation is required and the recommended treatment measure is appropriate to control the uneven settlement of the subgrade in the vicinity of the transition zone.
Keywords: Transition zone; Shield tunneling; Uneven settlement.

1 Introduction

Transition zones between railway tracks on embankments and structures are often associated with accelerated rates of geometry deterioration, high maintenance demand and poor ride quality (Read and Li, 2006). These problems may be aggravated by the construction of the shield tunnel beneath the transition zone. Nowadays the expansion of the city rail transit leads to more and more constructions of the metro shield tunnel beneath existed railway lines. When they are constructed in the vicinity of the transition zone, the influence will be not only on the track geometry deterioration, but also on the safety of the substructure such as bridges or culverts.

The construction of the shield tunnel will inherently lead to the disturbance of the surrounding soil e.g. the ground loss, the variation of the pore pressure and the redistribution of the soil initial stress. As a result the equilibrium state of the surrounding soil is destroyed and the deformation of the ground surface appears. The beginning of the study on the ground deformation induced by shield tunnel constructions is Peck formula (Peck, 1969) summarized from in site observations. Based on the work of Peck some revision of the parameters (Mair et al., 1993, Attewell and Selby, 1989) were carried out and new empirical formulas (Sagaseta, 1987) were put forward. Furthermore, analytical and semi-analytical methods are also widely employed to investigate the stratum displacement induced by the excavation of the shield tunnel. Most of these methods are based on cavity expansion theory (Verruijt and Booker, 1996).

With the development of computer technologies, the complicated influence of the shield tunnel excavation on the deformation of structures and soils can be investigated by numerical simulation methods. Compared with the empirical formulas and analytical methods, more comprehensive effect parameters of the shield tunnel excavation can be considered by the numerical simulation method e.g. finite element method and finite difference method. Mroueh and Shahrour (2003) investigated the interaction between tunneling in soft soils and adjacent structures with FE method. Gong et al. (2014) evaluated the safety of the elevated high-speed railway influenced by the excavation of the nearby shield tunnel with a 3D FE model. With the similar numerical simulation method Huo et al. (2011) investigated the characteristics and control technologies of the deformation of the existed railway tracks influenced by the construction of the metro tunnel beneath them. Although numerous research works have been taken to investigate the railway substructure deterioration and the subgrade settlement induced by the shield tunneling beneath the railway track, surprisingly little research has been carried out to identify the influence on the transition zone. In this paper this issue is investigated based on a project of a metro shield tunnel constructed beneath a culvert-embankment transition zone.

2 Background

The double line of shield tunneling of Metro line 2 in Hangzhou is planned to be constructed beneath an existed railway line (see Fig. 1 and Fig. 2). The double metro lines are almost perpendicular with the existed railway line as shown in Fig. 1. The intersection angle is 92 degree and the position of the intersection is in the vicinity of a railway culvert. The buried depth of the tunnels is 16.84m. In this section the tunnels are constructed in the silt clay layer and the clay layer (see Fig. 2). The distance between centers of these two tunnels is 12m and the smallest distance between the tunnel and the culvert is 10m as shown in Fig. 2. The external and the inner diameters are 6.2m and 5.5m, respectively. The double tunnels are entitled as left line and right line, respectively (see Fig. 2). The left line will be constructed earlier than the right line and the excavation direction of them is from west to east.

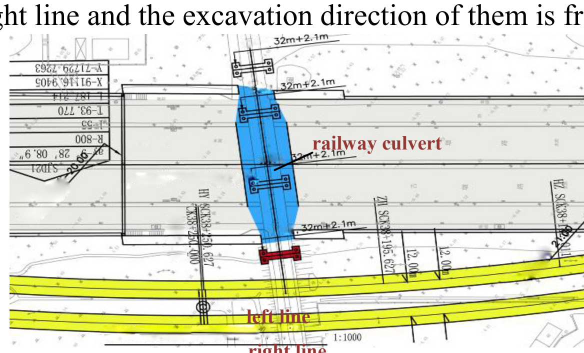

Figure.1. Top view of the intersection section

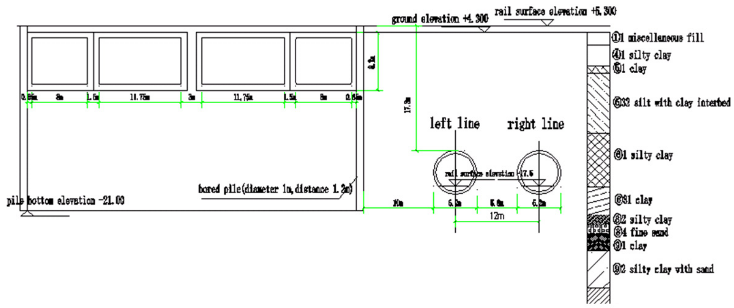

Figure.2. Cross section of the shield tunnel

In order to investigate the deformation of the transition zone induced by the shield tunneling, a steady-state analysis is taken by a 3D FE model (Shan et al., 2013).

3 Model

A 3D FE model is employed. The length, the width and depth of the model are 160m, 100m and 50m, respectively. The material model of the soil is hardening soil model. For the culvert, tunnel segment and piles the linear elastic model is implemented. The culvert, segment and the pile are simulated by plate element. The subgrade filler and soils are simulated by solid elements. In order to simulate the interaction of the soil and the structure, contact elements are employed on the interface between soils and structures. The origin of coordinate lies in the connection of the culvert and the transition zone as shown in Fig. 3. The coordinate axes X, Y, Z represent the longitudinal, transverse and vertical direction, respectively (see Fig. 3). Material parameters are shown in Table 1.

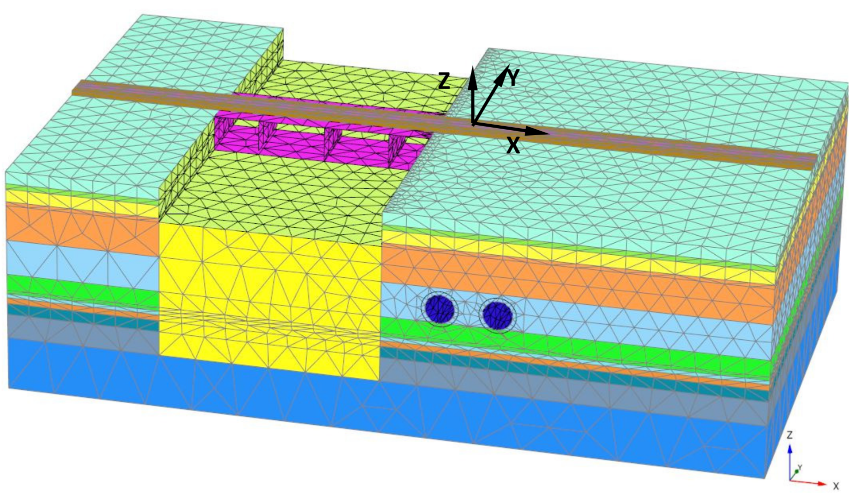

Figure 3. Finite element model the intersection section

Table 1 Material parameters

stratum	density (kN/m^3)	cohesion (kPa)	internal friction angle	Young 's modulus (Mpa)	Poisson ratio
①1 miscellaneous fill	1850	9	18.5	18	0.23
④1 silty clay	1750	9.5	12	8.4	0.4
⑤1 clay	1940	35.4	15.3	27	0.33
⑤32 silt with clay interbed	1900	10	25	15	0.28
⑥1 silty clay	1780	13.5	12.5	22.8	0.41
⑥31 clay	1790	15	12	24	0.4
⑧2 silty clay	1880	25	16	42	0.35
⑧4 fine sand	2000	1	20	78	0.26
⑨1 clay	1940	40	15	72	0.31
⑨2 silty clay with sand	1960	6	30	66	0.31

4 Boundaries and load conditions

Nodes on the bottom surface of the model are fixed. For the nodes on the side surfaces, the displacement of the x and y directions are fixed only the z direction is free.

The load conditions are shown in Fig. 4 which is employed as the design criteria of the new constructed railway track. The load distribution is transformed into uniform load on the ballast surface in this simulation.

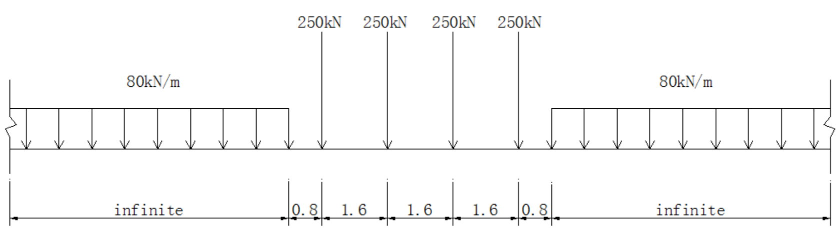

Figure 4. Train load

5 Calculation process and results

With the 3D FE model the excavation of the soil, the segment installation and the tail void grouting are simulated. The length of the excavation for each calculation step is 1.2m, which is equal to the length of a ring of segments. Step by step the whole process of the shield tunneling under-crossing the existed railway line can be simulated. For each calculation step the soil and structure deformations can be obtained. In order to investigate the most significant influence of the shield tunneling on the deformation of the transition zone, 8 key calculation steps are chosen following the planned construction sequence listed in Table 2.

Table 2. Construction steps

	construction of the left line
step 1	shield machine arrives at the west edge of the railway subgrade
step 2	shield machine arrives at the region under the subgrade
step 3	shield machine arrives at the east edge of the railway subgrade
step 4	construction of the left line is complete
	construction of the right line
step 5	shield machine arrives at the west edge of the railway subgrade
step 6	shield machine arrives at the region under the subgrade
step 7	shield machine arrives at the east edge of the railway subgrade
step 8	construction of the right line is complete

With the stratum loss rate of 0.8% the railway subgrade surface displacement as a function of the x coordinate is shown in Fig. 5. For each construction step a settlement curve can be observed. These settlement curves are not strict symmetry as classical empirical Peck curve. For the construction steps of the left tunnel, the largest settlement point of the subgrade surface appears above the center of left tunnel cross section. With the construction of the right tunnel, the largest settlement point of the settlement curve move to the middle between the left line and the right line step by step. For each settlement curve, the most abrupt change of the settlement appears in the first 10m from the connection between the culvert and the subgrade. The slop of the settlement curve in this area is larger than that of other sections due to the existence of the culvert structure.

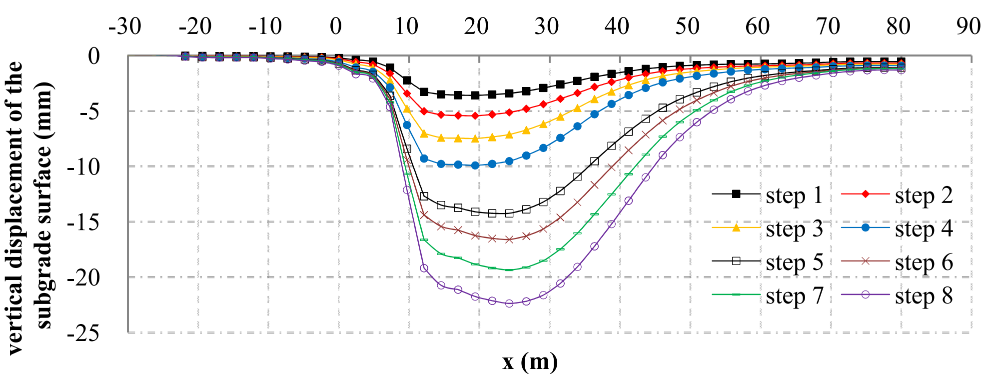

Figure 5. Railway subgrade surface displacement induced by shield tunneling

Fig. 5 shows that during the construction of the tunnels the largest settlement of the subgrade surface is 22.1mm, which is larger than the critical value of the largest subgrade settlement in the standard. Since the normal speed of the shield tunneling is

7.2m/24h, the maximum subsidence rate of the subgrade surface is 6.3mm/24h, which also exceed the required value of the standard. Consequently, in order to meet the requirement of the subgrade surface settlement signed in the standard as well as the subsidence rate, reinforcements of the transition zone should be designed and recommended.

The grouting reinforcement is recommended in the culvert-embankment transition zone. As illustrated in Fig. 6 the grouting reinforcement area can be divided into the main reinforcement zone and the secondary reinforcement zone by chemical churning piles. The reinforced vertical distance of piles is from ground surface to the bottom of the stratum ⑧$_{2}$ silty clay. The piles reinforcement zone is composed of 5 rows of piles with the diameter of 0.8m and the interlock amount of 0.2m (see Fig. 6). The function of piles reinforcement zones is to ensure the reinforcement quantity of the main reinforcement zone, which is reinforced by grouting method between the piles reinforcement zones. From the bottom of stratum ⑤$_{1}$ clay, which is 5m beneath the rail, to the bottom of stratum ⑥$_{31}$ clay (see Fig. 6). The distance between the piles and the center line of the railway is 10 meter. Two secondary reinforcement zones are constructed outside chemical churning piles with the same reinforce deepness of the main reinforcement zone.

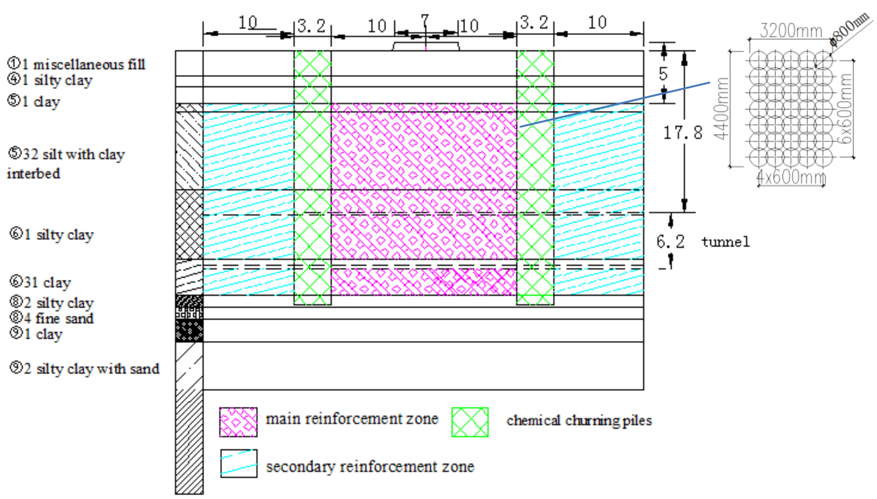

Figure 6. Grouting reinforcement

After the reinforce treatment the maximum deformation of the subgrade surface during the shield tunneling is 7.3mm and the subsidence rate is 1.5mm/24h. Compared with the critical value listed in the standard with 10mm for maximum settlement and 4mm/24h for limited subsidence rate, respectively, the reinforce treatment recommended is appropriate to control the uneven settlement of the subgrade in the vicinity of the transition zone.

6 Conclusions

The influence of the construction of shield tunnels beneath a culvert-embankment transition zone on the uneven settlement of the subgrade is investigated by FE method. Three conclusions can be drawn:

1) For each construction step the settlement curve is not symmetry as classical empirical Peck curve due to the existence of the culvert structure. The most abrupt change of the settlement appears in the first 10m from the connection between the culvert and the subgrade.

2) With the stratum loss rate of 0.8%, the largest settlement of the subgrade surface is 22.1mm and the maximum subsidence rate of the subgrade surface is 6.3mm/24h. They are larger than the critical value listed in the standard.

3) In order to meet the requirement of the standard, a reinforce treatment of the transition zone is recommended. Results showed that the recommended treatment is effective to control the uneven settlement of the subgrade in culvert-embankment transition zones.

Abstract: Build a dynamic analysis model about the coupling system of the vehicle and the underframe suspension structure. Different combination methods are employed in order to analyze the random vibration of the interior suspension structures of underframe structure, then 2 kinds of analysis model are built: the first one is the traditional analysis model of which elastic combination is ignored between the interior suspension structures, the combination are considered to be rigid combination; the second one is the model of which elastic combination is considered between interior suspension structures. In this paper the example is a structure of the traction converter under the car-body of high-speed train and the eccentric load of the electric machine installed in the structure of the traction converter is simplified and applied on the rotor spindle of the electric machine. The railway vehicles accurate random vibration analysis method is employed to analyze the random vibration on the 2 kinds of the analysis model. Calculated results indicated that the stress of the traction converter mainly focus on 3 frequency band that are 2Hz, 6Hz and 60Hz, correspond respectively the mainly vibration frequency of the car-body, rigid-body vibration frequency of the traction converter caused by the suspension stiffness between the car-body and underframe and the basic frequency of the eccentric load of the electric machine which is considered as the most significant impact. As the rubber damper is employed at the combination between the suspension steel beam and case in the traction converter the dynamics index of vibration and stress of the first one is superior to the second one which the rigid combination is employed and the impact caused by the eccentric load of the electric machine is obvious attenuated.
Keywords: Underframe equipment; Suspension method; Traction converter; Random vibration; Random stress.

At present, the underframe equipment is mostly suspended under the car-body of the high-speed train. In order to reduce the impact of the underframe equipment to the car body vibration, the elastic damping system is employed on the most high-speed train. The underframe equipment as an important part of the vehicle is also affected by the vibration of the running vehicle, especially the vibration will be more intense when the vehicle runs at high-speed. The underframe equipment should be also received enough attention when the researchers focused on the stability and the reliability of high-speed running vehicle, because it not only affect the performance of the equipment and the fatigue life of the structure, but also feeds back to the car body, affect the comfort of the passengers and even damage to the structure of the car body.

At present the research on the dynamics of coupling system between underframe equipment and car body generally based on the rigid-flexible coupling dynamic model, the structure of car body and bogie are considered as the flexible body, the structure of car body is mainly simplified as Euler-Bernoulli Beam or Timoshenko Beam, the underframe equipment and the wheelset are all simplified as the rigid body, then the rigid-flexible coupling dynamic model of the vehicle is built for the modal analysis(Yu, 2012. Yang, 2012) or the vibration analysis(Wu, 2012. Gong, 2011). Based on the analysis, in order to provide reference for the related design or optimizing of the underframe equipment, the vehicle dynamics performance is affected by underframe equipment distribution, suspension structure, suspension method, suspension stiffness and damp, other related parameter and so on is researched. The vibration of underframe equipment has been more and more attention due to the complexity of underframe equipment and the increase of vehicle speed, but the vibration of the interior structure of the underframe equipment couldn't be analyzed by the aforementioned research.

In this paper the railway vehicles accurate random vibration analysis method is employed. The car body of the high-speed train and the underframe equipment are considered as two separate parts, based on each finite element model instead of the beam structure that is the car body simplified and the rigid body that is underframe equipment simplified. Then Build a dynamic analysis model about coupling system of vehicle and underframe suspension structure. The simplified eccentric load of the electric machine which installed in the structure of the traction converter is applied on the rotor spindle of electric machine. The random vibration is analyzed by the different suspension methods between the interior suspension structures of the underframe structure and then the stress is also analyzed, so that the random vibration and the stress of interior suspension structures can be understood. As the vehicle run at high speed the dynamics performance of the coupling system of the vehicle and underframe structure and the coupling system of the interior structures of the underframe structure under the random vibration conditions can be simulated more accurately by the method which is employed in this paper, thus a number of references about the design and the simulation of the underframe structure are provided.

1 The Analysis System of Random Vibration of Car Body And Underframe Structure

In this paper the underframe structure is considered as one separate body. To build the accurate analysis coupling system of the random vibration of the car body and the underframe structure is based on the railway vehicles accurate random vibration analysis method. The finite element model of the underframe structure is employed and the combination between the car body and the underframe structure is simplified. The finite element model can reflect the interior structure well, so that the response of the interior structure can be analyzed. The theory, the formulas and the methods of analysis system had been introduced(Tong, 2013, 2014. Guo, 2014), Figure 1 for analysis flow chart.

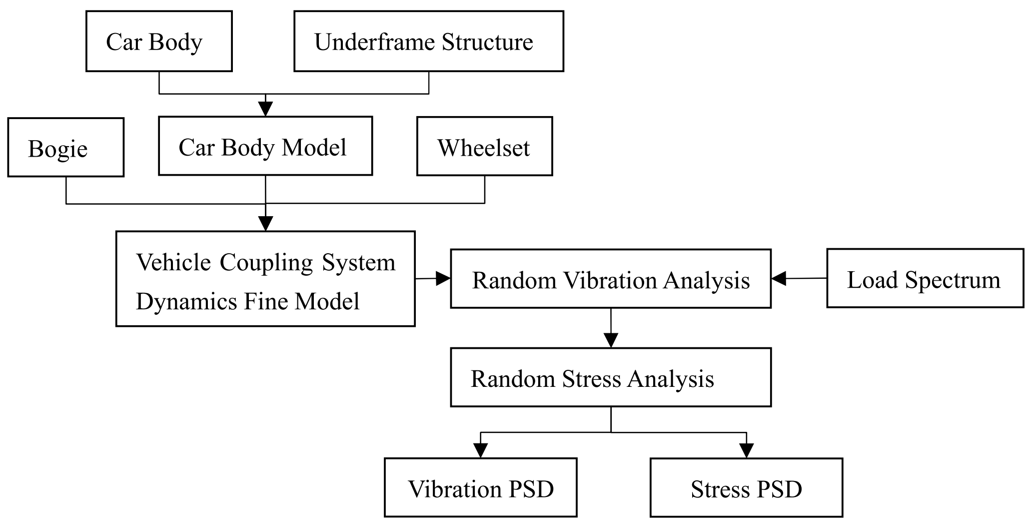

Figure 1.Flow diagram of analysis

2 Structure Dynamics Model

In this paper what employed are a type of the high-speed train of the car body, the bogie, the wheelset and a type of traction converter which is suspended under the car body and the material of which are steel and aluminum. Figure 2 for the FEM of traction converter, the combination is simplified. Figure 3 for the dynamics calculate model of vehicle coupling system including the car body, the bogie, the wheelset and the traction converter. The total number of the node of the vehicle coupling system FEM is 460656, including the car body is 298213, the traction converter is 39255, one bogie is 48634 and one wheelset is 6480.

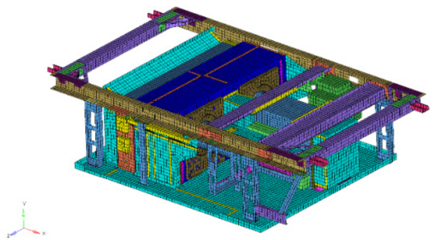

Figure 2. the FEM of traction converter

Figure 3. Dynamics calculate model of vehicle coupling system

3 Dynamics Analysis on Coupling System of Vehicle and Underframe Structure

The traction converter is combined with the slot of the underframe of the car-body by the rubber damper, figure 4 for the position of the traction converter under the car body. The vibration of the car body is equal to the source, the traction converter will be vibrated by the energy of the vibration is input to it through the rubber damper. The main source of the vibration of the car body is the wheel-rail excitation which is caused by the track irregularity. The energy of the excitation is reached the car body through the wheel, first suspension system, the bogie and the secondary suspension system, figure 5 for the dynamics analysis of the coupling system of the vehicle including the traction converter.

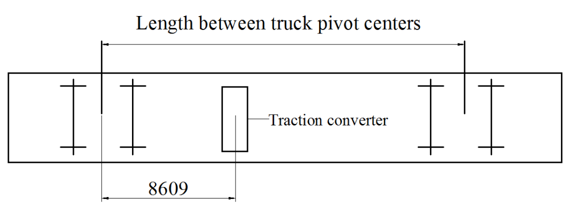

Figure 4. the position of traction converter under the car body

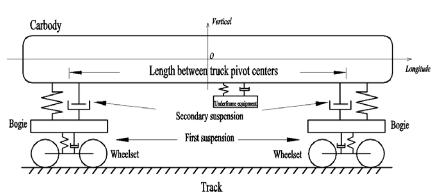

Figure 5.the dynamics analysis of the coupling system of the vehicle including the traction converter

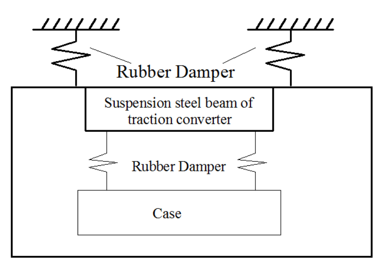

Figure 6.the interior structure of the underframe structure

The traction converter is combined with the car body by the V-liner clamp, this kind of combination has been widely used in engineering. Although the feature of the elastic combination of the V-liner clamp can be considered by the traditional method of the multi-body dynamics analysis, but it is difficult to make accurate analysis on the variation of vibration which is caused by the subtle interior structural change of the underframe structure. This is because that the elastic suspension structure is still designed in the underframe structure, for this kind of complex elastic suspension structure has been simplified as rigid body by employing the traditional method of the multi-body dynamics analysis, thus the interior structure cannot be reflected, so that it is difficult to analyzed the interior structure of this kind of complex structure, figure 6 for the interior structure of the underframe structure. The question can be solved well by employing railway vehicles accurate random vibration analysis method and the analysis about the variation of the structural vibration which is caused by the load change can be also solved well in the design process.

4 The calculation result analysis

In this paper the model which is a high-speed train, so the speed of calculation is set at 350 km/h which is the highest speed of actual operation state, then based on the speed German low interference spectrum is used, the excitation frequency range is 0 to 120 Hz, and the simplified eccentric load of the electric machine which is simplified as 3 direction which are lateral ,vertical ,longitudinal is applied on the rotor spindle of the electric machine.

The 2 kinds of analysis model are that:

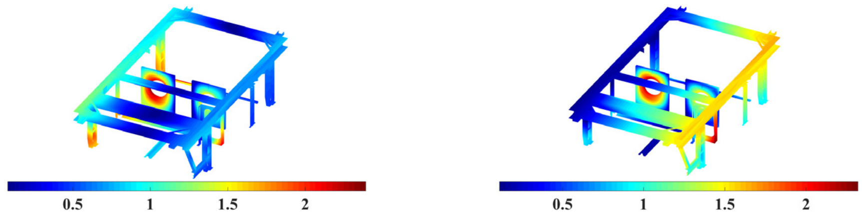
(1) Analysis model 1 is the traditional analysis model of which elastic combination between interior suspensions structures is ignored, the combination are considered to be rigid combination.

(2) Analysis model 2 is the model of which elastic combination is considered between interior suspension structures.

The calculation results include the lateral, vertical, longitudinal Root Mean Square (RMS) and the stress standard deviation are showed respectively as the traction converter is made of steel and aluminum. As the results show there are significant differences between the 2 kinds of models.

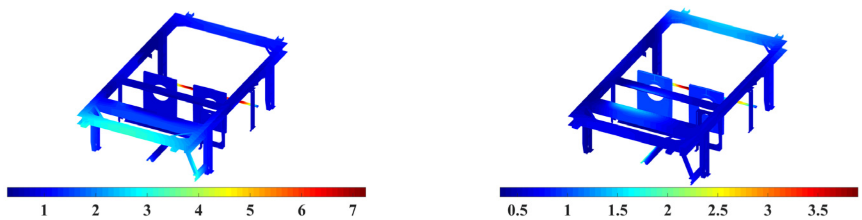
4.1 The calculation results of the steel structure

Figure 7, 8 and 9 show the lateral, vertical, longitudinal acceleration RMS of the steel structure.



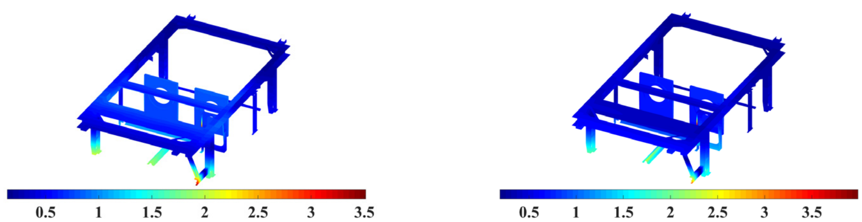
Analysis model 1 Analysis model 2

Figure 7.The lateral acceleration RMS of the steel structure



Analysis model 1 Analysis model 2

Figure 8.The vertical acceleration RMS of the steel structure

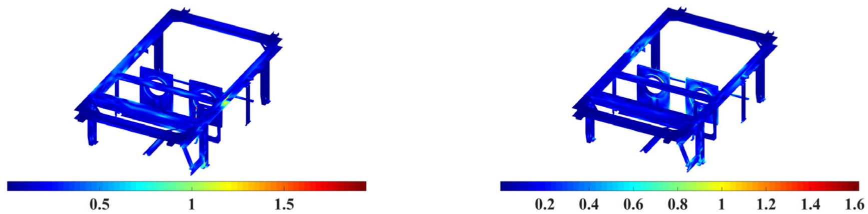


Analysis model 1 Analysis model 2

Figure 9.The longitudinal acceleration RMS of the steel structure

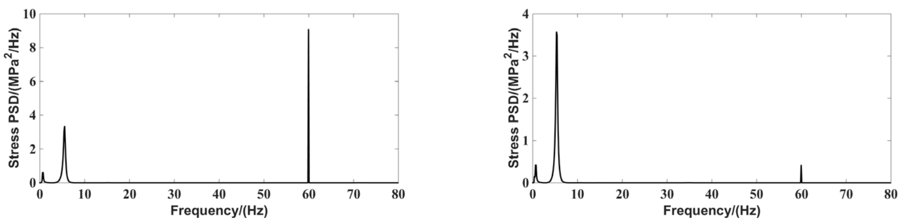
As shown in figure 6 the numerical value of the lateral and longitudinal acceleration RMS are no significant difference between the two, but the distribution of the lateral acceleration RMS is significant difference between the two .Due to the structure of the traction converter is not a symmetrical structure, so the distribution of the lateral RMS is also not symmetrical. It is indicates that the structural lateral vibration of the traction converter is influenced a lot by employing elastic combination methods. In the aspect of vertical, the numerical value of the analysis model 1 decrease by 50% than the analysis model 2, the results show that what direction the elastic combination influence most is the vertical which is focused much in the design process of underframe structure.

Figure 10 and 11 show the stress RMS of the steel structure and the PRMS of the point of the maximum stress RMS of the steel structure.



Analysis model 1 Analysis model 2

Figure 10.the stress RMS of the steel structure



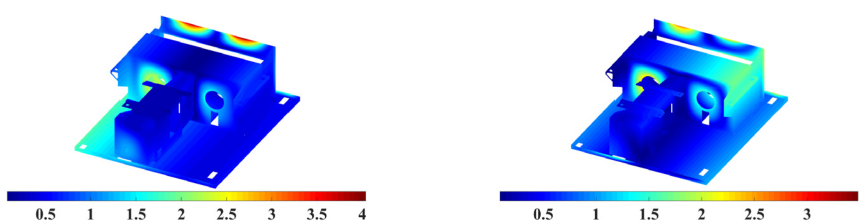
Analysis model 1 Analysis model 2

Figure 11.The PRMS of the point of the maximum stress RMS of the steel structure

From the compare of the stress RMS between the two it can be seen that the value of the maximum stress RMS of analysis model 1 is greater than analysis model 2, as figure 11 shows that the value of analysis model 1 at 60 Hz is much greater than analysis model 2.The frequency of the rotation of the fans is 60 Hz, so it is indicates that the steel structure of the traction converter is affected a lot by the eccentric load of the fans.

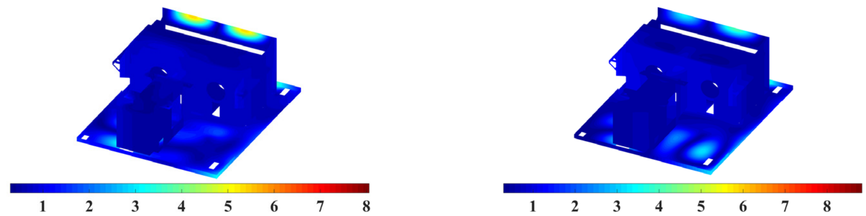
4.2 The calculation results of the aluminum structure

Figure 12, 13 and 14 show the lateral, vertical, longitudinal acceleration RMS of the aluminum structure.



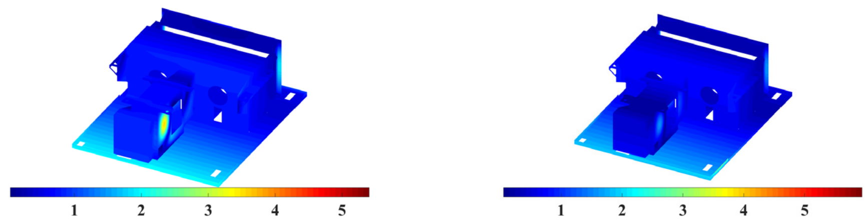
Analysis model 1 Analysis model 2

Figure 12.The lateral acceleration RMS of the aluminum structure



Analysis model 1 Analysis model 2

Figure 13.The vertical acceleration RMS of the aluminum structure

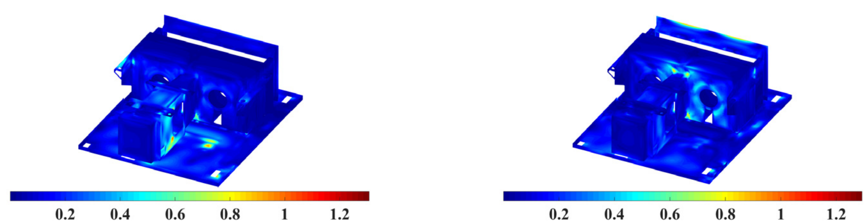


Analysis model 1 Analysis model 2

Figure 14.The longitudinal acceleration RMS of the aluminum structure

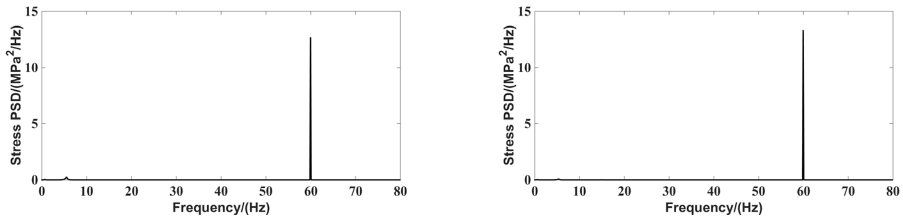
As the calculation results of aluminum structure show the difference of the acceleration RMS of the two is small, it is mainly due to that most of the aluminum structures are suspended structures, so the vibration of the aluminum structure is influenced a little by employing the different combination.

Figure 15 and 16 show the stress RMS of the aluminum structure and the PRMS of the point of the maximum stress RMS of the aluminum structure.



Analysis model 1 Analysis model 2

Figure 15.The stress RMS of the aluminum structure



Analysis model 1 Analysis mode 2

Figure 16.The stress PRMS of the point of the maximum stress RMS of the aluminum structure.

As the calculation results show the difference of the stress RMS of the two is also small. The values of the stress PRMS of the two at 60Hz are approximate equal. It is indicates that the elastic combination does little contribution to decaying the influence caused by the eccentric load of fans as which is set up on the aluminum structure. In the actual structure, the reinforcing plates are set up at where is the maximum stress RMS of the aluminum structure of the analysis model 2, but there are not the reinforcing plates are set up at where is the maximum stress RMS of the aluminum structure of the analysis model 1.In conclusion the influence of the elastic combination for the steel structure is greater than the aluminum structure.

5 Conclusions

1) The stress of the traction converter mainly focus on 3 frequency band that are 2Hz, 6Hz and 60Hz, correspond respectively the mainly vibration frequency of the car-body, rigid-body vibration frequency of the traction converter caused by the suspension stiffness between the car-body and underframe and the basic frequency of the eccentric load of the electric machine which is considered as the most significant impact.

2) As the rubber damper is employed at the combination between the suspension steel beam and the case in the traction converter the dynamics index of vibration and stress of the first one is superior to the second one which the rigid combination is employed and the impact caused by the eccentric load of the electric machine is obvious attenuated.

Dynamic Response Analysis of CRTSII Bi-Block Ballastless Track on a Viaduct of a High-Speed Railway

Jin Wang; Xinwen Yang; and Songliang Lian

Key Laboratory of Road and Traffic Engineering, Ministry of Education, Tongji University, Shanghai 201804. E-mail: wangjin0214@126.com

Abstract: According to the CRTSII bi-block ballastless track structure commonly used in high-speed railway, a 3D finite element model of CRTSII bi-block ballastless track structure on viaduct is established. Then characteristics of vertical displacement of the rail in frequency domain and dynamic responses of the ballastless track structure can be obtained by transient dynamic analysis, based on the finite element software (the speed of the train are 200, 250, 300 and 350 km/h respectively). Analysis results show that: (1) Without considering track irregularity, the frequencies corresponding to the peak of the vertical displacement of rail are approximately equal to the multiples of v/L_a, so the peak frequency can be adjusted by changing the speed when the length of a train is certain; (2) The vertical displacement of the track slab is less than 60% of the rail, and its vertical acceleration is only 2.1%, showing that fasteners play a good effect on reducing vibration; (3) Without other damping measures except fasteners, the vertical displacements of the track slab, supporting layer and viaduct are very close, but their vertical accelerations are some different; (4) The speed of the train has a great impact on the vertical acceleration, and the maximum vertical accelerations of the rail, track slab, supporting layer and viaduct at 350 km/h are 1.68, 1.82, 1.96, 1.65 times of 200 km/h respectively; (5) The vertical compressive stress of the track structure has a turning point.
Keywords: High-speed railway; CRTSII bi-block ballastless track; Characteristics of frequency domain; Dynamic characteristics.

1 Introduction

The technologies of high-speed railway in China have slowly become mature, and high-speed railway has become a viaduct connecting the world and our country. In recent years, many scholars have analyzed ballastless tracks commonly used in high-speed railway, but most of them are ballastless tracks on subgrade or slab ballastless tracks on viaduct (Sun Lu, 2014). Researches about bi-block ballastless track especially CRTSII bi-block ballastless track on viaduct are relatively few.

In this paper, a 3D finite element model of CRTSII bi-block ballastless track structure on viaduct is established. Characteristics of vertical displacement of rail in frequency domain and dynamic responses of each components of the track structure at different speeds are discussed. And references for dynamic optimization of bi-block ballastless track structure design are provided.

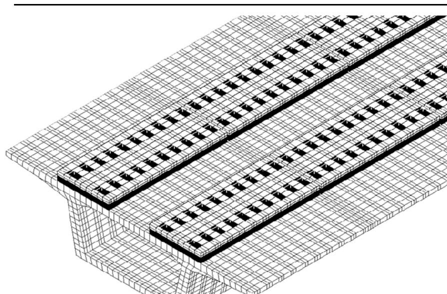
2 The finite model of CRTSII bi-block ballastless track and viaduct

2.1 The numerical analysis model and calculation parameters

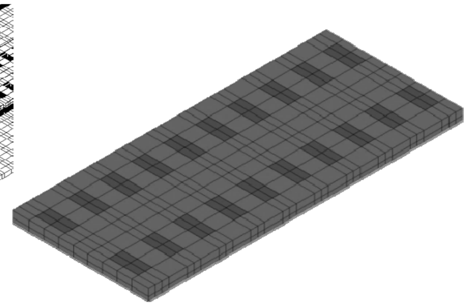
The CRTSII bi-block ballastless track on viaduct mainly consists of rail, fastener, slab, bi-block sleeper, supporting layer and viaduct etc. In this paper, all parameters are selected according to literature (Qu Cun, 2011) and (Zhu Yongjian, 2010), as shown in Table 1. The ends of rail are fully constrained, and the ends of viaduct are simply supported. The rail is represented by an Euler beam, and the fastener is represented by a liner spring-damper element, and the bi-block, slab, supporting layer and viaduct are represented by solid elements, as shown in Figure 1.

Table 1. Parameters of the CRTSII bi-block ballastless track structure modal

Components	Parameters	Values
Rail	Young's modulus (Pa)	2.1×10^{11}
	Density (kg • m^{-3})	7830
	Cross-section area (cm^2)	77.45
	Poisson's ratio	0.3
Fastener	Stiffness (N • m^{-1})	5×10^{7}
	Damping (N • s • m^{-1})	2.2656×10^{4}
	Spacing (m)	0.654
Bi-block sleeper	Young's modulus (Pa)	3.6×10^{10}
	Density (kg • m^{-3})	2500
	Length×Width×Thickness (m×m×m)	0.6×0.28×0.13
	Poisson's ratio	0.2
Slab	Young's modulus (Pa)	3.25×10^{10}
	Density (kg • m^{-3})	2500
	Length×Width×Thickness (m×m×m)	6.44×2.8×0.21
	Poisson's ratio	0.2
Supporting layer	Young's modulus (Pa)	5×10^{9}
	Density (kg • m^{-3})	2500
	Width×Thickness (m×m)	2.8×0.26
	Poisson's ratio	0.2
Viaduct	Young's modulus (Pa)	3.45×10^{10}
	Density (kg • m^{-3})	2500
	Length (m)	32
	Poisson's ratio	0.2



(a) Partial enlargement



(b) Bi-block track slab

Figure 1. Sketch of finite element model of CRTSII bi-block ballastless track structure on viaduct

2.2 Train loads

Considering the track irregularity or not, the train loads in this paper are divided into two types. The first wheel/rail force is selected according to CRH2 high-speed train, without considering track irregularity, taking axle load as 14 t, so the static load of one wheel is 70 kN, used to analyze the characteristics of vertical displacements of the rail in frequency domain (considering 8 trains). The second wheel/rail force is calculated by vehicle-track coupling dynamic model (Zhai Wanming, 2007), which considers track irregularity (the German high-speed spectrum). When the CRH2 high-speed train runs at 300 km/h, the wheel/rail force of one wheel is shown in Figure 2, which is used to analyze the dynamic responses of the track structure (considering only 1 train).

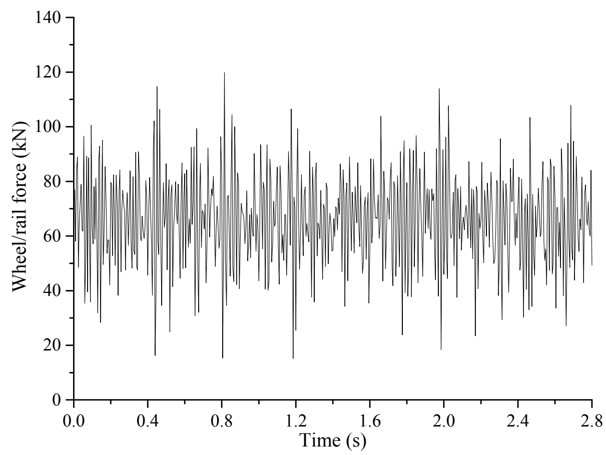


Figure 2. Time history of wheel/rail force

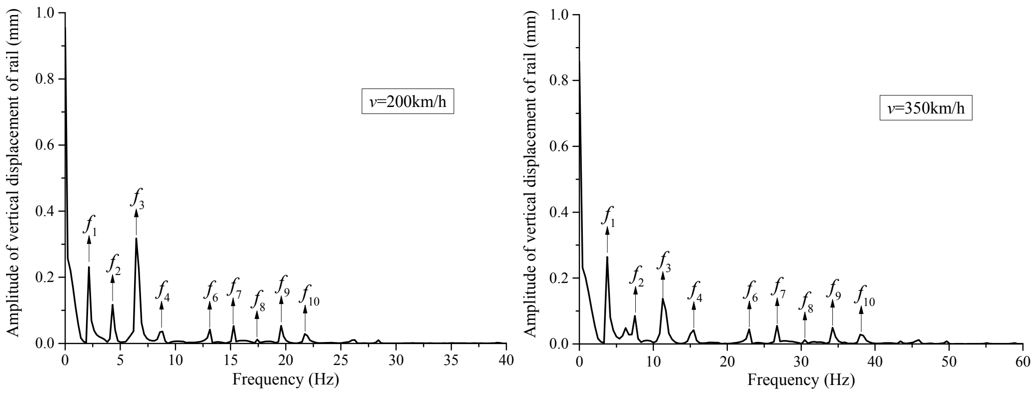
3 Analysis of dynamic responses of CRTSII bi-block ballastless track structure on viaduct

3.1 Analysis of characteristics of vertical displacements of the rail in frequency domain

When analyzing the vertical displacements of the track structure, we can ignore the effect of the track irregularity (Song Xiaolin, 2012). So in this section, the first wheel/rail force is selected to analyze the characteristics of the vertical displacements of rail in frequency domain when 8 trains pass by the track structure.

By doing Fourier-transform to the vertical displacements at four different speeds (200, 250, 300 and 350 km/h) respectively, the amplitude-frequency characteristic curves of them can be obtained. Because the amplitude-frequency characteristics at different speeds are similar, only two of them are shown in Figure 3. It is obvious that there are 9 peaks in the curve (marked in Figure 3), the corresponding frequencies shown in Table 2.



(a) 200 km/h (b) 350 km/h

Figure 3. Frequency spectra of vertical displacement of rail

Table 2. The frequencies corresponding to the amplitudes of vertical displacements of the rail (Hz)

Speed (km/h)	f_1	f_2	f_3	f_4	f_6	f_7	f_8	f_9	f_{10}
200	2.15	4.30	6.44	8.83	13.12	15.27	17.42	19.57	21.72
250	2.69	5.37	8.06	11.04	16.42	19.10	21.79	24.48	27.16
300	3.23	6.45	9.68	13.26	19.71	22.94	26.16	29.39	32.62
350	3.76	7.52	11.27	15.03	22.96	26.72	30.48	34.24	37.99

It can be seen in Table 2 that the 9 frequencies all approximately satisfy $f_1 \approx v/L_a$, $f_2 \approx 2f_1$, $f_3 \approx 3f_1$, $f_4 \approx 4f_1$, $f_6 \approx 6f_1$, $f_7 \approx 7f_1$, $f_8 \approx 8f_1$, $f_9 \approx 9f_1$ and $f_{10} \approx 10f_1$ (L_a is the length of a train). As shown in Figure 3, the amplitudes corresponding to f_1, f_2 and f_3 are bigger than the others, and there is no peak at the frequency corresponding to $5f_1$.

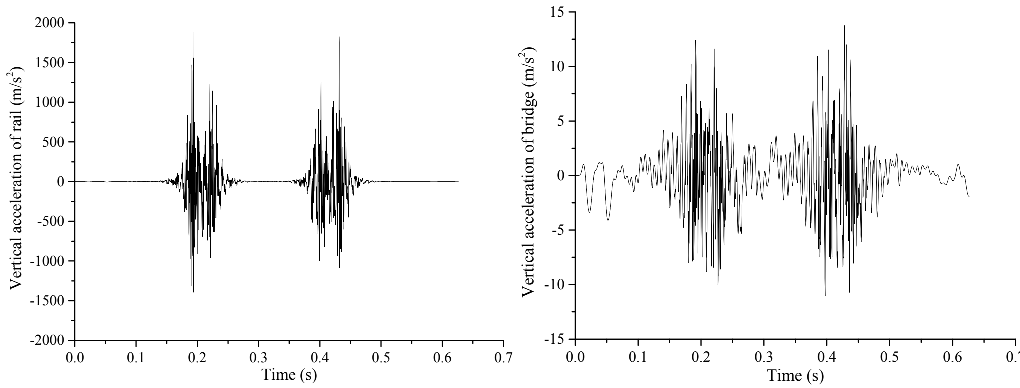
Based on the above analysis at four kinds of different speeds, it is known that there are 9 peaks on amplitude-frequency characteristic curves of the vertical displacements of rail, when 8 trains passing by the track structure with speed v, where the first peak frequency is v/L_a (L_a is the length of a train), and other peak frequencies approximately are integer times of the first peak frequency. And the conclusions are consistent with literature (Song Xiaolin, 2012) and (Xu Peng, 2011).

3.2 Analysis of dynamic characteristics

This part mainly analyzes the dynamic responses of each components of CRTSII bi-block ballastless track structure at four kinds of different speeds. Dynamic analysis indexes are shown in Table 3.

Table 3. The dynamic analysis indexes of CRTSII bi-block ballastless structure on viaduct

Components	Dynamic analysis indexes
Rail	Vertical displacement (absolute), Vertical acceleration
Slab	Vertical displacement, Vertical acceleration, Vertical compressive stress
Supporting layer	Vertical displacement, Vertical acceleration, Vertical compressive stress
Viaduct	Vertical displacement, Vertical acceleration, Vertical compressive stress



(a) The vertical acceleration of rail (b) The vertical acceleration of viaduct

Figure 4. Dynamic response of CRTSII bi-block ballastless track structure on viaduct at 300 km/h

Table 4. Dynamic responses of CRTSII bi-block ballastless track structure on viaduct at different speeds

Speed (km/h)	Vertical--	200	250	300	350
Rail	Displacement (mm)	1.09	1.04	1.06	1.11
	Acceleration (m/s^2)	1311.7	1746.5	1883.4	2202.4
Slab	Displacement (mm)	0.5870	0.6008	0.6221	0.6617
	Acceleration (m/s^2)	27.3	36.3	42.1	49.8
	Stress (kPa)	1104.78	1130.44	1132.48	1130.01
Supporting layer	Displacement (mm)	0.5872	0.6010	0.6223	0.6622
	Acceleration (m/s^2)	13.7	17.2	24.1	26.9
	Stress (kPa)	181.94	186.66	187.05	185.80
Viaduct	Displacement (mm)	0.5877	0.6015	0.6228	0.6629
	Acceleration (m/s^2)	0.92	1.24	1.37	1.52
	Stress (kPa)	32.17	33.38	33.47	32.74

As shown in Table 4, speed has a small influence on the vertical displacement of the slab, supporting layer and viaduct, and has a much smaller influence on the rail. The peak vertical displacements of the slab, supporting layer and viaduct at 350 km/h are 11.86% more than 200 km/h. The peak vertical displacements of the slab, supporting layer and viaduct at four kinds of different speeds are very close, and are all less than 60% of the peak vertical displacement of the rail.

It can be seen in Table 4 that the peak vertical compressive stresses of the slab, supporting layer and viaduct increase or decrease 2.3%, 2.6%, 3.8% at most respectively when speed increases 50 km/h (from 200 km/h to 350 km/h). But they don't strictly increase as the speed increases, the maximums all appear at 300 km/h. The peak vertical compressive stresses of the viaduct at four kinds of different speeds are 17.8% of the supporting layer and 2.9% of the slab.

It can be known from Table 4 that the speed of train has a great influence on all components of track structure, and the peak vertical accelerations of the rail, slab, supporting layer and viaduct at 350 km/h are 1.68, 1.82, 1.96 and 1.65 times of 200 km/h. The peak vertical accelerations of the slab at four kinds of different speeds are only 2.1% of the rail, showing that the fastener system has a very obvious effect on reducing vibration. And the peak vertical acceleration decreases from slab down to supporting layer to viaduct, decreasing 47.8% and 67.3% respectively.

4 Conclusions

(1) Without considering track irregularity, the frequencies corresponding to the peak of the vertical displacement of rail are related to the speed of train (v) and the full-length of a train (L_a), approximately equal to the multiples of v/L_a. So the peak frequency can be adjusted by changing the speed when the length of a train is certain, and we may consider changing the length to adjust the peak frequency in future design.

(2) The vertical displacements of the rail and the vertical compressive stress of the top surface of slab, supporting layer, and viaduct don't strictly increase as the speed increases, and there is a turning point.

(3) The peak vertical displacements of the slab, supporting layer and viaduct at four kinds of different speeds are very close, and all less than 60% of the rail; The vertical accelerations of each components of track structure are gradually reduced from top to bottom, and the vertical acceleration of the slab is only 2.1% of the rail, showing that fasteners play a good effect on reducing vibration.

(4) The speed of train has a big influence on all components of track structure, and the peak vertical accelerations of the rail, slab, supporting layer and viaduct at 350 km/h are 1.68, 1.82, 1.96 and 1.65 times of 200 km/h.

Abstract: In maglev engineering, the control network for monitoring function modules' deformations is the basis for accurately measuring the absolute position of the maglev guideway beams and the function modules. It is also the theoretical foundation for adjusting the guideway beams' position after operations. This paper introduces control network (CPIII) and demonstrates the feasibility of control network (CPIII) applied in monitoring deformations of function modules on guideway beams after the maglev project being operated, considering the main technology requirements and the layout features of control network (CPIII). Aiming at the special construction of function modules and providing that their measurement accuracy is ensured, the bury positions of function modules' location marks and measuring methods are specially designed. The bury positions of function modules' location marks and the layout and the measuring methods of the control network which monitors function modules' deformations were proposed.
Keywords: Maglev engineering; The control network for monitoring function modules' deformations; Track control network (CPIII).

1 Introduction

The maximum design speed of maglev train is 500 km/h. To ensure the safe operation of maglev train system, lines, guideway beams and function modules must have necessary accuracy, especially the function modules which are mounted on both sides of the guideway beams. Function modules positioning accuracy must meet ± 1mm, however, general measurement methods can not meet the requirements of such a high accuracy. To improve the accuracy of deformation monitoring, the control network for monitoring function modules' deformations must be used. To ensure the accuracy of the control network for monitoring function modules' deformations, the layout and the measuring methods of the control network and beam positioning marks must be specially designed.

2 Classifications of maglev engineering survey control network

There is no clear specification of the control network for monitoring function modules' deformations, by drawing on the specification of unballasted track control network, hoping to improve the methods of monitoring function modules.

Maglev engineering survey control network can be divided into three parts which are basic control network, primary datum point control network and densified control network (CHENG, 2009).

During the construction, basic horizontal control network is the basis for initial measurement and fitting measurement, and the spacing between two adjacent control network masks is about 9 km. Primary datum point control network is the basis for the construction of pier's foundation, the positioning of bearing and the positioning of guideway beam. The spacing between two adjacent control network masks is about 2-3 km, and all the marks shall be connected with positive centering observation pier. To meet the accuracy requirements of construction phase of route and precision positioning stage of guideway beam, densified control network must be set up in different construction stages such as construction of substructure, stakeout of bearing and precision adjustment of the guideway beams. The spacing between two adjacent densified control network masks is about 150-400 m.

3 Unballasted track control network

Unballasted track control network can be divided into horizontal control network and elevation control network and use the method of stepwise control forming control network. Control network use the method of hierarchical distribution network and controlling step by step. This method can restrict the transfer and accumulation of errors.

3.1 The accuracy requirements of unballasted track control network

Unballasted track control network includes basic horizontal control network (CPI), route horizontal control network (CPII), track control network (CPIII) (**Table 1**) (LI, 2012). Different levels of control network' functions and the main technical indicators are as follows:

(1) CPI mainly provides reference coordinates for surveying, construction, operation and maintenance.

(2) CPII mainly provides control reference for surveying, construction.

(3) CPIII mainly provides control reference for the laying of unballasted track and maintenance operations.

Table 1. Main technical indicators

Control network	Measurement methods	Measurement category	Point spacing	Relative mean square error of adjacent points
CPI	GPS	2	≤4km	10
CPII	route	3	400-800	8
CPIII	Free station angular intersection		50-70m	1

3.2 Establish and observation of track control network (CPIII)

The spacing between two adjacent CPIII fixed points is generally 60m. The height of adjacent CPIII fixed points should be roughly equal, and laying position should maintain a certain height difference in the orbital plane (**Figure 1**).

CPIII control network use the measurement method of free station linear angular intersection and shall be checked for the fixed points' unchanged position though the CPI and CPII fixed points. CPIII control network need to survey a CPII fixed point each 600m and each CPII fixed point need to observe at least 3 times (LIU, 2007).

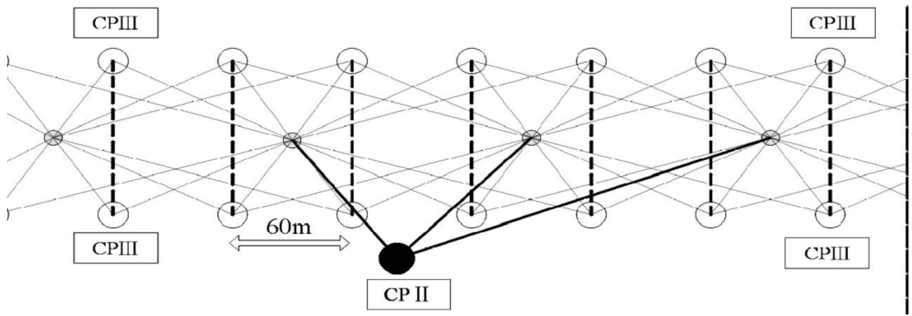

Figure 1. CPIII "the method of resection" network diagram

4 The feasibility analysis of using track control network (CPIII) in monitoring function modules' deformations.

The spacing between two adjacent maglev primary datum point control network masks is about 2-3 km and is close to the spacing between two adjacent basic horizontal control network masks (≤4km). The spacing between two adjacent maglev densified control network masks is about 150-400 m and the spacing is close to the spacing between two adjacent route horizontal control network masks. Track control network (CPIII) mainly provides control reference for the laying of unballasted track and maintenance operations (XIA, 2010).

So maglev engineering survey control network and unballasted track control network can survey analogously and the function of track control network (CPIII) can be applied to monitor the deformations of function modules on guideway beams after the maglev project being operated. Based on the known maglev engineering survey control network (basic control network, primary datum point control network, densified control network), control network for monitoring function modules' deformations is specially designed which is matched with the characteristics of maglev track and is similar to track control network (CPIII).

5 Bury positions and measuring methods of function modules' location marks

Aiming at the special construction of function modules and providing that their measurement accuracy is ensured, the bury positions of function modules' location marks and measuring methods are specially designed.

5.1 Bury positions of function modules' location marks

Dowel hole is precisely machined by CNC machine tools in the guideway beams, and the machining precision is ± 0.02 mm. In the construction of Shanghai magnetic suspension demonstration operation line, we use the dowel hole on both sides of the guideway beams to locate the position of the magnet suspension path precisely (**Figure 2**). When laying the fixed point, dowel holes can also be used (CHEN, 2009).

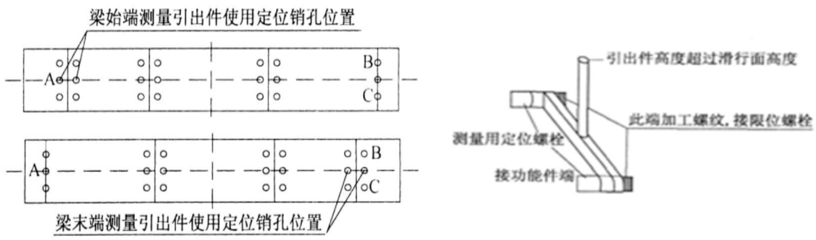

Figure 2. Locations of Dowel holes, Extension part

Dowel hole located within the side of the function module, and the space coordinates of center are provided by the design units. As the set of assembled reflector prism for CPIII cannot be mounted directly on the dowel hole, so we need to use locating bolts and extension parts which are specially made for positioning measurement. By using the space coordinates of the lateral side of the center point of the dowel hole and the space geometric relationship of extension parts of the dowel hole, the space coordinates of observation points of the extension parts can be calculated.

While monitoring measurements, we installed the set of assembled reflector prism for CPIII on the extension parts, thus it can be measured according to the control network for monitoring function modules' deformations.

5.2 The distribution of fixed points on the function modules

The length of maglev guideway beam is about 24m. To ensure the accuracy of function modules, the fixed points must be laid on each beam (SHAO, 2008).

Referring to the densified CPIII control network, fixed points are installed on the dowel hole on both sides of the lateral boundary in guideway beams. Points can be divided into A, B two categories, and these two kinds of points are arranged on each guideway beam **(Figure 3)**. A point: this kind of point is located on one side of guideway beam and the same side (All are on the left side or right side) of adjacent guideway beam. So the control network for monitoring function modules' deformations is composed of A points, and the spacing between two adjacent the points is generally 24m. B point: a pair of points on another lateral side of guideway beam. B points are used as relative measurement fixed point and are not included in the control network.

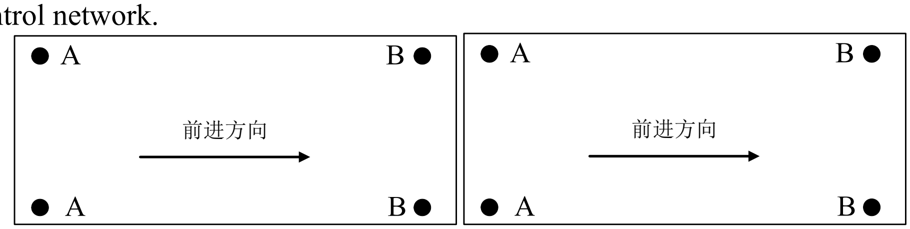

Figure 3. The distribution of fixed points

5.3 Measuring methods of the control network for monitoring function modules' deformations

According to the characteristics of maglev track beam, the measurement can be divided into two parts.

1) By referring to the measurement method of track control network (CPIII) and using the measuring methods of the control network for monitoring function modules'

deformations, the absolute position of fixed points on lateral boundary of guideway beams are accurately measured.

2) Through the relative measurement, the relative position of A points to B points on a adjacent guideway beam is accurately measured, so the absolute positions of the guideway beam and the whole line are accurately measured.

6 Measurement of fixed point and processing of data

Control network for monitoring function modules' deformations and track control network (CPIII) have similar method of measurement, calculation and instrument such as Lycra TCA2003, Trimble TrimbleS6 etc (HE, 2004).

Data processing includes inspection of on-site data and adjustment of control network, and it is similar to the track control network (CPIII) data processing method.

7 Conclusions

According to the characteristics of magnet suspension path and function modules and the reference to the burial location of marks which were used on the track beam accurate adjustment, the bury positions of function modules' location marks , measuring methods and control network for monitoring function modules' deformations are specially designed.

This study can provide theoretical basis for the formulation of standardized measurement of the high speed maglev line.

Abstract: Tunnel Intelligent Transportation Systems is an important part of highway intelligent transportation. Ventilation control of superlong road tunnels is mainly automatic control supplemented by manual control, which aims at maintaining good visual environment inside the tunnel with minimum power consumption, controlling the air pollution status within the prescribed permissible range and dealing with fires in a prompt and effective way. This study focus on the control strategies and methods of the highway tunnel ventilation systems, including axial fan, jet fans and other controlled object, and obtain highway tunnel ventilation intelligent control technology.

Keywords: Highway tunnel; Natural ventilation; Axial fan; Jet fan; Intelligent control.

1 Introduction

Highway as the two main modes of transportation, has always been the main force to promote the national economic development in china. With the rapid development of highway construction, the tunnel construction has come into a boom. In the construction of the tunnel, China has explored spontaneously and innovated bravely which leads to a leaping development in self-tunnel construction ability and makes China the country with the fastest speed of tunnel-growing. According to incomplete statistics, the number of highway tunnels has reached 8522 up to the end of 2011, whose total length is 6.25 million meters.

Thus, China has become a country possess the most tunnels and underground works around the word with the fastest development speed facing the most complex Geological condition and structural form.

With the growing scale of tunnel construction, the ventilation equipment designed in the extra-long tunnel has great power causing huge energy consumption.

2 Energy-saving analysis with the natural wind

According to the calculation, the values of the wind have a great influence on the power of fans. Because the natural wind speed has a relationship with the square of wind speed. The wind resistance in the ventilation system increased by three times. The power needed for ventilation increases when the wind resistance increases. And the situation of the wind resistance with different wind value is as followed taking Nibashan tunnel as an example the traffic of which adopts the value in 2015.

Table 1. Proportion of natural wind at different wind speed

natural wind speed (m/s)	natural wind resistance (kPa)	other resistance (kPa)	total wind resistance (kPa)	proportion of natural wind
0	0.00	51.86	51.86	0.00%
5	116.59	51.86	168.45	69.21%

Absolutely, the natural wind has a great influence on the power of ventilation. The power used to overcome the natural wind usually takes a part of 20%-50%, and specifications always take the natural wind as a kind of resistance. Actually, the natural wind acts as resistance or driving force with the change in the value and direction. But in the common ventilation calculation, the natural wind is regarded as resistance with a speed of 2.5～3.0 m/s. If the natural wind can be divided into two cases the positive and the negative then used as the driving force at the right time, a great economic profit will occur.

3 Month control Strategy

In the design stage, we built 4 automatic weather monitoring stations, monitored the meteorological conditions of Nibashan tunnel for a long time, collected the meteorological data and obtained the natu-ral wind movements rules. The arrangement of the weather stations is shown in the following figure 1.

Figure 1. Location of the automatic weather station:

We collected totally 93,120 groups of meteorological data by monitoring the tunnel weather conditions for up to 485 days, obtaining the histogram of monitoring data, the rose diagram of wind speed and directions by analysis the data. Take the station 1 for example, as shown in figure 2, where represent the distribution of these factors above.

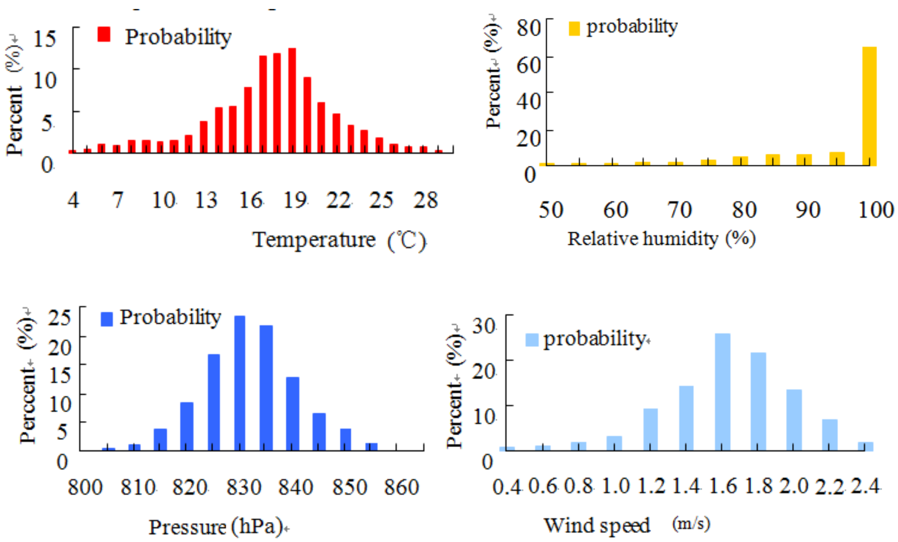

Figure 2. Meteorological data from the automatic weather station

Take Nibashan tunnel as an example the traffic of which adopts the value in 2015, calculate the arrangement situation of the fan on the condition that the natural wind is 2.5 m/s or the wind speed with a guarantee rate of 95%.The results are as followed:

Table 2. Power of the fan on the condition that the natural wind is 2.5 m/s or the wind speed with a guarantee rate of 95%.2.5m/s

working conditions		the first section (KW)		the second section (KW)			the third section (KW)		total power
		jet fan	axial flow fan	supply fan	jet fan	exhaust fan	jet fan	axial flow fan	KW
the fan required (2.5 m/s)	left tunnel	148	24	193	296	45	0	122	1601
	right tunnel	148	22	157	296	32	0	117	
	total	296	46	350	592	77	0	239	
the fan required (a guarantee rate of 95%)	left tunnel	148	24	193	370	45	148	122	1748
	right tunnel	74	22	157	296	32	0	117	
	total	222	46	350	666	77	148	239	

Table 3. Modes and the energy saving benefit in different period of time

period of time	left tunnel		right tunnel		power in total	
	jet fan (KW)	axial flow fan (KW)	jet fan (KW)	axial flow fan (KW)	total power (KW)	energy saving (%)
daytime in January	555	315	259	413	1542	3.7
nighttime in January	518	315	370	413	1616	0.0
daytime in December	555	315	259	413	1542	3.7
nighttime in December	185	315	370	413	1283	19.9

4 Detail control Strategy

Do the energy analysis by the control strategy of one hour then get the modes in different period of time and the corresponding energy efficiency by calculating. The following chart gives the data result in Nibashan tunnel.

The average condition can be obtained after take the average power calculated in different working conditions and at different time. And all the average conditions and the working condition with the speed of 2.5m/s are as shown below.

Table 4. Energy saving benefit in different period of time

working conditions	power of jet fans (KW)		energy saving
	left tunnel	right tunnel	
2.5 m/s	444	740	0
1 hour	128.7	543.5	43.2%

The chart above shows that energy-saving effect is great by rationally using the natural wind. And the effect would be more obvious if one hour control strategy was adopted. But the one hour control strategy would make the fan status changes too frequently which will reduce the life of fans. So what kind of control strategy to adopt needs a comprehensive consideration.

The natural wind probability distribution of each section in the main tunnel is shown in figure 3. It is shown that the main wind direction of section 1 is negative, the average value is about 2.4 m/s, the section 2 is positive, the average value is about 2.4 m/s, the section 3 is positive, the average value is about 1.2 m/s.

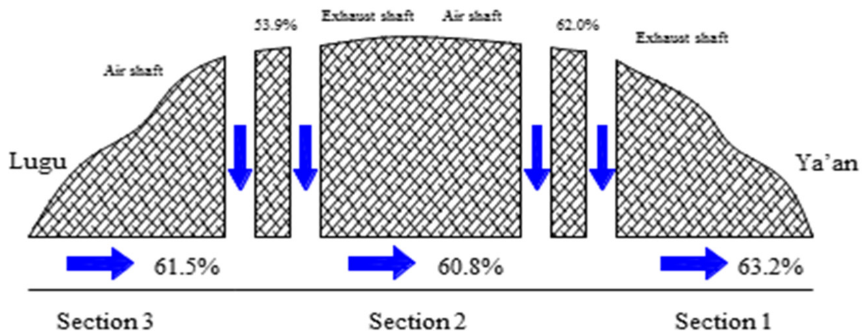

Figure 3. The annual probability distribution of Niba mountain (left line)

The original ventilation cost 21037140 yuan a year (1.5 yuan / kWh), and the cost will be 18231741 yuan a year after the monthly control optimization saving 2.8054 million yuan, The annual energy saving is 13.3%; the annual energy saving can be as much as 20.5% when six hours control strategy is adopted. What's more, the annual energy saving can be as much as 50.5% when real-time control strategy is adopted, the annual energy consumption can be 10624355 yuan saving electricity bill by 10.6244 million yuan.

5 Conclusions

The calculation shows that even the fan number designed according to the wind speed with a guarantee rate is more than that calculated with a wind speed of 2-3m/s recommended in the specifications, the actual number of fans turned on is less than that in the traditional conditions and better. Because Optimized design of the ventilation works. Reasons in detail are below:

(1) Wind speed adopted in the calculation is 2～3 m/s, but the natural wind of the tunnel located at climate boundaries usually is as much as 4～6 m/s, So the wind speed with a guarantee ratio is much more rational ensuring a better ventilation.

(2) The single hole tunnel can change the ventilation mode according to the speed and direction of the natural wind under the pattern of energy-saving. Thus, the tunnel can use the natural wind in different degrees, which will contribute to energy –saving.

(3) The conventional ventilation design takes both of the holes as the most unfavorable working condition in the double line tunnel. After adopting the energy-saving design one line will be in favorable condition and the other one will be in adverse condition.

Mechanism Analysis of the Box-Type Anti-Slide Pile with Vertical End-Curve-Arrangement Prestressed Tendons in Landslide Control

Xiaoqiang Hou[1]; Zhengxue Yao[2]; and Jingjing Wang[1]

[1]Gansu Construction Vocational Technical College, Lanzhou 730050.
[2]Geological Hazards Institute, Gansu Academy of Sciences, Lanzhou 730000. E-mail: houxq@foxmail.com

Abstract: In this paper, a comparison analysis using FEM calculation was carried out regarding three kinds of anti-slide pile, i.e. the common one, the box-type reinforced concrete one and the box-type one with vertical prestressed tendons, showing that the displacement and positive bending moment of the pile with vertical prestressed tendons are smaller than that of the rest ones under 2000 kN landslide thrust, with slight increases of negative bending moment on both ends, indicating that it has obvious advantages in resisting displacement and bending during landslide control; on this basis, the layout patterns of the prestressed tendons were optimized by comparing the 5 types of layout option, and negative bending moment and shearing force of the box-type pile with vertical end-curve-arrangement prestressed tendons were found to be smaller than that of the rest ones, while the maximum positive bending moment and positive shearing force on the sliding surface remaining the same, proving that it is more scientific, reasonable and appropriate for landslide control; a loading simulation was conducted, showing that the prestress shall be applied appropriately. Combined with the inherent structure characteristics and internal vertical end-curve-arrangement prestressed tendons, the landslide stability is improved for box-type pile.

Keywords: Landslide control; Box-type; Vertical end-curve-arrangement prestressed tendon; Anti-slide pile.

1 Introduction

Many measures can be adopted for landslide control, such as anchor bolt in fixing frame, retaining wall and anti-slide pile, etc, and the anti-slide pile is used herein for the retaining and landslide control in case of large residual sliding force. Due to the large design section size, big concrete volume, large reinforcement amount and deep embedded pile body in bedrock, the construction of common pile is very expensive and difficult. Additionally, the concrete strength may be affected by the fact that the hydration heat in large volume concrete casting is hardly released. With the accumulations of theoretical research and engineering practice, especially the research on calculation theory, many research achievements were obtained for anti-slide pile at home and abroad, e.g. a pile with prestressed anchor cable (externally prestressed) was introduced with anchor cable applied on the top. The pile with prestressed anchor cable changes the stress pattern of the common one, namely, making the stress state of cantilever pile from passive to positive, thus bringing obvious reductions of shearing force and bending moment on the lower part and a more reasonable stress state and distribution of entire pile body comparing with the common one. And under the anchoring force, the entire pile body is endowed with a function of actively reinforcing the landslide mass.

As for externally prestressed anti-slide pile, its slide resistance is to be achieved by anchoring the pile in the stable bedrock via a prestressed anchor cable set on the top, and the anchor cable is subject to the elastic tensioning with applying of the prestress and the slide-thrust. However, with the change of working condition, like climate, groundwater, and rock-soil properties in anchorage zone, the force applied on pile and anchor varies dynamically, which reduces the bond strength between rock-soil and anchor cable. Besides, its anti-sliding effect will be reduced when the free-section of prestressed anchor cable is overlong due to the gentle sliding surface or thick slip mass, or when the prestress loss exsists during the linear tension transfer under the earthquake action. Considering the disadvantages of box-type structure in releasing hydration heat of mass concrete in casting, a box-type pile with vertical end-curve-arrangement prestressed tendons inside, is herein proposed to overcome the bond strength reduction of anchor cable and to improve the mechanical properties of pile, such as bending tensile strength, for further ensuring the anti-sliding effect.

2 Calculation Principle and Method

2.1 Basic Assumptions

It assumed that the compressive stress is applied inside the tensile area of pile by prestressed tendons, being counteracted by tensile stress induced by landslide to an appropriate degree.

2.2 Mechanical Model

(1) Based on the calculation of thrust distribution on the pile and considering that most of the landslide mass is the loose mass made up of gravel soil, it is more reasonable to adopt a trapezoid-distribution.

(2) The stiffness of pile, compared with that of soil, can be seen as infinity; the soil layer underneath the sliding surface can be seen as an elastic medium; generally, the lateral subgrade coefficient of soil layer increases with increasing depth.

(3) The stress load on the box-type pile with vertical prestressed tendon is basically the same as that on the cantilever pile except for the generation and changes of internal stress.

(4) The box-structure takes full advantage of high-strength material and large anti-bending inertia moment to improve the flexural behavior.

(5) The layout of prestressed tendon shall be consistent with the stress change inside the pile as much as possible.

(6) Only 24% of the total area is hollow, and the area of shear reinforcement shall be properly increased in the parts subjected to great shearing force.

3 Stress Calculation and Analysis

3.1 Finite Element Model

A finite element model for stress analysis is established by MIDAS/CIVIL, with 20 elements, 21 nodes and boundary conditions, of which an elastic interlink is made for the 7 elements underneath the sliding surface. As a box-type structure with prestressed tendon, whose wall thickness is 0.5 m and length is 20 m, the pile's section dimension is 1.8m*2.2 m and its internal dimension is 0.8m*1.2m. In this analysis, C35 concrete is to be used for its small shrinkage and creep under the action of prestress, steel strand of 1860 MPa is to be adopted as the prestressed tendon bonded with concrete and constructed by post-tensioning method, and HRB335 steel bar is to be selected for shearing resistance. Besides, as an elastic medium, common soil is to be used as the foundation of anti-slide pile with nodes for elastic supporting. During the simulation of working process, it is to choose trapezoidal pattern (2:5) for the distribution of external load (i.e. landslide thrust).

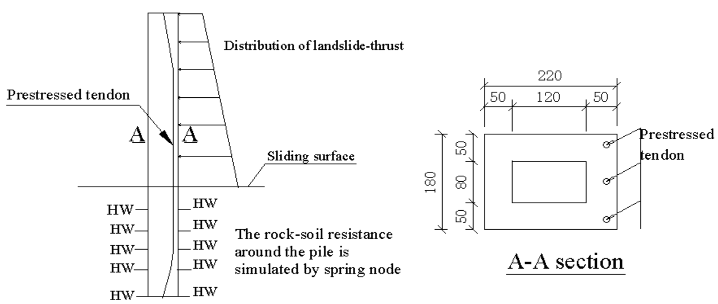

Fig.1 Structure of box-type anti-slide pile with vertical end-curve-arrangement prestressed tendon

3.2 Mechanical Calculation and Analysis under Various Conditions

To show the characteristics of pile with prestressed tendon, it is to compare the deformations of three kinds of anti-slide pile, i.e. the common one, the box-type reinforced concrete one and the box-type one with vertical prestressed tendon under the same load and boundary conditions. And to show the characteristics of prestressed tendon, it is to calculate its displacement and internal force changes, like changes of displacement, bending moment and shearing force and to do the mechanical analysis for curve-arrangement prestressed tendon after further optimization of prestressed tendon.

3.2.1 Comparison of nodal displacement and internal force change

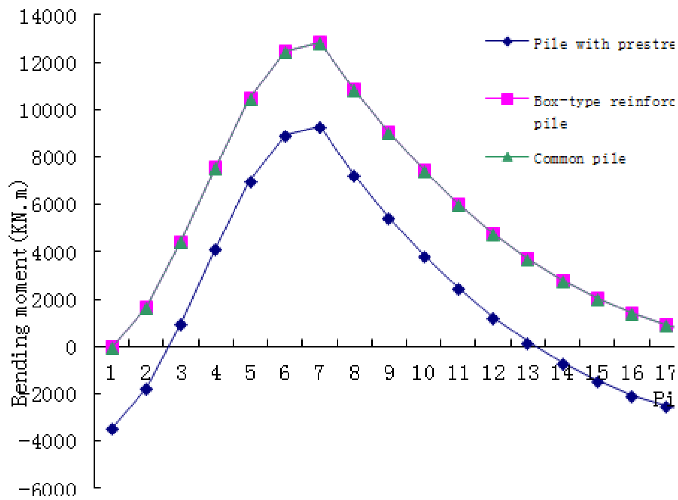

Fig. 3 Bending moments of three kinds of pile under the action of thrust

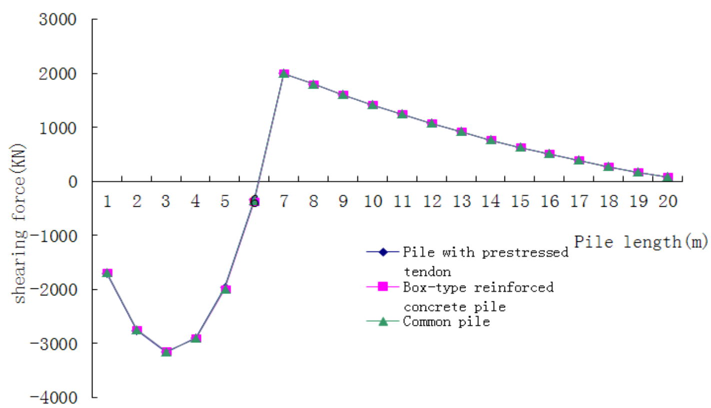

Fig. 4 Shearing force of three kinds of pile under the action of thrust

As shown in Fig.2, under 2000kN thrust, the displacements of three piles at the anchorage part of bottom are almost the same; their points with 0 displacement are all located at the 3.5m above the bottom, being considered as the pivot point for rotation. However, the closer to the pile top, the larger the displacement is. In general, the displacement of the box-type pile with prestressed tendon is the smallest, with 7.91% and 8.93% less than that of the common one and the box-type reinforced concrete one.

As seen in Fig.3, under 2000 kN thrust, the bending moment variation on common pile agrees with that on box-type reinforced concrete one and both of their bending moments are positive while the bending moment variation on pile with prestressed tendon is characterized by positive-negative alternating. On the whole, the maximum bending moments of the three piles are located at the same position, i.e. at the 7m above the bottom. But the maximum bending moments of the common pile and the box-type reinforced concrete one are 12857.25 kN.m, an excess of 38.44% compared with the 9787.28 kN.m of the pile with prestressed tendon, indicating that the bending moment of the pile with prestressed tendon is the smallest.

From Fig.4, it can be seen that the shearing forces and relevant variations of the three piles are almost the same under 2000 kN landslide thrust, namely, their maximum positive shearing forces are all about 2000 kN and located at the 7 m above the bottom (i.e. the sliding surface), and the maximum negative shearing force are all about 3150.93 kN and located at the 3 m above the bottom.

The results show that under the same load, the box-type pile with prestressed tendons has the smallest displacement and bending moment and nearly the same shearing force as that of the others, proving that it is more stable and owns a higher bending resistance compared with them.

3.2.2 Force comparison of piles with straight-arrangement tendon and curve-arrangement one

The prestressed tendon in concrete structure is subject to the tensioning or compressing depended on the internal force variation. It is necessary to adopt prestressed tendon arranged in curve form on both ends being applied 1500 kN landslide thrust, since the end bending moment trended to be 0 is reasonable. And the calculation of internal force of prestressed tendon is as shown in Fig.5 and Fig.6. In these figures, *Straight-arrangement Prestressed Tendon* refers to prestressed tendon arranged in straight form; *Top-curve-arrangement Prestressed Tendon* refers to prestressed tendon arranged in curve form near the top of pile; *End-curve-arrangement* refers to prestressed tendon arranged in curve form on both ends of pile. On these bases, *No.1 Adjusted Arragement Prestressed Tendon* represents the prestressed tendon with curve-form arrangement 12m above the bottom to the top; *No.2 Adjusted Arrangement Prestressed Tendon* represents prestressed tendon with curve-form arrangement 7m above the bottom (the position of maximum bending moment) to the top. The internal force variation shall be analyzed under the 5 working conditions.

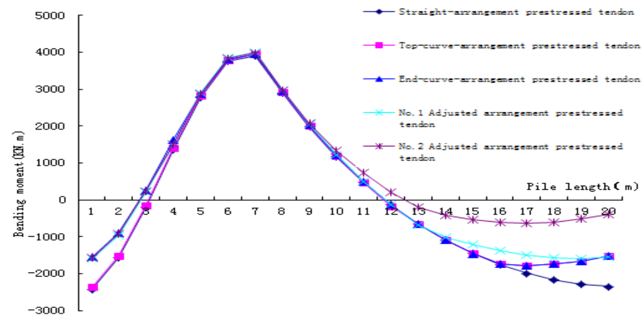

Fig. 5 Bending moment variation under various prestressed tendon arrangement

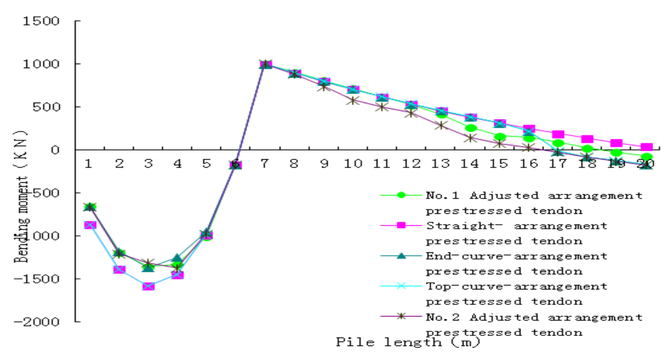

Fig6 Shearing force variation under various prestressed tendon arrangement

As shown in Fig.5, the maximum bending moments under the 5 conditions are nearly equal and all are located at the 7 m above the bottom. However, the closer the curved point of prestressed tendon is to the 7 m above the bottom, the smaller the negative bending moments are on both ends. And as shown in Fig.6, their maximum shearing forces are all located at the 7 m above the bottom. But the closer the curved point of prestressed tendon is to the 7 m above the bottom, the smaller the shearing forces are on both ends. Especially at the 3 m above the bottom of anchorage part, the shearing force varies considerably, which may reduce the shearing resistance of pile. Thereby, it indicates that the position of the maximum bending moment of pile with prestressed tendon is consistent with that of the common one, both on the sliding surface.

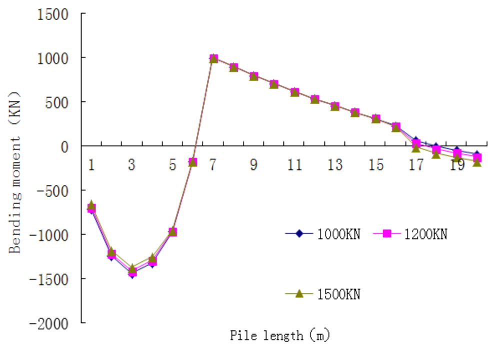

Fig. 7 Bending moment variation caused by prestress applied

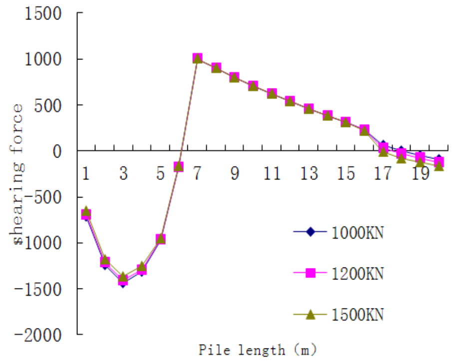

Fig. 8 Shearing force variation caused by prestress applied

Loading on prestressed tendon will cause a change of internal force, i.e. with an increase of loading, the positive bending moment of pile decreases gradually while the negative bending moments on both ends increase, as the analysis shown in Fig.7; with an increase of loading, the shearing force on the anchorage part of pile decreases while the negative shearing force near the top increases slightly, as shown in Fig.8. The results show that loading on prestressed tendon has effects on the bending moment, but no effect on the shearing force; prestress shall be applied appropriately.

3.2.3 Increasement of Grade and Area of Shear Reinforcement under the Maximum Shearing Force

Since the strength of C35 concrete to be adopted is higher than that of C25 concrete, it only needs to increase the stirrup quantity at the position of great shearing force for meeting the requirement of shearing resistance considering that the hollow area of box-type pile takes up only 24% of the total area and has slight effect on the shear-bearing capacity of anti-slide pile

4 Conclusion

The following conclusions are drawn from the mechanism analysis of box-type anti-slide pile with vertical end-curve-arrangement prestressed tendons:

(1) Based on the comparison using finite element modeling, the box-type pile with prestressed tendons conforms to relevant mechanics principle and plays an important role in reducing bending moment and pile displacement as well as improving the pile stability.

(2) Adopting the pile with prestressed tendons inside can resolve the following problems, such as the decreased bond strength between prestressed tendon and anchor cable induced by the rock-soil condition variation; the reduced anti-sliding effect under an overlong free-section of prestressed anchor cable induced by gentle sliding surface or thick slip mass or in a state of prestress loss caused by earthquake

during the linear tension transfer, etc.

(3) Using the unique hollow structure of box-type pile, the hydration heat produced by concrete casting can be effectively released to ensure the quality of concrete; the internal monitoring and maintenance for anti-slide pile can be implemented; the effective drainage inside the landslide mass can be achieved for improving its stability.

Abstract: The remaining life is usually taken into account for pavement maintenance or reconstruction. To determine the optimal reconstruction time of a certain composite airport pavement, the authors used 3 kinds of methods to predict the remaining life, respectively based on a former Federal Aviation Administration (FAA) design standard called as Layered Elastic Design Layered Elastic Design Federal Aviation Administration (LEDFAA), Airport Pavement Design Method of China (APDMC) and Pavement Condition Index (PCI) regression model. According to the in-situ data of Heavy Weight Deflectometer (HWD), PCI and air traffic volume in the past several years, the pavement remaining life of the composite airport pavement was predicted using the above three methods. The prediction results and their comparison are presented as well.
Keywords: Airport engineering; Composite pavement; Remaining life; Prediction method; PCI.

1 Introduction

The remaining life of airport pavement is one concern for pavement maintenance or reconstruction. To predict the remaining life of existing pavement is considered as the inverse procedure of new pavement design, in addition, the structural and material parameters of existing pavement used for the prediction should be different from those of new constructed pavement. The current design procedures for airport cement concrete pavement involve LEDFAA and APDMC developed by FAA and Civil Aviation Administration of China (CAAC) respectively. To better predict complex wheel load interactions of the next generation of large civil aircraft such as the Boeing B-777 aircraft and Airbus A380, LEDFAA was introduced as the design program by the FAA in 1995. LEDFAA implements advanced design procedures based on layered elastic theory and handles new and overlay design of both flexible and rigid pavements. The LEDFAA thickness design standard for airport pavements design for fatigue failure expressed in terms of a "cumulative damage factor" (CDF) using Miner's rule. Also, the major material property of the pavement layers is now uniformly expressed as an elastic modulus instead of the previous CBR (California Bearing Ratio) for flexible pavements or k-value for rigid pavements (Federal Aviation Administration,1995). APDMC is similar to the conventional FAA design procedures. In APDMC, the concept of design aircraft is developed for calculating the cumulative equivalent loads of many types of common aircraft gears, and thickness design standard is defined as fatigue damage due to repeated stress at bottom of the concrete pavement(Civil Aviation Administration of China, 2000). Ling Jian-ming (Ling, J. M., Zheng, Y. F., 2001) *et al.* (2001) and Wang Wei (Wang, W., 2004) (2004) had applied APDMC method to develop the prediction method of remaining life for cement concrete pavement of airport. Moreover, PCI recession model was also considered an approach to predict the remaining life. PCI is based on a visual survey of the number and types of distresses in a pavement. The result of the analysis is a numerical value between 0 and 100, with 100 representing the best possible condition and 0 representing the worst possible condition. PCI surveying processes and calculation methods have been standardized by ASTM for airport pavement. PCI regression model is established by in-situ PCI survey data in past several years and can be used to predict PCI in the future years(Ollerman, F. A., and Varma, A. ,1998).

As seen from literature, the present prediction methods are mainly developed for unique cement concrete pavement. However, The remaining life of composite pavement need attention as well. This paper discusses the alternatives to estimate the composite pavement with an example of a certain composite airport.

The research object is a certain composite airport pavement which has experienced several times of overlayed. The initial pavement consisted of 15cm PCC slab and 25cm block stone base course, and the nowadays runway pavement presents to be relatively complex composite structure. Figure 1 shows the thickness and the materials of typical runway pavement and subgrade layers which were constructed in different stages.

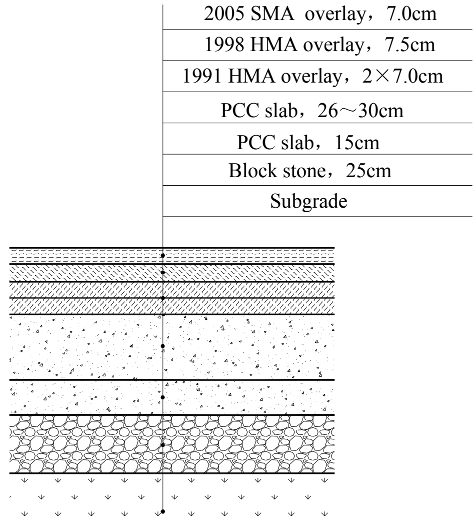

Figure 1. Cross-Section of the typical pavement of the composite pavement

To determine the optimal time for the next reconstruction of the pavement, the remaining life of the existing pavement should be accomplished as an import basis for decision-making. Three alternatives categorized as structural and functional methods are applied to predict the remaining life of the pavement which include LEDFAA pavement design procedure, APDMC pavement design method and PCI regression model.

2 Three methods to predict the composite pavement life

2.1 Appropriate Combination of Pavement Layers

To better account for the performance of various structural layers and decreasing the error level in the modulus back-calculation, the runway pavement is appropriately combined to five layers according to the pavement condition: 1998 and 2005 HMA overlays as one layer, 1991 HMA overlay, PCC slab, block stone and subgrade. The simplified pavement structure is shown in Figure 2.

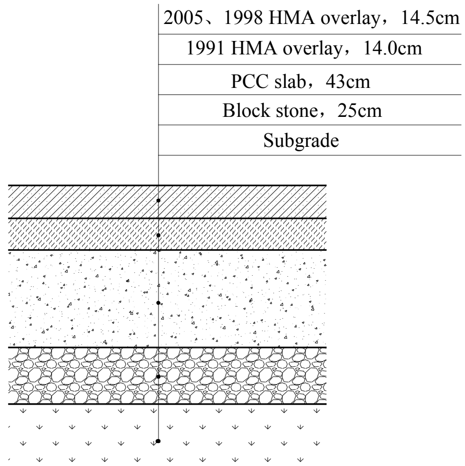

Figure 2. Simplified pavement structure

2.2 Pavement parameters determination

Since the existing pavement has been provided service for many years, the pavement materials have consumed a certain degree of structural life subject to a wide variety of loadings and climatic effects (Civil Aviation Administration of China, 2000). For this reason, the thickness of pavement layers must be appropriately discounted based on field testing results of pavement layers' condition, and elastic moduli of pavement layers and subgrade should also be back-calculated by HWD test. The FAA's back-calculation program, BAKFAA, is used to analyze deflection data to characterize the pavement and obtain the material properties of each pavement and subgrade layer.

Figure 3 shows the comparison of the calculated deflections and measured deflections, and table 1 shows the calculation parameters for predicting the remaining structural life of runway pavement conducted by LEDFAA pavement design procedure.

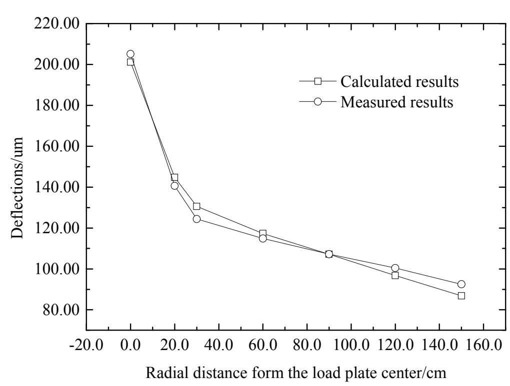

Figure 3. The comparison of the calculated deflections and measured deflections

Table 1. Calculation parameters for predicting the remaining structural life

Structural layer	Discounted thickness/cm	Back-calculated moduli/MPa	Poisson's ratio	Flexural strength/MPa
2005、1998 HMA overlay	13.0	1385	0.35	—
1991 HMA overlay	10.5	981	0.35	—
PCC slab	30.1	27600	0.15	5.5
block stone	25.0	280	0.35	—
subgrade	—	25	0.40	—

2.3 LEDFAA to Predict the Remaining Structural Life

LEDFAA program is applied to predict the remaining structural life of the runway due to present air traffic volume as shown in table 2. The integrated life of the overlaid pavement has two parts (Navneet, G., Edward, G., and Roy, M.,1998): (1) the number of years needed to overlay to the minimum value at the end of the life and (2) the number of years needed to cause reflection cracks to propagate through the asphalt overlay (the propagation rate is assumed to be one year per inch of overlay thickness). The inverse procedure of design method for asphalt overlay on PCC pavement is applied, theoretically, pavement structure life is an unknown variable while the thickness and the moduli of pavement layers and subgrade are deterministic. Based on above calculation parameters, the predicted pavement structural life is 9.6 years.

Table 2. The prediction annual air traffic volume

Aircraft Name	Prediction annual departures	Aircraft Name	Prediction annual departures
A320	31697	B767-200	5994
A300-600	5886	B777-200	3024
A330	1242	B737-800	1134
A340-500/600	216	MD-82/88	4734
B737-700	87766	MD-90-30	8928
B757	16056	CRJ-200	8046
B747-200	1602	Y-8	2412

2.4 Airport Pavement Design Regulation of China (APDMC) to Predict the Remaining Structural Life

2.4.1 Prediction Method

According to the loading response of the typical structure of the existing runway pavement, the PCC slab of the composite pavement is the main layer for contributing stress, so fatigue cracking at the bottom of the PCC layer is used as the critical index for predicting the remaining structural life. Based on the inverse procedure of specifications for cement concrete pavement design for civil transport airport of China, a model is established to predict the remaining structural life of the existing runway pavement:

$$f_{rm} = f_{cm}(0.885 - 0.063\lg N_e) \quad (1)$$

where:

f_{cm}= the concrete flexural strength, determined by field testing;

f_{rm}= the working horizontal stress at the bottom of concrete layer, determined by stress analysis of the composite pavement under design aircraft;

N_e= the remaining number of coverages to failure model for design aircraft.

2.4.2 Prediction Parameters

(1) Air Traffic Volume

"A300-600" is selected as the design aircraft on the basis that most of aircrafts operated on runway belong to type "D". The conversion to equivalent annual departures of the design aircraft is followed by the formula $N_s = \sum_{i=1}^{n} (\delta_i N_i)^{\sqrt{P_i / P_s}}$ and the results are 40912, then the equivalent annual coverages of the design aircraft followed by the formula $Y_s = 0.75 n_w W_t N_s / 100T$ are 3481.

(2) Stress Analysis

Bisar Program based on the elastic layer theory is used to analyze the stress on the bottom of slab on the response to one main loading gear of aircraft A300-600. Figure 4 shows assembly position for pavement stress analysis.

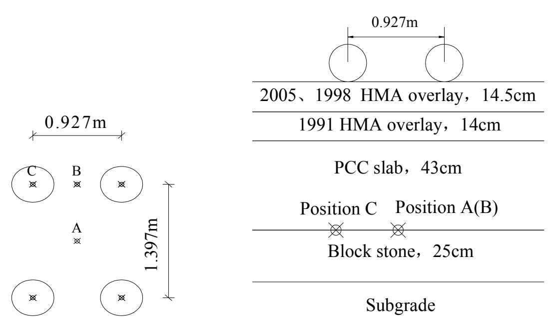

Figure 4. Assembly Position for Pavement Stress Analysis

2.4.3 Prediction results by APDMC

Table 3 shows the procedure of determining the remaining structural life based on APDMC。

Table 3. Procedure for determining the remaining structural life based on APDMC

Design aircraft		A300-600
The equivalent annual departures of the design aircraft N_s		40912
The length of tire print L_t/cm		53.88
The width of tire print W_t/cm		32.33
The passing width of pavement T/m		11.4
The equivalent annual coverages of the design aircraft Y_s		3481
The largest horizontal tensile stress on the bottom of slab/MPa	Position A	3.327
	Position B	3.122
	Position C	3.362
Concrete flexural strength/MPa		5.5
The remaining number of coverages of the design aircraft N_e/ Position C		22125
The remaining structural life t/years		6.4

The predicted runway structural life based on APDMC is 6.4 years due to the failure model of fatigue cracking on the bottom of slab. The predicted remaining structural life has a difference of 3.2 years between the prediction method of LEDFAA pavement design procedure and APDMC. The reason for causing the difference is that the failure model defined in individual method is different, and the control index conducted by LEDFAA program is that Structural Condition Index(SCI) drops to 80 and the reflection cracks propagate through the asphalt overlay while APDMC due to the appearance of fatigue cracking on the bottom of slab.

2.5 PCI Regression Curve to Predict the Remaining Functional Life

In-situ PCI survey data in past several years is provided to establish PCI regression model for the future years. FAA pavement evaluation method specifies that the critical value of PCI is between 55 and 70. For runway, and the value of 65 is adopted. The PCI regression model is established based on in-situ PCI survey data. The value of PCI for regressive curve is presented in Table 4.

Table 4. The Value of PCI for Regressive Curve

n(the service years)	0	2	3	4	5	6
PCI	100	91.5	88.0	80.7	74.6	68.6

Based on the calculation data, the curve was fit as quadratic equation, cubic equation, logarithm equation and exponential equation. The results show that the equation with the general form as $PCI = a \cdot e^{bn^2+cn}$ can fit the data preferably. The reasons are herein: (1) high coefficient of relativity; (2) PCI approximates to 100 in the initial years; (3) the trend of curve is consistent with the characteristic of PCI decreasing.

The regressive equation is determined with the form as $PCI = 99.97e^{-0.0055n^2-0.0301n}$ of which the coefficient of relativity is 0.9974. Following the regressive equation , it will take 6.5 years for PCI to drop from the value of 100 to 65.

3 Conclusions

The predicted pavement structural life based on LEDFAA and APDMC are 9.6 years and 6.4 years respectively. These differences are caused by different failure models defined in individual method. The LEDFAA thickness design standard is that Structural Condition Index (SCI) decreases to a critical value 80 and reflection cracks propagate through the overlay. The APDMC thickness design standard is slab fatigue damage due to repeated stress at bottom of the concrete pavement. In addition, the remaining structural life predicted by APDMC is much sensitive to the working horizontal stress (f_{rm}). A slight increase in f_{rm} has great impact on pavement structural life. Therefore, the remain life estimated by LEDFAA would be longer than that by APDMC, for it will take several years for fatigue cracks occurred in the slab bottom to propagate through the overlay. As a result, APDMC appears to be more suitable for unique concrete pavement than an old concrete pavement with a couple of asphalt concrete overlays. LEDFAA would be more reliable to predict the remaining life of composite pavement structure.

The predicted pavement functional life based on PCI regression model is 6.5 years which is approximately consistent with the result predicted based on APDMC. PCI regression model is established by realistic PCI survey data in past several years. Therefore, predicted by PCI regression model is also a feasible approach to estimate the remaining life for composite pavement if there are successive PCI data in past years available.

Abstract: This paper offers an integrative approach to evaluate factors contributing to efficiency and flexibility of the Russian section of the Eurasian Continental Bridge and examines characteristics that should be focused on to improve both. A survey approach was used to evaluate the efficiency and flexibility characteristics of the Eurasian Continental Bridge. Multistage stratified random sampling approach was adopted to sample respondents. The evaluation was based on analysis of railway transport characteristics in the Russian section of the Continental Bridge. Findings were that the characteristics related to information system, physical distribution, logistics processes and transport service delivery have significant impacts on efficiency and flexibility of the continental bridge. Main Conclusion from the analysis was that to improve efficiency and flexibility levels practitioners and policy makers should focus on the characteristics. The findings of this research will be valuable in realizing the most efficient, flexible and cost-effective railway transport improvements.

Keywords: Eurasian continental bridge; Efficiency; Flexibility; Railway; Transport.

1 Introduction

Eurasian Continental Bridge is rail transport route Pacific seaports in Russia and China to seaports in Europe. The land bridge was developed with the aim of improving international trade, globalization and regional integration between the West and East (Figure 1). Effective use of land bridge services could be the cornerstone of reconstruction of the world economy.

The main concerns about the land bridge by La-Roche (1997) are that: i) only a small proportion of traffic between Europe and Asia is by railways; ii) ways through which container volume transported by intermodal land bridge services between Europe and Asia could be increased; iii) ways of attaining efficiency, cost reduction and time saving in the railway transport; and iv) ways by which the land bridge countries can overcome political, economic and ideological differences and start to collaborate in order to achieve efficiency, cost reduction and time saving.

Previous research on Eurasian Continental Bridge mainly focused on regional collaboration in infrastructural development. Transport flexibility has been identified as an important aspect of overall supply chain flexibility. Flexibility encompasses infrastructure, physical movement of goods and communication. Flexibility of transport along railway line like the Eurasian Continental Bridge is vital in addressing uncertainties in the supply chains depending on it.

The Russian section of the Eurasian Continental Bridge runs from Vladivostok and Nakhodka through Chita, Oms and Moscow. Figure 1 shows the Eurasian Continental Bridge; blue line in the map shows Moscow – Vladivostok line. The Eurasian Continental Bridge connects Moscow to Vladivostok, a distance of 9,289 km with track gauge of 1.520 m. The Trans-Manchurian line connects Moscow to Beijing through Manzhouli border station which is 6,638 km from Moscow. The continental bridge also consists of Trans-Mongolian line to Beijing through Russia/Mongolian border station at Sükhbaatar, a distance of 5,921 from Moscow.

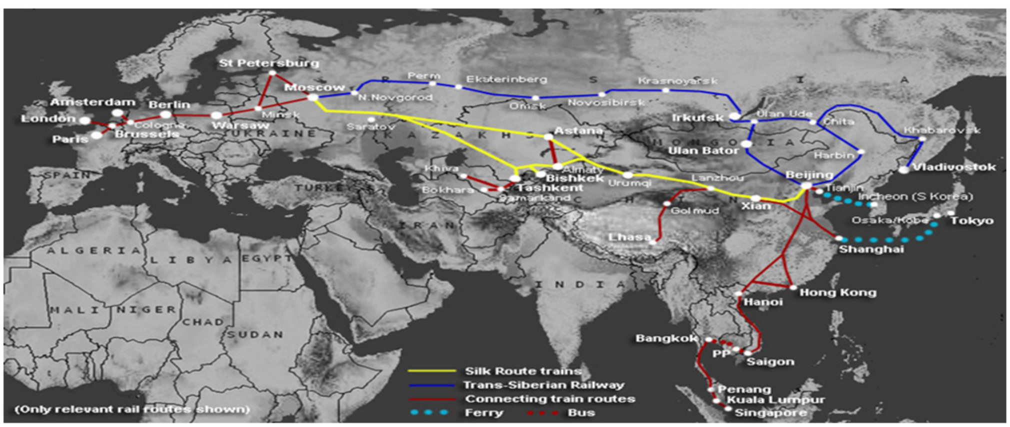

Figure 1. Eurasian continental bridge

This paper aims to address the concerns of La-Roche of attaining efficiency and flexibility in the land bridge as a step towards making the land bridge become cornerstone of reconstruction of world economy. It attempts to fill research gaps in the areas of railway efficiency and flexibility by adopting an integrative approach combining two. The research evaluates the current efficiency level of the Russian section of the land bridge as recommended by Ilie (2010) and Rodrigue (2012) among other researchers.

2 Literature Review

Several researchers have studied efficiency and flexibility of in transport systems. Performance based aspects of efficiency like cost efficiency, cost and service effectiveness (Tennenbaum, 2001; Fielding, Babitsky & Brenner, 1985; Rodrigue, 2012). Other researchers focused capacity and volume aspects of efficiency (Schiller Institute, 2001; Ilie, 2010).

Efficiency has been the main focus of previous railway research (Padila & Eguia, 2010). Zhu (2001) used simulation approach to analyze carrying capacity utilization of railway (European Commission, 2006; Vrugt & Robinson, 2007; Zitzler & Thiele, 1999). Some researchers used survey methods (Bussieck, Winter & Zimmermann, 1997; Cordeu, Toth & Vigo, 1998) but were not specific to Eurasian Continental Bridge. A number of researchers studied economic efficiency of railway transport (McCullough, 2005; Oum & Yu, 1994). Economic efficiency is divided into productive and allocative efficiencies (Oum & Yu, 1994). Determinants of railway efficiency have also been identified in literature. US Department of Defense (2005) noted that efficiency is impacted on by train characteristics, transit time, labor relations and time to clear customs. Federal Railway Administration Research Board (2006) identified key determinants of railway efficiency as human resource, information systems and railway logistics processes.

Research on flexibility has dwelt on both internal and external transport flexibilities. Gosling, Purvis and Naim (2009) classified internal transport flexibility into three: physical movement of goods, infrastructure related flexibility and capacity associated categories. Flexibility of physical movement of good encompasses mode, fleet and vehicle flexibility (Christopher & Juttner, 2000). Infrastructure related transport flexibility includes node, link and temporal flexibility (Gosling, Purvis & Naim, 2009; Christopher & Juttner, 2000). Node flexibility in international railway transport refers to ability of the concerned governments and other stakeholders to plan, approve, implement or remove transport nodes in a railway network. Link flexibility is the ability to establish or remove transport links between nodes. Temporal flexibility is defined as the ability to sequence transport infrastructural investments and the extent to which its use requires user coordination (Noteboom, Keters & Debruyne, 2013; Peppers & Rogers, 1996).

3 Research Methods

3.1 Objectives

There are two objectives:

To analyze efficiency and flexibility characteristics of the Eurasian Continental Bridge; To propose a model of flexibility and efficiency of the Eurasian Continental Bridge.

3.2 Methodology

This research adopted a survey approach to evaluate the efficiency and flexibility levels of the Eurasian Continental Bridge. It used multistage stratified random sampling method to sample respondents from the government ministry of transport, freight companies and Russian Railways. Table 1 shows sample of respondents.

Data collection was done using structured closed ended questionnaires. Determinants of flexibility were identified as: physical movement of goods;

infrastructure; capacity; speed; mobility; service delivery and ownership. Tables 2 and 3 summarize attributes of efficiency and flexibility, respectively. All the characteristics of efficiency and flexibility were rated using Likert Scale with 1= strongly disagree; 2=disagree; 3=agree; 4=strongly agree; 5=very strongly agree.

Table 1. Sample of Respondents

	Target Respondents	Number of participants	Percentage
Ministry of Transport	30	21	70%
Russian Railways	50	43	86%
Freight Companies (15 companies)	150	122	81.3%
Total	**230**	**186**	**80.87%**

Table 2. Efficiency attributes of the continental bridge

Question 1: To what extent do you agree that the following characteristics contribute to efficiency of the Eurasian Continental Bridge?				
Code	Category	Characteristics	Code	Rating
TC	Train characteristics	Train energy efficiency	TC1	
		Reliability of trains and wagons	TC2	
		Train capacity	TC3	
		Train speeds	TC4	
TF	Time factor	Transit speed and gauge characteristics	TF1	
		Automated fast train driving	TF2	
		Timely scheduling and planning	TF3	
		Time to clear customs	TF4	
HR	Human resource	Nature of Human Resource Utilization	HR1	
		Labor relations	HR2	
		Human Resource development	HR3	
IS	Information systems	Level and nature of data collection	IS1	
		Level of transport decision support system	IS2	
		Efficiency of wayside and onboard detection systems	IS3	
		Improved visibility of goods in transit	IS4	
		Data accuracy and timeliness	IS5	
LP	Railway logistics processes	Reliability of railway infrastructure	LP1	
		Ability to improve railway hardware management system	LP2	
		Reliability of railway physical infrastructure	LP3	
		Ability to increase throughput	LP4	
		Ability to reduce train idling	LP5	

Table 3. Flexibility attributes of the continental bridge

Question 2: To what extent do you agree that the following characteristics contribute to flexibility of the Eurasian Continental Bridge?				
Code	Determinant Category	Characteristics ability to:	Code	Rating
PD	Physical Distribution	1.Plan, approve, implement or remove transport nodes by concerned governments and other stakeholders	PD1	
		2.Adjust transport speeds in response to customer demand	PD2	
		3.Redeploy transport asset	PD3	
		4.Avoid under-utilization of organizational transport resources	PD4	
IN	Infrastructure	1.Improve railway infrastructure	IN1	
		2.Effect nodal (station) improvements	IN2	
		3.Have adequate warehousing facilities	IN3	
CP	Capacity	1.Have various transit options	CP1	
		2.Manage different types of information by transport service provider	CP2	
		3.Accommodate different routes	CP3	
		4.Improve carriage capacity to meet traffic demands	CP4	
SD	Service delivery	1.Implement quick response	SD1	
		2.Empower workforce	SD2	
		3.Have flexible planning system	SD3	
		4.Deliver quickly and effectively	SD4	
		5.Have an effective motivation system	SD5	
		6.Tailor service to customer demands	SD6	

Reliability and regression analysis was used in this research. Reliability analysis was done using SPSS software to obtain Cronbach's alpha. Regression analysis involved calculation of coefficient of determination R^2 between groups of correlated characteristics as shown in Tables 4 and 5. Test for multi-collinearity was done using Variance Inflation Factor (VIF) statistics of which VIF values of less than 10 indicate that there is no multi-collinearity (Hair, et al, 2009).

3.3 Research Hypotheses

H1: The characteristic studied is significant to efficiency of the Eurasian Continental Bridge. H2: The characteristic studied is significant to flexibility of the Eurasian Continental Bridge.

4 Discussions of Results

4.1 Results of Reliability Analysis

Tables 6 and 7 show calculated Cronbach Alphas for all the characteristics of efficiency and flexibility of Eurasian Continental Bridge are well ahead of the cut off rate of 0.70 which proves good reliability. It means that all the factors used to evaluate the efficiency and flexibility of the land bridge were found to be reliable so factors would produce consistent results irrespective of time period.

Table 6. Reliability and regression analysis results of efficiency characteristics

Latent variable	Independent variable	Cronbach's Alpha	Dependent variable	Independent variable	Cronbach's Alpha
TC	TC1	0.85	IS	IS1	0.72
	TC2	0.71		IS2	0.77

HR	HR1	0.83		LP4	0.70
	HR2	0.91		LP5	0.83
	HR3	0.82			

4.2 Results of Regression Analysis

Infrastructure and capacity characteristics create significant positive impact on physical distribution of the land bridge as regression coefficients are significant (IN β – 0.928 and CP β – 0.725). The value of R2 shows 74.5% variations in physical distribution. The Variance Inflation Factor (VIF) statistics shows the value of 2.33 for both independent factors, which is very far from cut off rate of 10. Therefore there is no concern of multi-collinearity among independent factors. Physical distribution creates significant positive impact on service delivery (PD β – 0.724).

Table 7. Reliability and regression analysis results of flexibilitiy characteristics

Latent variable	Independent variable	Cronbach's Alpha	Dependent variable	Independent variable	Cronbach's Alpha
PD	PD1	0.76	CP	CP1	0.70
	PD2	0.70		CP2	0.90
	PD3	0.81		CP3	0.73
	PD4	0.75		CP4	0.77
IN	IN1	0.86	SD	SD1	0.81
	IN2	0.88		SD3	0.76
	IN3	0.79		SD4	0.72
				SD5	0.89
				SD6	0.82

The value of R2 shows 64.3% variations in Service Delivery. Train Characteristics, Time Factor and Human Resource factors create significant positive impact on Information System (TC β – 0.683, TF β – 0.749 and HR β – 0.786, respectively). The value of R2 shows 56.1% variations in Information Systems. Information System create significant positive impact on Logistics Processes as regression coefficients are significant (IS β – 0.941). The value of R2 shows 62.7% variations in Logistics Processes. The VIF statistics shows the value of 2.28 for both independent factors, which is very far from cut off rate of 10. So there is no concern of multi-collinearity among independent factors.

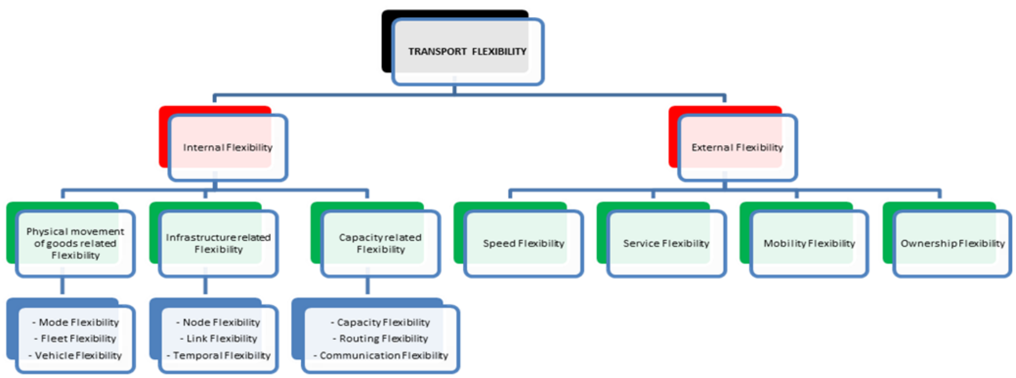

Figure 2. Transport flexibility

4.3 Implications of Research Findings

Infrastructure and capacity are key factors in flexibility of Eurasian Continental Bridge. Key factors influencing efficiency are train characteristics, time factor and human resource. However, physical distribution flexibility and service delivery flexibility cannot be achieved also without flexibility in infrastructural and capacity development. The role of physical distribution flexibility and service flexibility are very important in case of urgently required or fast transit goods. It requires timely and cost effective distribution of varieties goods to distant lands in Middle East and Europe across Russia.

Efficient logistics processes are important in meeting strict lead times. In order order to satisfy varieties of customer transport requirements in the Eurasian Continental Bridge bound supply chains, customized and timely transport and logistics services should be offered through effective and flexible service delivery and efficient logistics processes (Figure 3).

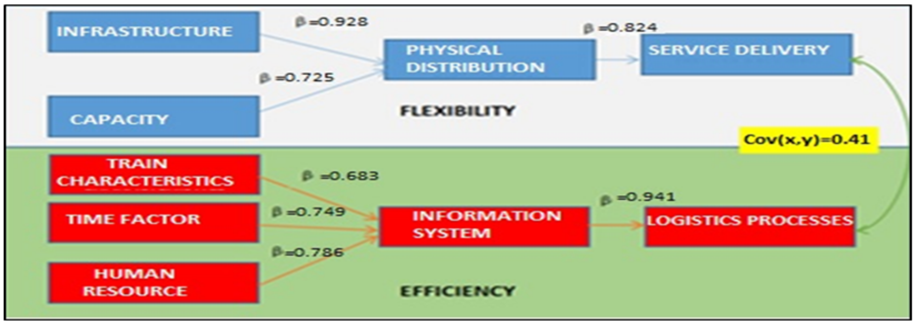

Figure 3. Relationship between efficiency and flexibility characteristics

5 Conclusions

The following conclusions can be drawn from the findings of this research:

(1) Main characteristics influencing efficiency and flexibility of the Eurasian Continental Bridge are train characteristics, time factor and human resource;

(2) Infrastructure and capacity characteristics create significant positive impact on physical distribution along the land bridge. This implies that improvement of infrastructure and capacity can positively improve physical distribution thereby increasing efficiency and flexibility.

(3) Train characteristics, time factor and human resource factors have significant positive impact on the use of railway information system. Trains should be made such as to allow for proper installation and use of onboard railway information system. Improvement of human resource capacity and train speeds (time factor) of the land bridge can lead to efficiency and flexibility improvement.

(4) Railway information systems have positive significant impacts on logistics processes of the land bridge. Most modern logistics processes need information system to ensure fast information processing to boost both flexibility and efficiency.

It is concluded that to improve efficiency and flexibility levels practitioners and policy makers should focus on the characteristics studied in this research.

Abstract: Reinforcement corrosion caused by chloride is one of the major reasons of reinforced concrete durability failure, and chloride in RC railway bridge is mainly derived from marine environment. Therefore, a resistance degradation model of axial compressed structure calculated on bearing capacity limited state is established against the background of the marine environment, considering the deterioration of reinforcement and concrete. Consequently, durability assessment of a coastal railway bridge pier is made by way of the reliability calculation program.
Keywords: Marine environment; Chloride corrosion; Deterioration; Durability.

1 Introduction

Professor P.K. Metha (Luo Fuwu, 1996) identified reinforcement corrosion as the first factor affecting durability of concrete structures. Furthermore, a large number of practice has proved chloride is the major cause of reinforcing bars corrosion. Statistical data showed that durability failure of concrete structures caused by chloride has brought about huge economic loss around the world. Therefore, concrete durability has already become a world's major problem. Reinforcement corrosion caused by chloride is different from the one under ordinary atmospheric environment. Its corrosion mechanism is macro cell corrosion and corrosion form is local pitting corrosion. Chloride corrosion caused the decrease of effective section area of reinforcement, which would result in degradation of reinforcement yield stress and concrete strength. For accurately predicting reliability and durability of the structure, many researchers (Mark G. Stewart, David V. Rosowsky, 1998) (Mark G. Stewart, 2004) (Peng J., Mark G. Stewart, 2008) (Vu K, Mark G. Stewart, 2005) proposed the pitting model of steel reinforcementand deterioration and time-dependent reliability model of concrete structures corrosion-induced cracking. In regard to railway bridge, chloride induced reinforcement corrosion is mainly derived from marine environment. Therefore, based on time-dependent reliability theory, durability assessment of a coastal railway bridge pier is implemented using Monte Carlo Method and considering reinforcement and concrete deterioration.

2 Reinforcing steel subjected to chloride-induced corrosion

2.1Time to initiation of reinforcing steel corrosion

In an atmospheric marine zone, the chloride content at a distance x from the concrete surface and at time t is(Mark G.Stewart,1998)

$$C(x,t) = 2W\left\{ \sqrt{\frac{t}{\pi D}}\exp\left(-\frac{x^2}{4Dt}\right) - \frac{x}{2D}\left[1-erf\left(\frac{x}{2\sqrt{Dt}}\right)\right]\right\} \tag{1}$$

where W is the diffusion flux on the concrete surface, D is the apparent diffusion coefficient.

The time to initiation of rebar corrosion is

$$T_i = \frac{(d_i - d_0/2)^2}{4D}[erf^{-1}(\frac{C_{cr}-C_0}{C_i - C_0})]^{-2} \tag{2}$$

where d_i is the distance from concrete surface to rebar centre, d_0 is the diameter of initiation rebar, C_0 is the surface chloride content, C_{cr} is the critical threshold chloride concentration, C_i is the initiation chloride content.

Above all, this paper proposes the chloride content $C(x,t)$ of reinforcing steel surface is expressed by numerical solution at time t (10~50 $years$) and at distance x (30~ 50 mm) from concrete surface, see Table 1.

Table 1. The chloride content of rebar surface with numerical solution

x \ t	10	20	30	40	50
30	0.296	0.638	0.930	1.187	1.419
40	0.174	0.456	0.717	0.954	1.171
50	0.096	0.317	0.542	0.756	0.957

The chloride content of reinforcing steel surface at time t can be confirmed shown in Table 1, according to the time to initiation of rebar corrosion is

$$T_i = \begin{cases} t, & C(c,t) = C_r \\ t+1, & C(c,t) < C_r < C(c,t+1) \end{cases} \tag{3}$$

2.2The deterioration model of reinforcing steel

2.2.1 Pitting model

The pit configuration is used to predict the cross-section area of the pit, as shown in Figure.1.

The maximum pit depth (Mark G. Stewart, 2008) along a reinforcing bar with surface area A is

$$P(t) = 0.0116 \times i_{corr} \times R \times t \quad (4)$$

Where, $R = P_{\max} / P_{av}$, $P_{\max}$ is the maximum pitting depth, P_{av} is the uniform corrosion depth, i_{corr} is the corrosion rate measured as a current density.

The pitting width a and cross-sectional area A_{pit} can be expressed as

$$A_{pit}(t) = \begin{cases} A_1 + A_2, & p(t) \leqslant \frac{D_0}{\sqrt{2}} \\ \frac{\pi D_0^2}{4} - A_1 + A_2, & \frac{D_0}{\sqrt{2}} < p(t) \leqslant D_0 \\ \frac{\pi D_0^2}{4}, & p(t) \geqslant D_0 \end{cases} \quad (5)$$

where D_0 is the initial diameter of reinforcing rebar.

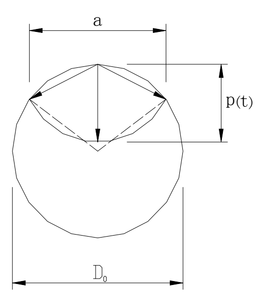

Figure 1. Pit configuration of reinforcing bar

2.2.2 Strength Loss Model

Reinforcement corrosion brought about not only the loss of bar section area, but also the mechanical and the bond properties deterioration of reinforcement. In this paper, mechanical property deterioration is only considered. It is recommended that the nominal yield strength standard value of reinforcement at time t can be expressed as (Niu ditao, 2002)

$$f_s = \begin{cases} f_y & t < T_i \\ f_y[1 - 1.077\eta_s) & t \geqslant T_i \end{cases} \quad (6)$$

where f_y is yield strength of non-corroded reinforcement, η_s is loss ratio of reinforcement section area. It is suggested that when $\eta_s \leqslant 15\%$, nominal yield strength of reinforcement is calculated as formula (6); when $\eta_s > 15\%$, it will be processed as hot rolled steel bar without yield point.

3 Concrete deterioration caused by chloride

Concrete strength still obeys normal distribution through statistical analysis of concrete strength of buildings used many years, only average value and standard deviation has changed. $\mu_f(t)$ and $\sigma_f(t)$ are average value and standard deviation of concrete strength after t years respectively, expressed as

$$\mu_f(t) = \xi(t)\mu_0 \quad , \sigma_f(t) = \eta(t)\sigma_0 \tag{7}$$

where μ_0 and σ_0 are average value and standard deviation of concrete strength at t =0 (i.e. 28 days), respectively.

Through statistical regression of actual measurement and test, the time-dependent models of average concrete strength and standard deviation of concrete strength are obtained, respectively. (Niu ditao, 1995)

$$\xi(t) = e^{-0.0347(\ln t - 0.3468)^2}, \eta(t) = 0.0143t + 1.0624 \tag{8}$$

Once $\xi(t)$ and $\eta(t)$ are determined, the time variation of average value and standard deviation of concrete strength can be completely determined by Formula (7).

4 Limit State Equation

Concrete structural resistance after the reinforcement is corroded will gradually decrease over time. A time-dependent function of structure at one limit state by stochastic process can be express as

$$Z(t) = R(t) - S(t) \tag{9}$$

where t is in-service time of structure, $R(t)$ is stochastic process of structural resistance, $S(t)$ is stochastic process of structural load effect.

The principle of durability failure of concrete structure under marine environment generally adopts the principle of bearing capacity. Based the analysis of reliability theory, the principle of bearing life can be described as: as to the functions representing the limit state of bearing capacity, when cumulative failure probability of structure reaches a certain value, it is called durability failure at the limit state.

4.1 Resistance Model

Taking circular section reinforced concrete eccentric compression member with longitudinal steel reinforcements uniformly provided along the periphery for example, its normal section compressive bearing capacity and resistance function can be expressed as

$$R = K_P N_u = K_P[\alpha f_{cd} A(1-\frac{\sin 2\pi\alpha}{2\pi\alpha}) + (\alpha-\alpha_t) f_{scd} A_s] \quad (10)$$

where A is sectional area of member, A_s is total sectional area of longitudinal reinforcements, f_{cd} and f_{std} are design value of compressive strength of concrete and longitudinal reinforcements, respectively, r is radius of circular section, r_s is radius of circumference where the centroid of longitudinal reinforcements is situated, α is the value for ratio of the central angle of concrete sectional area in compression zone to 2π , α_t is relative area of longitudinal tensile reinforcements, K_P is statistical parameter of resistance of structural member. Generally, for axial compression or small eccentric compression member, the average value and standard value will take 1.37, variation coefficient is 0.15.

4.2 Load Model

Bridge load includes dead load and live load. As to dead load, it is assumed that the mean of nominal values (G/G_n) of concrete bridge is taken as 1.02, and variation coefficient is 0.02. As to live load, the live load of train is the main load on railway bridges. The railway lines in China tend to the lines with passenger and freight traffic. Taking freight train as statistical object, statistical contents includes vehicle overload coefficient K_i , vehicle dead-weight variation correction coefficient K_g artificial recording deviation coefficient of vehicle load K_w. Taking K_i, K_g and K_w as parameters, its probability distribution function is fit using Beta distribution

$$F_{(x)} = \frac{(x-a)^{q-1}(b-x)^{r-1}}{\beta(b-a)^{q+r-1}}, a \le x \le b \quad (11)$$

Statistical analysis results are shown in Code for Railway Bridge (2005). Probability distribution of railway train live load Q1~N (1.0179, 0.0657^2) can be obtained by average value and standard deviation of these three parameters. Taking one of railway standard train live load as standard load, the distribution and parameter reflect the variability of railway train load.

4.3 Monte Carlo Simulation

Monte Carlo Method is also known as Random Simulation. The advantage of Monte Carlo Method for the research of structural reliability is to avoid mathematical difficulties in the analysis of structural reliability. This is to eliminate the need to consider complexity of limit state curved surface. The method is a way to seek the approximate solution of mathematical problem or physical problem adopting sampling statistics theory. Although calculating amount is large, it is considered to be a more accurate method in the current structural reliability calculation. In order to better simulate real process of resistance deterioration, and to obtain the more accurate structural failure probability, Monte Carlo Method is adopted in the process of durability analysis of one cross-sea bridges under chloride environment illustrated later in this paper.

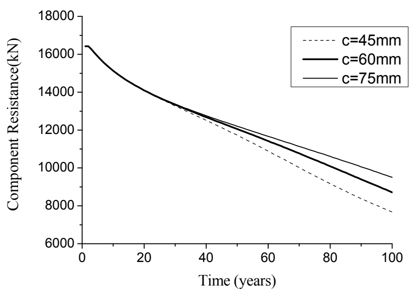
5 Illustrative example

A coastal railway bridge is located in off-shore salty soil area which belong to the strong chloride erosion environment, and the bridge pier corrosion is most serious than any other members. Calculating parameters: diameter of bridge pier d_{pier} is 1500 mm; uniformly providing 28 pieces of longitudinal reinforcements with diameter d_{rebar} of 25 mm, design value of tensile strength of longitudinal reinforcements f_y =340MPa, design value of compressive strength of concrete f_{cd} =23 MPa, water cement ratio W/C =0.4, for thickness of cover c, taking 40 ~60 mm respectively; distribution type of structural resistance is lognormal distribution, its variation coefficient V_R =0.15, axial pressure under permanent load bearing on bridge pier is S_G, axial pressure under live load is S_Q. Statistical data of parameters used in calculation are shown as Table 2.

Table 2. Statistical parameters for chloride diffusion and loading variables

Parameter	Mean	Coefficient of Variation	Distribution
D	$2.0E\text{-}8\ cm^2/s$	0.75	Lognormal
W	$7.5E\text{-}15\ kg/cm^2 s$	0.6	Lognormal
C_0	$2.95\ kg/m^3$	0.5	Lognormal
C_r	$0.9\ kg/m^3$	0.19	Uniform (0.6—1.2)
S_G	$4488\ kN$	0.021	Normal
S_Q	$960\ kN$	0.064	Normal

Due to eccentric compression model of pier used in this example, it should consider the combined action of reinforcement deterioration and concrete deterioration when establishing reinforcement deterioration model. This paper put out the curve of structural resistance and cumulative failure probability as the time applying Monte Carlo Method.



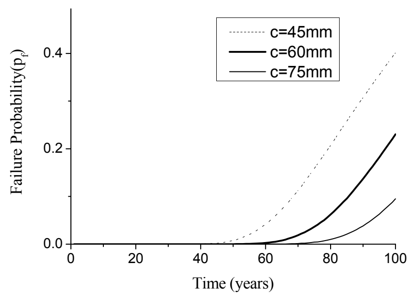


Figure 2. Mean component resistance **Figure 3. Time-dependent failure probability**

As known from the calculation, when cover thicknesses are taken as 45 *mm*, 60 *mm* and 75 *mm* respectively, its corresponding failure time are36 *years*, 45 *years* and 50 *years*, respectively. It is evident from Fig. 3 that reduced cover leads to an increase in failure probabilities, which conforms to the rule of reinforcement deterioration model. The larger cover thickness is, the longer initial corrosion time is, and the lower the reinforcement corrosion velocity is. Therefore, increasing properly concrete cover thickness is helpful to improve structural durability.

6 Conclusions

Corrosion initiation reduces the cross-sectional area of the reinforcing bars, leading to a loss in structural strength. Against the background of the reinforcing steel pitting induced-chloride under marine environment, a time-dependent probability deterioration model of resistance was developed considering deterioration of reinforcing steel and concrete. Based on time-dependent reliability theory, durability assessment of a coastal railway bridge pier is implemented using Monte Carlo Method. By comparing different concrete cover thicknesses, properly increasing the cover thickness is an effective measure which could improve structural durability under chloride-induced corrosion environment.

7 Recommendations for Future Research

The deterioration mechanism of corroded reinforcing model is important to study structural durability. Further work is clearly needed in refining these models and their associated parameters, and in the inclusion of other factors affecting corrosion initiation. Meanwhile the bond performance and seismic behavior of structure after the corrosion initiate are needed to further investigate.

Abstract: High embankment with geogrid can restrict the deformation and improve the strength and stability of soil. In order to study the characteristics of geogrid reinforced high embankment, the stability based on geogrid reinforced high embankment project of Hebei province and compare reinforced embankment under different conditions by using the $FLAC^{3D}$ and analyze the mechanism of reinforced embankment were studied in this paper. The results show that the maximum deformation happened in the center of high embankment, and relatively small deformation appear at the edge of high embankment. The interface friction angle the greater the better, it can make the better friction between geogrid and soil, and could reduce vertical additional stress within a certain depth. Geogrid can improve the redistribution and decrease horizontal stress and vertical stress of reinforced embankment. Plastic zone appears the slope angle at top and bottom of the slope. Stretching damage of plastic region of embankment is located in the bottom of the embankment, tensile failure occurs in the slope of top of the embankment, shear failure and tensile failure appears at the bottom of the embankment.

Keywords: Geogrid; Reinforced soil; High embankment; Numerical analysis.

1 Introduction

FLAC program based on Lagrangian finite difference method is a common geotechnical engineering analysis software internationally with powerful computing capabilities and extensive simulation capabilities. The advent of $FLAC^{3D}$ based on three dimensional fast Lagrangian analysis program provided a powerful simulation tool for geotechnical engineering research, especially elasto-plastic analysis, large deformation analysis and simulate construction process, etc. $FLAC^{3D}$ has been widely application, for example: Hegde (2014), Hambleton (2013), TAO Hui (2014), Tafreshi (2013), ZHANG Hong (2009).

CHEN Xiangjun and TANG Jinsong (2002) have studied on the stability and deformation analysis of Maya slope using $FLAC^{3D}$. YU Zehong (2005) have studied on numerical analysis of reinforced embankment. The study shows that the performances of the shear zones of reinforced slope are correlated directly with the reinforcement effect, changes of shear zone morphology reflected the stability mechanics of reinforced embankment. WANG Mingyuan (2009) have carried out the numerical simulation on the pullout process of reinforced soil interface. The study shows that it is rational and feasible by setting boundary element to simulate interaction between reinforcement and soil. WANG Jiaquan and other people (2010) have carried out the field test on treat the old and new high embankments by using geocell associated with a mountainous expressway widening project. They analyzed the variation rules of the lateral displacement, settlement and soil pressure of high embankment and the effect of geocell treatment. Kevin and Jonathan (2006) analyzed the ultimate bearing capacity of foundation based on limit equilibrium theory. They compared two design methods for embankment reinforced with geogrids.

This paper simulated numerically reinforced embankment in mountainous area in Hebei by using the $FLAC^{3D}$ software. It discussed the reinforced effect of high embankment from the ground surface settlement, vertical displacement, horizontal displacement, plastic state distribution, and provides the reference for the future design and construction.

2 The establishment of numerical model

2.1 Project overview

The project is located in Hebei a mountainous area , the geological condition is the fully weathered light yellow gneiss, rock fragmentation and local irregular granular, basement is largely strong-fully weathered bedrock. The high embankment are mainly the stone. The embankment height varied with different slope ratios: when the slope height of embankment is less than or equal to 8 m, the slope ratio takes 1:1.5. It needs to set platform with 2 m width at 8 m; when the slope height of embankment is more than 8 m and less than 20 m, the slope ratio takes 1:1.75. It also needs to set platform with 2 m width at 20 m. When the slope height of embankment is more than 20 m, the slope ratio takes 1:2.0.

2.2 The basic assumption

Without considering horizontal tectonic and the influence of groundwater, surface water seepage and earthquake, the initial stress field of model takes self-weight stress field. Without considering the influence of temperature change of the structure, and the effect of soil consolidation and pore water pressure. This model makes the convergence of numerical calculation as a criterion of instability, it mainly considered the stress and the deformation under different conditions during the construction of high embankment.

2.3 The geometric model

The actual problem is simplified in this paper. Considering the symmetry of the embankment, this paper established on the left half of calculation model and divided network by using Mohr-Coulomb nonlinear constitutive model in $FLAC^{3D}$ and associated flow rule. Interface between geogrid and FLAC^{3D} solid element generates the friction. The model set without thickness geogrid unit between geogrid and soil.

The constraints of model boundary are fixed at the bottom of the model, and are normal at the left and the right sides of model, are free boundary at the upper of model. Horizontal direction is as X axis and vertical direction is as Y axis. The initial stress field of model takes self-weight stress field, network is divided into 2340 nodes and 1660 units. Sketch map and network division of analysis model are shown in Figure 1.

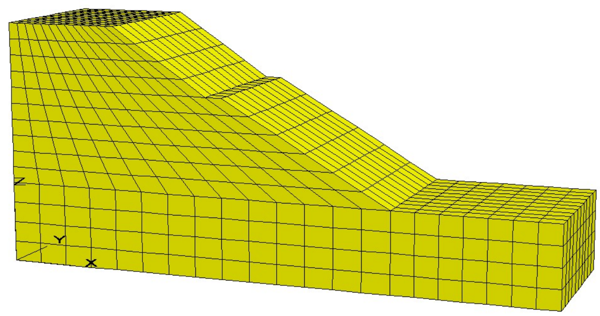

Figure 1. Sketch map and network division of analysis model

The geometric parameters of embankment model are as follows: half of the top of embankment width is 14 m, the embankment height is 20 m. On the basis of the survey data, the mechanical parameters of rock and soil mass are shown in Table 1. The model selected the EG3030 bidirectional plastic geogrid from the indoor test, physical and mechanical indexes are shown in Table 2.

3 Analysis of numerical calculation results of reinforced embankment

In order to analyze the reinforced influence of deformation and stability of embankment, this paper studies the reinforced effect of embankment by laying geogrid compared with not laying geogrid.

To control the excessive vertical settlement of embankment, the reinforced location choose to be at concentrated area in the vertical settlement of embankment, that is to say in the middle and lower of embankment. Position of geogrid is shown in Figure 2.

Table 1. The mechanical parameters of rock and soil mass

Structure layer	Bulk modulus K /MPa	Elastic modulus G /MPa	Density ρ /kN·m^{-3}	Cohesion c /kPa	Friction angle φ /°
Filling	12	3.0	2020	20	34
The upper layer of foundation	12	6.0	2260	25	22

The lower layer of foundation	15.8	7.3	2330	40	25

Table 2. Physical and mechanical indexes of geogrid

Bulk modulus K /GPa	Poisson ration υ	Geogrid thickness t /mm	The coupling spring stiffness k /N·m^{-3}	Coupling spring cohesion kPa
26	0.33	5	2.3*10^{6}	0

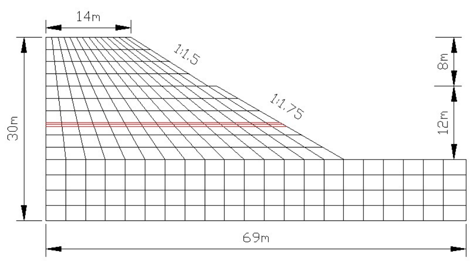

Figure 2. Sketch map of position of geogrid

3.1 Displacement analysis of reinforced embankment

The contour of displacement of reinforced embankment is shown in Figure 3. It can be seen that the whole deformation of embankment is mainly vertical settlement, the maximum deformation appeared at the top center of embankment from this figure. Centered on the top center of embankment, transverse radius is larger than 14 m, the vertical radius is approximately 10 m oval formed within the scope of a centralized settlement area, the region has the maximum deformation. The contour of displacement map of reinforced embankment is shown in Figure 4.

According to the analysis of the friction characteristics of reinforced soil interface, the results showed that the friction angle of reinforced soil interface is the bigger the better, so that reinforcement and soil produce better friction effect which can decrease vertical additional stress in certain depth of soil and stress distribution is more uniform in the cross section.

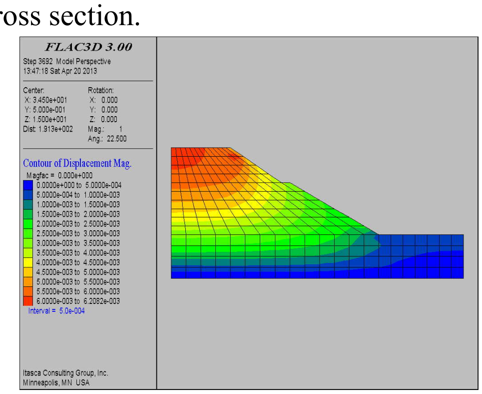

Figure 3. The contour of displacement of reinforced embankment

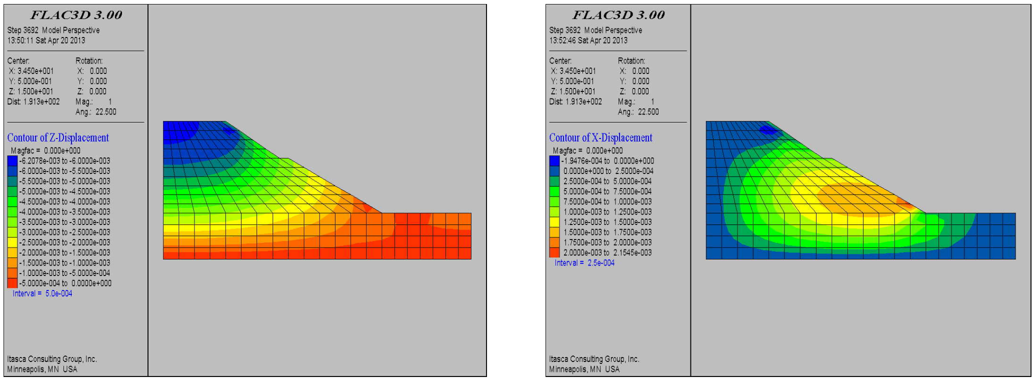

(a) The contour of vertical settlement (b) The contour of horizontal settlement

Figure 4. The contour of displacement map of reinforced embankment

Although the reinforcement has little effect on decreasing the vertical settlement of embankment from Figure 5, it was effective to lessen the differential settlement of embankment. Through constraining the lateral displacement of embankment, and decreasing the level of slope stress and the inhibition of the plastic zone development, thus the embankment is more stable.

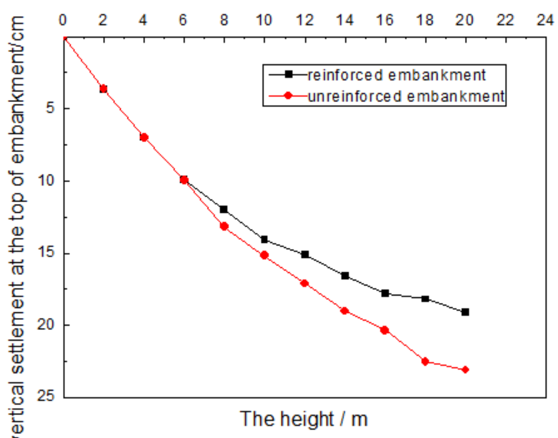

Figure 5. Relational graph between the height and vertical settlement

According to Figure 6 which is relational graph between the height and horizontal displacement at the foot of embankment, the result shows that lateral displacement at the foot of un-reinforced embankment is 9.23 cm, the horizontal displacement decreases to 8.12 cm after reinforcement, and decrease of 13.7%. These show that reinforcement can restricted lateral displacement to a certain extent when laying geogrid in the embankment.

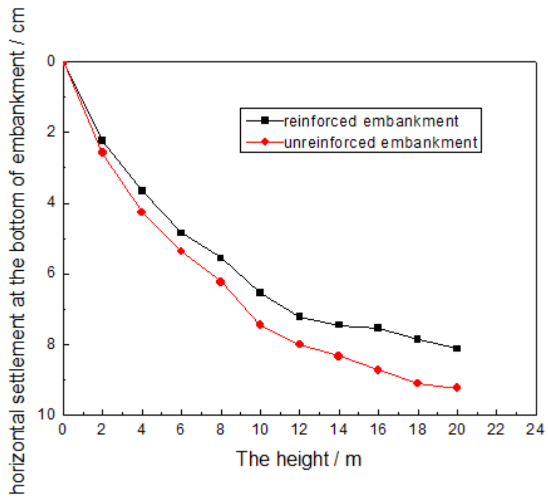

Figure 6. Relational graph between the height and horizontal settlement

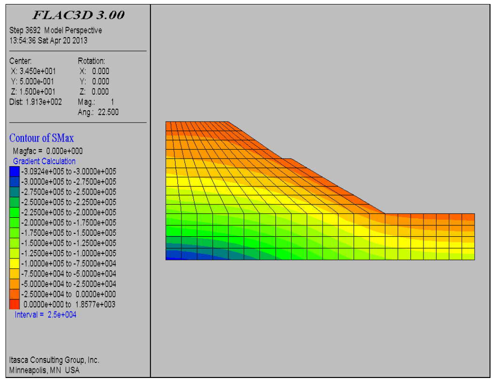
The soil has high compressive strength and shear strength, but the tensile strength is lower, so after laying geogrid at the tensile direction in the soil, the friction bite force between geogrid and soil enhances lateral restraint of soil and limits lateral deformation of soil. Lateral displacement is an important reason to lead to the occurrence of settlement deformation under the external loads. It can improve the slope stability through reinforcement to restrict lateral displacement of embankment.

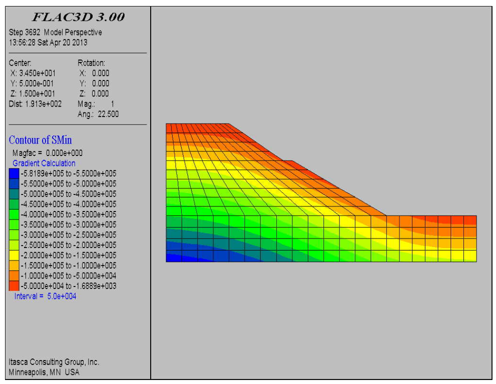
3.2 Stress analysis of reinforced embankment

It can be seen from Figure 7 of the contour of the main stress of reinforced embankment that the maximum principal stress increases with increasing fill depth, the main stress can reach the maximum at the bottom of embankment, the stress concentration area appears in the slope toe and the upper part of the embankment, and the main stress decreases gradually from inside to outside. The principal stress of slope reaches the minimum. The maximum of the minimum principal stress still appear in the bottom of embankment from the contour of the minimum principal stress.

The calculation result shows that the reinforced effect of embankment is not obviously, the whole deformation situations before and after reinforced embankment are the same by comparing the contour of displacement of reinforced embankment before and after. Comparison the contour of the maximum principal stress and the contour of the minimum principal stress of reinforced embankment, the study found that the maximum principal stress increases with soil depth, and reaches the maximum at the bottom of embankment. This suggests that the friction effect between geogrid and soil decrease the principal stress of embankment.



a. The contour of the maximum principal stress



b. The contour of the minimum principal stress

Figure 7. The contour of main stress of reinforce embankment

3.3 Plastic zone analysis of reinforced embankment

Plastic zone distribution is greater, this suggests that plastic yielding area of slope is larger. The case of the plastic zone illustrates distribution and development trend of the slide of slope. Once plastic zone through, the whole sliding surface is formed basically, the damage appeared along the sliding surface. The contour of the plastic zone of reinforced embankment is shown in Figure 8, the contour of shear strain increment of reinforced embankment is shown in Figure 9.

It can be seen from Figure 8 of the plastic state distribution, the tensile failure of plastic zone of embankment slope is located at the foot of embankment slope, tensile failure appeared at the top of embankment, and shear failure and tensile failure appears at the bottom of slope toe of embankment, the plastic zone is not through in a whole range of embankment, which can determine the embankment slope currently in stable.

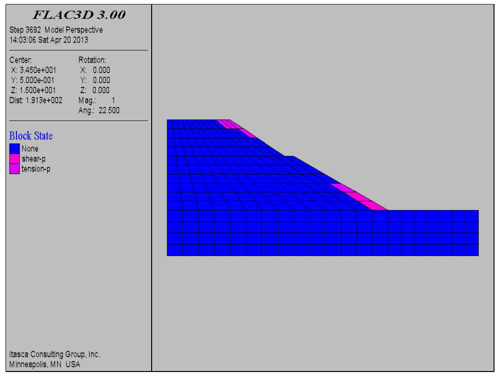


Figure 8. The contour of the plastic zone of reinforced embankment

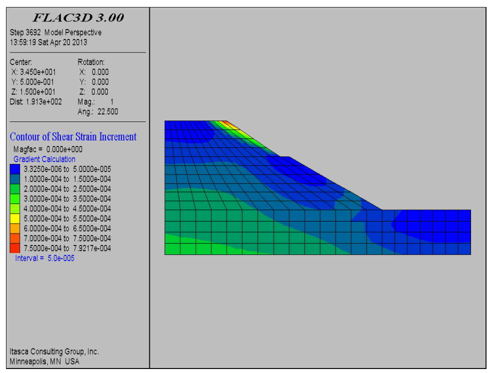

Figure 9. The contour of shear strain increment of reinforced embankment

When designing the geogrid position, it puts geogrid in plastic zone of embankment which can meet the engineering requirements, not necessarily laid in the whole embankment. The contour of shear strain increment has not yet run through from Figure 9, it suggests that the sliding force which provided by slope not enough to create shear failure of slope and slope is in the steady state. Shear strain increment of in the lower of embankment is very small, some close zero. These parts usually does not exist the potential sliding surface, and does not occur large deformation and the failure. Shear strain increment is larger at the top of slope of embankment, the shear failure zone appear easily in the region which exist a potential slip surface and happened easily the deformation damage. Shear strain increment is very small at lower part of embankment, it indicates that this region is in the shear condition which can provide better skid-resistance to keep the stability of embankment.

From the contour of plastic state distribution and the contour of shear strain increment of reinforced embankment, the result shows that the plastic zone and the contour of the maximum shear strain of reinforced embankment expand to embankment inner, the scope of the plastic zone gradually expand, but the maximum shear strain decreases. The location of slip surface of reinforced embankment moves downwards, it illustrates the resistance deformation ability of reinforced embankment are enhanced, the friction between geogrid and soil plays a role in a certain extent.

4 Conclusions

(1) Embankment deformation dominates by vertical, the maximum horizontal deformation appears in the toe of embankment slope. Through the numerical simulation of reinforced embankment, the study shows that with laying geogrid in embankment, it inhibites vertical deformation and horizontal deformation and enhances the overall stability of embankment, especially the stability of the embankment slope.

(2) The friction angle of reinforced soil interface is bigger, so that better friction effect produced between geogrid and soil, it decreases the vertical additional stress of soil in certain depth of embankment and stress distribution is more uniform in the cross section. Although the reinforcement has little effect on decreasing the vertical settlement of embankment, it is effective to decrease the differential settlement of embankment. Geogrid could inhibit the horizontal displacement of embankment, and lesson the stress of slope and inhibit the plastic zone development, thus tend to a more stability of embankment.

(3) With laying the geogrid in embankment, the stress of reinforced embankment will redistribute, the vertical stress and horizontal stress are decreased. Through the friction between geogrid and soil, the shear strength of reinforced embankment is enhanced, and the stress state is improved, so that reinforced embankment could stand greater load, anti-deformation ability and anti-crack ability are enhanced.

(4) The plastic zone of embankment appears at the slope angle in the top of embankment and in the toe of embankment slope, the tensile failure of plastic zone of embankment slope is located at the foot of embankment slope. Tensile failure appears in the top of embankment and shear failure and tensile failure appear in the bottom of slope toe of embankment.

Abstract: In order to investigate ambient temperature and vehicle loading influence on asphalt pavement rutting development, ABAQUS is utilized to build pavement structure three-dimension model. Based on the actual temperature data, heat transfer theory, creep model and 3-D finite element method, the temperature filed variation law in pavement is calculated. And asphalt pavement rutting developments under different vehicle loadings in different ambient temperatures are analyzed. The results indicate that pavement rutting develops nonlinearly as ambient temperature varies; the rutting developing rate under high temperature condition is much higher than under low temperature condition; there is a linear correlation between rutting depth and vehicle loading under the same loading times; the rutting proportion developed in hottest season is much higher than any other seasons.
Keywords: Road engineering; Asphalt concrete pavement; Rutting development; Environment temperature; Vehicle loading.

1 Introduction

Finite element analysis method is utilized to study asphalt concrete pavement rutting development by many researchers. However, daily and seasonal periodical variations of ambient atmospheric temperature were ignored in traditional researches. As a temperature sensitive material, asphalt concrete rutting calculation results influenced by temperautre field very significant. Thus two-step analysis method is utilized in this paper. Fist, pavement temperature fields under different ambient temperatures are obtained by heat transfer analysis utilizing ABAQUS. Based on temperature field calculation results, rutting development laws under different ambient temperature and vehicle loading are analyzed.

2 Temperature Field Analysis Theory

Because of solar radiation, the atmospheric temperature varies greatly between day and night, and presents a periodical variation on a yearly cycle. Effect of solar radiation can be described as boundary condition which varies periodically.

The main factors which influence asphalt concrete temperature are daily maximum temperature $T_a^{\max}$, daily minimum temperature $T_a^{\min}$, total amount of daily solar radiation Q, effective duration of sunshine c, and daily average wind speed v_w.

2.1 Solar radiation

According to the research achievements of Barber, Yan zuo-ren etc, daily variation of solar radiation $q(t)$ can be simulated by using follow equations:

$$q(t)=\begin{cases}0 & 0\le t<12-c/2\\ q_0\cos m\omega(t-12) & 12-c/2\le t\le 12+c/2\\ 0 & 12+c/2<t\le 24\end{cases} \qquad (1)$$

Where: q_0 is maximum radiation in a day where $q_0=0.131mQ$, $m=12/c$; Q is total amount of daily solar radiation; c is effective duration of sunshine, with the unit of hour; ω is angular frequency, and $\omega=2\pi/24$, the unit is rad.

2.2 Heat exchange of atmospheric temperature and convection

Variation of ambient atmospheric temperature can be simulated by using a line combination of two sine functions. The simulation results accurately predict this variation.

$$T_a=\overline{T_a}+T_m[0.96\sin\omega(t-t_0)+0.14\sin 2\omega(t-t_0)] \qquad (2)$$

Where: $\overline{T_a}$ is daily average atmospheric temperature, $\overline{T_a}=(T_a^{\max}+T_a^{\min})/2$, the unit is ℃; T_m is amplitude of daily atmospheric temperature, $T_m=(T_a^{\max}-T_a^{\min})/2$, $T_a^{\max}$ and $T_a^{\min}$ are maximum temperature and minimum temperature respectively; and t_0 is initial phase, t_0 usually takes the value of 9 in normal conditions.

$$h_c=3.7v_w+9.4 \qquad (3)$$

Where: h_c is the heat convection coefficient, the unit is $W/(\mathrm{m}^2\cdot ℃)$, and v_w is the daily average wind speed, m/s.

2.3 Effective radiation of pavement

Effective radiation of pavement relates to pavement surface layer, atmospheric temperature, cloud cover, humidity levels, and so on.

This paper presents effective radiation of pavement by using the following equation:

$$q_F = \varepsilon\sigma[(T_1|_{Z=0} - T_Z)^4 - (T_a - T_Z)^4] \quad (4)$$

Where: q_F is ground effective radiation, $W/(m^2 \cdot ℃)$; ε is emissivity; where asphalt concrete pavement usually takes the value of 0.81; σ is the Stefan-Boltzmann constant; $T_1|_{Z=0}$ is the pavement surface temperature, ℃ ; T_a is the atmospheric temperature; and T_Z expresses the absolute zero temperature.

2.4 Creeping parameters of asphalt concrete

Creepage and plasticity of asphalt concrete cannot be treated respectively becuase the tests can only observe the combined effect of these two phenomenon in recently. Creeping model in ABAQUS is utilized to simulate asphalt concrete creepage in this paper. Material properties in high temperature is described as followed.

The deformation of material ε_c is expressed as the function of temperature *T*, stress σ and time *t*:

$$\varepsilon_c = f(T, \sigma, t) \quad (5)$$

The expression of Bailey-Norton law which used widely in material deformation analysis is shown as:

$$\dot{\varepsilon}_c = A\sigma^m t^n \quad (6)$$

Where: $\dot{\varepsilon}_c$ —strain rate (the strain variation in unit time);
σ —axle deviator stress (the difference between axle and confining pressure);
t —the loading cumulative acting time;
A, *m*, *n* —material related parameters, rely on the temperature and stress, can be determined by material tests.

3 Analysis Results

3.1 Influence of ambient temperature

Figure 1 and Figure 2 show the rutting developments in different month under standard loading and double times overloading.

According to the results shown in Figure 5 and Figure 6, it can be found that rutting develops most rapidly during July which is the hottest month in one year. The rutting depth under standard vehicle loading is about 735mm. in January, February and March, the rutting develops least, and the rutting depth under standard vehicle loading is about 0.54mm. The largest rutting depth is about fourteen times larger than the least rutting depth. Therefore, the rutting disease in high atmospheric temperature is much more serious than in low temperature. The anti-rutting performance of asphalt concrete should be paid mainly attention, and it is very coincidence to the actual engineering experience.

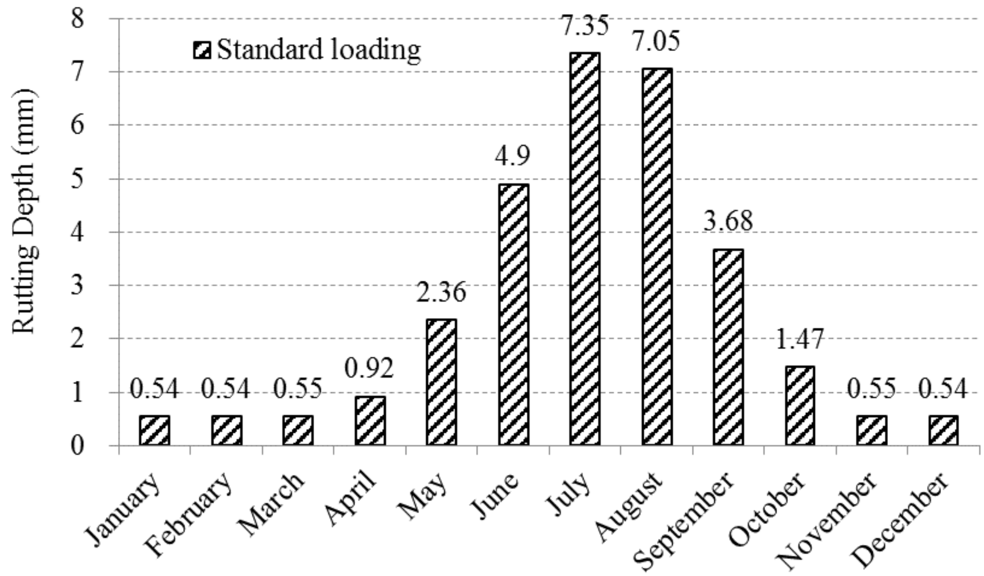

Figure 1. Rutting Developments under Standard Loading

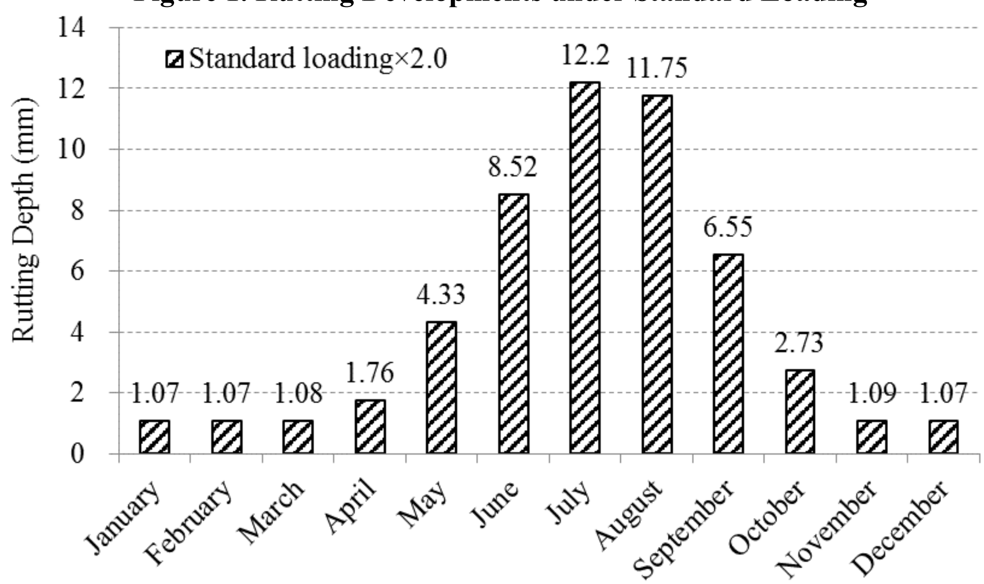

Figure 2. Rutting Developments under Double Times Overloading

In sum, the rutting disease is more serious while the ambient temperature rising, there is no linear relation but non-linear relation with transient variation between them. Therefore, the actual engineering material designation should focus on the asphalt concrete anti-rutting performance under high temperature.

3.2 Influence of vehicle loading

In order to evaluate the vehicle loading influence on rutting development, rutting developments under different loading in coldest month: January and hottest month: July are shown in Figure 3 and Figure 4.

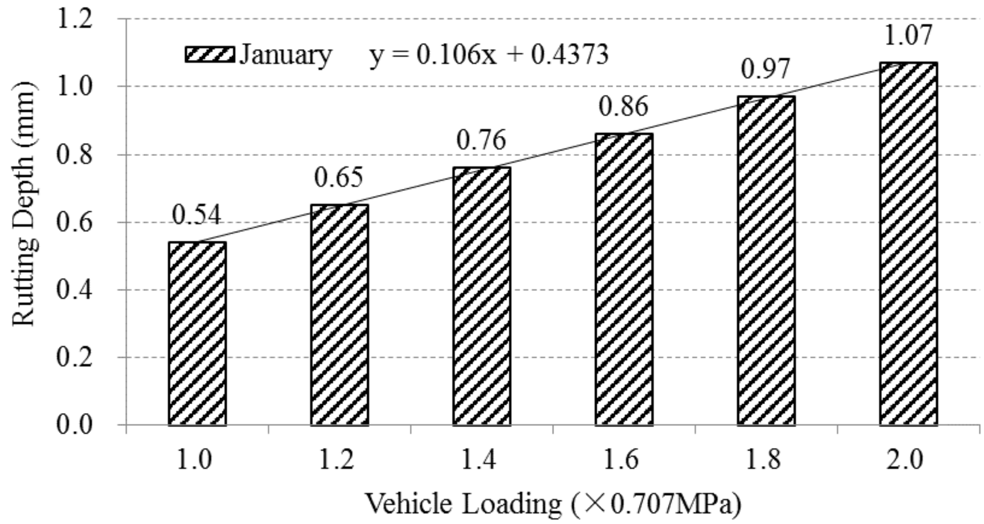

Figure 3. Rutting Developments under Different Loading in January

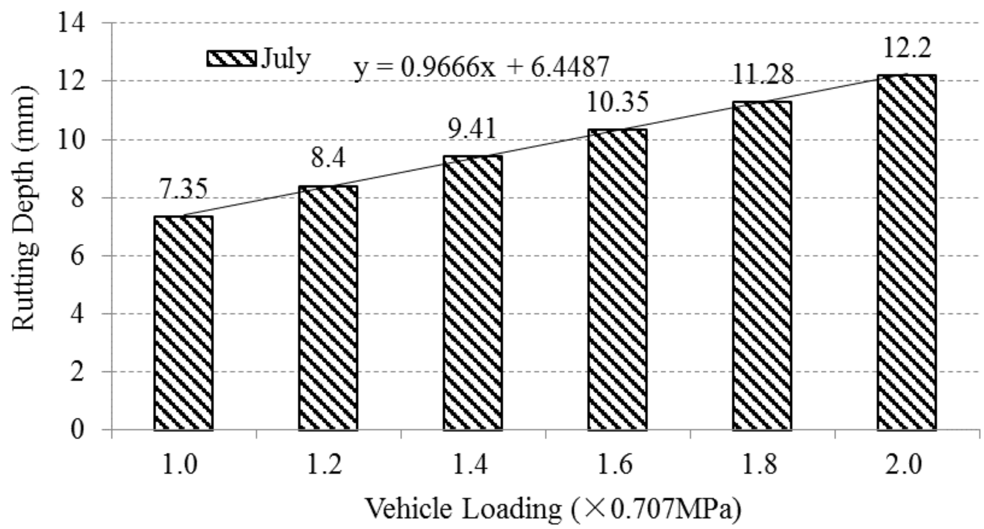

Figure 4. Rutting Developments under Different Loading in July

According to the results shown in Figure 3 and Figure 4, no matter in high temperature or low temperature seasons, rutting depths increase linearly related to vehicle loading.

3.3 Rutting Development Proportion in High Temperature Seasons

From the analysis results mentioned above, pavement rutting develops with different rates in different months because of the temperature difference. In one year, rutting develops much faster in hot seasons than in cold seasons. There are three months that maximum ambient temperatures are exceeding 30℃, they are June, July and August. And maximum ambient temperature in one more month is almost 30℃:

September. Make a statistic to rutting development proportion in these three or four months. The results are shown in Figure 5.

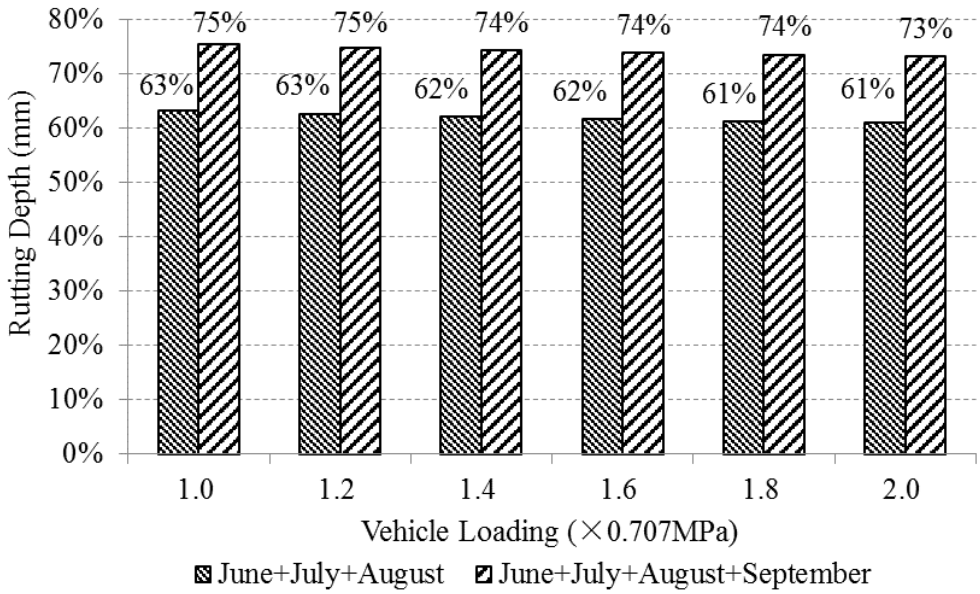

Figure 5. Rutting Development Proportion in High Temperature Seasons

According to the results shown in Figure 5, it can be found that the rutting development proportion of three hottest months in one year is about 61%~63%; the proportion of four hottest months is about 73%~75%. Pavement rutting in hot months is much more serious than in cold months.

All mentioned above, the rutting growing linearly while the vehicle loading increasing. Therefore, the overloading of vehicle can accelerate the the asphalt concrete rutting disease growing rapidly and shorten the pavement normal service lifetime. It is very necessary to control the overloading phenomenon to avoid the rutting disease developing rapidly. The rutting growing rate is much less in high temperature seasons than in low temperature seasons, but the absolute value of rutting depth is still bigger, the effect of overloading under high temperature condition is more serious, it should be paid more attention in actual engineering.

4 Conclusions

This paper utilize finite element method, based on heat transfer theory, and analyzed the asphalt pavement structural temperature field. ABAQUS creeping model is utilized to simulate and analyze the rutting development of asphalt concrete under vehicle loading. The main conclusions are followed:

(1) Rutting growing rate under high temperature is much more bigger than under low temperature condition, material anti-rutting performance must be considered first;

(2) Rutting development and temperature variation are basically following same law, but there is non-linearly relation between them. Rutting develops rapidly once asphalt concrete temperature achieving a certain level.

(3) In any ambient temperature condition, rutting growing rate is linearly related to the vehicle loading. The absolute rutting depth under high temperature is much larger than under low temperature. Thus, the overloading action on asphalt concrete pavement under high temperature can accelerate the rutting developing procecuere much more.

Rutting proportion develops under high temperature is much higher, rutting disease is much more serious in June, July, August, September in which moths the ambient temperatures are very high.

In summary, both the condition of high temperature and overloading can lead more serious rutting disease. Therefore, asphalt concrete anti-rutting performance under high temperature must be considered and paid enough attention. Traffic vehicle overloading phenomenon must be restricted as less as possible to avoid rutting development acceleration. By these ways, normal service capability of asphalt concrete pavement can be protected and the service life can be extended.

Urban Road Speed Humps Setting Technology

Yongqiang Zhang[1,2]; Zhuang Hu[2]; and Aijuan Chen[2]

[1]College of Transportation Engineering, Tongji University, Shanghai 201804, China.
[2]College of Automobile and Traffic Engineering, Nanjing Forestry University, Nanjing 210037, China. E-mail: zyqnjfu@sina.cn

Abstract: Set the speed control humps scientifically, both from the reminder and to decelerate purpose, effective protection of urban road traffic safety. The paper describes the function of speed humps' reducing accidents. Basing on the comprehensive analysis of domestic and foreign studies of speed humps, it further analyzes the influencing factors of deceleration zone's speed limit effect and a preliminary method of setting humanized speed humps is proposed. Finally, the paper chooses a selection from student apartment area 1 to area 2 in Qishan campus of Fuzhou University as an example to analyze decelerating effect of speed humps on all types of vehicles and conclude the relationship between the speed limit effect of deceleration and vehicle speed, some suggestions of setting speed humps are put forward.

Keywords: Speed humps; Speed limit effects; Traffic safety; Experimental analysis.

1 Background

In recent years, with the fast development of urban traffic and rapid growth in vehicle ownership, urban roads are under increasingly heavy traffic burden, road traffic safety problems have frequently happened. The speeding phenomenon are existing although repeated banning, this not only caused deaths and huge property loss, but also has serious impact on the entire economic and social development. Especially in the speeding deaths and property loss is most serious, speeding is still a typical traffic accident inducement. To solve the speeding problem, in addition to depending on legislation, promoting safety awareness, setting the sign and marking to remind drivers, it is more important to set some mandatory facilities to constrain driving speed. As a typical speed limit facility, speed humps is widely used.

Speed humps is an enhanced road traffic safety facilities on smooth roads, set the deceleration zone in moving vehicles, non-motor, both from the reminder and to decelerate purpose, effective protection of urban road traffic safety. Speed humps has advantages of simple construction, low cost of building and maintaining and quick effect, in recent years it has made great recognition in the domestic industry.

Scientific settings to slow down, we can reduce noise with environmental pollution, improve efficiency with speed reducer, effectively improve road traffic safety conditions, on the other hand, it may be ineffective or even become human barricades which cause second accident. Furthermore, the negative effects such as energy consumption, noise pollution caused by lack of humanistic consideration on the model, set position and range of speed humps can not be ignored.

2 Research Status at Home and Abroad

Foreign research on speed humps is deeper, they optimize control mode mainly based on the influence on driver behaviors, model and algorithm of speed humps, and on the basis of theoretical study on stochastic point process, further analysis and research on control problem have been done. Foreign experts have made a profound summary on the relationship between speed humps and drivers, systematically and vividly drew the effect of speed humps on the driver's driving behavior, they also got a conclude that vehicle’s through speed humps will result road vibration and even cause property damage, so the setting location need to be considered seriously to avoid the vibration nuisance. Some scholars came to a conclusion, that is, a longer speed humps can not necessarily achieve better slow effect, and we can know the best setting position based on the comparison on the horizontal section of speed humps.

With the introduction of foreign advanced technology research and ideas, domestic scholars also do a large number of studies, it mainly analysis the impact on the traffic flow, control effect on vehicle speed, effect on vehicle vibration, etc. Meng Jianping, Zhang Jiefang and others developed advanced methods, hat is, whether need to set a speed humps can be relatively accurate calculated by predicting traffic flow, to make the traffic safety and efficiency achieve the double priority. Wang Chao, Sun Xiaoduan, Shi Yang put forward the method to evaluate slow effect of speed control facility, this is a positive reference for the future related researches and decisions.

3 Influencing Factors of Speed Limit Effect

Due to the driver, vehicle factors and its own material, designed grade, passage length, it can generate impact force when vehicles have collision with speed humps and it will make people feel uncomfortable when under a excessive high speed, forcing the driver to get through speed humps at a low speed.

An ideal road speed humps must ensure that the vehicle is always under control, as well as those important safety components will not produce the dangerous situation, such as fracture, which means it should have high driving and structure safety. The driving safety of vehicles never be allowed to continue reducing with the increase of the speed, it should be kept at a stable level as it reduced to a certain degree, or even there is some increase with the increase of the speed.

3.1 Driver's Speed Selection

Road speed humps to slow down the speed are realized by influencing the drivers' driving psychology. When a vehicle get through the deceleration zone at a high speed, severe vibration from tire will be passed to the driver through the body and seat, producing strong physiological stimulation (including vibration stimulation and visual stimulation) and mental stimulation. Physiological stimulation will produce a strong discomfort, mental stimulation will deepen the unsafe concerns, further reducing the drivers' sense of security on the road environment. In general, the more uncomfortable, the less safe people feel, namely the smaller sense of security.

Therefore, to a large extent, the vehicle's speed depends on the driver's expected speed and the expected speed is decided according to the driving safety and comfort. A high sense of security and good ride comfort make the expected speed higher, On the other hand, the driver's expected speed will be lower. When a vehicle get through the speed humps, it will greatly reduce the driver's expectations of driving safety and comfort. Without any outside pressure, the driver will take the initiative to make the vehicle at low speed under the guidance of expected speed in order to achieve the expected requirements when the vehicle is close to the road speed humps .

Some speed limit effect is not obvious instead under the case of high entering speed because the nonrigid turbulence is quickly absorbed the impact before the vehicle responding to it. For those roads with higher traffic speed, the width of road speed humps should be further increased according to the relationship between limited speed and speed humps' design width, the specific design size should be determined after a lot of experimental research.

3.2 Model and Layout of Speed Humps

The height and width size of the rubber speed humps is very important for traffic safety. If the height is too high, the through vehicle will get a greater impact from the speed humps and its damping effect is not obvious, especially for two-wheel motorcycles, it can cause the vehicle out of control, leading to traffic accidents. If the height is too low or the width is too wide, the slow effect is not obvious. Considering the above factors, urban road rubber speed humps must have a certain hardness to ensure the safety of the through vehicle, however, the hardness cannot be too high in case that greater impact effect and increased noise be caused .

When different types of vehicles get through road speed humps of different structure size, car body acceleration and car axle acceleration varies with the speed of the car. Researches show that : the design width of speed humps is proportional to the control speed while the design height is inversely proportional to the control speed. For roads of which speed less than 40 km/h, width of 400~500mm and height of 40~50mm can achieve good speed control effect, while for roads of which speed less than 60 km/h, width of 500~600mm and height of 30~40mm can achieve good speed control effect. The width of the existing urban road speed humps is generally narrow as 300~500mm and the height size design is more casual, this not only severely affects the speed control effect, but also brings new hidden trouble to the urban road traffic safety.

The setting distance should also be considered when we set speed humps for urban roads, it increases with the increase of the design speed when at constant slope. If conditions permitted, the combination of antiskid pavement and vibrate speed humps can be considered to improve the slow effect.

4 Experimental Analysis on the Speed Limit Effect of Speed Humps

The height and width of road speed humps are the most two key design parameters of the vehicle speed limit, which directly affect the the speed control effectiveness and use safety of the road speed humps, but different types of vehicles will bring out different speed limit effect.

To analyze speed limit effect of speed humps, a real vehicle test from the angle of speed humps' speed limit effect on different types of vehicles has been conducted. Because of the various types of vehicles, the survey just chose buses, minivans and cars as the sample vehicles, selected a certain number of samples of each model and detected their speeds, eliminating some too high or too low speed data, to analyze speed humps' different speed limit effect on different types and speeds of vehicles.

4.1. Test Object

The research selected a section of Fujian Medical School in Fuzhou university town which has speed humps to control vehicle speed. Because the section is long, straight and flat, some other influencing factors can be eliminated, considering that the speed changes is just caused by the speed control facilities, which can reflect the slow effect of speed humps.

We eliminated some too high speed to ensure the data accuracy as we just study speed humps' whole efficiency on vehicles. Due to the constraints, we just investigated a speed humps. The experimental instrument that used are BUSHNELL VELOCITY of radar and a speed humps of which the width is 38cm and the height is 5cm. The survey time is on the daytime of working days, sample size and location information are shown in table 1.

Table 1. Sample Size and Location Information

Type of Speed Humps	Number of Buses	Number of Minivans	Number of Cars
Width:38cm;Height:5cm	43vel	27vel	30vel

4.2 Experimental Instrument

The two main measuring tools: BUSHNELL VELOCITY of radar(measuring speed), a fiber tape of Changcheng brand(measuring width and height).

The Doppler Effect principle that speed measuring radar use: When the goal towards radar antenna, reflection signal frequency will be higher than the transmitter frequency, On the other hand, when the target far away from the antenna, reflection signal frequency will be lower than the transmitter frequency. We can calculate the relative speed between the target and radar by the change value of frequency.

4.3 Test Method

Firstly, use a tape to measure the specifications of speed humps(the width is 38cm,the height is 5cm). Observation location is 20m ahead of the object speed humps, then use BUSHNELL VELOCITY radar to measure the vehicle speeds before and after speed humps, lastly, measure and record the data according to the method of data collection.

4.4 Test data analysis

The test data is collected from a city road of which limited speed is 30 km/h, it uses speed humps to control vehicle speed. Because the section is long, straight and flat, some other influencing factors can be eliminated, considering that the speed changes is just caused by the speed control facilities, which can reflect the slow effect of speed humps, as table 2.

Table 2. Statistical Result of Bus/minivan/car Speed（km/h）

Bus/minivan/car	Entering Speed (Bus/minivan/car)	Out of Speed (Bus/minivan/car)
Average speed	36.7/30.3/37.7	33/24.8/34.4
$V15$	26/25/23	21/21/22
$V50$	37/29/39	31/22/36
$V85$	48/33/48	46/27/45
Minimum Value	22/25/22	18/21/20
Maximum Value	53/37/61	50/29/61
Variance	77.3/19.8/95.3	95.3/9.9/89.5
Standard Deviation	8.8/4.4/9.8	9.8/3.2/9.5

As can be seen from the statistical results, vehicle speed is relatively high before the speed humps, the 85th Percentile Speed of the three types are all over the limited speed of 30km/h, after the speed humps, their speeds have a certain decline, 4.17% for buses, 18.18% for minivans and 6.25% for cars. The mean velocity and run speed of the vehicles are basically down to the limited speed. It can be seen that the current speed humps play a good role through the data comparison.

In order to better reflect the effect of speed humps, weeding out useless data, we divided the entering speed into a few section: <30km/h, 30~40km/h, 40～50km/h, 50～60km/h. We used the velocity decrement which is equal to the speed reducing values divided by the entering speed to inspect the slow effect, as table 3.

Table 3. Entering speed（<30/30～40/40～50/50～60km/h）

	Entering Speed (<30/30～40/40～50/50～60km/h)	Out of Speed (<30/30～40/40～50/50～60km/h)	Deceleration value (<30/30～40/40～50/50～60km/h)
Average speed	25.8/34.2/45/51.2	21.6/30.2/41.9/49	4.2/4/3.1/2.2
$V15$	22/30/41/50	19/26/37/48	3/4/4/2
$V50$	26/33/45/50	21/29/42/49	5/4/3/1
$V85$	29/38/50/53	23/35/48/50	6/3/2/3
Minimum Value	22/30/40/50	18/22/36/48	Slow Effect
Maximum Value	29/40/50/55	26/40/49/50/50	
Variance	7.26/13.79/13.15/3.19	4.65/13.94/20.18/0.75	17.5%/11.3%/6.8%/4%
Standard Deviation	2.69/3.71/3.63/1.79	2.16/3.73/4.49/0.87	

4.5 Experimental Conclusions

It can be seen by contrasting and analyzing the results:

(1) Speed humps can't slow down all vehicles of different speed to a roughly same speed, but only have a corresponding slow effect on vehicles of different speed.

(2) When the entering speed is lower than 30 km/h, the slowing down phenomenon is most obvious, the slow effect will gradually become worse due to the increase of speed. The speed reduction theory is that the higher the vehicle speed, the more uncomfortable the driver feel with the vibration,which will make the driver reduce speed. This phenomenon seems to conflict with the theory, but we cannot rule out the driver's improving speed by sacrificing the ride comfort.

(3)When the entering speed is higher than 40 km/h, it still can't meet the limited speed of 30 km/h after slowing down. Assuming that the limited speed is reasonable, from the data, the proportion of this part of vehicles is very large, so the speed humps still can not solve the speeding problem most effectively.

5 Conclusions and Suggestions

The paper has a deeper understanding of speed humps' characteristics basing on observing and comparative analyzing the vehicle speed which get through the speed humps, it also presents a good method to evaluate the slow effect of speed humps. The following can be found from the research:

The slow effect of speed humps on three types of vehicles is as follows:minivan (18.15%), bus (10.08%) and car (8.75%).

The slow effect of this speed humps becomes less obvious instead with the increase of vehicle speed.

The speeding problem still cannot be solved most effectively just by speed humps.

An Improved Method of Evaluating Technical Conditions of a Concrete Bridge

Liang Yang

The Key Laboratory of Road and Traffic Engineering, Ministry of Education, Tongji University, Shanghai, China. E-mail: 398934727@qq.com

Abstract: Bridge detection and evaluation are designed for bridge maintenance and repair decision service. Current bridge technical condition evaluation method can't response the main performance decay process of the structural members. Through the analysis on 398 reinforced concrete bridges' detection data, a bridge performance decay model is established. Based on the existing bridge evaluation specifications, an optimum method of classified evaluation of technical condition between structure and nonstructural members, together with classified detection method of bridge structure based on structural design principles, was set up. It can provide important basis for the structural and non-structural repairing on bridge maintenance. At the same time, it's helpful for establishing the correlation between the structural defects and the decay of the structural bearing capacity.
Keywords: Bridge inspection; Evaluation of technical condition; Load-carrying capacity; Structural design; Service life.

1 Introduction

In 2013, China's National Highway Bridges amounted to 735,300 in number, 39,778,000 meters at length (Ministry of Transport). Reinforced concrete bridges accounted for the majority of all the bridges. In order to ensure operation safety, bridge inspection and evaluation is becoming increasingly important. The purpose of the evaluation of bridge technical condition is to get the bridge's defects through a comprehensive inspection, evaluate the technical condition of the bridge, provide basis for decision making on bridge maintenance and repair. The study on getting Bridge Evaluation Method improved is helpful for bridge maintenance management.

2 Literature review

Currently, Bridge technical condition evaluation method based on appearance defect detection is commonly used both in domestic and abroad (LIU Guojin,2009; Kawamura K,2003; ZHU Yan,2012; GAO Zhibo,2013; CHEN Dongliang,2013; Melham H.G,1996; Rene B.Testw,2002). Based on the right to check on the current status of the bridge components, a key indicator of experts for fuzzy classification and index weights are given, then grading and weighted summation, evaluation findings at last. Many countries have developed their own hierarchical ordering of evaluation criteria, but the basic method is of the same. The evaluation method is wildly used in many country's technical standards such as "China highway bridge technical condition assessment standard", "China urban bridge maintenance technical specification", "German Bridge Disease and evaluate the technical condition of the new technology", "British road bridge monitoring priority standard," "American highway bridge defect classification standard".

3 Bridge evaluation results using current method

3.1Statistical Analysis of Bridge evaluation results

Statistical analysis of assessment data of 398 highway RC bridges is carried out. The relationship between bridge age (distribution range of 4 to 62 years) and technical condition scores of the whole bridge, deck, superstructure and substructure is built up, which helps fitting out performance decay models (shown in Formula1).

$$f(x) = p_1 x^3 + p_2 x^2 + p_3 x + p_4 \quad (1)$$

Through time-to-space conversion method (SUN Lijun, 2009), the fitting curves and parameters of bridge, deck, superstructure and substructure were brought out. As shown in Figure 1-4 and Table 1.

Table 2. Fitting Analysis of the condition decay model of reinforced concrete bridges

Fitting curve BCI	Decay model parameters				Minimum point		Maxima point		Fitting parameters	
	P_1	P_2	P_3	P_4	age/year	Minimum	age/year	Maxima	R^2	RMSE
bridge	-0.000876	0.07763	-1.985	98.24	18.7	82.5	40.4	87.0	0.05507	10
deck	-0.0004608	0.03603	-0.7153	83.5	13.3	79.3	38.8	83.1	0.01341	14.16
superstructure	-0.000963	0.09213	-2.708	105.7	23.0	80.4	40.8	83.2	0.042	17.17
substructure	-0.0009673	0.08095	-1.812	97.64	15.5	85.4	40.3	92.8	0.06485	11.43

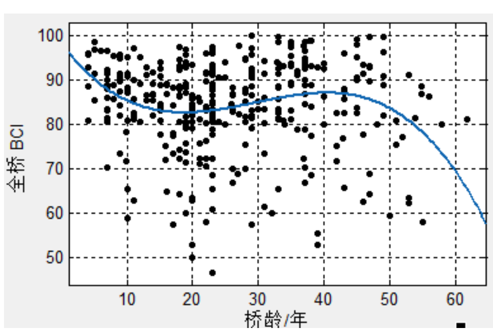

Figure 1. Fitting curve of bridge

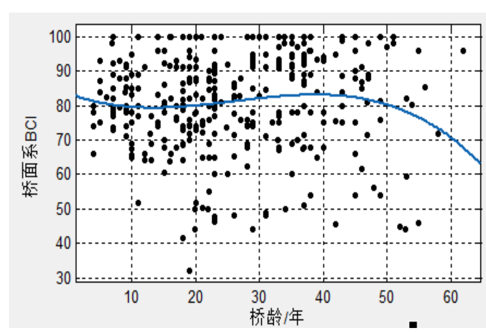

Figure 2. Fitting curve of bridge decking

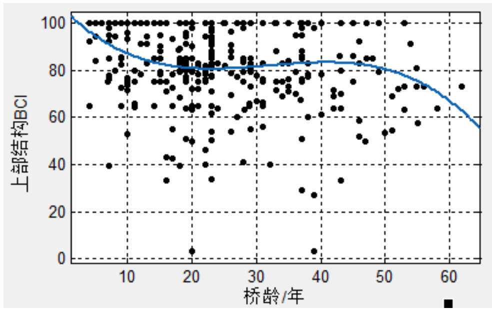

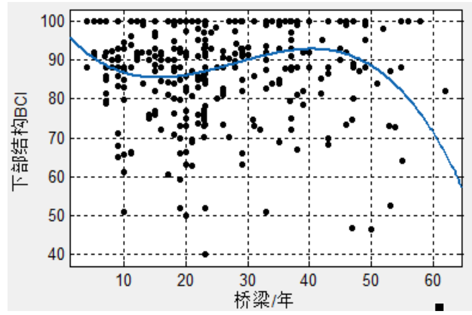

Figure 3. Fitting curve of superstructure Figure 4. Fitting curve of substructure

Fig.1-4 shows, when bridge age distributing from 1 to 19 years, the bridge performance curve shows a clear downward trend under the effects of traffic loads and environmental factors; when bridge age 20 to 40 years, part of the bridges go into the medium and large repair phase, bridge performance curve shows upward trend slightly; when bridge age more than 50 years, the bridge performance curve appears accelerated decline.

Tab.2 shows, when the bridge age is18.7 years, BCI of Bridge reaches its lowest point of 82.5.Then it gradually increases, getting to the highest point 87 at the year 40.4. BCI of Deck System declines fastest, it reaches its lowest point of 79.3 at the minimum age of 13.3 years. Fitting Curves objectively reflect the actual RC bridge performance decay law in the recent r 50 years.

3.2 Problems in current evaluation methods

(1)The current specification use comprehensive technical condition index Dr or BCI, in which includes diseases of structural and non-structural components. Therefore，it cannot objectively reflect the safety performance and the development process of structural disease of the bridge structure.

(2)The deck system’s life and the bridge structure’s life are not synchronized (TAN Jinhua, 2004). The life of the former is much shorter, which results in frequent maintenances. Apparently, this will cause fluctuations of BCI (or Dr) Index.

(3)BCI (or Dr) Index can’t give clear guidance for the decision making of maintenance scope and scale. Therefore, the current evaluation methods are fit for network-level bridge management, but not fit for the project level management.

4 Improvement of bridge evaluation method

4.1 Separate evaluation of structure and bridge deck system

First, evaluate bridge structure and deck system separately. Then, evaluate bridge deck system in the whole length, using index BDCI; evaluate bridge span structure, using index SSCI; evaluate bridge superstructure, using index SPCI; evaluate bridge substructure, using index SBCI.

4.2 Evaluation of bridge structure

Bridge structure can be divided into a total of six levels, including full-bridge, plot (according to the type of interchange ramp or structural division), span (or Continuous beam), of the upper and lower structure, parts, components, shown in Figure 5. Scoring rules and evaluation standards are referring to the current specification. The score of Span structure (SSCI) is the weighted average of the score of superstructure (SPCI) and the score of substructure (SBCI). (As shown in Formula 2)

$$SSCI_i = \mathrm{a}_p \times SPCI_i + a_b \times SBCI_i \qquad (2)$$

Generally, $\mathrm{a}_p = a_b = 0.5$

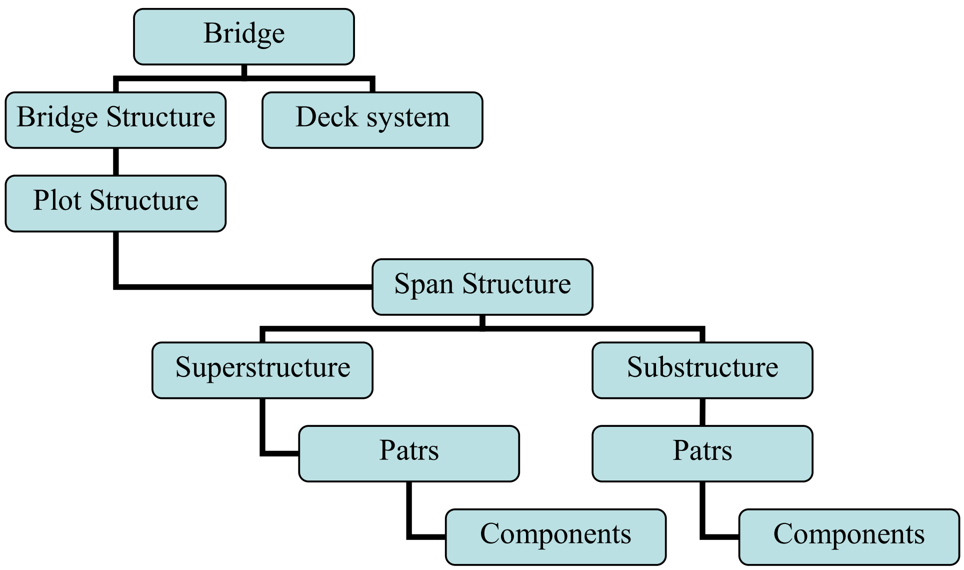

Figure 6. Hierarchical division of bridge structure

5 Applications

5.1 Project summary

A highway bridge was built in 1991, the bridge length 66m, span combination of 4×16m, bridge width 2×1m+7m=9m. The bridge is simply supported reinforced concrete with 4 spans of T-beam; double-column pier substructure, lightweight reinforced concrete abutments; cement concrete bridge deck. Bridge inspection and evaluation was carried out in May 2012.

5.2 Results of the several evaluation methods

Three methods were used in the evaluation of the bridge, including "China highway bridge technical condition assessment standard", "China urban bridge maintenance technical specification" and improved Method. The result is shown in Tab.

Table 3. Comparative analysis of bridge condition evaluation between the present specifications and the optimum method

Bridge Evaluation method	Bridge layer	Bridge evaluation scores					Evaluation index	Evaluation results
		1st span	2nd span	3rd span	4th span	Bridge BCI		
Highway bridge standard	Superstructure	46.6	64.2	69.2	66.3	61.6	Dr=72.6	Bridge in Class 3
	Substructure	84.2	85.2	85.2	85.2	85.0		
	Deck	69.7	69.7	69.7	69.7	69.7		
	Assessment					72.6		
Improved method	Superstructure	46.6	64.2	69.2	66.3	61.6	SSCI1=46.6 SSCI2=64.2 SSCI3=69.2 SSCI1=66.3	1 span in class4, 3 spans in class 3
	Substructure	84.2	85.2	85.2	85.2	85.0		
	Deck	46.6	64.2	69.2	66.3			
	Assessment	Class 4	Class 3	Class 3	Class 3

	Substructure	93.5	93.5	93.5	91.5	93.0		
	Deck	51.9	65.9	67.8	66.2	78.7		
	Assessment	Class D	Class D	Class C	Class C			

6 Conclusions

(1) Through Statistical analysis of assessment data of 398 highway RC bridges, bridge performance decay models were fitted out. The models show that when bridge ages distributing from 1 to 19 years, the bridge performance curve shows a clear downward trend under the effects of traffic loads and environmental factors; when bridge ages distributing from 20 to 40 years, part of the bridges go into the medium and large repair phase, bridge performance curve shows upward trend slightly; when bridge ages are more than 50 years, the bridge performance curve appears accelerated decline.

(2) In the improved evaluation method, bridge structure and deck system are evaluated separately, bridge span index (SSCI) becomes the Evaluation Criteria. The evaluation results can clearly reflect the technical state of each span structure, which is very helpful for grasping the structure condition and locating the repair cite.

(3) The improved evaluation method focuses on the structural members without the disturbing of non-structural members, which can help building the correlation between structural diseases and structure decay properties gradually.

Abstract: Recently, a number of four or six-lane freeways have been widened to account for the increasing traffic demand. However, there is no specific study about capacity models of multi-lane freeways with more than eight lanes. Based on the data from Shen-Shan Segment of Jing-Ha Freeway, this paper aimed to develop different capacity models of 12-lane freeways for two different cross section layout modes, including, the integral mode and the passenger-freight separated mode. VISSIM simulation studies were conducted to obtain different speed-flow curves, based on which, the calibrated parameters were developed for different capacity models.. The research results can help transportation professionals determine proper cross section layout and organizational modes in reconstruction and expansion projects of multilane freeways. They can also be used to calculate capacities of 12-lane freeways.

Keywords: Multilane freeways; Freeway; Capacity; Cross section mode.

1 Introduction

With the development of Chinese economy in recent years, transportation demand increased rapidly. To account for the increasing traffic demand, numerous freeways are changed into 8 or more than 8-lane freeways by reconstruction and expansion. It is the future trend to construct multilane freeways in pivotal transport corridors. For safe and well-ordered traffic, lane management is common to be operated on freeways with more than 8 lanes overseas to restrain disorder driving between lanes. Previous studies of multilane freeways in China have not developed adequately and are deficient in capacity calculating theories for freeways with more than 8 lanes.

Gene Daigle and Michelle (1998) conducted a simulation study to get accurate capacities in different lane management methods for reconstruction, but the study is not suitable for freeways in China. Calculating theories in China so far have taken the method for motor/non-motor vehicles mixed traffic mode, established on lane management of 4-lane freeways without consideration of lane changing impact (CHEN K. et al.,2003). Han et al. (2007) analysed driving states and levels of service of multilane freeways under different traffic organizations from Hu-Ning Freeway reconstruction and expansion project, and developed an improved calculating model for traffic volume calculation. Based on road segment and ramp flow conservation and traffic volume constraint, Tan et al. (2002) proposed a multilane freeway dynamic discrete traffic flow model in which the lane changing and origin-destination (OD) of vehicles are considered.

In domestic studies of multilane freeway capacity, parameters, modes and capacity analysis systems suited to China's national conditions are deficient. Technical Standard of highway engineering ('Standard' for short) uses the capacity from several foreign research achievements, which cannot show actual operating characteristics of Chinese road traffic. Thus, considering analysis above, this paper choose a 12-lane freeway from Shen-Shan Freeway as analysis object and does analysis and modeling of capacity under different traffic organizations.

2 Traffic Organizational Modes of Multilane Freeways

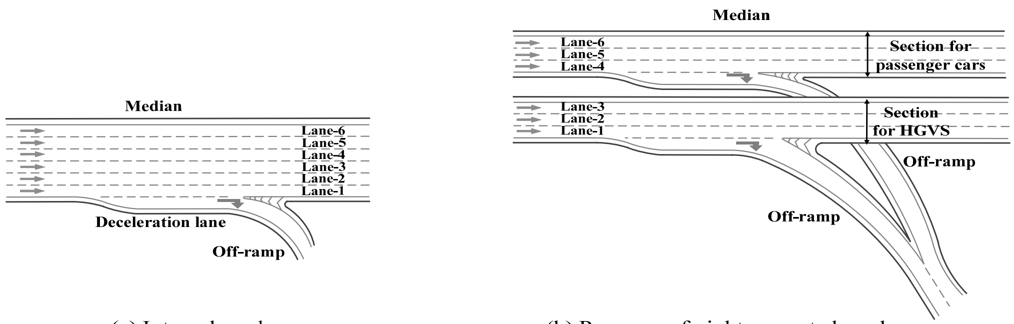
To meet requirements of different vehicle categories, vehicle safety and convenient access and improve operation efficiency and driving security of multilane freeways effectively, two traffic organizational modes of cross sections are generally used in multilane freeways: integral mode and passenger-freight separated mode (Traffic planning and design institute of Liaoning province ,2014).

(1) Integral mode

Integral mode is usually used by freeways with 6 to 8 lanes, as well as 10-lane and 12-lane freeways when roadside land is limited. Figure 1 (a) illustrate the integral cross section of Shen-Shan Segment of Jing-Ha Freeway, which was broadened to 6 lanes in each direction. All lanes serve both passenger and freight vehicles. This mode is usually used when roadside land is limited.

(2) Passenger-freight separated mode

When there are more lanes in cross sections, separated modes are usually used in each direction. There are two types of separated modes. One type is that inner and outer parts are separated totally, which is called passenger-freight separated mode. In this mode, lanes of outer parts only allow freight vehicles to use while lanes of inner parts only serve passenger vehicles. In this case, Ramps of interchanges need to connect relatively with lanes of inner and outer parts. A 12-lane freeway in passenger-freight separated mode actually serves as a 6-lane passenger freeway and a 6-lane freight freeway. Inner and outer part have individual ramps. Figure 1 (b) illustrate the passenger-freight separated cross section of Shen-Shan Segment of Jing-Ha Freeway, which was broadened to 6 lanes in each direction.



(a) Integral mode (b) Passenger-freight separated mode

Figure 1. Aerial view of each mode

3 Calculating Methods for Capacity of Different Traffic Organizational Modes

3.1 The calculating method for capacity of integral mode

According to Standard (JTG B01-2014), freeways should be designed to provide for a minimum of level of service of Third class. Maximum Service Volume (*MSV*) of each level of service are shown in Table 1. C_D is defined as the design capacity of each lane. Considering a driver population and its characteristics, the design capacity of each lane is converted to C_D*f_p, where f_p.is the adjustment factor for driver population.

Table 1. Level of service criteria for freeways

Level of Service	***v/c* ratio**	**designing speed (km/h)**		
		120	**100**	**80**
		Maximum Service Volume (*MSV*) (*pcu/h/ln*)		
First-class	$v/c \le 0.35$	750	730	700
Second-class	$0.35 < v/c \le 0.55$	1200	1150	1100
Third-class	$0.55 < v/c \le 0.75$	1650	1600	1500
Fourth-class	$0.75 < v/c \le 0.90$	1980	1850	1800
Fifth-class	$0.90 < v/c \le 1.00$	2200	2100	2000
Sixth-class	$v/c > 1.00$	0~2200	0~2100	0~2000

Note: The *v/c* ratio is the ratio of the *MSV* to the based capacity of the facility. The based capacity is maximum hour volume of the corresponding level of service.

Lanes under the integral mode are available for both heavy and light vehicles. Because of the differences in automobile dynamic performance and criteria for design speeds, the decrease to the capacity caused by heavy-vehicle mixing rate need to be considered during the calculating. So the adjustment factor for the presence of heavy vehicles is introduced as f_{HV}. The non-divided road cross section is used in the 6-lane freeway and the ramps only connect to the outer lane, which causes frequent lane changes between inner and outer lanes. Lane change disturbs the driving of vehicles on the outer lane and reduce the capacity. The adjustment factor for the outer lane is introduced as f_{OL} therefore. Vehicles on the inner lanes normally travel with higher speed and more freedom, so they have to travel in long headway to ensure safe driving. Thus, the traffic volume of inner and median lanes should decrease. The adjustment for inner and median lanes is denoted as f_{IL}. (Roger P. Roess et al.,2011; HCM 2010) According to the analysis above, the actual capacity of a 12-lane freeway may be expressed as :

$$CAP = C_d * N * f_P * f_{HV} * f_{OL} * f_{IL} \qquad \text{Eq. (1)}$$

where： N = number of lanes (in one direction) of the freeway

f_p = adjustment factor for driver population

f_{HV} = adjustment factor for presence of heavy vehicles

f_{OL} = adjustment factor for outer lane

f_{IL} = adjustment factor for inner and median lanes

3.2 The calculating method for capacity of passenger-freight separated mode

The operation of passenger and freight vehicles don't disturb each other, so the heavy-vehicle mixing rate doesn't need to be considered in this mode. The actual capacity of a 12-lane freeway may be expressed as the algebraic sum of the capacity of a passenger freeway and a freight freeway:

$$CAP = C_D^p * N^p * f_P^p * f_{OL}^p * f_{IL}^p + C_D^f * N^f * f_P^f * f_{OL}^f * f_{IL}^f \qquad \text{Eq. (2)}$$

where: factors with superscript 'p' denote parameters of the passenger freeway while factors with superscript 'f' denote parameters of the freight freeway. Concrete meanings of related parameters are the same with above.

4 Simulation Analysis of Adjustment System

4.1 Calibration of VISSIM simulation models

VISSIM is one of the commonly used traffic simulation platforms to simulate the operation of traffic flow in freeways and output multiple simulation operation parameters of traffic flow. VISSIM is a microscopic simulation tool that was originally developed in Germany at the University of Karlsruhe in the early 1970s. One of the major benefits of VISSIM is that it allows users to model detailed geometric configurations such as medians, driveways, and turning bays, as well as drivers' behavioral characteristics encountered in the transportation system (LIU P. et al., 2012; HUANG F. et al., 2013). On the basis of results from the field research in Shen-Shan Segment of Jing-Ha Freeway, Speed- flow curve was plotted and illustrated as Figure 2. With curves in

Figure 2 as calibrated target of simulation platform, this study made adjustments of distributions of desired speed under free flow condition of cars and heavy vehicles which take high ratios in traffic composition. The method to test capacities was utilized to verify simulation models. Through inputting traffic flows over capacities, capacity was ascertained as 2196 veh/h, critical speed as 75.1 km/h and calibration error as 0.2% when cars are only served while capacity was ascertained as 1064 veh/h, critical speed as 44.1 km/h and calibration error as 3% when heavy vehicles are only served. Simulation was verified at a 95% confidence level. Adjusted plans of driving behavior parameters for different heavy-vehicle mixing rates is listed in Table 2.

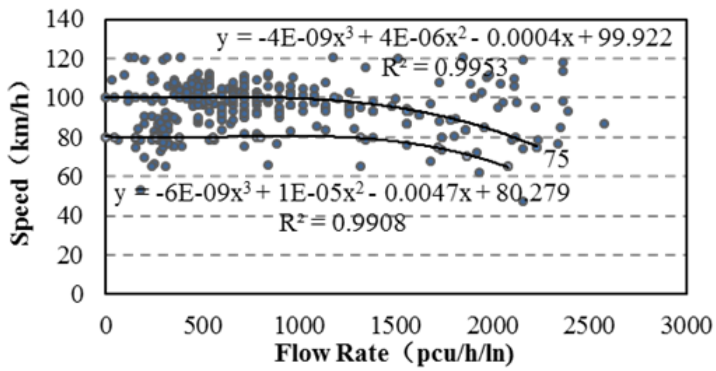


Figure 2. Actual flow-speed curve in Shen-Shan Segments of Jing-Ha Freeway

Table 2. Parameter adjustment of car following model in driving behaviors

Plan	a	b	c	d	e	f	g	h
Adjusted parameters	Percentage of HGV（%）							
	0	5	10	20	30	40	60	100
CC0	1.50	1.58	1.65	1.80	1.95	2.10	2.40	3.00
CC1	1.50	1.53	1.55	1.60	1.65	1.70	1.80	2.00
CC8	3.50	3.43	3.35	3.20	3.05	2.90	2.60	2.00
CC9	1.50	1.45	1.40	1.30	1.20	1.10	0.90	0.50

4.2 Calibration of adjustment factors

Through the simulation platform with adjusted parameters, simulations were conducted for 4-lane, 6-lane and 12-lane freeways under integral mode and passenger-freight separated mode respectively to calibrate adjustment factors under each mode.

4.2.1 Adjustment factor for outer lanes f_{OL}

Based on the analysis of field research and simulation results, in interchange areas of multilane freeways, capacities of two outer lanes decrease because of vehicles changing lanes to access ramps. Simulation schemes utilized single variable control method when calibrating f_{OL} and eliminates impacts of heavy-vehicle mixing rate, switching lanes and cross-section layout and traffic organizational modes. Integral mode was utilized and the ability obtained from Simulation Scheme A was adopted as based capacity. In simulation scheme A, freeways were 2 lanes in one direction and traffic compositions were only cars and parameters of driving behaviors adopted Plan a in Table 2. f_{OL} of integral mode for 12-lane freeways was calibrated by ratio of capacity obtained from simulation scheme B to based capacity. In Simulation Scheme B, freeways were 6 lanes in one direction and traffic compositions were only cars and parameters of driving behaviors adopted Plan a in Table 2. f_{OL}^{p} and f_{OL}^{f} of passenger-freight separated mode for 12-lane freeways were calibrated by ratio of capacity obtained from simulation scheme C and D to based capacity. In Simulation Scheme C, freeways were 3 lanes in one direction and traffic compositions were only passenger vehicles and parameters of driving behaviors adopted Plan a in Table 2. In Simulation Scheme D, freeways were 3 lanes in one direction and traffic compositions were only freight vehicles and parameters of driving behaviors adopted parameters from Plan h in Table 2. Simulation schemes to calibrate f_{OL} were Simulation Scheme A-D, as illustrated in Table 3. Speed-flow curves obtained by simulation were shown in Figure 3 and results of calibration were illustrated in Table 3.

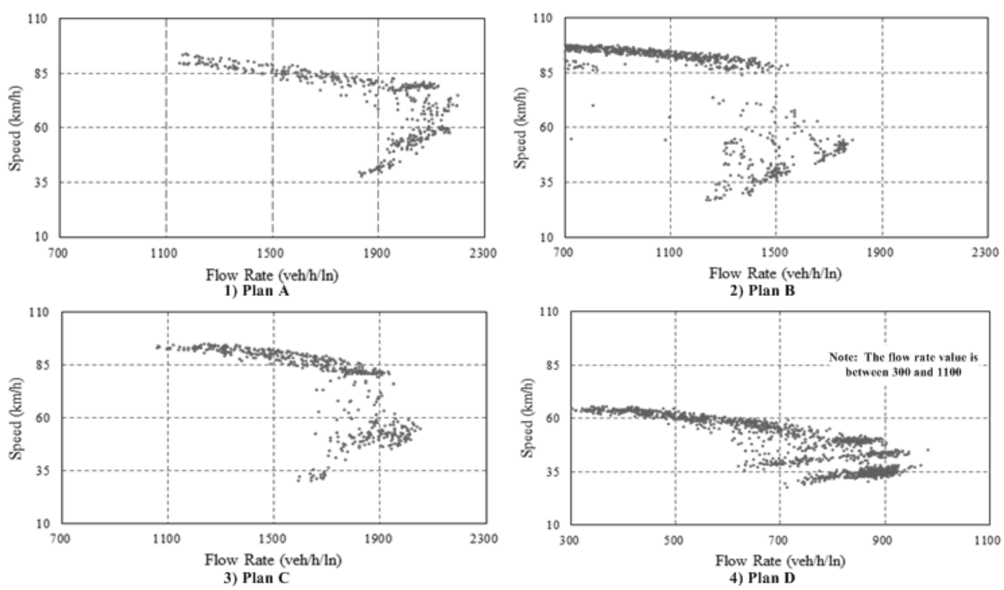

Figure 3. Speed-flow curve of the two outer lanes in scheme A、B、C and D

Table 3. Calibration values of f_{OL}

f_{OL}	Lanes in one direction		
	2	3	6
Integral	1.0	0.94	0.82

Passenger-freight separated	passenger	——	0.94	——
	freight		0.92	

4.2.2 Adjustment factor for inner lanes f_{IL}

Simulation Schemes adopted for calibration of adjustment factor for inner lanes are identical with those adopted for calibration of adjustment factor for outer lanes. The value of f_{IL} is the ratio of capacity of two inner lanes to based capacity. Speed-flow curves obtained by simulation were shown in Figure 4 and results of calibration were illustrated in Table 4.

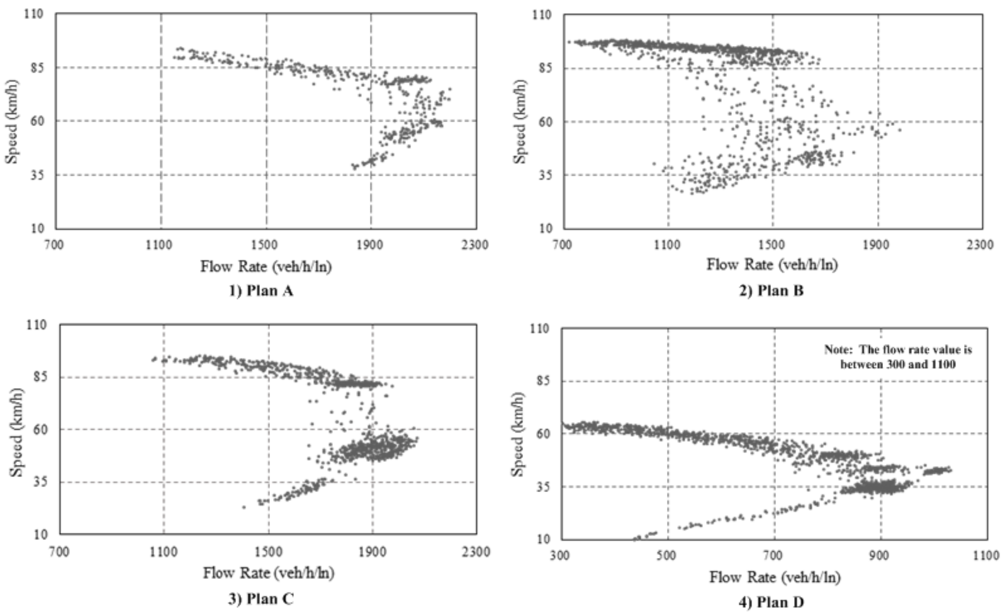

Figure 4. Speed-flow curve of the two inner lanes in scheme A、B、C and D

Table 4. Calibration values of f_{IL}

f_{IL}		Lanes in one direction		
		2	3	6
Integral		1.0	0.96	0.90
Passenger-freight separated	passenger	——	0.96	——
	freight		0.97	

Table 5. Calibrated values of f_{HV}

Simulation Scheme	A	E	F	G	H	I	J	K
Heavy vehicle mixing rate(%)	0	5	10	20	30	40	60	100
f_{HV}	1.00	0.96	0.93	0.84	0.71	0.65	0.61	0.48

4.2.3 Adjustment factor for presence of heavy vehicles f_{HV}

Simulation schemes utilized single variable control method when calibrating f_{HV}

and eliminates impacts of outer lanes, inner lanes, switching lanes and cross-section layout and traffic organizational modes. Simulation schemes were formulated by adjusting the ratio of cars to heavy vehicles of 2-lane freeways in integral mode, as shown in Table 6. The value of f_{HV} is the ratio of capacity of each scheme to based scheme. Speed-flow curves obtained by simulation were shown in Figure 5 and results of calibration were illustrated in Table 5.

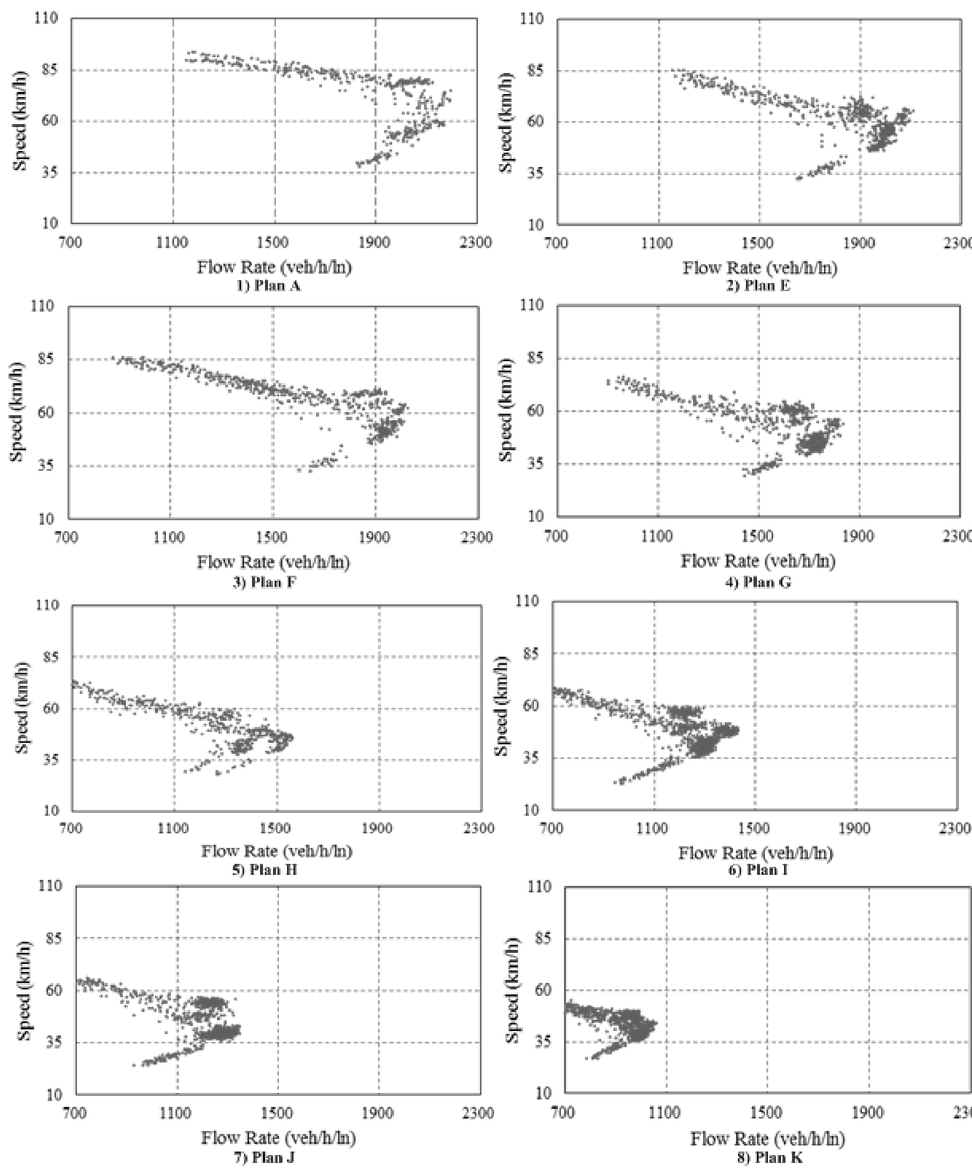

Figure 5. Speed-flow curve of the two lanes in Scheme A and E to K

Table 6. Simulation schemes in this research

Scheme	Lane in one	Traffic composition	Driving behavior

	direction		plan (see Table 2)
A	2	all cars	a
B	6	all cars	a
C	3	all cars	a
D	3	all HGVs	h
E	2	95%cars & 5%HGVs	b
F	2	90%cars & 10%HGVs	c

J	2	40%cars & 60%HGVs	g
K	2	all HGVs	h

5 Comparison among Capacities of Different Traffic Organizational Modes

Based on field data from Shen-Shan Segment of Jing-Ha Freeway, the heavy-vehicle mixing rate is approximately 40%. If this freeway is extended to 12-lane freeway, capabilities of it are not equal to each other when various cross-section layout and traffic organizational modes are adopted. For integral mode, capacity is 2200 2200pcu/h/ln at a designed speed of 120km/h and lanes in one direction is 6. The adjustment factor for driver population is 0.981. Adjustment factors for outer and inner lanes are selected as follows:

f_{OL} = 0.82 (Table 3, integral, 6 lanes in one direction)

f_{IL} = 0.90 (Table 4, integral, 6 lanes in one direction)

Using Eq. (1), CAP = 6021pcu/h. For freeways in passenger-freight separated mode, CAP = 8732 pcu/h through the same calculation. Detailed comparison between two modes are illustrated in Table 7.

Table 7. Comparison of capacities of Shen-Shan Segment of Jing-Ha Freeway in each cross-section layout and traffic organizational mode

Modes	Calculating Equation	Values of factors	Capacity (pcu/h)
Integral	Eq. (1)	$C_D = 2200$, $N = 6$, $f_P = 0.981$, $f_{HV} = 0.63$, $f_{OL} = 0.82$, $f_{IL} = 0.90$	6021
passenger-freight separated	Eq. (2)	$C_D^p = 2200$, $C_D^f = 1100$, $N^p = 3$, $N^f = 3$, $f_P^p = 0.981$, $f_P^f = 0.981$, $f_{OL}^p = 0.94$, $f_{OL}^f = 0.92$, $f_{IL}^p = 0.96$, $f_{IL}^f = 0.97$	8732

6 Conclusion

This paper developed models about capacities of 12-lane freeways in two cross section layout and organizational modes, which are integral mode and passenger-freight separated mode. Simulation of traffic flow operation was conducted by VISSIM simulation platform. Different speed-flow curves were obtained and related parameters were calibrated. This research utilized field data from Shen-Shan Segment of Jing-Ha Freeway. Thus, ratios of volumes in off-ramp and on-ramp to volume in arterial are fixed. As a matter of fact, the phenomenon of changing lanes would be more prominent with these higher ratios and calibrated values of related factors would be different. However, the research idea of this paper applies to researches about capacities of freeways with various lanes and different ratios of volumes in access ramps to volume in arterial. Subsequent researches will be about the extent of impacts of those ratios.

Abstract: Traffic safety is a perpetual theme in the development of automobile traffic, with the rapid increase of vehicle population, road traffic accidents, particularly the high incidence of serious accidents; safety problems have become increasingly prominent. The factors influencing Dalian road traffic accidents are analyzed under the current Dalian road transport safety situation. Gray correlation method was adopted to quantify the factors causing traffic accidents. The main factors include the population, number of driving, number of passengers, freight volume and passenger transport circulation. The correlation order among the factors was determined to provide data for the management.

Keywords: Macro factors; Dalian road traffic safety; Gray correlation method.

With the rapid development of economy and changing urban structure, vehicle population especially private cars continue rapid growth, combined with low sense of law and not law-abiding behavior of a little number of transport travelers, and various other uncivilized behavior seriously affect traffic safety. Therefore, the gray correlation analysis on macro factors affecting Dalian road traffic safety plays an increasingly important role in improving road safety level and reducing traffic accidents.

1 Macro factors analysis of influencing Dalian road traffic safety

(1) Population(Yuzhuo Men, 2012)

If the population of a region rises (including the floating population), the population travel times and the probability of traffic accident also will increase.

(2) Economy

The increase of economic strength will expand the range of people's activities and influence the regional population flow. The change undoubtedly makes the possibility of the occurrence of road traffic accidents increase.

(3) Traffic mileage

The speed of increasing in the road mileage is far less than the car ownership, which will cause the emergence of vicious spiral in road traffic accidents.

(4) Passenger and freight volume

The increased passenger and freight volume will undoubtedly affect road traffic risk level.

(5) Travel times

The increased travel times will make travelers and vehicles contact frequently, resulting in an increased number of road traffic accidents.

(6) Drivers number

If we ignore the driver's quality and ability, and simply focus on drivers number. It is undoubtedly associated with road accident frequency.

(7) Motor vehicles number

The rising number of motor vehicles increase the vehicle collision chance.

2 Gray correlation analysis

Steps of gray correlation analysis is summarized as follows：

(1) Analysis sequence (Sifeng Liu, 2014)

On the basis of qualitative analysis on the question，determine the dependent variable factors and multiple independent variable factors. The dependent variable data set constitute a reference sequence X_0', independent variables constitute comparative sequence X_i'（i=1，2, 3. . . n） the following matrix is listed as follows:

$$(X_0, X_1, \cdots, X_n) = \begin{pmatrix} x_0(1) & x_1(1) & \cdots & x_n(1) \\ x_0(2) & x_1(2) & \cdots & x_n(2) \\ \vdots & \vdots & & \vdots \\ x_0(N) & x_1(N) & \cdots & x_n(N) \end{pmatrix}_{N\times(n+1)} \quad (1)$$

(2) Dimensionless initialization of variables sequence

The initial value method of dimensionless data processing is listed as follows:

$$x_i(k) = \frac{x_i'(k)}{x_i'(1)} i = 0,1,\cdots,n; k = 1,2,\cdots,N \quad (2)$$

(3) Difference sequence, the maximum difference and minimum difference

Calculate the absolute difference in the first column (reference sequence) and the remaining columns (comparative sequence), and form the following absolute difference matrix:

$$\begin{pmatrix} \Delta_{01}(1) & \Delta_{02}(1) & \cdots & \Delta_{0n}(1) \\ \Delta_{01}(2) & \Delta_{02}(2) & \cdots & \Delta_{0n}(2) \\ \vdots & \vdots & & \vdots \\ \Delta_{01}(N) & \Delta_{02}(N) & \cdots & \Delta_{0n}(N) \end{pmatrix}_{N\times n}$$

$$\Delta_{0i}(k) = \left| x_0(k) - x_i(k) \right| i = 0,1,\cdots,n; k = 1,2,\cdots,N \quad (3)$$

The maximum and smallest numbers in the absolute difference matrix is the maximum difference and minimum difference:

$$\max_{\substack{1\le i\le n\\1\le k\le N}}\left\{\Delta_{0i}(k)\right\}\triangleq\Delta(\max) \tag{4}$$

$$\min_{\substack{1\le i\le n\\1\le k\le N}}\left\{\Delta_{0i}(k)\right\}\triangleq\Delta(\min) \tag{5}$$

(4) Calculating the correlation coefficient

Transform the data of absolute difference matrix as follows:

$$\xi_{0i}(k)=\frac{\Delta(\min)+\rho\Delta(\max)}{\Delta_{0i}(k)+\rho\Delta(\max)} \tag{6}$$

Get the correlation coefficient matrix:

$$\begin{pmatrix} \xi_{01}(1) & \xi_{02}(1) & \cdots & \xi_{0n}(1) \\ \xi_{01}(2) & \xi_{02}(2) & \cdots & \xi_{0n}(2) \\ \vdots & \vdots & & \vdots \\ \xi_{01}(N) & \xi_{02}(N) & \cdots & \xi_{0n}(N) \end{pmatrix}_{N\times n} \tag{7}$$

(5) Calculating the correlation degree

The correlation degree of comparative sequence Xi and reference sequence X0 is reflected by N correlation coefficient (equation7), the correlation degree is listed as followed：

$$r_{0i}=\frac{1}{N}\sum_{k=1}^{N}\xi_{0i}(k) \tag{8}$$

(6) Correlation degree analysis

The higher the value of correlation degree, the better the correlation may be. The change of comparative sequence and reference sequence is relative identification.

3. Applications of gray correlation method analyze in Dalian road traffic safety

(1) The dependent variable of 2003-2012 year for Dalian road traffic safety is shown in table 1, and the independent variable is shown in table 2(Dalian Municipal Bureau of Statistics,2013)：

Table 1. The dependent variable of 2003-2012 year

(4) According to the formula 4 and formula 5, Y_0 maximum differential and the minimum difference are showed as follows:

$$\max_{i=1}^{10}\min_{k=1}^{10}\left|Y_0(k)-X_i(k)\right|=5.887$$

$$\max_{i=1}^{10}\min_{k=1}^{10}\left|Y_0(k)-X_i(k)\right|=0.000$$

(5) Calculate the correlation coefficient

According to the formula 6, ρ =0.5,calculate the correlation coefficient of Y_0, which is listed in table 6.

Table 6. correlation coefficient of Y_0

ε_{01}	ε_{02}	ε_{03}	ε_{04}	ε_{05}	ε_{06}	ε_{07}	ε_{08}	ε_{09}	ε_{10}
1.000	1.000	1.000	1.000	1.000	1.000	1.000	1.000	1.000	1.000

4 Result analysis

According to the gray correlation matrix, the result analysis is listed as follows:

For the reference sequence Y_0 (The number of traffic accidents), $x_1 > x_8 > x_3 > x_5 > x_4 > x_{10} > x_7 > x_9 > x_2 > x_6$, x_1 (population) is the optimal factor, x_8 (travel times) are the secondary factors, x_3 (passenger volume) is the worst factor.

For the reference sequence Y_1 (The number of traffic deaths), $x_1 > x_8 > x_3 > x_5 > x_4 > x_{10} > x_7 > x_9 > x_2 > x_6$, x_1 (population) is the optimal factor, x_8 (travel times) are the secondary factors, x_3 (passenger volume) is the worst factor.

For the reference sequence Y_2 (The number of traffic injuries), $x_1 > x_8 > x_3 > x_5 > x_{10} > x_4 > x_7 > x_9 > x_2 > x_6$, x_1 (population) is the optimal factor, x_8 (travel times) are the secondary factors, x_3 (passenger volume) is the worst factor.

For the reference sequence Y_3 (Economic losses),

$x_1 > x_8 > x_3 > x_5 > x_4 > x_{10} > x_7 > x_9 > x_2 > x_6$, x_1 (population) is the optimal factor, x_8 (travel times) are the secondary factors, x_3 (passenger volume) is the worst factor.

For the independent variable factors, the result analysis is listed as follows:

$$\sum_{j=0}^{3} X_{j1} > \sum_{j=0}^{3} X_{j8} > \sum_{j=0}^{3} X_{j3} > \sum_{j=0}^{3} X_{j5} > \sum_{j=0}^{3} X_{j4} > \sum_{j=0}^{3} X_{j10} > \sum_{j=0}^{3} X_{j7} > \sum_{j=0}^{3} X_{j2} > \sum_{j=0}^{3} X_{j9} > \sum_{j=0}^{3} X_{j6}$$

$x_1 > x_8 > x_3 > x_5 > x_4 > x_{10} > x_7 > x_2 > x_9 > x_6$, x_1 (population) is the optimal factor, x_8 (travel times) are the secondary factors, x_3 (passenger volume) is the worst factor.

For the dependent variable factors, the result analysis is listed as follows:

$Y_2 > Y_1 > Y_0 > Y_3$, Y_2 （The number of traffic injuries） is the optimal factor.

To sum up, the factors of population, travel times, passenger volume and freight volume are the main macro factors influencing Dalian road traffic safety.

We should strengthen the force of propaganda campaign for birth control to control population growth there, and improve the travels quality. At the same time, enhance exploration and promote basic research in the forecasts and analysis of passenger and freight demands in Dalian.

Abstract: This article builds a model of the actual engineering using Midas/Civil, and makes an analysis of the impact on the deformation and stress of the bridge of concrete shrinkage and creep. Midas/Civil software uses the shrinkage and creep formulas in the "highway reinforced concrete and prestressed concrete bridge and culvert design specifications (JTG D62-2004). First, through changing the two parameters of relative humidity and creep coefficient of the model in the shrinkage and creep formulas specified in JTG D62-2004 specification, it analyses the effects of the shrinkage and creep on bridge deformation. Second, in and without the consideration of shrinkage and creep, it makes simulation analysis of the internal forces of the bridge to determine the degree of the influence of shrinkage and creep on bridge stress. By contrasting the parameters under different conditions, it obtains that the linear influence of the different relative humidities on the bridge is 25% in maximum. The concrete shrinkage and creep may also exert a relative great impact on the internal forces of the whole bridge. The stress of the upper flange decreases 1.9 MPa at most and the lower decreases 3.81 MPa at most. Through making an analysis on the impact of changing parameters and considering the shrinkage and creep on the actual engineering model linear and internal force, the author obtained the conclusion of the rule in the influence on a continuous girder bridge under the action of concrete shrinkage and creep, which provides a direction for the design and construction of continuous girder bridge using prestressed concrete.
Keywords: Loss of prestress; Shrinkage and creep; Relative humidity; The deflection; Cantilever construction.

1 Introduction

Shrinkage and creep is one of the basic characteristics of concrete materials, it not only has a great impact on the bridge structure, but a long lasting time of complex and various changing process. The prestressed concrete continuous girder bridge is widely used since it has the characteristic of good entirety, construction simple, large structure stiffness, and good vibration resistance. But with the bridge span increases gradually, many bridges across in the problems of large deflection and cracking in different degrees, these issues are related with construction methods, temperature changes and concrete shrinkage and creep. Wherein, the material shrinkage and creep is one of the most important reasons. The alignment of main beam in appearance and stress safety are related to the concrete shrinkage and creep. In our country, the shrinkage and creep in concrete box girder bridge is a very important and difficult problem, especially the concrete continuous beam that was built in the early 90s, has a lot of problems during its construction and operation period. Excessive midspan deflection during the process of operation causes the craze problem and so on, which related to many factors and the shrinkage and creep is the main reason. Now as the component is more and more thin, the strength of the material is increased. The influence of shrinkage and creep to concrete member is more and more obvious. Due to the insufficient consideration on effect of concrete shrinkage and creep, this leads to the bridges across cracking and excessive downwarping. Shrinkage and creep on the prestressed concrete box girder bridge deflection has a greater influence. To ensure the prestress concrete continuous box girder bridge of completed bridge geometric shape and its running process are in long-term deflection, it has positive and realistic significance to analysis and research the concrete shrinkage and creep.

2 The generating mechanism of shrinkage and creep of concrete and the influencing factors

2.1 The generating mechanism of contraction

The shrinkage deformation of concrete is happened under the condition of unloaded, the deformation of concrete member slowly deformed over time. The shrinkage strain under the condition of unloaded-time curves in Figure 1. Shrinkage of concrete contains three types which are the spontaneous, drying shrinkage and carbonization contraction. Spontaneous contractions means the contraction without of the water transfer, which is the cement volume participate in the hydration reaction is greater than the volume of cement hydrates, so it’s a kind of inherent shrinkage. Drying shrinkage refers to the disappearance of the adsorption of water inside the concrete, concrete volume contraction, this is the main part of the concrete shrinkage strain. Carbonization contraction refers to the concrete cement hydrates and CO_2 in the chemical reaction. The reason of shrinkage of concrete is the precipitation of calcium carbonate and calcium hydroxide dissolved.

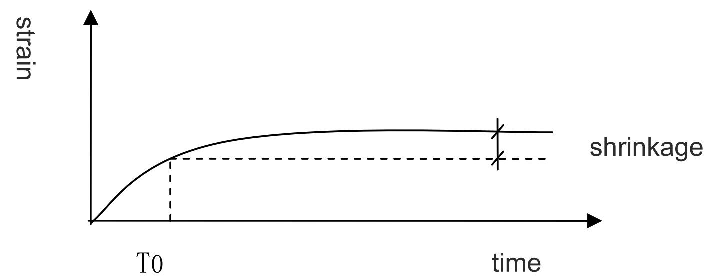

Figure 1. The contraction of unloaded component

2.2 The mechanism of creep

The concrete creep is load on the concrete specimen, the specimen firstly occurs instantaneous elastic deformation, and then, slowly increases the deformation furtherover time. Creep of concrete is concrete in the long-term effects under constant load; the compressive strain phenomenon continues to grow over time. Concrete creep can recover when initially loaded, viscoelastic theory to explain this phenomenon; continue to load reaches a certain degree, creep and strain is not a linear change, creep will tend to be stable. Concrete creep – time Figure 2.

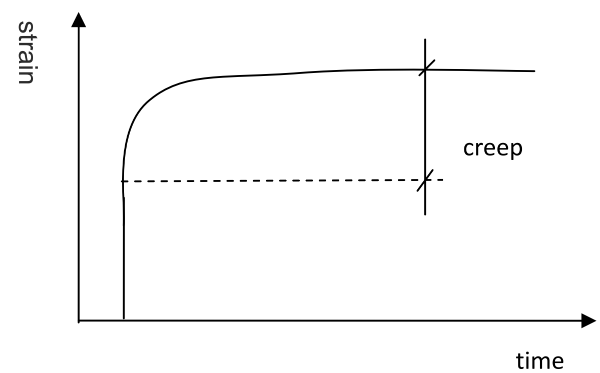

Figure 2. The creep of concr

2.3 Factors of impact on concrete shrinkage and creep

Impacts on the concrete shrinkage and creep have both internal factors and external factors. The main factors that affect the concrete shrinkage and creep are shown in Table 1.

Table 1.The main factors impact on shrinkage and creep

the main factors	internal factors	external factors
1	the types of cement	The environment temperature
2	curing conditions	stress
3	water cement ratio	Load duration time

Internal factors are the kinds of cement, curing condition, water cement ratio, etc.

(1) The types of cement

In general, load the same situation, cement strength quickly, shrinkage and creep will be lower. As a result, shrinkage and creep of concrete strength cement according to the low thermal cement, Portland cement and drought decline in turn.

(2) Curing conditions

There are three kinds of curing conditions: The curing time, curing environment humidity and temperature. Curing conditions have more influence on the concrete shrinkage and creep. Effective control of temperature and humidity can control the degree of hydration, so as to increase the strength development of concrete fast, decrease the influence of concrete shrinkage and creep.

(3) Water cement ratio

Water cement ratio is proportional to the values of shrinkage and creep of concrete. In a certain range, the greater the water cement ratio of concrete, the greater shrinkage and creep value.

External factors are temperature, applied stress, load, duration, etc.

(1) The surrounding environment temperature

Workplace surrounding environment temperature also has a great influence on the shrinkage and creep of concrete. Under the other conditions being the same, the hydration reaction is accelerated with the temperature increase, thus the contraction speed is also accelerated. Before a certain critical point of temperature, the temperature is increased, as well as the creep is also increased.

(2) Stress

As practice has shown, the concrete creep and stress has a direct connection, stress increases, concrete creep also increases. In the project, continuous load of concrete member is bad.

(3) Load duration time

Creep in concrete will last a long time, with the growth of time, the creep rate is decreased. Initial loading, due to the hydration thermal response, low concrete strength, and creep change is big.

3 The theoretical calculation of the concrete shrinkage and creep

The "highway reinforced concrete and prestressed concrete bridge and culvert design specifications" (JTG D62-2004) has specified the calculation formula of shrinkage and creep.

General expression of the concrete shrinkage strain:

$$\varepsilon_{cso} = \left[160 + 10\beta_{sc}\left(9 - f_{cm} / f_{cmo}\right)\right] \cdot 10^{-6} \cdot 1.55\left[1 - \left(RH / RH_0\right)^3\right] \tag{1}$$

$$\beta_s\left(t - t_s\right) = \left[\frac{\left(t - t_s\right)/t_1}{350\left(h/h_0\right)^2 + \left(t - t_s\right)/t_1}\right]^{0.5} \tag{2}$$

$$\varepsilon\left(t, t_s\right) = \varepsilon_{cso} \cdot \beta_s\left(t - t_s\right) \tag{3}$$

Type: ε_{cso} ,nominal contraction coefficient; RH, annual average relative humidity (%); $\varepsilon(t,t_s)$,age at the beginning of the contraction for t_s,calculating considering the age of t shrinkage strain; h, component theoretical thickness h=2A/u, A, component cross-sectional area; u, peripheral length of components in contact with the atmosphere; RH0=100%；h0=100mm;

Starting from the time t0 effect of concrete under uniaxial stress to the unit, in t time to produce the total strain, commonly referred to as creep function. Creep coefficient calculation formula:

$$\phi(t,t_0) = \phi_0 \cdot \beta_c(t-t_0) \tag{4}$$

$$\phi_0 = \left[1 + \frac{1 - RH/RH_0}{0.46(h/h_0)^{1/3}}\right] \cdot \frac{5.3}{(f_{cm}/f_{cmo})^{0.5}} \cdot \frac{1}{0.1 + (t_0/t_1)^{0.2}} \tag{5}$$

$$\beta_c(t-t_0) = \left[\frac{(t-t_0)/t_1}{\beta_H + (t-t_0)/t_1}\right]^{0.3} \tag{6}$$

Type: t_0 ,age of concrete(d) in loading; $\phi(t,t_0)$,loading age is t0, calculating considering the age of t of the concrete creep coefficient.

Based on the analysis of internal and external factors of influencing on the concrete shrinkage and creep, the author builds model with actual engineering, by changing the theoretical calculation of the parameters such as relative humidity and creep coefficient are calculated respectively, studying the effect of changing parameters on the linear and stress.

4 Engineering background

Bridge(48m+80m+48m) is a variable cross-section prestressed continuous box girder, using construction technique of cantilever casting method. Wherein, the 0 # 8 m, 1 # ~ 2 # 3.5 m, 3 # ~ 9 # 4.0 m, straight line segments(the side span cast-in-place section) 7.5 m, side span closure segment 1.5m, the middle span closure segment 2.0m. Continuous beam cross section is using the form of single box single room direct plate. Midspan bridge pier beam height H=6.4m, midspan and side span fulcrum girder high H = 3.6m. Beam height longitudinal changes by parabola. Midspan fold length is 2m, side span folded length 1.5m, cast-in-situ length 7.5 m. Box girder top width of 7.2m(Including sidewalks on both sides), box width 4.6m, To meet the needs of continuous beam support installation, midspan fulcrum Box girder width widened to 5.6m, side across fulcrum is not widened. Box girder roof thickness is 35cm, the baseplate thickness is gradually changed from 105cm to 40cm; the plate thickness from 105cm to 40cm. The whole beam support position and midspan set total of 7 transverse partitions, the diaphragm plate thickness of the fulcrum is 200 cm, the diaphragm plate thickness of the side support is 145cm, the diaphragm plate thickness of midspan is 100cm. The author uses Midas/Civil finite element program to analyze and calculate, and uses document design specification. The finite element model is shown in Figure 3.

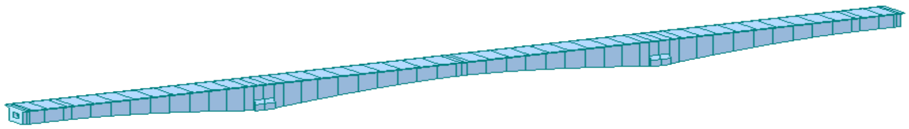

Figure 3. Bridge finite element model

5 The influence of shrinkage creep on the prestressed concrete box girder bridge

Concrete is a kind of material with a time effect. The shrinkage will happen after pouring the concrete, and the creep will happen under the load. So, shrinkage and creep on the prestressed concrete bridge has great effect on stress and linear. When continuous girder bridge closure that it happens system transformation, the concrete shrinkage and creep will cause the change of structural internal force, thus result in stress variation of reinforcement; eventually lead to the reinforced prestressed loss. As a result, it is necessary to research shrinkage and creep for continuous girder bridge linear, stress and the steel beam loss of prestress.

5.1 The concrete shrinkage and creep analysis of the influence on deflection

During the simulation analysis was carried out to the bridge, calculating the model by using theregulations of shrinkage and creep which specified in "China JTG D62-2004". On the parameters of the model were compared under different conditions, analysis of the influence of concrete shrinkage and creep on the bridge deflection.

(1) The control of relative humidity on the influence of concrete shrinkage and creep analysis. Shrinkage and creep are very sensitive to environment humidity change, therefore the humidity parameter in three cases analysis: Case 1: Relative humidity is 80%; Case 2: Relative humidity is 60%; Case 3: Relative humidity is 40%. Long-term deflection is produced by different humidity as shown in Figure 4(abscissa is half bridge unit location).

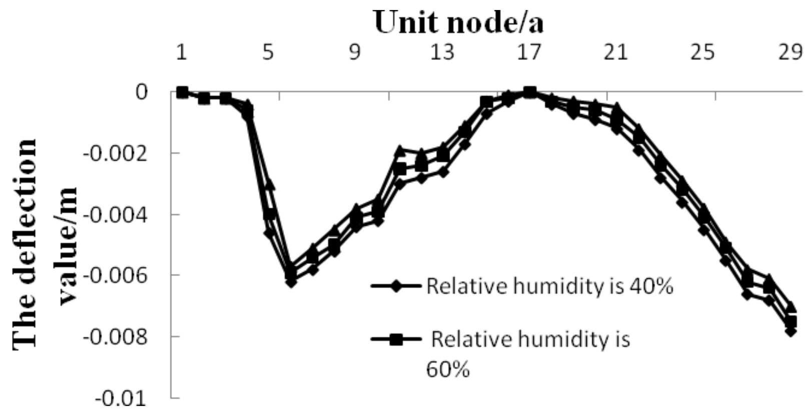

Figure 4 The influence of different relative humidity on the deflection

From Figure 4 we can see that relative humidity is 80% and the maximum difference of relative humidity 60% is 0.001 m, relative humidity 60% and the maximum difference of relative humidity 40% is 0.0006 m, relative humidity 80% and the maximum difference of relative humidity 40% is 0.0016 m. Relative humidity affects the concrete shrinkage and creep, the lower the relative humidity, the larger the shrinkage increases, while the shrinkage promotes the creep, especially in midspan affected by humidity is more obvious. Therefore, the lower the relative humidity, the larger the bridge deflection is. During curing the proper increase of relative humidity can reduce long-term deflection of the bridge. Relative humidity increases, the long-term deflection of bridge is reduced, an appropriate increase in humidity can reduce the impact of creep on the long-term deflection of the bridge.

(2) The influence analysis of creep coefficient on bridge deflection. Condition 1: Creep coefficient is 1.6; Condition 2: creep coefficient is 2.0; Condition 3: creep coefficient is 2.4. Bridge deflection values shown in Table 2.

Table 2 Bridge deflection value

node	Condition 1 (m)	Condition 2 (m)	Condition 3 (m)	1、2 difference (m)	2、3difference（m）
1	0.000	0.000	0.000	0.000	0.000

16	−0.001	−0.001	−0.003	−0.000	−0.002
17	−0.000	−0.000	−0.000	−0.000	−0.000
18	−0.001	−0.002	−0.004	−0.001	−0.002
19	−0.002	−0.005	−0.007	−0.003	−0.002
20	−0.005	−0.007	−0.011	−0.002	−0.004
21	−0.008	−0.011	−0.014	−0.003	−0.003
22	−0.012	−0.016	−0.025	−0.004	−0.009
23	−0.021	−0.025	−0.031	−0.004	−0.006
24	−0.028	−0.032	−0.038	−0.004	−0.006
25	−0.035	−0.041	−0.049	−0.006	−0.008
26	−0.047	−0.052	−0.055	−0.005	−0.003
27	−0.053	−0.058	−0.067	−0.005	−0.009
28	−0.059	−0.065	−0.068	−0.006	−0.003
29	−0.058	−0.062	−0.065	−0.004	−0.003

The analysis results are shown in table 2, maximum difference of condition 1 and conditions 2 is 0.012 m, maximum difference of condition 2 and conditions 3 is 0.011 m. Under the situation of other conditions being same, creep has a greater impact on the long-term deflection of the bridge. Through changing the parameters of creep coefficient, the larger the coefficient, the larger the bridge deflection is. So, creep has a greater impact on deflection of the bridge. Creep coefficient is one of the most important factors that cause long-term deflection of bridge. Take measures to determine the creep coefficient is necessary for bridge linear.

5.2 The concrete shrinkage and creep analysis of the influence on stress

Shrinkage and creep function can be seen, shrinkage and creep function is a function which related to the time development. Bridge stage at different times of shrinkage and creep effects on the internal forces of the bridge is not the same, after three years completion of the bridge, the stress of the bridge is analyzed. Tensile stresses are positive, compressive stress is negative. Two cases to analyze calculation model: considering the shrinkage and creep， regardless of the shrinkage and creep。

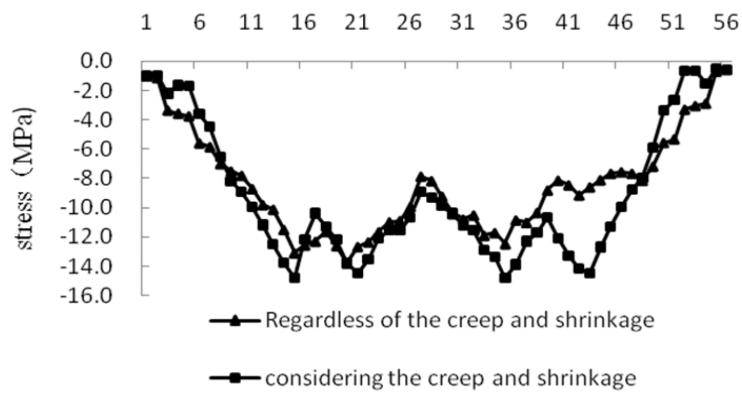

Figure 5. The bridge cross section upper flange stress diagram

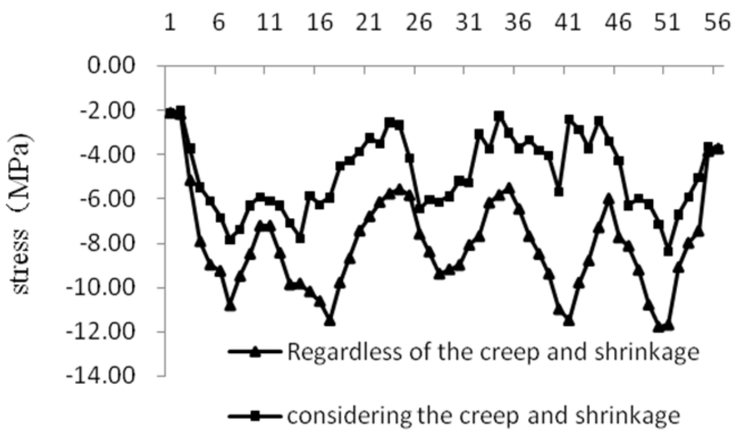

Figure 6 The bridge cross section bottom flange stress diagram

From Figure 5 we can see that after three years completion of the bridge, upper flange of cross section are compressive stress, the maximum compressive stress is -14.5MPa, which is in the range of allowable compressive stress of concrete. Considering compare with does not consider the shrinkage and creep side span piers's stress is decreased, the maximum difference of decrease is 1.9 MPa. Considering compare with does not consider the shrinkage and creep that upper flange of midspan cross-section stress increases obviously, the largest difference is 0.78 MPa. Near the bridge pier considering shrinkage and creep decrease bridge stress maximum 15.4%; near the midspan considering shrinkage and creep make stress maximum increased by 7.3%.

From Figure 6 we can see that after three years completion of the bridge, bottom flange of cross section are also compressive stress, under the effect of shrinkage and creep stress significantly decreased. The largest Midspan can maximum decrease 3.81 MPa. So, considering the shrinkage and creep of stress is advantaged for the lower flange of the longitudinal section.

In conclusion, after continuous girder bridge closed to become a statically indeterminate structure, under the effect of shrinkage and creep bridge structure produce time internal force, these Secondary internal forces cause bridge internal force redistribution, Therefore, shrinkage and creep on the internal forces of the statically indeterminate beam bridge structure have great influence.

6 Conclusions

By the analysis of the above:

(1)The influence of shrinkage and creep displacement of the bridge is very big, this article selects two parameters to analyze and demonstrate. There are some shrinkage creep parameters and correlation coefficient which needs a large number of the actual project data to further analyze.

(2)This paper using analysis of the influence of considering shrinkage and creep on the upper girder cross sectionand lower flange after three years completion of the bridge. The secondary internal force produced by shrinkage and creep causes the internal force redistribution between concrete and prestress steel beam. This has a great influence on stress and strain of upper or lower flange. Considering the shrinkage and creep has very important significance on bridge during its design and construction.

Abstract: Lining crack is the main form of tunnel disease. Tunnel lining crack undermines the integrity of the tunnel structure and reduces the strength and stiffness of lining structure. Thus it influences the normal operation of tunnel. Through the detection of a highway tunnel lining appearance and by using the software Midas GTS to conduct numerical calculation for typical section of tunnel lining are used to analyze the influence factors of cracking of tunnel. At the same time through analyzing the cause of crack and combining the actual condition of the tunnel this paper puts forward the regulation scheme of pasting CFRP to expect it can have the essential reference for the similar project in the future.
Keywords: Tunnel; Crack; Cause; Lining.

1 Introduction

Our country has become a veritable tunnel superpower. We have accumulated rich experience in tunnel construction, but still have a gap with the world advanced level in engineering technology. And our country has a vast territory, so the engineering geological and hydrogeological condition of the mountains that the tunnel goes through is complex and natural conditions have large differences. This makes our country become one of the countries that have most serious tunnel disease. Most of the tunnels have different levels of disease, especially the crack diseases. For different tunnels, the cause of the crack is not identical the same and the improvement measures are also different. This paper combines the actual tunnel engineering to analyze and discuss the main causes of crack of the tunnel according to the actual situation of the tunnel and puts forward specific improvement measures so as to achieve the desired effect.

2 Engineering General Situation

The primary tunnel is composed of the north line and south line and is designed as motor vehicles and non-motor vehicles mixed traffic. Wherein, Traffic capacity of motor vehicle is just two-way two-lane. And the clear width of the two holes both is 7m. The south hole of the tunnel is completed in 1983. The entrance and the exit stake no .are K0+204.72 and K0+647.97. The total length of the tunnel is 443.25m. The north hole of the tunnel is completed in 1993. The entrance and the exit stake no .are K0+190.21 and K0+661.69. The total length of the tunnel is 471.48m. And the height limit of the traffic is 4.5m. The total length of the two holes is 914.73m and the clear width of the two holes is 23-24m. The traffic height limit of the two tunnels both increases to 5.5m and the clear width of the two tunnels also increases to 12m.

The site of this tunnel belongs to the low mountain hilly terrain landform. The highest mountain (ridge) that the tunnel goes through is 176 m and the lowest is 96 m. In a small area of the ground the site is located in the tumor upwarping north part. The surrounding rock that the tunnel holes area goes through is mainly the breeze of the mixed granite rock and weathered rock, local weak weathered and rock integrity is good. Degree of surrounding rock which is influenced by geological structure is heavy and no large fault zone goes through the rock mass. In the middle of Tunnel hole area of the central hole there is rock fracture water and the water level is not stable. The water level of the mountain body in high area is higher above hole body around 30 m, so the water pressure should be considered in designing. PH of rock fissure water is 7.1 which belongs to calcium magnesium bicarbonate water. Rock body is weak permeable layer which has no corrosive to concrete and weak corrosive to steel. Seismic fortification intensity is 7 degrees and designing basic acceleration is 0.1 g. Site which belongs to class I lies to the favorable seismic area.

3 Detection of Crack Disease of Tunnel

Appearance test is a comprehensive inspection of the basic technical conditions of the tunnel. Appearance test can find lining crack diseases and other anomalies. Through the test, we can systematically master the basic technical condition of structure, evaluate function of the structures and determine the countermeasures to provide evidence for the work plan.

3.1 Type of lining crack

(1) Longitudinal crack damage Concrete lining of arch crown is generally the outer stretch lining cracking because of outer tension. Concrete of hance and side-wall are mainly opened because of inner tension that has the greatest harm.

(2) Circumferential crack is mainly caused by the different geological condition of surrounding rock, uneven load which is not improper handled and other factors. And it has little effect on the normal bearing of lining structure.

(3) Oblique crack its hazardous is second only to longitudinal crack damage that is caused by concrete which is influenced by many kinds of tensile stress.

3.2 Crack damage detection

In the south hole about 180 cracks are found. There are 52 cracks in the arch crown, 50 cracks in the hance and 78 cracks in the side-wall. All the cracks are mainly longitudinal crack and also have a part of circumferential crack and oblique crack. The widthest crack which lies in arch crown k0+557.57 (See Fig.1) is 1.3mm and is longitudinal. In the north hole about 151 cracks are found. There are 19 cracks in the arch crown, 22 cracks in the hance and 110 cracks in the side-wall. All the cracks are mainly longitudinal crack and circumferential crack and also have part of oblique crack. The widthest crack which lie in the left arch hance k0+420.49 (See Fig.2) is 1.1mm. Cracks are crossed in the longitudinal and circumferential. There are more longitudinal cracks than other kinds of cracks in north and south holes of tunnel, some of which are through cracks and falling cuts. It has caused potential safety concerns.

Fig 1. Longitudinal crack of secondary lining

Fig 2. Cross cracks of secondary lining

4 Crack Cause Analysis

4.1 Analysis of preliminary formation

(1) The surrounding rock integrity is good. Degree of surrounding rock which is influenced by geological structure is heavy and no large fault zone goes through the rock mass. There is no unfavourable condition for geology structure, so geology structure is not the reason that causes cracks.

(2) Thickness of the secondary lining is not enough, uneven distributed and void between the first lining and the secondary lining when the tunnel is constructed. These factors may be one of the reasons that tunnel lining appears cracks and spall.

(3) When the tunnel is designed, level of surrounding rock is divided incorrectly and type of lining is selected improperly, which causes the lining structure do not adapt with the actual load of the surrounding rock. This situation causes cracks. Objectively, because the mountain of the tunnel going through possesses complex engineering geology and hydrogeology conditions, so the depth and the number of

reconnaissance design work is limited. A number of tunnels only have geological drilling holes. In the design phase it is difficult to achieve complete and accurate geological data, in some areas the level of the surrounding rock is not accurately classified and type of lining is chose incorrectly. If in the construction it is not rectified or the right design is made the wrong change, the condition of lining structure not match the actual load of surrounding rock will occur. Not consistent load may be one of the reasons to causes of crack damage.

(4) When tunnel is constructed, the bad engineering quality is caused because of restricted technical conditions, undeserved method and mismanagement. Improper process cooperate, lining ring formation not in time, dangling on arch lining section is too long when horse's mouth digged in fall mouth slot and the deformation of arch support sinking and other reasons are all easy to causes the arch lining produce uneven subsidence, which leads to the early construction cracks in hance and arch crown lining. If vault is not sticked closely with surrounding rock hole, holes will occur. Under the action of "saddle" stress tensile cracks occurs in hance. To pursuit the construction progress and demould too early make low strength concrete early to bear loads, deformation of primary support has not reached a stable state, lining concrete bears too large loads or structure changed may also be a direct reason to cause lining crack damage.

According to the above preliminary analysis, the main reason of tunnel lining crack damage may be that lining concrete undertakes excessive load which causes bending crack damage, insufficient of the lining thickness and holes behind the lining.

4.2 Modeling build

Typical section which lies in zk0+215 is chose to perform plane analysis using midas GTS. The secondary lining of this section is chose to be calculation model. The cross section is 15m in depth and close to alternate place of open cut hole and dark cut hole. The thickness of the surface silty clay is 0.5m to 2.5m. Bedrock is mixed granite rock.

The area that the hole body goes through is mainly slightly weathered rock and local is weak weathered rock. The thickness of mountain body is a little thin and has already had a renovation expansion. So surrounding rock is disturbed a few times. The consequence is that surrounding rock is loose when it is excavated. For safety considerations, we assume that surrounding rock can not form a stable pressure arch. The initial support of tunnel and wall of secondary lining use bride unit. Then foundation uses only compression elastic connection to build the model. Solid pressure, linear girder unit load which is combined by ground springs and load, curve spring support and combined load are put to the girder unit. Then compression-only unit is only used to build ground springs to conduct boundary non-linear dynamic analysis. The calculation parameters are shown in table 1.

Table 1. Calculation parameters

project	gravity density /（kN · m^{-3}）	modulus of elasticity/Gpa	poisson ratio	coefficient of thermal expansion
initial support concrete:C30	25	30	0.2	1e-5
Secondary lining concrete:C30	25	30	0.2	1e-5

4.3 Secondary lining model analyse

If ground springs use compression only function which is in the elastic connection to conduct non-linear analysis, the loads is impossible become to a linear combination. Therefore exact result can not get according to the function of combination value of linear static force. So before the analysis using the function of the combined load to be a new group will see load combination transformation as a static load. Overall displacement, bending moment, axial force and shearing force diagram of secondary lining under the effect of load are shown in fig.3-fig.6. We can see from fig.4 that bending moment at arch crown and inverted arch is the biggest, about 812.449kN · m and the bending moment at two sides is the smallest.

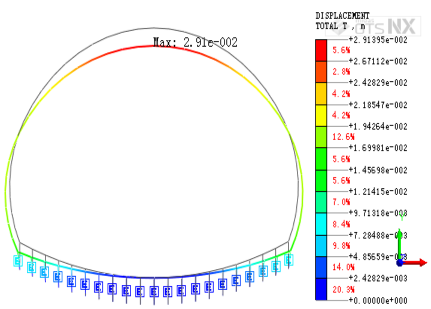

Fig 3. Overall displacement diagram of secondary lining under the effect of load (m)

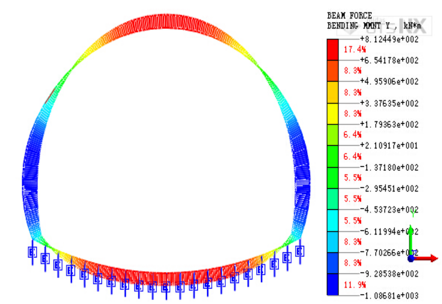

Fig 4. Overall bending moment diagram of secondary lining under the effect of load (kN · m)

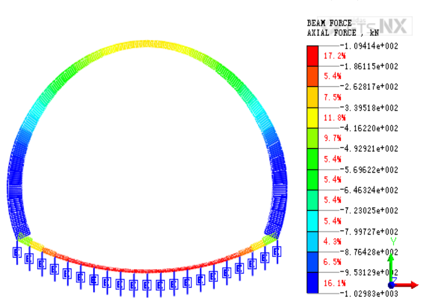

Fig 5. Overall axial force diagram of secondary lining under the effect of load (kN）

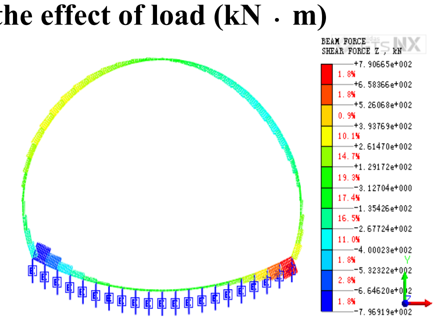

Fig 6. Overall shearing force diagram of secondary lining under the effect of load (kN)

When bearing capacity calculation for flexural members is conducted, the flowing assumptions should be made:（1）After bending deformation, component still keep the section plane. (2) Do not take the tensile strength of concrete into consideration. That is pull force is undertaken by the steel. (3) Concrete compressive stress-strain relationship should comply with the rules and regulations of the corresponding design curve. (4) Reinforcement stress taken is equal to the strain and modulus of elasticity of the product, but not greater than the strength design value.

It is known that strength grade of concrete is C30, HRB335 steel, 1m strip chose to calculate, size of section :b×h=1000×700,h_0=665mm, tensile bar: 4Φ22(1520mm^2), compression reinforcement: 4Φ22(1520mm^2), C30 concrete, fc=14.3N/mm^2，α_1=1.0; HRB335 steel, εb=0.55， fy=300N/$mm^{2.}$ Because the size of tensile bar and compression reinforcement is equal, so the height of compressive zone is x=h/2=350mm.

$$2as' = 70\text{mm} < x < \varepsilon bh0 = 0.55 \times 665 = 365.75mm$$

$$\begin{aligned} Mu &= \alpha 1fcbx(h0-0.5x) + fy'As'(h0-as') \\ &= 1\times14.3\times1000\times350\times(665-0.5\times350)+300\times1520 \\ &\times(665-35) = 2739.73\text{kN}\cdot\text{m} \end{aligned}$$

Mmax=812.449kN · m<Mu=2739.73. From this we can see the surplus of structure is larger, so it is safe.

5 Plan of Renovating Secondary Lining

According to overall analysis of secondary lining crack of tunnel, more reasonable, safer, more effective and more economic regulation measures are put forward. Because the highway tunnel lies in major urban traffic trunk road, in order to minimize effect on normal operation of the tunnel, regulation measures to the tunnel lining crack should try to be quick, convenient, economic and security.

5.1 Maintenance treatment measures

During the tunnel construction, there are holes behind the lining, especially at the arch crown of the tunnel. When a tunnel is renovated, we should test the place which has cracks using GRP. If holes are found, we should backfill the holes to improve the structure stress taking the measure of drilling grouting.

Nowadays the measures to renovate the tunnel cracks mainly include seam filling and grouting, pasting fiber cloth, adding steel arch, changing the arch, grouting hollow holes grouting behind the lining, pasting steel plate and other measure. Through compared with various aspects, seam filling and grouting and pasting fiber cloth are used as the renovation.

Different renovation measures are taken according to whether the crack is leakage of water.

(1) If the crack is dry (not leakage of water), according to the width of crack: more than 0.3mm and less than or equal to 0.3mm, these two situations are divided

and applying epoxy mastic directly, betting epoxy slurry and other measures are used respectively to deal with the problems.

(2) According to the width of crack: more than 0.3mm and less than or equal to 0.3mm,these two situations are divided for ring crack and applying two-component polyurethane binder directly, betting two-component polyurethane sealing slurry and other measure are used respectively to deal with the problems.

(3) For some places its Lining crack cracks more serious, including map cracking area near the arch and vault near longitudinal cracks distribution more populated areas, the measures of crack closed or potting first and then local paste CFRP are taken to renovate. If in some of these areas the width of the crack which is longitudinal stress is more than o.5mm, further measures that across the seam paste CFRP will be taken.

5.2 Construction technology process

5.2.1 Drilling grouting to void of secondary lining

According to the test report two rows of grouting side hole are drilled at the void behind the secondary lining. Middle holes should be drilled in the middle of the side holes. Grouting is started from the two side holes and water-cement radio is 1:1. The level of a single hole of finishing grouting is that the grouting pressure gradual rises to the design final pressure 0.5MPa, sustains more at least 10min. Grouting speed should less than one fourth of the initial admission speed and when the grout outflows from the middle hole, side holes finish grouting. Then press the grout from the middle holes. Because thickness of the arch crown is thin, grouting pressure should be controlled appropriately. And temporary support measures are also essential. At the same closely observe the lining deformation and development of surrounding cracks to ensure the safety of construction. Grout should be cement or cement mortar. Details can be seen from Fig.7 and Fig.8.

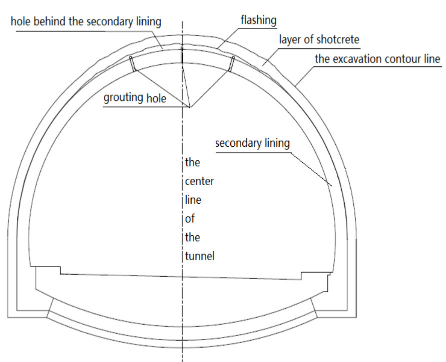

Fig 7. Grouting and air flow section

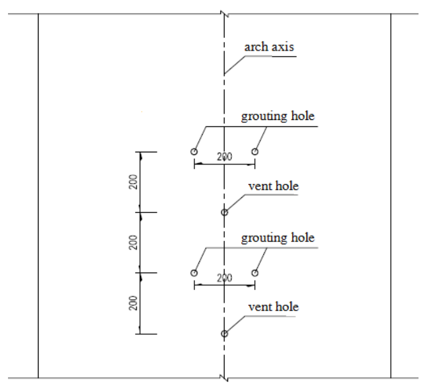

Fig 8. Grouting and air flow plan sketch

During drilling grouting holes, depth of drilling holes should be adjusted flexible according to the thickness of lining in the test report and physical truth. And try not to damage the flashing or existing waterproof system. If grouting in one time can not pack tightly, weakly expansive early-strength cement mortar should be used and grouting repeatedly several times after the concrete hardening. It is shown in Fig.9.

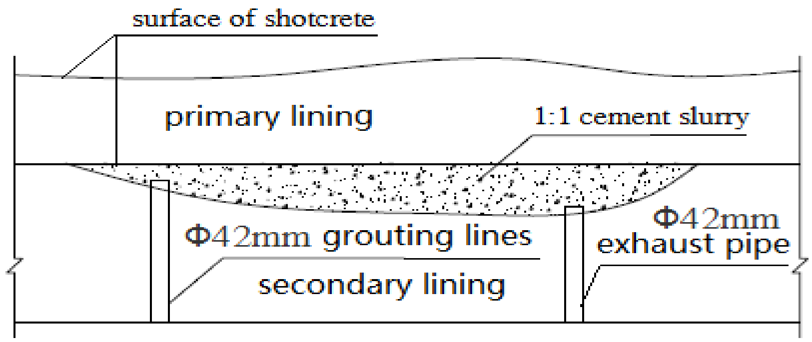

Fig 9. Installation of grouting holes and air flow holes

5.2.2 Crack renovation steps of lining

According to the different width of lining cracks, renovations measures which are based on different properties and different levels are taken to renovate cracks respectively. Various properties of crack renovation steps of lining are as follows.

(1)Daubing directly, namely closed treatment: base treatment, crack-cleaning, daubing, surface treatment.

(2) Grouting to seal joint, namely grouting processing: base treatment, crack-cleaning, crack pouring, maintenance, checking.

(3) Firstly, grouting uses low pressure; secondly, carbon fiber cloth is pasted. But Longitudinal and oblique cracks which are in the area of local crack treatment should be closed or glued. Detail process can be seen in "（1）" and "（2）". Carbon fiber cloth of 100cm in width should be pasted to reinforce the cracks which are in the area of local treatment and its width δ is more than 0.5mm. And carbon fiber cloth which is 30cm in width and its longitudinal spacing is 60cm should be pasted in the area of local crack treatment no less than 50cm.

6 Conclusions

Tunnel lining crack causes bad effect on stabilization of tunnel, traffic and personal safety, as well as facilities in the hole, even threatens and reduces the life of tunnel. What was worse, it will harm the normal operations of the tunnel. Studying the cause of tunnel lining is basement to us to solve the engineering problems. But the cause of tunnel crack includes construction, designing, geology and other aspects and the treatment plan is also different. Therefore only studying the cause of tunnel crack can we design technology appropriately and using better ways and processes to deal.

This paper preliminary analyse the various cause of tunnel crack. Then build model according to the midas GTS to analyses the bearing capacity, and the more accurately judge the main reason to cause lining crack. Taking the pasting carbon fiber cloth and grouting the holes behind as renovation measures, which makes the tunnel is completed renovation measures more safely, more rapidly and convenient. So it can be used as reference for similar maintenance and renovation projects.

Metrological Traceability Technology for the Pavement Frictional Coefficient Using the Law of Conservation of Energy

Guangwu Dou; Na Miao; Yixu Wang; and Lu Liu

Research Institute of Highway Ministry of Transport, No. 8 Xitucheng Rd., Beijing, China. E-mail: gw.dou@rioh.cn

Abstract: Pavement frictional coefficient using the law of conservation of energy is widely used in the evaluation of the pavement in China. To improve the reliability of evaluation, it is in urgent need of building the metrological traceability system of the pavement frictional coefficient. By deeply analyzing the operational principle and definition of Baizhi of the pavement frictional coefficient measuring instrument and considering the economy and portability needs, the project team proposed a two-level-deliver programme of metrological traceability. I level indoor standard is consist of a photoelectric encoder, a force sensors and a sampling control system, etc. Ⅱ level outdoor standard are lave and textured glass. The results show that the expanded uncertainty of I level standard is 0.42 (k=2), and the uncertainty of II level standard is 0.98 (k=2).The research will be effective support to the pendulum friction tester calibration.
Keywords: Road engineering; Pavement anti-slide performance; Friction coefficient; Energy loss; Metrological traceability.

1 Introduction

Antiskid performance is one of the key technologies which affects the traffic safety. The relevant factors include the abrasive performance of stone and the level of the bituminous pavement roughness shaped by the gap between bituminous pavement aggregates. And standards of transportation industry put forward different requirements for different levels of pavement. Pendulum friction tester was introduced from Britain since the 90's of last century and widely used in the final acceptance evaluation. While, as the main measuring instrument of antiskid performance evaluation, there are lots of knotty problems, such as the lack of technical supervision, the disparity of market price（1500~25000yuan）and cannot meet demand of stand. These problems debase the reality of the antiskid performance in China. Though industry standard JT/T 763-2009“Pendulum Friction Tester”has the requirements of product technology, the accurate results still cannot be guaranteed in actual detection work. JJG（Traffic）053-2009“Pendulum Friction Tester” has solved the problem of how to check-up the basic measurement parameters, but it doesn’t point out the traceability path clearly. Therefore, it is in urgent need of establishing the actual available traceability system to ensure the accuracy and reliability of measurement data.

2 Measuring Principle

2.1 Operational principle

Pendulum friction tester is consists of a pendulum, a slippery block, a sheet rubber, a dial and a upright column, etc. The sheet rubber is fastened to the slippery block. The distance between the swing center and the pendulum bob center is (410±5) mm. The slip distance of the measured object is (126±1) mm. The quality of the pendulum and connections is (1500±30) g. In the law of conservation of energy, the kinetic energy loss of the pendulum bob from the friction of the measured object is equal to friction energy of the sheet rubber overcome.

Measurement: Level and adjust the slip distance by up-down knob. Fasten the pendulum on the right cantilever and make the needle left parallel with the pendulum pole. Purl some water on the measured surface and press the release-push, then the pendulum bob free down and fall over the measured object surface. When the pendulum dropt, hand it. While reads and marks the measurement result. The same swing distance of the slippery block can ensure the same friction work and friction. Thus, the adjustment of the swing distance is a key step in the measurement.

2.2 Definition of Baizhi

Baizhi is the characterizes of pavement frictional coefficient which is expanded 100 times, measured by pendulum fiction tester under wet condition. It is denoted by BPN. According to the law of conservation of energy, the initial gravitational potential energy of the pendulum in the measurement converted into two parts: overcoming the friction work and the residual potential, as shown in figure 1.

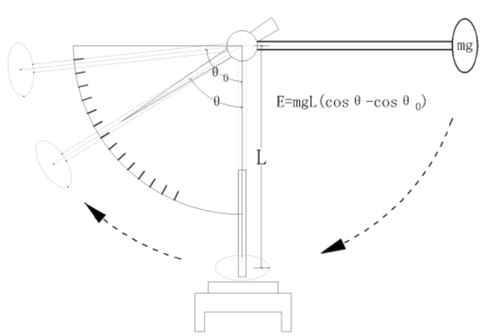

Figure 1. Diagrammatic sketch of the mechanical model of pendulum friction tester

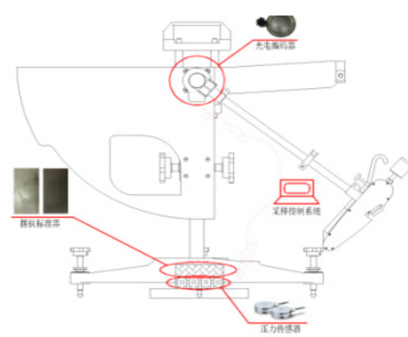

Figure 2. Structure diagram of I level standard

Energy conservation can be expressed as:

$$mgL(1-\cos\theta_0) = \mu\int_0^S N(x)dx + mgL(1-\cos\theta) \qquad (1)$$

The coefficient of friction is changing during the measurement process. The slippery block and the tested positive pressure integral calculation friction work between objects and the inverse, but it is hard to achieve. The actual project doesn't need real-time variation to characterize the antiskid performance, so the positive pressure is simplified as the maximum positive pressure *N* (Quantitative), as follows:

$$mgL(1-\cos\theta_0) = \mu NS + mgL(1-\cos\theta) \tag{2}$$

$mgL(1-\cos\theta_0)$ represents when the friction free, gravitational potential energy of the pendulum swing to the highest position in the air. μNS represents the pendulum to overcome the friction work. $mgL\cos\theta$ represents the potential energy of pendulum swing to the lowest position. $\mu_{BPN} = 100\cdot\mu$ represents Baizhi.

$$\mu_{BPN} = \frac{mgL(\cos\theta - \cos\theta_0)}{NS} \times 100 \tag{3}$$

with: μ_{BPN} - Baizhi;

S - the friction distance, mm;

N - the pressure between the measured project and the slippery block, N;

m - the quality of the pendulum, kg;

g - the local acceleration of gravity, g= 9.8m/s^2;

L - the distance between the center of gravity of the pendulum bob and the swing axis, m;

θ - the max deflection angle of the sheet rubber, rad;

θ_0 - the max deflection angle under with no friction, rad.

Visible, non-dimensional Baizhi is chosen to be the Characterization of value to evaluate the pavement surface resistance in highway industry. Its essence is the nature of friction coefficient but it is not the actual one. So it cannot be directly trace to the friction coefficient. Thus there is need for establishing a separate traceability system.

3 Metrological Traceability

3.1 Needs analysis

"Law on Metrology of the People's Republic of China" stipulates size tracing should follow the principle of economy and rationality, being carried out on the spot or in the vicinity. At present, there are more than two thousand test labs and nearly over a field laboratory in the transportation sector. Polished stone value and friction coefficient of pavement is the basic ability of test department. Pendulum friction tester is one of the enormous quantity wide instruments in the transportation sector. According to an incomplete statistics, there are a number of sets which mostly used in the field. The pendulum, needle, and the inside spring rigging of the pendulum friction tester is easily damaged in the transportation. It doesn't fit long-distance transportation. Therefore, studying the technical scheme of metrological traceability programme should consider the portability and efficiency requirements.

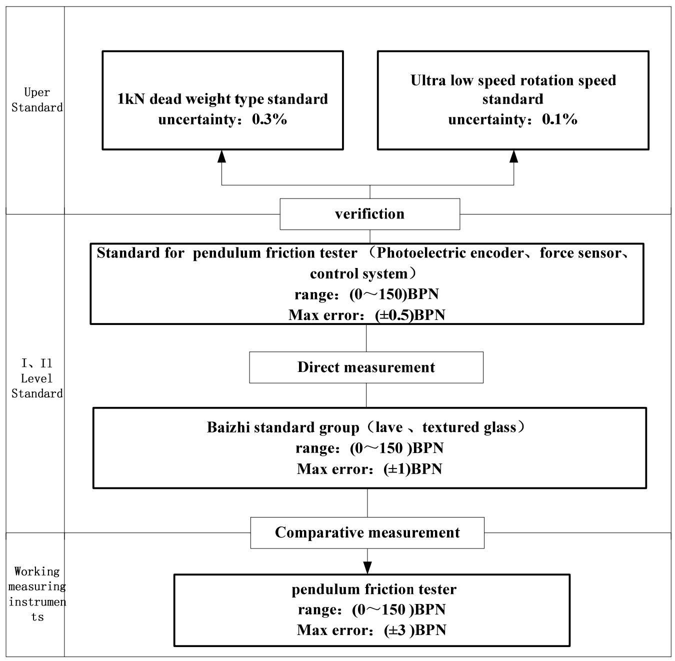

Figure 3. Hierarchy scheme of the pendulum friction tester

Combined with pavement antiskid performance evaluation of the actual engineering requirements, the paper designs a two-level-deliver programme of metrological traceability. Ⅰlevel indoor standard traced Baizhi to its definition with high accuracy requirement. Meanwhile, it also gives assignment to Ⅱlevel standard group which should be placed in the environment avoiding vibration and windage. Ⅱlevel outdoor standard is used to keep the assignment and actually verification which need accuracy requirement. The chosen of the standard block will be economic and portable. Now, the regulation for verification stipulates the accuracy is 2BPN, but it can't meet the demand in real. Besides, that high accuracy demand is unnecessary in engineering, so the paper confirm 3BPN, the hierarchy scheme is shown in fig.3.

3.2 Programme

The structure of I level standard is shown in fig.2. Formula (3) shows the potential energy loss to friction distance ratio is friction and friction to the max pressure ratio is Baizhi. So Ⅰ level standard needs to measure friction and pressure on the slippery and measured surface to gain Baizhi. In the law of conservation of energy, the friction can be achieved by calculating ratio of the potential loss energy and pressure. The potential loss energy can be obtained by measuring the rotational angle of the pendulum with photoelectric encoder. Friction distance can be received by using control system to measure the contact position of the sheet rubber and the measured object. The pressure can be calculated by the force sensor.

II level standard (hereinafter referred to as the standard group) need to be capable of covering (0~150) BPN measurement range. Whether be qualified can be judged through calculating the error of indication of the measurement results of pendulum friction tester and standard assignment. Taking into account the actual using premises, the standard group should be cheap, easy transfer, and field engineering calibration. Therefore, the paper chooses a group of lave and textured glass to be the standard group, its reproduction Baizhi interval distribution in different measurement range, with the character of stable, portable and economic.

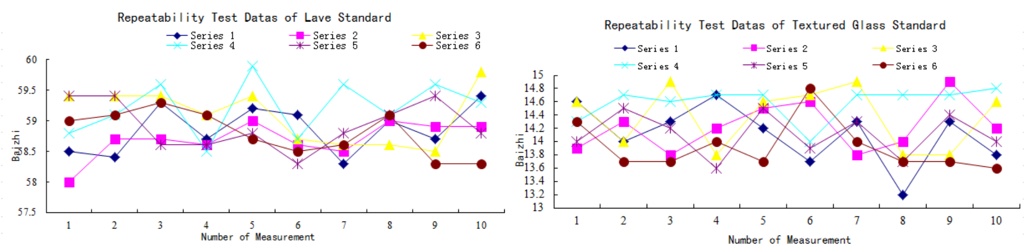

Figure 4. Measurement Repeatability Data Trend

As shown in fig.4, the abscissa is the number of the measurement and the ordinate is Baizhi. There are 6(Series 1-6) Ⅰ level standard to measure Ⅱ level standard group 10 times (we did the experiment with 3 pieces standard group, considering the limited space listed only one). Through the data trend in the figure, can we know that the Baizhi kept by the standard group is stable. The maximum standard deviation is chosen for evaluation of uncertainty, as seen in Table 1.

Table 1 standard group repeatability test sample data

number of measurements	1	2	3	4	5	6	7	8	9	10	average	standard deviation
textured glass	14.6	14	14.9	13.8	14.6	14.7	14.9	13.8	13.8	14.6	14.37	0.464399
lave	59.4	59.4	59.4	59.1	59.4	58.7	58.6	58.6	58.5	59.8	59.09	0.455705

4 Evaluation of Uncertainty

4.1 I level standard

The uncertainty of Ⅰ level standard is the uncertainty of surface friction coefficient (Baizhi). Based on its definition, the paper built the measurement model as shown in fig.3. Baizhi is the ratio of energy loss of the pendulum and the friction distance. Then, the branch of uncertainties of physical factors influence: 1) u_m that related with the quality of the pendulum bob; 2) u_g that related with the local acceleration of gravity; 3) u_L that related with the distance between the center of gravity of the pendulum bob and the swing axis; 4) u_θ that related with the max deflection angle of the sheet rubber; 5) u_{θ_0} that related with the max deflection angle under with no friction; 6) u_N that related with the pressure between the measured project and the slippery block; 7) u_s that related with the friction distance. In view of the fact that each branch of uncertainties is independent, while differentiate every branch of uncertainties, we can get the torsion relative standard uncertainty.

$$u_r(\mu_{BPN}) = \frac{u(\mu_{BPN})}{\mu_{BPN}} = \sqrt{\left(\frac{u(\mathrm{m})}{m}\right)^2 + \left(\frac{u(g)}{g}\right)^2 + \left(\frac{u(\mathrm{L})}{L}\right)^2 + \left(\frac{u(\cos\theta)}{\cos\theta}\right)^2 + \left(\frac{u(\cos\theta_0)}{\cos\theta_0}\right)^2 + \left(Nu(\mathrm{N})\right)^2 + \left(Su(\mathrm{S})\right)^2} \quad (4)$$

$$即 u_r = \sqrt{u_{r,\mathrm{m}}^2 + u_{r,\mathrm{g}}^2 + u_{r,\mathrm{L}}^2 + u_{r,\theta}^2 + u_{r,\theta_0}^2 + u_{r,\mathrm{N}}^2 + u_{r,\mathrm{S}}^2} \quad (5)$$

Among: $u_{r,m}$—the relative standard uncertainty related with the quality of the pendulum bob which less than 1/10 of the maximum error; $u_{r,g}$—the relative standard uncertainty related with the local acceleration of gravity which less than 10%; $u_{r,L}$—the relative standard uncertainty related with the center of gravity of the pendulum bob and the swing axis which less than 1/10 of the maximum change; $u_{r,\theta}$—the relative standard uncertainty related with max deflection angle of the sheet rubber. The pendulum angle is measured by the photoelectric encoder whose scale division maximum change is ±30″; u_{r,θ_0}—the relative standard uncertainty related with that related with the max deflection angle under with no friction. The pendulum angle is measured by the photoelectric encoder whose scale division maximum change is ±30″; $u_{r,N}$—the relative standard uncertainty related with the pressure between the measured project and the slippery block. In the law of conservation of energy, the response frequency of the force sensor is 5 kHz, the max margin of error is about 0.3mm; $u_{r,S}$—the relative standard uncertainty related with the friction distance, the uncertainty of the force sensor is 1.0%.

In addition, a slight change in temperature, the deformation of mechanical and the sensor affected by temperature will call the branch of uncertainty u_T. While u_T is far less than above branches of the uncertainty that can be omitted. In summary, the s branch of uncertainties is shown in table 2.

Table 2 List of the uncertainty

No.	Symbol	Classif-ication	Distribution	Figure	Remarks
1	$u_{r,\mathrm{m}}$	B	equidistribution	$\Delta_m/2\sqrt{3}$	Δ_m —max error of the quality of the pendulum which is 3g
2	$u_{r,\mathrm{g}}$	B	equidistribution	0.1%	On the certification
3	$u_{r,\mathrm{L}}$	B	equidistribution	$\Delta_L/2\sqrt{3}$	Δ_L —max error of the distance between the center of gravity of the pendulum bob and the swing axis which is±1.5mm
4	$u_{r,\theta}$	B	equidistribution	$\Delta_\theta/2\sqrt{3}$	Δ_θ —the max error of the photoelectric encoder 30″
5	u_{r,θ_0}	B	equidistribution	$\Delta_{\theta_0}/2\sqrt{3}$	Δ_{θ_0} —the max error of the photoelectric encoder 30″
6	$u_{r,\mathrm{N}}$	B	equidistribution	1.0%	On the certification
7	$u_{r,\mathrm{S}}$	B	equidistribution	$\Delta_S/2\sqrt{3}$	Δ_S —max error of the distance measurement which is 0.3mm
8	u_T	—	—	0	0

The combined standard uncertainty of the standard is

$$u_{\mathrm{I}} = \sqrt{u_{r,\mathrm{m}}^2 + u_{r,\mathrm{g}}^2 + u_{r,\mathrm{L}}^2 + u_{r,\theta}^2 + u_{r,\theta_0}^2 + u_{r,\mathrm{N}}^2 + u_{r,\mathrm{S}}^2 + u_{r,T}^2} \approx 1.06\% \qquad (6)$$

Thus, the expanded uncertainty of Ⅰ level standard $U_{\mathrm{I}} = 2 \cdot u_{\mathrm{I}} = 2.1\%\,(k=2)$, the maximum permissible error of full range is 0.31 BPN. It fits the requirement of the calibration of Ⅱ level standard group.

4.2 Ⅱ level standard

The factors affect the uncertainty of the standard group mainly come from the upper level standard and the measurement repeatability. The combined uncertainty of Ⅰ level standard $u_1 = u_{\mathrm{I}} = 0.156\,\mathrm{BPN}$. Choosing the maximum standard deviation from table 1 as the related with the repeatability $u_1 = 0.464\,\mathrm{BPN}$. The combined standard uncertainty of the standard group $u_{\mathrm{II}} = \sqrt{u_1^2 + u_2^2} \approx 0.49\mathrm{BPN}$, and the expanded uncertainty $U_{\mathrm{II}} = 2u_{\mathrm{II}} = 0.98\mathrm{BPN}\,(k=2)$.

5 Conclusions

Evaluate the pavement surface resistance with the use of pendulum friction tester is an important mean of final acceptance. But the traceability system of pendulum friction tester is faulty in current China. Therefore, this paper proposes a pendulum friction tester program of traceability, using I level standard and the II level standard group transfer quantity. I indoor level standard keep the value stable. II level standard has the characteristic of stable, low cost, portability strong which can fit the demand of field pendulum friction tester metrological verification. The results show that the uncertainty of I level standard is 0.42(k=2), the uncertainty of II level standard is 0.98(k=2), which fits the requirement of calibration of the pendulum friction tester. The research will be the strong support to the metrology of the pendulum instrument. In the light of the rubber sheet plays an important role in the measurement of Baizhi, the team considered there is strong need to develop the technical standard of the rubber sheet.

Abstract: This article introduces the characteristics of the gilsonite and the natural bitumen gilsonite .It also discusses the performances, effect, modified mechanism and using of the natural bitumen gilsonite modified bitumen. A series of tests of the natural bitumen gilsonite modified bitumen were made. These included asphalt technical property, rutting test a high temperature, marshall test. The result showed that the stability of natural bitumen gilsonite modified bitumen was markedly increased. The effects of the natural bitumen gilsonite modified bitumen were made in highway application.
Keywords: Natural bitumen gilsonite; Gilsonite; Modify; Application.

1 Introduction

With the focus of the economic construction transfer from the east to the Midwest in our country, the development of highway construction will be continued and be accelerated in our country. Most of the highway surface pavement adopts material asphalt concrete, asphalt concrete as a kind of road materials has some advantages such as convenience construction, low cost, the advantages of driving comfort, etc, but also it has inherent performance unstable faults. Therefore improve the performance of gilsonite in the road can make the gilsonite pavement have excellent performance under different weather conditions, and the effect of different vehicles, it is a task facing each road workers.

At present the methods of improving the performance of gilsonite materials can be achieved by mainly adopting different nature of the modifier in asphalt, this paper mainly introduces using natural bitumen as a modifier to improve the performance of gilsonite.

2 The characteristics of the gilsonite and natural bitumen comparative analysis

2.1 The characteristics of the gilsonite

Currently the gilsonite using in highway pavement basically all is petroleum asphalt, it is the product of crude oil after refining. Analysis of chemical composition of the asphalt material is very complicated by using chemical analysis method. To facilitate the work, usually will pitch into several chemical group for research of a similar nature, the so-called components. Gilsonite is generally divided into saturates, aromatics, colloid and asphaltene four components.

Asphaltene is solid matters, saturates and aromatics are liquid, colloidal is semi-solid material. In gilsonite solid asphaltene absorption semi-solid colloid can reverse micelle, it disperses in liquid saturates and aromatics, saturates is a gels among it, in the mixture saturates prevents the asphalt and colloid separation from the micelles, the gel structure can keep. Therefore the asphalt is not solid, not liquid, but a colloid. The gel due to its different components, so the characterization of colloid is different also.

When the asphalt content is rarely in the asphalt, less in tar micelle, asphalt micelle due to the effect of peptization of the colloid, completely dispersed in aromatic points and saturated medium, micelle attraction between minimal or no, this kind of asphalt is sensitive to temperature, type in the colloid theory belongs to the sol.

When asphalt content in asphalt appropriate, formed between asphalt micelle has a certain appeal, so the temperature is appropriate, elastic effect of asphalt performance is very obvious, but when the deformation increases to a certain value, and for the plastic deformation. This kind of circumstance belongs to the solubility of the colloid theory – gel structural.

The third kind of asphalt content a lot of asphaltene, micelle formation asphalt contact each other, form the space network structure, the asphalt has obvious elastic effect, it is called the gel structure. On the road performance, it is low temperature sensitivity, but low temperature deformation ability is poor.

Due to the crude oil refining asphalt composition and properties is different, and the methods of refining is also different, so content of various components in asphalt is different , properties of the asphalt is Larger differences.

2.2 The characteristics of the natural bitumen gilsonite

The natural bitumen is a kind of contains natural resin of the asphaltenes which it had be formed after long period of complicated changes under natural conditions, this kind of material is mostly by the oil in the rock fracture, after the earth's crust changes, which is caused by high temperature and high pressure, the role of oxygen in a series of chemical - physical reactions and generated, so it is with asphalt, lake asphalt have bigger difference in nature:

1) The natural bitumen's molecular weight is very big, from several thousand to more than ten thousand, so a high softening point, from 1300C ~ 2700C.

2) The purity of natural bitumen is higher, and very few impurities such as dirt in it.

3) The nitrogen content of natural bitumen as much as 2.5% ~ 7.5%, the nitrogen mainly exists as functional groups such as pyrolle and benzoyl ammonia nitrogen, so the natural bitumen have stronger invasive and high resistance of the free base oxide.

2.3 Comparison of characteristics

General asphalt in the outdoor exposure after a long time, due to the effect of ultraviolet radiation, in just a few years has strong oxidation, so that the asphalt aging metamorphism, but the natural bitumen asphalt has good resistance to weathering. The natural bitumen has mostly used in due to produce black paint, used in industries such as bicycle paint, and the black paint for outdoor conditions has a long application life(SHEN Jinan 1999,2001).

The natural bitumen has the strong affinity of stone, because natural bitumen contains high content of nitrogen, the equivalent of infiltration in the asphalt antistripping agent , so when we are in the asphalt mixture extraction experiment was carried out, the aggregate surface black trichloroethylene after several times of washing, still not to drop.

Shown in table 1 for DaQing crude oil of asphalt and north American natural bitumen and the comparison of domestic natural bitumen components.

Table 1. All kinds of asphalt components in contrast table

Parameter	Type			
	Nsphalt(Ⅰ)	Nsphalt(Ⅱ)	North America	Domestic
Saturates%	7.6	3.1	2.76	2.43
Aromatics%	33.0	43.5	2.76	3.99
Colloid%	55.3	51.6	60.91	63.79
Asphaltene%	4.0	1.8	30.65	29.30

3 The modification effects of natural bitumen of petroleum asphalt

North American natural gilsonite as DaGang asphalt modifier used in SMA pavement construction in 307 national road rebuilding project of HeBei province. North American natural modified domestic petroleum pitch contrast test results such as table 2.

Table 2. North American gilsonite modified domestic index detection

Modifier added amount %	Penetration 25℃	Ductility 15℃	Softening point /℃
0	99	21	43
2	78	18	44.5
3	70	15	45.5
4	63	13	46
5	59	11	46.5

Experimental results show that the north American natural gilsonite modified gilsonite has better efficacy, and modified asphalt and stone adhesive increased significantly. But look from the ductility index, DaGang asphalt itself can not meet the requirement of the indicators, therefore with north American natural gilsonite modified asphalt, indicators can not meet the required value(ZHOU Fuqiang,2006).

On the basis of indoor test, north American natural gilsonite as DaGang asphalt modifier pave the contrast test sections in 307 national road rebuilding project of HeBei province, asphalt mixture field sampling the rut dynamic stability test results shown in table 3.

Table 3. Dynamic stability test results

Gradation type	Dynamic stability time/MN	Asphalt type	Bitumen aggregate ratio %
AC-16I	480	DaGang asphalt	4.7
SMA-16	5040	DaGang asphalt	4.7
SMA-16	7000	North American Modified DaGang	6.3

Indoor test and outdoor experimental results have confirmed that the north American natural gilsonite modified domestic petroleum significantly effect. Is worth a special emphasis on the north American natural gilsonite fusible in domestic petroleum pitch, modification technology and modification equipment are relatively simple, it can even artificial added, so more its popularization and application provided favorable conditions(Hebei Traffic Science Research Institute 2009,Shijiazhuang City Transport 2011,YANG Yang 2007).

In addition, through the study found that the United States NA -u natural gilsonite modified pavement asphalt can significantly improve the adhesion of asphalt and stone, can greatly improve the asphalt surface thermal stability because of its high softening point, so using the modified asphalt, building roads can have very good resistance to deformation. Blending technology of asphalt performance is shown in table 4.

Table 4. NA-U modified Nandagang Asphalt technical performance tables

Parameter	Name of the asphalt	
	Nandagang asphalt	Mix 4% NA-U
Thixotropic Index 25℃,100g,5s	99	63
Brittle point /℃	-12	-9
Softening point /℃	43	46
Ductility 5cm/min,15℃	21	13

Rutting test results and the actual pavement rut has good correlation, this study adopts high temperature conditions evaluated the stability of the mixture. The stability testing is shown in table 5. As can be seen from the experimental data in the table: when natural bitumen gilsonite content of 4%, dynamic stability of the natural bitumen gilsonite modified asphalt is 2 times higher than asphalt (LI Zhongqiu 2004, ZHANG Dengliang 2003).

Table 5. Rutting test

Name of asphalt	Dynamic stability time/MN
Nandagang asphalt	1800
Mix 4% NA-U	4500

Lanzhou produces the natural gilsonite in china ,through experimental study by lanzhou Tianli company shows that using domestic natural gilsonite modified pavement asphalt is also very significant effect, modified asphalt properties as shown in table 6.

Table 6. Modified asphalt performance tables

Natural gilsonite content %	Thixotropic Index 25℃	Ductility 15℃	Softening point /℃
0	87	47.5	114
1.9	58	50.5	121
3.3	47	54	114
4.95	42	55.5	115

4 The reasons of natural bitumen modified petroleum asphalt

According to the introduction of the relevant information, natural gilsonite can improve performance of petroleum asphalt, basically has the following several reasons (JI Genzhong 2002, SHEN Jinan 2000):

1) When natural bitumen added to the asphalt, the interaction of thermal and molecular solvents, large molecular weight micelle rupture, micellar active substances can be adsorbed and combined by small molecules of asphalt, structure formation with natural bitumen as the core internal restructuring, such reprogramming will determine the modification by adding the size of natural gilsonite molecular and the activity of sulfur, nitrogen ,oxygen in internal asphalt.

2) After joining the natural bitumen in asphalt, due to the high activity of natural bitumen molecular weight, thus adsorption colloid and asphaltene of original asphalt, the size of the micelle combined with the most densely populated in the asphalt's gel, the dense combination strengthened the forces between them, prompting base asphalt from sol to gel type ,cohesiveness enhanced obviously, and restructuring is stable, modification effect is not decline over time.

3) Natural bitumen of high nitrogen, infiltrating force strong, can combine well with stone and have the effect of antistripping agent commonly used stoned.

4) Because the natural bitumen is formed by oil in the long geological evolution, so it is the same as the basis of asphalt composition, when use it to modified road asphalt, it put itself stability, oxidation resistance and other excellent properties of passing into asphalt and asphalt matrix does not produce, modified asphalt performance is

very stable, with the other adding agent, such as resin, rubber, compared with incomparable superiority (MA Jingkun 2004, ZHANG Junchao2006).

5 Conclusion

Natural bitumen good modification effect petroleum asphalt has been gradually to be known and accepted by internal and external highway, especially in some higher requirements of engineering, such as long span steel box girder of asphalt pavement, the application effect is good, there are other kinds of modified asphalt can not replace the effect.

Through our research to the following conclusions:

1) Using natural bitumen gilsonite modified asphalt can make its Penetration slash, softening point, the high temperature performance is improved.

2) Marshall stability, dynamic stability and high temperature performance of bituminous mixture is improved after natural bitumen gilsonite modified asphalt, but the low temperature performance basic remain unchanged.

3) The natural bitumen gilsonite modified asphalt technology is simple, low prices, has great popularization value in the highway.

Abstract: In order to study the unique accident characteristics of mountain roads to guarantee safety. Through careful investigation and information search on mountain roads and on the basis of a large number of data and cases of actual accidents, this paper summarized the main features of accidents in mountainous areas. According to the core idea of intrinsic safety, more attention should be paid to the design stage of road construction in mountain areas. Using both qualitative and quantitative methods, this paper sums up the main factors that influence the safety of mountain roads, they are road geometry, road condition and unique road environment in mountain areas. On the basis of the three factors, this paper proposes the principles and methods of dangerous section of governance. Through various analysis and comparison, this paper provides a more reasonable method of identifying black spots. The research results show that: the main reason of road accidents is a continuous curve and stadia, the tunnel without lighting equipment and water seepage inside the tunnel after earthquake are the factors that lead to accident, and the existence of the hidden dangers of accidents are mainly caused by the loosening mountain rocks and the lack of Kanawha rail.
Keywords: Traffic safety; Mountain roads; Accidents; Governance.

1 Introduction

In our country, more and more highways are being constructed in mountain areas in these years. From the situation of road safety, although the absolute number of mountain highway accident is relatively low, but the severity of traffic accidents is very high, the mortality rate of ten thousand vehicle significantly higher than the national average level. In addition, mountain accidents has the characteristics of more major accidents, the accident at night more high mortality, the more rear end collision accident, and more single accidents.

According to the characteristics of mountainous highway accidents, foreign scholars from system of accident characteristics of mountainous highway, studied in detail and found out the standard of a series of mountain highway safety facilities (Hu, Xiang, Babe). China started late, the research has been focused on the road linear design (Zheng), the causes of mountain accident analysis (Wang, Tang), and the strengthening of protection facilities (Wang, 2009).

Unlike the plain areas, restricted by terrain, the steep and sharp downhill linear of mountain road is common and difficult to avoid. The majority of mountain highway will use limit or near limit geometrical index, though do exceed the standard requirements, but in the highway complex environmental condition of mountainous area, easy to cause the driver to the spirit of high tension. So this paper, the characteristics of mountain highway road hazard analysis and control, in order to improve its safety level, with certain practical significance.

2 A method of identifying dangerous sections

On road traffic system, accident-prone points or sections is called an accident black spot (black-spots).There are many conventional methods to identify accident black spots, such as the number of accidents, expert empirical method, quality control method, the accident rate method, but for a long and small traffic road, the analysis of accident black spots does not apply. When an equivalent number of accidents as an indicator, identify accident black spots of mountain road based on non-fixed-length segments is more reasonable. The so-called non-fixed-length segment is divided into segments not refer to sections of equal length, but according to the actual location of the accident to be segmented. Simply put, that is, when the accident location adjacent points are in close proximity, we have consolidated their position and the corresponding extension of the accident segment length; when the position adjacent to the accident spot is more than a certain distance, we will split off them.

Specific steps of this method (Fan):

(1) Collecting data. Find a complete and accurate data of a road traffic accident in the traffic police department, including the absolute number of accidents, location of the accident, injuries, deaths and other data;

(2) Determine the shortest length of the segment and can be classified as the same accident accident point adjacent segments of the maximum distance. The length of the shortest in general can be set to 50m; which can be classified as the same accident point adjacent segments maximum distance and road survey involved years are of a great relationship, the shorter highway mileage is 200m,the longer is 400m.

(3) Statistical analysis. On the statistical data collected: the site of the accident as classification based statistical number, the number of injuries and deaths from the accident within each segment.

(4) Determine the parameter values. All parameters needed for the investigation, the final decision. The number of accidents due to the use of equivalent method, the formula and the required parameters are as follows:

$$A_{EQ} = A + k_1 D + k_2 W \quad (1)$$

Type: A_{EQ} is the equivalent number of accidents; A is the actual number of accidents; D is the number of deaths; W is the number of injured people; k_1 and k_2 are the weights of the number of deaths and injuries, these two parameters are needed to determine the specific sections of specific analysis, there is no value or standard.

(5)Calculation. After the determination of the conditions are thoroughly investigated, according to the formula, calculate the equivalent number of accidents each segment A_{EQ}, and then follow the equivalent number of accidents in the size of the sort, the larger point A_{EQ} is that the value of accident black spots.

3 The example analysis

According to the method of identifying dangerous sections, choose State Road 213 for analysis. 213 State Road (or "State Road 213", "G213 line") is one of China's national highway from north to south, starting on Lanzhou, Gansu, ending in Yunnan Mohan, the entire 2827 km. G213 line through Gansu, Sichuan and Yunnan three provinces, including Wenchuan -Dujiangyan segments on the network was named one of China's top ten killer road, the main reason is that the segment is very muddy, back and forth a driveway, carts, bad car more, one side is the mountain, the other side is the Minjiang River, the speed limit of 40 km. After the Wenchuan earthquake, the road is life channel, after renovation, road conditions have improved, but the rain prone to mudslides and landslides, the risk is still high. Based road hazard identification methods to get more significant incidents sections, and elaborated their dangerous characteristics.

3.1 Analysis of dangerous sections

The main danger point's situation is as follows:

In common State Road and State Road 213 and State Road 317 at 50km + 600m, there is a continuous curve, shown in Figure 1, due to poor mountain, trees, houses of shelter, driver sight distance on corners is bad, road width is narrow, very prone to crash out of the vehicle and vehicle road accident.

Figure 1. Continuous curve

In common 213 State Road and State Road 317 and State Road 52km + 200m, at the side of a mountain road, after the 512 earthquake, because of loose rock mountains, flying rocks often smashed the protective net after falling, rain is a factor of landslides, there is a big traffic hazards. The other side of the road is a fast flowing river, only a layer of guardrail can intercept the vehicle, if the vehicle out of control out of the way, it will lead to serious injury or death. As shown in Figure 2.

Figure 2. Roadside flying rocks

In common State Road 213 State Road 317 and State Road 52km + 900m (grass tunnel exit), there is a sharp bend, because the 5.12 earthquake, the old State Road 213 in the segment bridges were destroyed, making the new line is designed to a small radius corners, change bend road located beside the tunnel exit. No lighting in the tunnel, is the high point of the accident, there is a fork in the road near profiled, because of the green belt to block the line of sight, and it is easy to cause traffic accidents.

In common State Road 213 State Road 317 and State Road 53km, grass tunnels, power plant dam built on the tunnel, the tunnel seepage long since March 2011 and there is no lighting, water potholed roads, slippery roads inside the tunnel , poor road conditions, it is easy to cause traffic accidents too.

In common State Road and State Road 213 and State Road 317 at 53km + 800m (grass on the 2nd North Bridge, Railway Tenth), a slight landslides during the rainy season often block the road that leads to fewer cases of traffic accidents. As shown in Figure 3:

Figure 3. Minor mudslides segment

3.2 Countermeasures

The main cause of the accident is a continuous curve and line of sight is bad. There are three control points:①Set a reasonable speed. You should give the reasonable speed limit for the driver to have a sufficient emergency response and processing times, however, in our country, some drivers do not mind the speed limit, we can set the speed at the starting point of a continuous curve and capture facilities, make drivers force to slow down.②Set obvious warning signs at both ends of a continuous curve, reminding front of a continuous curve and accident-prone. Warning signs should be ergonomic, concisely, to the drawings, Fig should be simple and easy to read and understand. The warning signs should be eye-catching color, and night must have strong reflection effect, and warning sign distance continuous curves start distance should be reasonable.③Remove the roadside obstacles, give the driver enough corner vision. For the mountain, can clear the effect of the prominent part of the driver's field of vision, to form a concave cavity; the trees should be cut off or cut the height, to not affect the driver's field of vision.

The hidden dangers of accidents is mainly the problem of mountain rocks loose and Kanawha barrier caused by. There are two control points:①The mountain of rock debris is more, can send special vehicle to clean up, remove the clastic stone. At the same time increase the conservation efforts have protective net, once the damage is to be replaced as soon as possible.②The buffer is set in the Kanawha side, can be accumulated on the clastic Hill Road in Kanawha end of the guardrail, debris have very good effect for alleviating the vehicle kinetic energy, when the vehicle decelerates rapidly broke through the barriers, so as not to fall into the river.

For small radius section and tunnel lighting bad situation.①The small radius bend vehicle centrifugal force is larger, and increases with the increasing speed, so limiting vehicle speed is the best treatment, set up warning signs in the reasonable position of curve ends, to remind the driver in front of a small radius, and set a reasonable speed limit;②A great relationship between the frequent accidents in the tunnel with no lighting equipment. The longer time of dark adaptation of human, adequate lighting effects can effectively help the body fight the dark adaptation, the tunnel speed also have reasonable limits;③the fork in the road of the aliens, plus not to the driver to provide adequate vision, natural accident prone. At a distance of alien three fork reasonable position setting briefly graphics to illustrate three fork shape, clear or green trim facilities so that it does not affect the driver's field of vision.

The present situation of grass slope tunnel and earthquake also has a certain relationship. The seepage in the tunnel and the uneven road surface, leading to accumulation of water inside the tunnel, and there is no lighting facilities, poor road conditions, traffic accidents easily occur. The main control scheme are: ①The reinforcement of tunnel. The use of cement will lead paint, but with the seepage of the accumulation of time, cement is likely to fall off, the actual implementation may be difficult.②The construction of the lighting facilities. Part of the funds for the lighting facilities settings, select waterproof device, ensuring enough lighting.③On the tunnel road renovation, adding drainage ditch. The key is the refurbishment of longitudinal slope of 2%~3% set, so that infiltration of water can naturally along the drain outflow, but not the whole wet pavement; repair of hollows, reduce pavement roughness degree.

Debris flow treatment focuses on prevention and cure is not in. In view of mud rock flow occurred, the priority is to place built after debris flow blocking stone dam, to prevent debris flow down the spread of. Secondly it should start from the source, to reduce the debris on the reinforcement of mountain, rainwater drainage, not to the debris flow formation provide conditions, planting trees and grass is the most economical way.

4 Conclusions

(1) Combining with accident data carries on the analysis to the present situation of mountain highway safety, according to current research status at home and abroad, get the necessity to carry on the research of highway in mountainous area of the dangerous section of the road.

(2) Give a reasonable identification method of the mountain road accident black spots: Based on the equivalent number of accidents as an indicator of mountain highway segmentation method of non-fixed length. Investigate mountainous highway concrete road, select State Road 213 and State Road 317 public sections of several accident black spots, carries on the risk analysis, and puts forward the more reasonable countermeasures in theory.

(3) The main factors affecting the mountain road safety is linear, road and environment, combining accident principle, using the knowledge to present reasonable corrective principles and methods, to provide a theoretical basis for the safe management of mountain roads.

5 Recommendations for Future Research

The next step of research is the establishment of mountain highway safety audit index system.

Abstract: Based on the connotation of decision problem of expressway pavement preventive maintenance, multi-target multi-attribute pavement preventive maintenance decision is divided into four layers as the target layer, criteria layer, indicator layer and measure layer. Considering the cost of preventive maintenance measures, traffic characteristics, technical factors, construction factors as the evaluation value of the target layer, and using the group decision model to reduce the subjective factors, we can get the best preventive maintenance decision measures. Finally, the article illustrates how to develop a reasonable conservation measure by using the case studies.
Keywords: Road projects; Preventive maintenance; Conservation measures decision; Technique for order preference by similarity to an ideal solution (TOPSIS); Complex multi-attribute decision making.

1 Introduction

Traditional maintenance decision sometimes cannot be better to prolong and keep the usability of expressway. Preventive maintenance management system is developed in abroad, like The United States, Japan and so on .British use modern management techniques to play the efficiency of the original road, in order that the road can be better to serve the socio-economic development, peoples travel demand and environmental need. Cuelho E, Mokwa R and Akin M (2006) through the decision tree method, WeiCJ and Tigh S(2004) through decision matrix method choose preventive maintenance measures, But the transplant performance is not good enough. Some advanced methods have been used for maintenance decision, such as expert system, neural network. Neural network and expert system have been widely used in the selection program of foreign maintenance measures, and show tremendous superiority, however the two methods at present in our country are not widely used. In domestic, based on the interaction between the each factor of the maintenance system, ZengFeng (2013) use the analytic network process to analyze preventive maintenance measures. It will bring great difference to appraise a same problem due to many experts having different viewpoint on each index and exiting deviation, although researchers have done a large amount of research on the preventive maintenance decision. Therefore, how to assemble the experts' opinion in the decision-making process is a key link in the maintenance decision. Based on level analysis, the article analyze the problem of the expressway pavement preventive maintenance decision, use the TOPSIS (technique for order preference by similarity to an ideal solution) to aggregate groups of experts decisions to reduce the subjective factors, and then get the optimal preventive maintenance measures to guide decision-makers to adopt reasonable preventive maintenance measures in order to enhance the comprehensive service level of freeway.

2 Construction of the index system for preventive maintenance decisions

2.1 The process of preventive maintenance measures implemented

Expressway preventive maintenance measures firstly must be on the basis of the basic characteristics of the road to analyze the expressway, and then judge whether it can carry out preventive maintenance. When it satisfies the preventive maintenance conditions and then we should make the comprehensive evaluation of each program measures cost, technical features, constructional difficulties and measures for the driving effect, aggregate groups of experts' decision, and then determine the best maintenance measures program so as to achieve the corresponding goal. The process of preventive maintenance decision is following in Fig1.

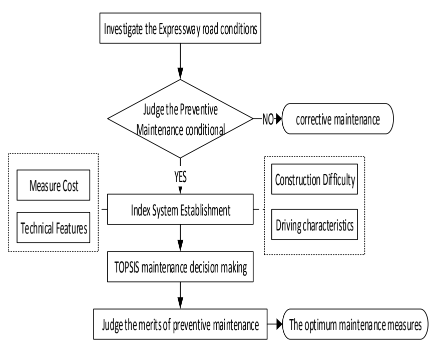

Figure 1. Implementation process of preventive conservation measures

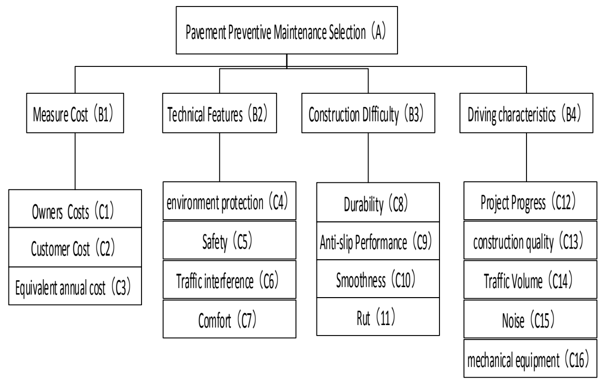

Figure 2. Preventive Maintenance indicator system structure diagram

2.2 The confirm of the system of preventive maintenance decision index

When selecting the best preventive maintenance measures, we should consider many factors, for instance, preventive maintenance measure costs, and the construction difficulty of measures itself, the security of measures and so on. On this basic the impact on the vehicle must be considered. According to the related literature, using a set of evaluation system to evaluate the entire situation is unreasonable and we should base on management departments and owner's specific requirements for specific analysis.

The constructed evaluation index system of preventive measures in figure 2 is divided into four levels: measures cost factors, factors of affecting traffic characteristics, the technology itself of measures and construction factors. Among them, the sub-indexes of measure costs factors belong to the quantitative index; the other indexes can be denoted respectively the influence degree of the measures by using index 0-1 in the process of calculation.

3 Based on the analytic hierarchy process to determine the index weight

As the preventive maintenance decision of our road has the characteristics of multi-factor, multi-level and multi-objective, and the method of AHP ranks vector to represent the relative importance of different factors. So the preventive maintenance measures can be divided into four basic steps when we use this method.

(1) Build the hierarchical structure model of multi-objective decision-making. Hierarchical structure model include target layer *A*, criterion layer *B*, layer criteria *C* and measures *Q*.

(2) Construct judgment matrix and single-level sorting. Experts use the Delphi method and the 1-9 scaling method combining the actual problems to construct the both judgment matrix of the factors of each layer

(3) Single-level sort. Let *B* layer number is n, using the sum-product method to normalize each column of the judgment matrix *A* of *A*-*Bi,* and then get the

normalized matrix $\left(\overline{a_{ij}}\right)_{n\times n}$

$$\overline{a}_{ij} = a_{ij} / \sum_{i=1}^{n} a_{ij} \, (j = 1, 2, \cdots, n) \tag{1}$$

The summation of each row of normalization judgment matrix,

$$W_i = \sum_{j=1}^{n} \overline{a_{ij}} (i = 1, 2, \cdots, n) \tag{2}$$

Let $W = (W_1, W_2, \cdots, W_n)^T$,and normalize it, and then the relative weight of the target layer A relative to the criterion layer B is

$$W^{(1)} = \left(W_1^{(1)}, W_2^{(1)}, \ldots W_n^{(1)}\right)^T \tag{3}$$

Similarly, the relative weight of the sub-criterion layer C relative to the criterion B is:

$$W_i^{(2)} = (W_{1i}^{(2)}, W_{2i}^{(2)}, \cdots, W_{mi}^{(2)})^T (i = 1, 2, \cdots, n) \tag{4}$$

Among it, the *m* is the criterion layer in *Bi* criterion layers.

The relative weight of the sub-criterion layer C relative to the criterion D is:

$$W^{(2)} = \left(W_1^{(2)}, W_2^{(2)}, \ldots W_n^{(2)}\right)^T \tag{5}$$

(4) Consistency test. Consistency index *CI* and random consistency index *CR*:

$$CI = \left(\lambda_{\max} - n\right) / \left(n - 1\right), \quad CR = CI / RI \tag{6}$$

Among (6) *CI* is consistency index; $\lambda_{\max}$ is the biggest eigenvalue of the judgment matrix; n is the order of judgment matrix; *RI* is the average random consistency index.

The average random consistency index as follow（in table 1）

.

Table 1. Consistency index table

Order	1	2	3	4	5	6	7	8	9
RI	0	0	0.52	0.89	1.12	1.36	1.41	1.46	1.49

When CR<0.1, we consider that the consistency of the judgment matrix is acceptable, then continue the solution. Otherwise we must adjust the judgment matrix until it satisfies the requirement of consistency.

(5) The total level of sorting. The total level of sorting is the criterion layer relative to the target layer, and the comprehensive weight is:

$$W^{(0)} = W^{(2)} \cdot W^{(1)} \tag{7}$$

4 The method of TOPSIS to select preventive maintenance decision measures

In reality, experts may have different opinion on the identity of each index and also have deviation on it, then to evaluate the same problem may have difference. Therefore, how to assemble the experts' opinion in the decision-making process is a key link in the maintenance decision. Choose TOPSIS method to select maintenance decision. The basic idea is to first select a positive ideal and negative ideal solution, and then find a scheme that is most close to the positive ideal solution and is most far away from the negative ideal solution as the optimal scheme. The TOPSIS introduce the relative closeness coefficient to weigh two distances, and judge the quality of solution.

(1)Q preventive maintenance measures and m indexes determine the judgment matrix $G=(g_{ij})_{Q\times m}$, then normalize the judgement matrix, finally obtain the normalized judgment matrix $U=(u_{ij})_{Q\times m}$.

(2)Construct weighted standardization decision matrix:

$$S = (s_{ij})_{Q\times m}, \quad s_{ij} = w_{ij} \cdot u_{ij} \,(j = 1, 2, \cdots, m) \tag{8}$$

(3)Determine the evaluation of the positive ideal solution $V+$ and negative ideal solution $V-$,

$$V^{+} = \left\{ (\max_{i} s_{ij}), (\min_{i} s_{ij}) \right\} \begin{pmatrix} i = 1, 2, \cdots, p \\ j = 1, 2, \cdots, m \end{pmatrix}, \quad V^{-} = \left\{ (\min_{i} s_{ij}), (\max_{i} s_{ij}) \right\} \begin{pmatrix} i = 1, 2, \cdots, p \\ j = 1, 2, \cdots, m \end{pmatrix} \tag{9}$$

(4)Determine the relative closeness coefficient of the positive and negative ideal solution of the preventive maintenance measures

$$R_i = D_i^- / (D_i^+ + D_i^-) \tag{10}$$

$$D_i^+ = \sqrt{\sum_{j=1}^{m}(s_{ij} - V^+)^2}\,(i = 1, 2, \cdots, m),\ \ D_i^- = \sqrt{\sum_{j=1}^{m}(s_{ij} - V^-)^2}\,(i = 1, 2, \cdots, m) \tag{11}$$

The bigger of R_i in (10) the better of the scheme of preventive maintenance measures, namely the corresponding measure is more appropriate.

5 Application of group decision-making level

5.1 Case description

A section of an expressway single-track length is 10km, two-way six-lane in Hubei, opened in August 2009. A comprehensive survey conducted in May 2013 shows that the expressway is good road conditions and part of the road is short of anti-sliding and local sections have cracks. Management hopes through appropriate conservation measures to improve pavement anti-sliding performance, at the same time can repair the pavement crack, improve the pavement smoothness level, reduce maintenance costs, shorten the construction period, and reduce the degree of disturbance to traffic.

5.2 Calculation and analysis of the case

The main restricting factors of decision goal which is divided into the construction difficulty, cost, technical measures, measures of driving and so on as the traffic analysis index, according to the index of dominance and subordination, the article has the whole structure of index system is divided into 4 levels and establish the decision model as shown in Figure 2, according to figure 1 preventive process. According to the figure 1 process have 3 options, micro surfacing, composite seal, and thin overlay.

(1)Calculate the comprehensive weights On the basis of Delphi method and 1-9 scaling method and formula (1) ~ (7) to be the weight coefficient of the TOPSIS evaluation.

$W^{(0)} = (0.074, 0.148, 0.078, 0.034, 0.071, 0.062, 0.033, 0.044, 0.026, 0.052, 0.078,$
$0.076, 0.072, 0.063, 0.04, 0.049)$

(2)Evaluate the index quantification to the 3 kinds of preventive maintenance measures according to Figure 2, as follow (Table2).

Table 2. Candidate Evaluation Table preventive conservation measures

	C_1	C_2	C_3	C_4	C_5	C_6	C_7	C_8	C_9	C_{10}	C_{11}	C_{12}	C_{13}	C_{14}	C_{15}	C_{16}
Q_1	14	6	10.3	0.82	0.88	0.91	0.85	0.8	0.9	0.94	0.84	2	1	0.74	0.73	0.87
Q_2	10	6	8.25	0.69	0.76	0.63	0.91	0.7	0.6	0.94	0.79	1	1	0.83	0.81	0.97
Q_3	8	8	5	0.82	0.73	0.91	0.84	0.9	0.9	0.94	0.84	3	1	0.76	0.62	0.79

(3)Calculate the weighted norms of decision matrix $S=(s_{ij})_{Q\times m}$ According to the formula (8), (3 kinds of preventive measures such as table 3).

Table 3. Three kinds of preventive measures decision table specification

	C_1	C_2	C_3	C_4	C_5	C_6	C_7	C_8
Q_1	0.0323	0.0444	0.0341	0.0119	0.0263	0.0230	0.0107	0.0146
Q_2	0.0231	0.0444	0.0273	0.0100	0.0227	0.0159	0.0115	0.0128
Q_3	0.0185	0.0592	0.0165	0.0119	0.0218	0.0230	0.0106	0.0165
	C_9	C_{10}	C_{11}	C_{12}	C_{13}	C_{14}	C_{15}	C_{16}
Q_1	0.0097	0.0173	0.026	0.025	0.024	0.020	0.0135	0.0162
Q_2	0.0065	0.0173	0.024	0.012	0.024	0.022	0.015	0.0180
Q_3	0.0097	0.0173	0.026	0.038	0.024	0.020	0.0114	0.0147

(4) Calculate V^+ and V^- according to the formula (9).

$$V^+=(0.0323,0.059,0.0341,0.0119,0.026,0.023,0.011,0.0165,0.0997,0.0173,0.0265,\\ 0.038,0.024,0.0224,0.0150,.018072)$$

$$V^-=(0.0185,0.0444,0.0165,0.0100,0.0218,0.159,0.0106,0.0128,0.0065,0.0173,\\ 0.249,0.0126,0.024,0.020,0.011,0.0147)$$

(5)Determine the distance from every index of 3 preventive maintenance measures to positive and negative ideal solution according to the formula (10) ~ (11), and then calculate the relative closeness of the supplier and the ideal solution. (The results in table 4).

Table 4. Candidate evaluation results of preventive conservation measures

	Q_1	Q_2	Q_3
D_i^+	0.0921	0.0988	0.092
D_i^-	0.262	0.266	0.263
R_i	0.259	0.270	0.261

Management hopes through appropriate conservation measures to improve pavement anti-sliding performance, repair the pavement crack, improve the pavement smoothness level, reduce maintenance costs, shorten the construction period, and reduce the degree of disturbance to traffic. The preventive measures and the ranking is a composite layer (R_2=0.270)>thin overlay (R_3=0.261)> micro surfacing (R_1=0.259). So the Optimal for Expressway Preventive Maintenance Measure is the composite seal.

6 Conclusions

Preventive maintenance decision has the character of multiple attributes, multi object properties, and proper preventive maintenance treatment selection is complex system engineering. It is scientific and applicable to combine the AHP and TOPSIS to analyze the pavement preventive maintenance decision, providing an effective method for the selection of the proper preventive maintenance measures, guiding the scientific maintenance to improve the social and economic benefits of expressway.

Microstructure of Modified Asphalt of PPA in Conjunction with SBS

Yaodong Wu

Liaoning Provincial Communications Science Institute, Shenyang 110015, China; and Expressway Maintenance Technology, Key Laboratory of Transport, Ministry of PRC, Shenyang 110015, China. E-mail: vpwyd@163.com

Abstract: The traditional polymer modified asphalt is stirred and sheared using the specialized equipment in order to making modifier is evenly dispersed in the asphalt. This belongs to physically blending modification. So there are some problems of poor compatibility and insufficient heat storage stability between asphalt and modifier. However, PPA modified asphalt belongs to the chemical modification which can effectively make up for the inadequacy of traditional polymer modified asphalt and improve the road performance. Microstructure of modified asphalt of PPA in conjunction with SBS is deeply researched base on these four tests in this paper. These tests include four constituents、fluorescence microscopy、infrared spectroscopy and DSC. Modification mechanism of PPA modified asphalt is explored from different angles. The internal reasons are analyzed and discussed that PPA can effectively improve the high temperature performance, ageing resistance and thermal storage stability performance by using the principle of the micro chemistry. The optimum dosage of PPA is 0.75~1.5%.
Keywords: Poly-phosphoric acid; Microstructure; Modified asphalt; Modification mechanism.

1 Introduction

Polyphosphoric acid (PPA) can effectively improve the high temperature performance，fatigue resistance and aging-resisting performance of asphalt. But it is making less contribution at the low temperature performance of asphalt. The modified asphalt of PPA in conjunction with SBS can enhance not only the high temperature performance and low temperature performance but also the thermal storage stability. It is more suitable for the application in northern China. However, modified asphalt of PPA belongs to the chemical modification and SBS modified asphalt belong to physical modification. The internal microscopic structure change of asphalt of PPA in conjunction with SBS is researched base on these four tests in this paper. These tests include four constituents、fluorescence microscopy、infrared spectroscopy and DSC. Internal factors of modified asphalt are in-depth analyzed after blending two kind of asphalt modifier of PPA and SBS in order to explore modification mechanism of asphalt of PPA in conjunction with SBS.

2 Four Constituents

Four constituents analysis utilize the principle that material dissolve in alternative in different organic solvent and absorb in the alternative in different adsorbent. So the asphalt can be separated four chemical similar characteristics constituents such as asphaltene、saturated fraction、aromatic fraction and colloid. It is analyzed four constituents of asphalt by solvent sediments and chromatographic columns in this experiment. As is well known, polymer is dispersed many granules by swelling and high speed shearing when polymer is joined in asphalt. It is physical miscible process and polar of the swelling polymer is similar to colloid. It is considered that the SBS has little influence on performance of asphalt because polymer is used as part of colloid. So it is major studied on that PPA influence on each component of asphalt in this paper. The proportion of PPA is 0%、0.5%、1%、1.5% and 2% . The test results are shown in fig1.

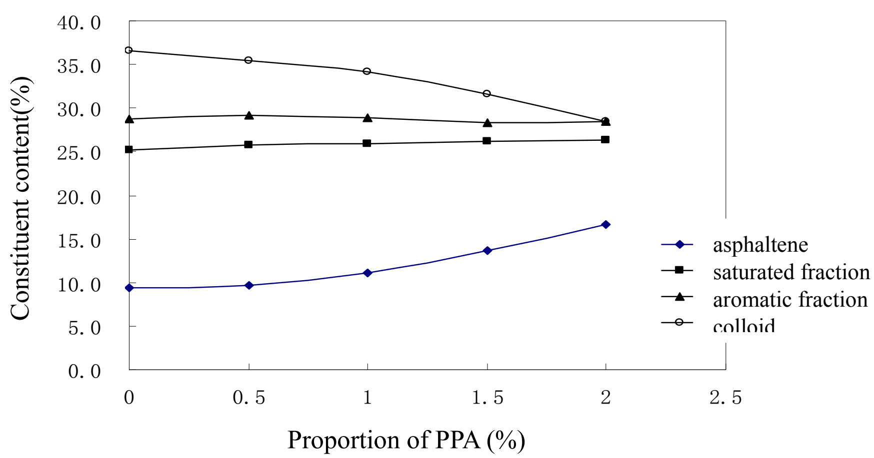

Fig1. The relationship between different proportion of PPA and asphalt

The content of asphaltene obviously increase and the content of colloid obviously decrease When the proportion of PPA increase from 0% to 2% from fig1. The content of asphaltene increase from 9.4% to 16.7% and the content of colloid decrease from 36.6% to 28.5%. The content of saturated fraction and aromatic fraction has no significant change. Changes in constituents of asphalt can affect changes of colloidal structure according to modern colloidal theories. The contents of asphaltene increases will lead to the contents of colloidal core increase. Colloidal core can absorb surrounding oil which results in the formation larger micelle. The number of micelle increase means the distance of micelle decrease and part of micelle even come into contact with each other. So the viscosity of asphalt increases because the forces of between micelles increase. As the same time, the forces of between micelles increase with the volume of micelles which lead to form the intensive space network structure. That is helpful to enhance the storage stability of asphalt.

PPA contributes to the colloidal structure of asphalt conversion from sol to sol-gel structure. The content of asphaltene increase and colloid decrease which lead to asphalt stiffness increase, the softening point and viscosity increase and penetration reduce. So PPA can effectively improve the high temperature performance and storage stability of asphalt.

3 Infrared absorption spectroscopy

Infrared absorption spectroscopy belongs to the category of molecular absorption spectra which is usually used to analyze chemical structure of substances. The principle is what polar molecules absorb infrared ray correspond of vibration energy levels. Parts of wavelengths radiation are absorbed into sample when the sample is irradiated by different wavelengths infrared ray. Some wavelengths of radiation are absorbed by the sample, then weaken, thus formed the infrared absorption spectrum. We can analyze group and molecule structure of the material from the position、the number、the relative intensity and the shape of absorption peak of the infrared absorption spectrum.

First the asphalt is dissolved in 5 percent carbon tetrachloride solution. Then this solution is smeared on flake of potassium bromide in order to form a thin film coating. Finally we can analyze the sample which carbon tetrachloride solution is volatilized using the spotlight. We consider that the coating thickness of asphalt is not being the same on the potassium bromide[1]. It's only comparison of the spectral curve of different samples is pointless because the different coating thickness will affect the strength of the absorption peak. So we can compare changes of different asphalt absorption peaks using the area ratio method.

It is chosen the proportion of SBS is 0%、3% and 4% and the proportion of PPA is 0%、0.5%、1 %、1.5% and 2% under each SBS dosage. We can know that absorption peak of asphalt is mainly located in 1030 cm^{-1} from spectrum of asphalt. So we calculate percentage of absorption peak area in 1030 cm^{-1} by the sum of absorption peaks area within 600 cm^{-1}-2000 cm^{-1} as the reference area. It is showed by the index of $I_{s=o}$ and the test results are shown in Fig2. At the same time we can know that the absorption peak of SBS modified asphalt mainly located in 6965 cm^{-1} and 97 cm^{-1}. It is showed by indexes of $I_{C=C}$ and I_{C-H}. The test results are shown in fig3 and fig4.

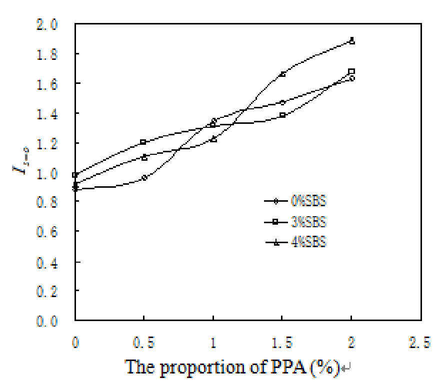

Fig2. The relationship between the index of $I_{s=o}$ and different proportion PPA

We know that the index of $I_{s=o}$ increase with the proportion of PPA increases in the different dosage of SBS from fig2. It is due to the index of $I_{s=o}$ corresponds Pressure sulfonic functional group what belong to polar group. Its can Interact with asphalt to form Larger and more closely new group. So it leads to increase the viscosity of asphalt. At the same time, the dosage of SBS has little effect on the index of $I_{s=o}$.

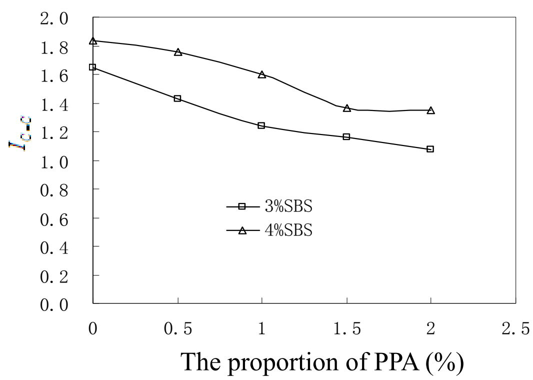

Fig3. The relationship between the index of $I_{C=C}$ and different proportion PPA

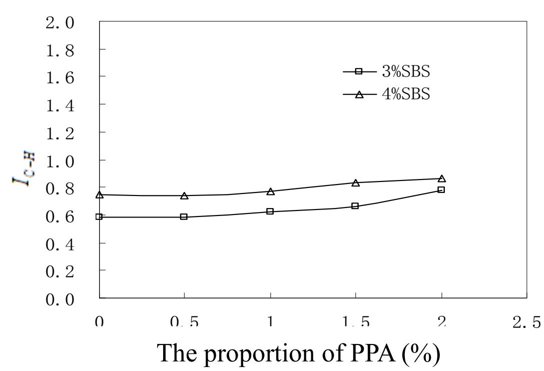

Fig4. The relationship between the index of I_{C-H} and different proportion PPA

We know that the index of $I_{C=C}$ gradually decrease with the proportion of PPA increases but I_{C-H} basically unchanged from fig3 and fig4. The index of $I_{C=C}$ decrease indicates that more $-C=C-$ double bond of butadiene block have been disconnected when the PPA is added. Asphalt activity increasing can increases the crosslinking effect between SBS and the grafting function between SBS and asphalt. Crosslinking of SBS contributes to form a network structure that asphalt be wrapped in the network structure and prevent separation between SBS and asphalt. There are products present in the interface of SBS and asphalt by the grafting function between SBS and asphalt[2]. It is can be prevent the aggregation of SBS and inhibit the separation of SBS and asphalt. Obviously, PPA is added to the SBS modified asphalt that it's can enhance network structure to improve high temperature storage performance of SBS modified asphalt.

4 Fluorescence microscope

Fluorescence microscope is an effective tool for analysis of phase structure of polymer modified asphalt. Polymer phase will produce a fluorescent of the modified asphalt while asphalt phase does not inspire any light when they are inspired by Shortwave light of ultraviolet ray. Fluorescence microscope using this principle can clearly distinguish the polymer phase and asphalt. Fluorescence microscopy can real observe phase structure of the modified asphalt and won't destroy the morphology of polymer phase and asphalt phase because of using the reflected light field.

It is chosen the proportion of SBS is 3% and 4%，the proportion of PPA is 0% 、0.5%、1 %、1.5% and 2% under each SBS dosage. The test results are shown in fig5.

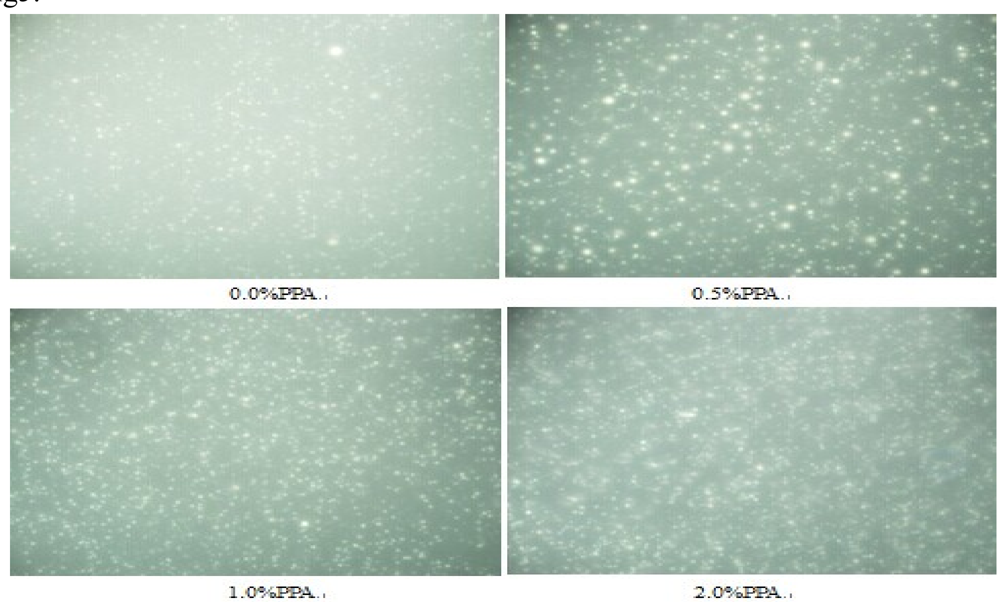

Fig5. 4% SBS+PPA（different proportion）

Particle size of SBS has larger difference having a lot of big size particles and uneven distribution when the PPA is not added from fig5. SBS particle mutual independent suspend in the asphalt and does not form network structure. Particle size of SBS is less and there is an increased in the number of particle with the increasing of proportion of PPA that the distribution is more even. Big size particles of SBS cannot be basically detect when the proportion of PPA more than 1%. Its show that PPA can effectively prompt SBS to disperse into tiny particles in the process of making modified asphalt. It is can effectively shorten the particle spacing because of the number of SBS particle increases and uniform distribution and make the synergy improved. The synergy was occurred by the long-term effect of many particles through interface layer[3]. That is can enhance network structure of modified asphalt and improve the high temperature storage performance.

At the same time, the smaller the SBS particle is, the easier light component of asphalt will penetrate. It is conducive to penetrating through macromolecule network of SBS which can promote infiltration and adsorption between asphalt and SBS and swelling of SBS particle. Obviously PPA can effectively reduce the cost of the asphalt and improve its storage stability using the modified asphalt of PPA in conjunction with SBS.

5 Differential scanning calorimetry（DSC）

DSC analyzes the power difference and temperature curve between sample and reference under a certain temperature. So the glass transition temperature of material can be found in order to evaluate its low temperature performance. The glass transition temperature of asphalt is a reversible change from viscous flow state or rubber state to a relatively rigid of glassy state. The glass transition temperature of asphalt is the temperature of glass transition when the asphalt starting to happen.

Asphalt is a complex structure that it is made of high polymer and low polymer and some small molecule. Asphalt is the state of solid and liquid aggregation at different temperature. The change of the aggregation state determines the changes of asphalt performance which mainly reflect the transformation from plastic to brittle. The optimum glass transition temperature should be lower than its service temperature in order to ensure the low temperature performance of asphalt. So asphalt has a good ability of deformation resistance during the whole service. The lower the glass transition temperature is, the better the low temperature performance will be.

It is chosen the proportion of SBS is 0%、3% and 4% and the proportion of PPA is 0%、0.5%、1 %、1.5% and 2% under each SBS dosage. The test results are shown in fig6.

We can see that the glass transition temperature has little change during the process of the proportion of PPA is gradually added from 0% to 2% under different SBS dosage. So PPA has little impact on low temperature performance of asphalt. Meanwhile we can also see that the glass transition temperature of modified asphalt is decreased with the increase of SBS dosage[4]. This is mainly due to the glass transition temperature of SBS is lower than asphalt in low temperature (the glass transition temperature of SBS is usually - 80 □ or so). Therefore, the increase of SBS dosage is helpful to improve the low temperature performance of asphalt.

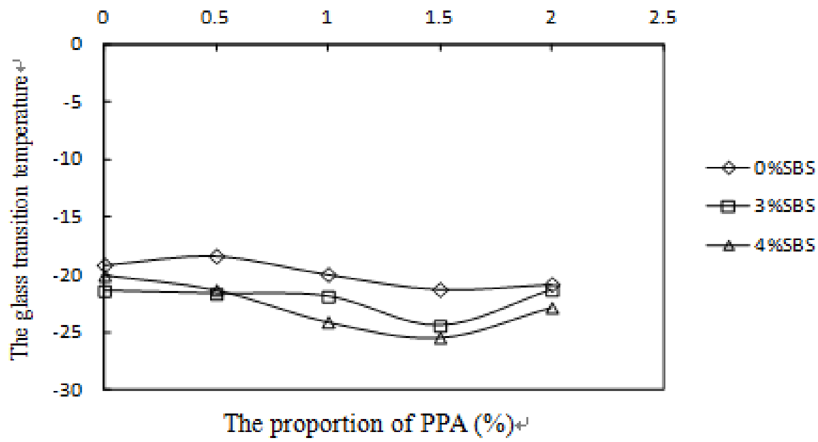

Fig6. The influence of PPA proportion on the glass transition temperature

6 Conclusions

(1) PPA is added in the asphalt which results in asphaltene and saturated fraction content increase but the aromatic fraction and colloid content have no obvious change. That is can improve softening point and viscosity and reduce the temperature sensitivity. So PPA can effectively improve the high temperature performance of asphalt.

(2) PPA contributes to the colloidal structure of asphalt conversion from sol to sol-gel structure. It is can increase the crosslinking effect between SBS and the grafting function between SBS and asphalt in order to enhance the network structure of asphalt. That is helpful to improve high temperature storage performance of SBS modified asphalt.

(3) PPA has little impact on low temperature performance of asphalt but the increase of SBS dosage is helpful to improve the low temperature performance of asphalt.

Abstract: Considering the durability of concrete, properties of raw materials have a marked effect, especially the properties of coarse aggregate which takes most position in concrete. In this paper, effects of elongated and flaky particles content on the durability of concrete were studied. 6.8%, 16% and 25.2% were chose as the dosages of elongated and flaky particles. The workability, compressive strength, drying shrinkage and impermeability were studied. The results revealed that all properties which were mentioned above were weakened with the increasing of elongated and flaky particles content. According to the results of this research the content of elongated and flaky particles should be fewer than 16%, while the workability and maximum packing density can be achieved.
Keywords: Concrete; Coarse aggregate; Durability; Elongated and flaky particles.

1 Introduction

Concrete is wildly used all over the world due to its excellent properties. Properties of concrete are determined by raw materials, such as cement, fine aggregate, coarse aggregate and chemical admixtures. Coarse aggregate takes almost 40% in concrete, so it has marked effect on concrete properties. Elongated and flaky particles content of coarse aggregate is an important property factor, and it is considered as a harmful factor (Sengupta, 2009) (Zeng, 2011). The effects of elongated and flaky particles content on workability and compressive strength were studied by many researchers (Zhang, 2013) (Liu, 2012), but its effect on durability has not been studied so widely. As the developing of construction industry, the durability of concrete attracts more and more attention. So it is necessary to study the relationship between durability and elongated and flaky particles content. In this paper, effects of elongated and flaky particles content on the durability of concrete were researched.

2 Materials and experimental methods

Cement of P·O 32.5, P·O 42.5 and class Ⅰ fly ash were used in all mixtures, and the properties of cement and fly ash were given in Table 1 and Table 2. Cement of P·O 32.5 was used in C30 concrete, and Cement of P·O 42.5 was used in C60 concrete. Fine aggregate used was river sand with the special gravity of 2.63g/cm^3

and the fineness module of 2.6. Coarse aggregate was crushed limestone rock with the elongated and flaky particles content of 6.8%, 16% and 25.2%. Air content and workability were adjusted by adding appropriate amounts of SJ-2 saponin air entraining agent and UNF-5 naphthalene formaldehyde sulphonated superplasticizer. The proportion of concrete mixture was given in Table 3. In order to study the effects of paste aggregate ratio on the durability of concrete, two paste aggregate ratios were chosen, and *P*/*A* stands for the ratio of paste to aggregate.

Table 1. The properties of cement

Type	Water requirement (%)	Time of initial setting [min]	Time of final setting [min]	Flexural strength [MPa] 3d	Flexural strength [MPa] 28d	Compressive strength [MPa] 3d	Compressive strength [MPa] 28d
P·O 32.5	27.8	207	334	4.7	7.5	22.1	45.8
P·O 42.5	28.0	195	320	5.9	8.5	24.7	53.7

Table 2. The properties of fly ash

Fineness, amount retained, (80μm) sieve [%]	Water requirement [%]	Loss on ignition [%]	Content of SO_3 [%]	Strength activity index [%]
4.9	94.7	2.8	0.25	83.3

Table 3. Mixture proportions of concrete

P/*A*	Group	*W*/*C*	Water [kg/m^3]	Cement [kg/m^3]	Fly ash [kg/m^3]	Sand [kg/m^3]	Coarse aggregate [kg/m^3]	SJ-2 [‰]	UNF-5 [%]
32.5/67.5	C30	0.53	172	326	75	606	1068	0.35	0.49
	C60	0.38	146	380	87	597	1068	0.21	1.6
35/65	C30	0.53	186	351	80	578	1028	0.36	0.49
	C60	0.38	157	409	94	569	1028	0.21	1.4

The specimens of concrete with the sizes of 100mm×100mm×100mm and φ100mm×300mm were cast and demoulded 24h after casting. Mechanical properties and chloride diffusion coefficient were tested after curing in standard condition (20±2℃ and 95% RH) for 28 days, and the dry shrinkage properties were tested after curing for 3 days.

3 Results and discussions

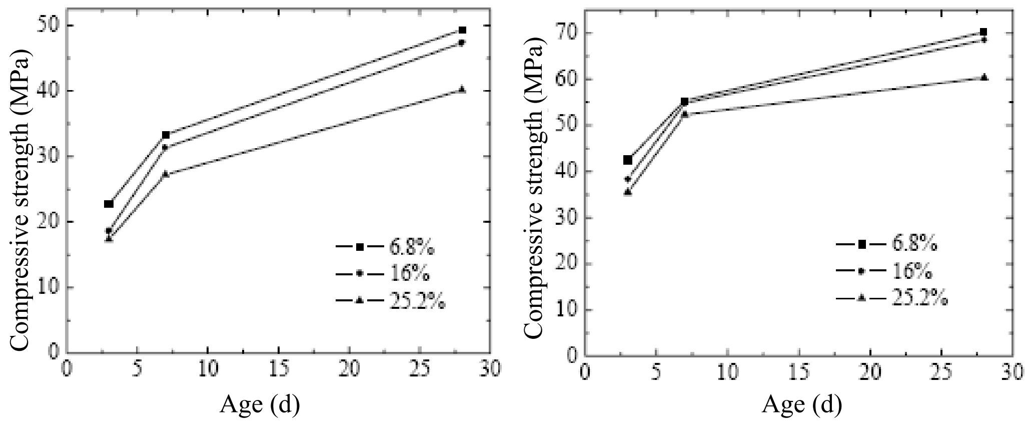
3.1 Effect of elongated and flaky particles content on the workability of concrete

Table4. Relationship between elongated and flaky particles content and slump

P/*A*	Group	Elongated and flaky particles content (%) 6.8	16.0	25.2
32.5/67.5	C30	90	81	55
	C60	93	85	52
35/65	C30	85	75	56
	C60	94	81	55

Table 4 indicated that when the content of elongated and flaky parties increased the slump of both C30 concrete and C60 concrete decreased, and concrete with higher strength has higher decreasing amplitude. Meanwhile, when the contents changed from 16.0% to 25.2%, the slump of concrete sharply dropped. With different *P*/*A*, the tendency of the variation is similar. The higher surface area of elongated and flaky parties is the main reason for the decrease of slump, and the second one is the augment of bite force between elongated and flaky parties, which could cause a less fluidity.

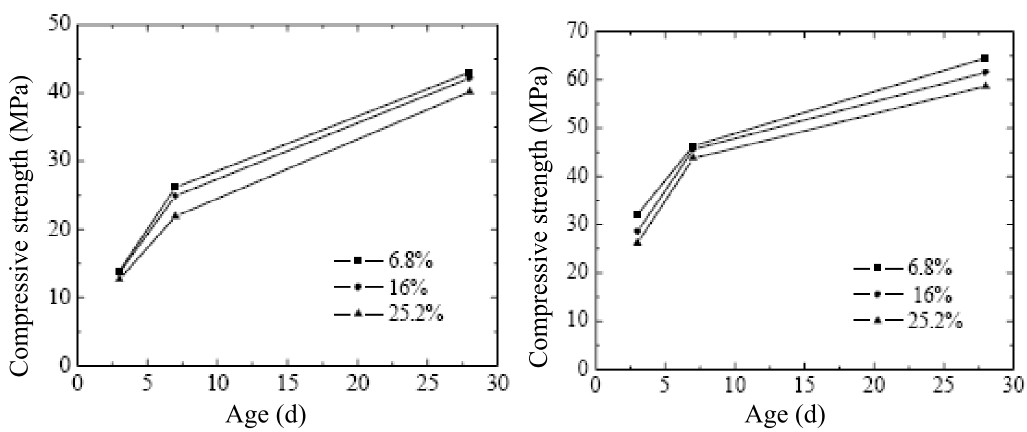
3.2 Effect of elongated and flaky particles content on compressive strength of concrete



a) C30 b) C60

Figure1. Relationship between elongated and flaky particles content and compressive strength

（*P*/*A*=32.5/67.5）



a) C30 b) C60

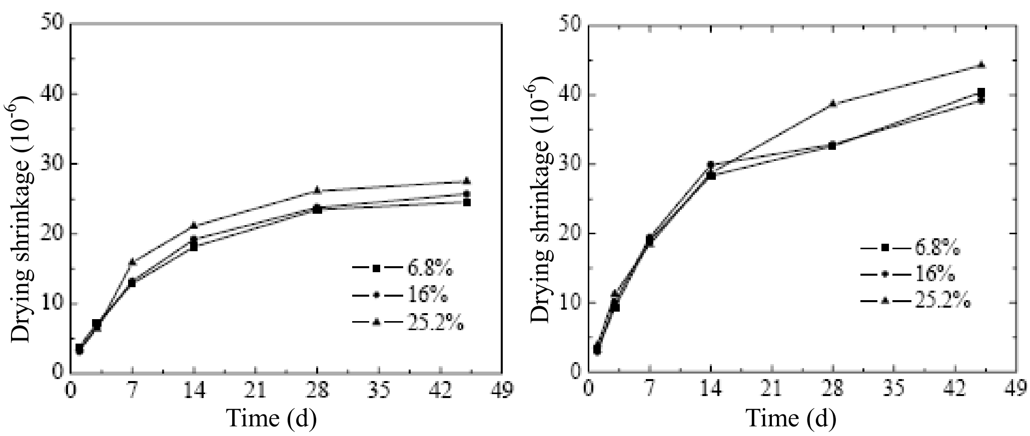
Figure 2. Relationship between elongated and flaky particles content and compressive strength

（*P*/*A*=35/65）

Compressive strengths of concrete with different strength grades and *P*/*A* were shown in figure 1 and figure 2. From these two figures, it is can be seen that the compressive strengths of concrete dropped with the increasing of elongated and flaky particles contents. But when *P*/*A* changed from 32.5/67.5 to 35/65, the decreasing amplitude of compressive strengths was declined. When the *P*/*A* is lower, surface of aggregate can not be packed by the paste, so the surface would have more defects and the intersurface is much weaker. On the other hand, the elongated and flaky particles trend to be horizontal, it will cause the increase of water binder ratios under the particles and more cracks in the intersurface. The two effects make more defects formed in concrete, so the compressive strength decreased when the contents of elongated and flaky particles rise. When the *P*/*A* is 35/65, there would be more paste, so the surface of aggregate can be packed much better and has fewer defects.

The decrement of compressive strength became larger during the increasing of elongated and flaky particles content, especially when the *P*/*A* is lower. When the contents of elongated and flaky particles were 6.8% and 16%, the compressive strengths were equal to each other. But when it was 25.2%, the compressive strength declined sharply. This indicated that the effect of elongated and flaky particles on compressive strength is nonlinear, and the similar results have also been found by other researchers (Wu, 2001) (Zhang, 2013).

3.3 Effect of elongated and flaky particles content on dry shrinkage of concrete



a) C30 b) C60

Figure 3. Relationship between elongated and flaky particles content and drying shrinkage

（P/A=32.5/67.5）

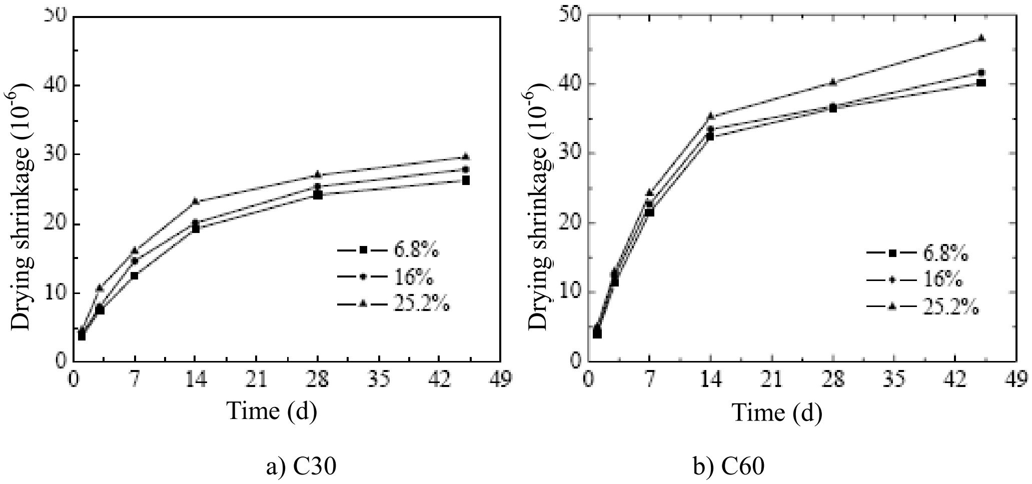


Figure 4. Relationship between elongated and flaky particles content and drying shrinkage（P/A=35/65）

The effects of elongated and flaky particles contents on drying shrinkage of concrete with different strength grades and *P*/*A* were shown in figure 3 and figure 4. From the two figures, it is can be found when the paste quantity increased, the drying shrinkages became larger, and it is marked when the concrete has higher strength grade. When the contents of elongated and flaky particles changed from 6.8% to 25.2%, the increment of drying shrinkage of both C30 and C60 concrete were over 10%. At the same time, with the increasing of elongated and flaky particles content, the growth rate of drying shrinkage of different ages of C30 concrete was stable, but for C60 concrete, the growth rate of drying shrinkage of early age was smaller than later age.

3.4 Effect of elongated and flaky particles content on chloride diffusion coefficient of concrete

Table 5. Relationship between elongated and flaky particles content and chloride diffusion coefficient

($\times 10^{-12} m^2/s$)

Group	*P*/*A*	Elongated and flaky particles content (%)		
		6.8	16.0	25.2
C30	32.5/67.5	2.74	3.27	3.71
	35/65	4.52	5.14	5.46
C60	32.5/67.5	2.22	2.52	2.95
	35/65	2.53	3.01	3.09

The effect of elongated and flaky particles content on chloride diffusion coefficient was displayed in table 5. Chloride diffusion coefficient increased as the increasing of elongated and flaky particles content, because of the inferior compactness. Meanwhile, chloride diffusion coefficient increased with the increasing of *P*/*A* and decreased with the increasing of compressive strength. The impermeability is determined by the size and character of porosity. The quantity of porosity increased with the increasing of elongated and flaky particles content, so the chloride diffusion coefficient also increased with the increasing of elongated and flaky particles content. When water binder ratio was constant, there would be more paste and less aggregate in concrete as the increasing of *P*/*A*, and more porosity appeared, so chloride diffusion coefficient increased with the increasing of *P*/*A*. When *P*/*A* was constant, concrete with higher strength had lower porosity because of the lower content of free water, so the chloride diffusion coefficient of C60 concrete was lower.

4 Conclusions

In this study, test results showed the workability, the compressive strength, the drying shrinkage and impermeability of concrete decreased with the increasing of elongated and flaky particles content. Therefore, in order to achieve the durability, the content of elongated and flaky particles should be controlled. According to the results of this research and the content of elongated and flaky particles should be fewer than 16%, while the workability and maximum packing density can be achieved.

Abstract: The researches for cable area beams of single cable plane low-pylon cable-stayed bridge were summarized; Based on plane frame theoretical mechanics, the simplified model for cable area beams of single cable plane low-pylon cable-stayed bridge with wide box girder is elaborated; and mechanical characteristics of the cable zone beams were studied by changing the structural properties. The Conclusions has some reference value.
Keywords: Low-pylon cable-stayed bridge; Single cable plane; Cable zone beam; Simplified calculation modalities; The mechanical characteristic.

1 Introduction

The applications of low-pylon cable-stayed bridge as a beam-cable composite system is becoming more and more, due to the advantages of cost and landscape. Therefore, the study of the characteristics for cable area beams of single cable plane low-pylon cable-stayed bridge with wide box girder has well theoretical and practical value.

Currently, scholars has researched on longitudinal stress distribution of wide box girder under the cable force (Han, 2010, Xie, 2006, Xu, 2012), mechanical characteristics of cable area beam with a large cable force (Zou, 2010), live load calculation method for cable area beam (Lu, 2012), key construction of Nanping Bridge (Lai,). And some results have been achieved. But there are less research results for cable area beams of single cable plane low-pylon cable-stayed bridge with wide box girder. AoJiang fifth bridge which is single cable plane low-pylon cable-stayed bridge with wide box girder is set as an example in this paper to raise a practical calculation method and analyze the relationship among of the cable zone beams stiffness, cable tension, transverse prestressing steel and box girder internal forces. Furthermore, a better understanding of structure properties of cable area beams of single cable plane low-pylon cable-stayed bridge is made.

2 Project Overview

AoJiang fifth bridge with two towers is single cable plane low tower cable-stayed bridge, using 85 m+150 m+85 m span and tower pier beam consolidation system. Full-bridge sites tower in the middle position with 40 pairs of cables, shown in Figure 1.

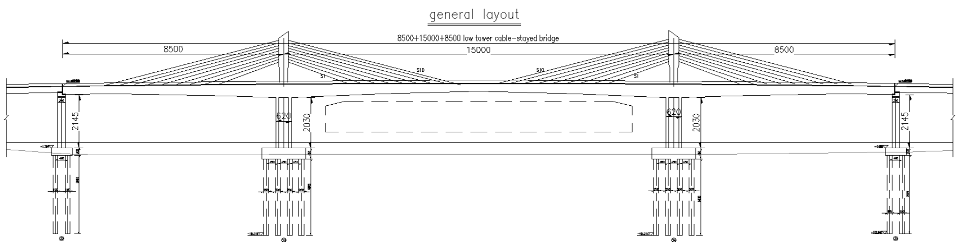

Figure 1. Bridge layout in general (unit cm)

Box girder full width is 38 m, with 4.75 m cantilever, cross slope by tilting box girder roof. A typical box girder cross-section is shown in Figure 2. Spacing of cable at beam is 3.75 m. Prestressed crossbeam thickness is 30 cm. Crossbeam arrangement is shown in Figure 3, and the steel arrangement of cable zone prestressed crossbeam is shown in Figure 4.

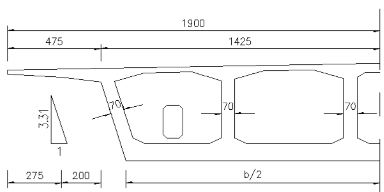

Figure 2. Typical section layout of girder (unit cm)

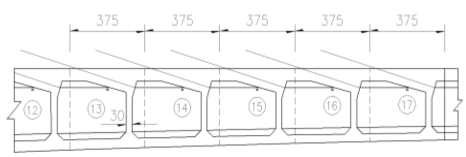

Figure 3. Crossbeam arrangement layout (unit cm)

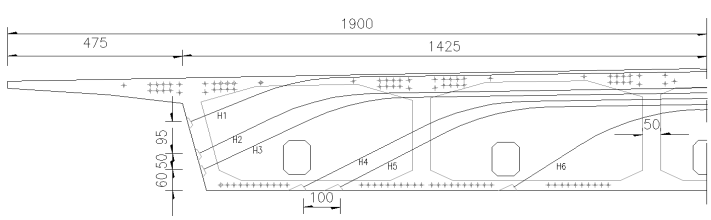

Figure 4. Cable zone crossbeam prestressed steel arrangement layout (unit cm)

3 Cable Area Crossbeam Simplified Calculate Mode

3.1 Load Mode

For spatial unevenness serious stress in the cable area beam calculations, the way load pass to the beam is the key of plane frame practical computing model.

Mechanical properties of low tower cable-stayed bridge is close to continuous beam. its dead and live load still pass from the midspan to the fulcrum. No.N segment, for example, bears No.N+1 segment load F_{N+1}, while the load F_N again passes to No.N-1 segment (Figure 5).

No.N segment the force balance analysis,

$$F_{N+1} + G_N - F_N - T_N \times \sin\theta_N = 0 \text{ (Vertical component)} \qquad (1)$$

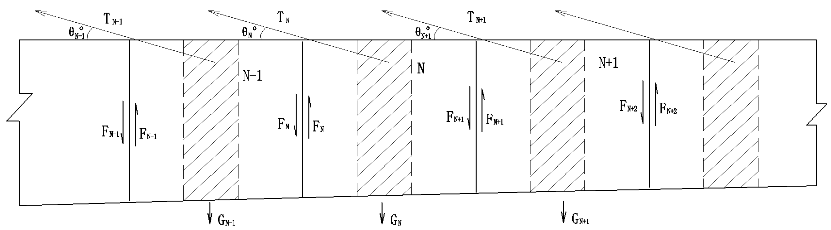

Figure 5. Beam segment force analysis (unit cm)

Figure 5 shows that the difference of load between longitudinal segment is bore by cable, and is allocated according to the stiffness of cable, beam and main beam. Considering the load delivered by cantilever is negligible (Xu, 2012), shear F_N can be considered that it's delivered to the beam by webs, roof and floor. So, the cable zone beams can be considered as continuous beams elastically supported by web, roof and floor. Then,

$$F_N = F_{N+1} + G_N - T_N \times \sin\theta_N \qquad (2)$$

According to equation (2), considering load delivered by the roof and floor is little. So, the cable zone beams can be simplified as continuous beams elastically supported by web. Stiffness of each elastic support in simplified model (Figure 6) support is directly related to the web thickness and the beam segment position.

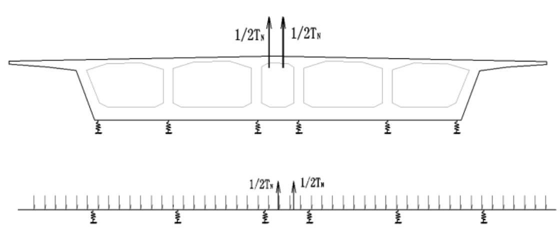

Figure 6. Crossbeam simplified calculation mode

3.2 Support Stiffness

Since the main beam web thickness is often designed fairly, so the main beam stiffness can be allocated according to the thickness of the web. Each support stiffness of the web: K/n (K is support stiffness, n is the number of the web).

Support stiffness is a unit displacement corresponding support force. For constant section beam, the expression is:

$$K = \frac{3EI}{L^3} \qquad (3)$$

Among, I is the moment of the beam, L is cantilever length, K is elastic support stiffness.

For variable cross-section beams, the equivalent stiffness method will be used in calculation (Zou, 1995).

$$E_x I_x = E_e I_e \qquad (4)$$

Among, $E_e I_e$ is the equivalent stiffness, $E_x I_x$ is variable stiffness.

3.3 Effective Width

Multi-elastic-supported continuous beams calculation of internal force and reinforcement needs the impact beam width to be considered (Code JTG D62-2004). the effective width $B_m = b + 2b_h + 12h_f^{'}$ (b_h supporting the length , b beam thickness, $h_f^{'}$ thickness of the roof or floor).

4 Calculation Results

Set the No.16 beam segment as an example, using the simplified calculation model, crossbeam calculation is carried out with the external cable force. Considering of dead load and live load, prestressing effect, crossbeam internal forces, anti-force calculation results are shown in Figure 7, Figure 8.

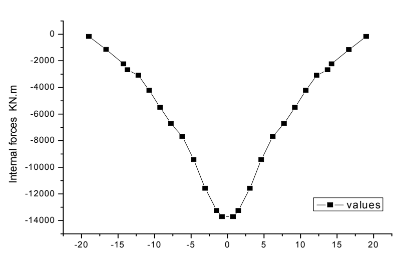

Figure 7. internal forces results

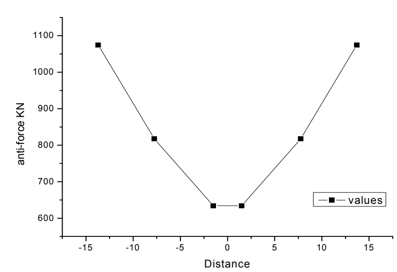

Figure 8. anti-force results

Figure 7 shows, beam moment doesn't change as the parabolic law due to the multi-point elastic support. Figure 8 shows the shear distribution is uneven between the box girder webs, shear greater edge web. Affected by beam stiffness, each web shear distribution has large differences (Han, 2012), which is consistent with the law of the solid elements calculation. So, elastic support continuous beam pattern can simulate the mechanical characteristics of the cable zone beams.

5 Parametric Analysis

Through changing the stiffness of the support beams, beam stiffness, prestress degrees and cable force, the effects of the stress state and internal forces of the stringer beams are analyzed.

(1) support stiffness

0.1, 0.5, 1.0, 2.0, 5.0 times support stiffness were taken for analysis, dead load results are shown in Figure 9 and Figure 10.

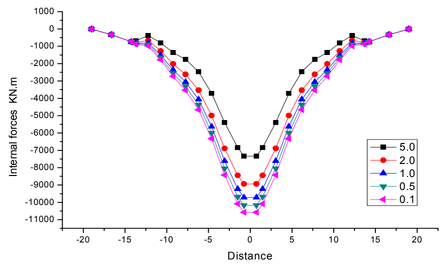

Figure9. internal forces results of various support stiffness

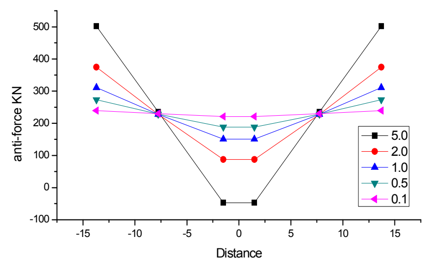

Figure 10. anti-force results of various support stiffness

Figure 9 shows as the support stiffness increases, the beam internal force distribution tends to be uniform; Figure 10 shows the difference between the webs force increases while the support stiffness increases; Results reflects the beam characteristics affect the internal forces and stringers internal force distribution and the mechanical characteristics of the different cable position.

(2) beam stiffness

0.1, 0.5, 1.0, 2,5 times beam stiffness were taken for analysis, dead load results are shown in Figure 11 and 12.

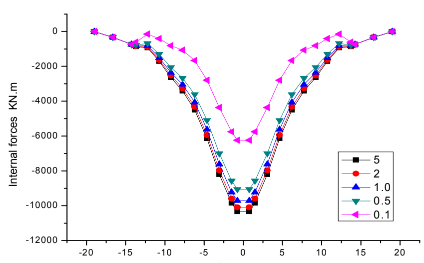

Figure 11. internal forces results of various beam stiffness

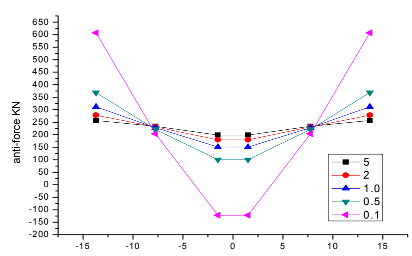

Figure 12. anti-force results of various beam stiffness

Seen from Figure 11 and Figure 12, as the beam stiffness increases, the internal force distribution between the beams increases; each web brace force tends to be uniform; the stress responds to characteristics of different cable beam position.

(3) prestressed degree

0.1, 0.5, 1.0, 2,5 times Prestressed beams degree were taken for analysis, dead load results are shown in Figure 13 and Figure 14.

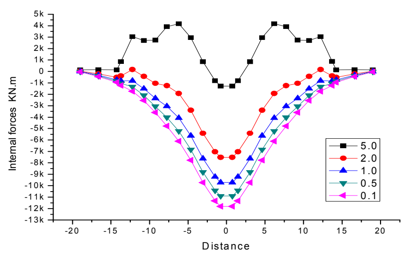

Figure 13. internal forces results of various prestressed degree

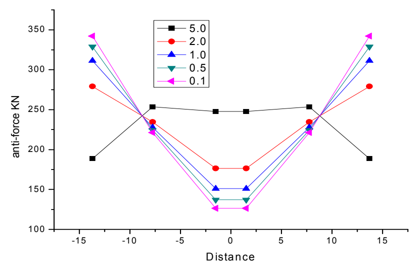

Figure 14. anti-force results of various prestressed degree

Seen from Figure 13 and Figure 14, as the increase of prestressing, beam internal force distribution tends to be uniform; each web brace force difference increases; the choice of the prestressed design has a greater impact on internal forces.

(4) cable force

0.1, 0.5, 1.0, 2, 5 times cable force were taken for analysis, dead load results are shown in Figure 15 and Figure 16.

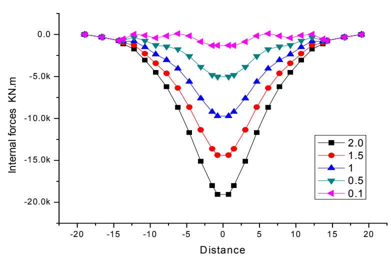

Figure 15. internal forces results of various cable force

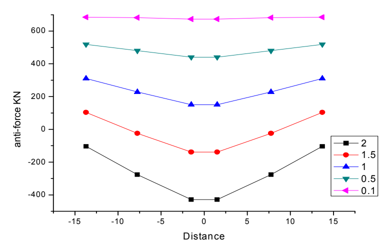

Figure 16. anti-force results of various cable force

Seen from Figure 15 and Figure 16, as the increase of cable force, beam internal forces difference increases; each web brace force difference increases, with a negative reaction; increased cable force is detrimental to the beam.

5 Conclusion

Here we may draw the following conclusions.

(1) Elastically supported continuous beam simplified model is an appropriate calculation method, and can be used for similar engineering design.

(2) Calculations of the elastically supported continuous beam simplified model

is determined by cable area crossbeam support stiffness and the various load applied to the crossbeam.

(3) The structural characteristics of crossbeam has a greater impact on internal force distribution of box girder.

[3]State Key Laboratory of Traction Power, Southwest Jiaotong University, Chengdu 610031.

Abstract: Researches on rail corrugation were briefly reviewed. A rail corrugation model for the whole vehicle and the slab track was developed. It considered a combination of the coupling dynamics model of a whole vehicle and track, the modified Kalker's non-Hertzian rolling contact model for wheel and rail, a material wear model and an accumulated wear model. It takes not only the effect of wheel/rail transient dynamic interaction on the formation and development of corrugation into account, but also the effect of the accumulated corrugation on the wheel/rail contact and coupling dynamics. That is, this model can take into account a feedback process between the long-term effects of the rail corrugation and the transient coupling dynamic of whole vehicle. This model can be used to study the formation mechanism of rail corrugation. And the initiation and development of the corrugations caused by various track defects, such as track gap, scratch, dent and random geometry irregularities, can be analyzed. A numerical example was presented to verify the procedure. The numerical results of the example are reasonable and indicate the development of corrugation in the initial stage after grinding.
Keywords: Rail corrugation; Mechanism; Vehicle-track coupled dynamics; Rolling contact; Material wear.

1 Introduction

Rail corrugation (periodic surface irregularities with distinct wavelengths) is a serious problem experienced by many railway networks worldwide. Its formation and development causes fierce vibrations of structures of the railway vehicle and track, as well as noise, and also reduces the life of structural parts. In addition, sometimes serious corrugations of rails can lead to derailment accidents. Thus, railway engineers have to adopt regular and expensive grinding to manage the problem. Such a treatment deals only with the symptoms. An investigation of the underlying causes is necessary in order to determine more fundamental remedies through the optimization of vehicle and track parameters. This emphasizes the need for an accurate simulation model of corrugation to understand the mechanism and give some measures for mitigation. This is exactly the purpose of this paper.

The phenomena of rail corrugation has been observed and studied for more than one hundred years. Much progress in recognizing the mechanism of initial formation and evolution of corrugation was made (Frederick, 1986; Ahlbeck, 1991; Tassilly, 1991; Groβ-Thebing, 1992; Kalousek, 1992; Grassie, 1993; Igeland, 1997; Diana, 1998; Nielsen, 1999; Gómez, 2001; Muller, 2001; Matsumoto, 2002; Sato, 2002; Suda, 2002; Wild, 2003; Wu, 2004; Jin, 2007; Sun, 2007; Baeza, 2008; Jin, 2008; Knothe, 2008; Collette, 2009; Grassie, 2009; Xie, 2010). The studies on corrugation mainly include three parts: (a) observation and measurement in file site (Ahlbeck, 1991; Tassilly, 1991; Kalousek, 1992; Bracciali 2006); (b) theoretical and numerical model (Tassilly, 1991; Diana, 1998; Wu, 2005; Sun, 2007; Daniel, 2008; Jin, 2008; Collette, 2009; Baeza, 2011; Kurzeck, 2011); and (c) experimental methods (Baumann, 1996; Diana, 1998; Suda, 2002; Wild, 2003; Jin, 2007; Bellette, 2011). Studies with theoretical and numerical methods primarily involve vehicle/track dynamics, rolling contact theory, material wear. Conventionally, a simple vehicle/track dynamics model, which ignores the flexible deformation of track structure, and approximate contact model were used in the long-term simulation of corrugation growth. In this paper, the coupling model of vehicle and track in (Jin, 2008). was further developed to study the dynamic response of vehicle and track and the corrugation on the slab track system. A corrugation model was put forward based on the vehicle/track dynamics model, a non-Hertzian rolling contact model, and a material model. This model takes not only the effect of wheel/rail transient dynamic interaction on the formation and development of corrugation into account, but also the effect of the accumulated corrugation on the wheel/rail contact and coupling dynamics. That is, it can take into account a feedback process between the long-term effects of the rail corrugation and the transient coupling dynamic of whole vehicle. It can also be used to study the formation mechanism of rail corrugation. And the initiation and development of the corrugations caused by various track defects, such as track gap, scratch, dent and random geometry irregularities, can be analyzed.

2 Calculation Model of Rail Corrugation

2.1 General description

The corrugation model is based on the vertical and lateral coupling dynamics of railway vehicle and track, Kalker's three-dimensional rolling contact theory with non-Hertzian form, and the frictional work wear model. It is roughly depicted in Fig. 1 which expresses a feed-back process between the transient coupling dynamics of the vehicle and track and the long-term wear process.

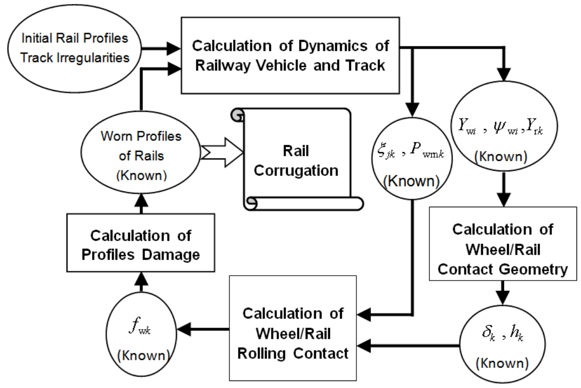

Figure 1. General description of rail corrugation model

In Fig. 1, Y_{wi} and ψ_{wi} are, respectively, the lateral displacement and the yaw angle of wheelset *i*, subscript *i* denotes the number of the wheelset considered in the calculation model, Y_{rk} is the lateral displacement of the rail head under wheel *k*, and subscript *k* is the number of the wheel in the model, δ_k and h_k are, respectively, the contact angle and the normal distance between wheel *k* and the rail. The ranges for *i* and *k* selected depend on the total numbers of the wheelsets and the wheels in the calculation model. ξ_{jk} and P_{wrnk} are, respectively, the creepages and the normal loads between the wheels and the rails, subscripts j = 1, 2, 3 indicate, respectively, the longitudinal, lateral and normal directions at the contact point of wheel and rail, subscripts *w* and *r* denote, respectively, wheel and rail, *n* indicates the vertical direction of the track. f_{wk} denotes the frictional work density in the contact area under wheel *k*. Carrying out the dynamic analysis obtains $Y_{wi,}$ ψ_{wi}, Y_{rk}, δ_k, ξ_{jk}, P_{wrnk}, Using $Y_{wi,}$ ψ_{wi}, Y_{rk}, and the spatial calculation method of the W/R contact geometry, h_k is calculated. ξ_{jk}, P_{wrnk}, h_k and δ_k are used in calculating the rolling contact behavior of the W/R (i.e. Wheel/Rail), in which the modified Kalker's model for three-dimensional elastic bodies in rolling contact is introduced to calculate the normal pressure, the tangent traction component, the sliding distance, the stick/slip areas, etc. The frictional work density is used to determine the wear depth of the running surface in the normal direction of the contact patch. Before the next loop calculation is performed, the profile of the rail is renewed using the wear depth at the present step. After the repeated loop calculations the accumulated material wear and its distribution on the rail head are obtained.

2.2 Model for coupling vehicle and track

The coupling dynamics model for a vehicle and a track is illustrated in Fig. 2. In the model, the vehicle considered is treated as a rigid multi-body system with 35 degrees of freedom. It is equipped with a pair of two-axle bogies with double suspension systems. The wheelset and the bogie are connected by the primary suspension, while the carriage is supported on the bogie through the secondary suspension. The track, which is treated as a dynamic flexible structure, is considered as a 2-layer model with rails, fixed slabs. Two layers of discrete springs and dampers represent the rail fastenings and subgrade. Each rail of the track is modeled with a Timoshenko beam resting on discrete rail pads. The slab is modeled as a three-dimensional flexible structure based on finite element method. The vehicle couples with the track through wheel/rail contact which includes a normal model and a tangent model. The normal model, which characterizes the relationship between the normal load and deformation of the wheel-rail, is described by a Hertzian nonlinear contact spring with a unilateral restraint. Shen-Hedrick-Elkins's model is adopted as the tangential model determining the relationship between the creepages and the total creep forces of the wheel/rail (Shen, 1983).

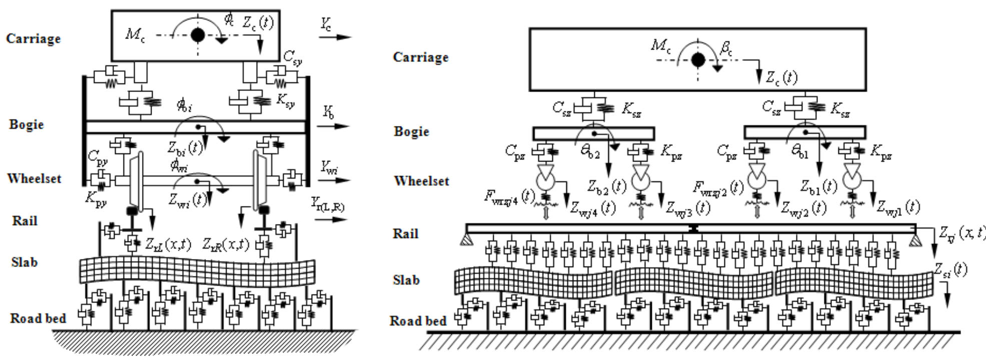

Figure 2. Coupling vehicle/track model: (a) Elevation; (b) Side elevation

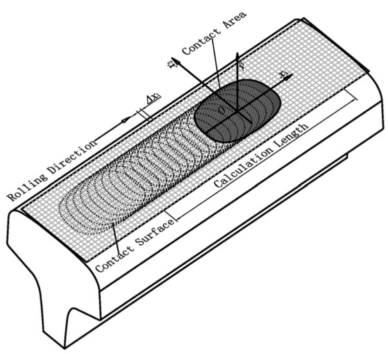
2.3 Rolling contact model for wheel and rail

The analysis on the detailed information in the wheel/rail contact patches, such as the distribution of the normal and tangential forces, the total slip and the frictional work, is carried out by means of Kalker's theory. In order to consider the effect on the normal gap of the cumulative wear depth $w^k{}_3$ obtained at the previous steps, the principle of complementary virtual work of wheel and rail in rolling contact was modified as follows:

$$\begin{cases} \min\limits_{p_{Jj}} C = \frac{1}{2} p_{Ii} A_{IiJj} p_{Jj} + \left[\left(h_J^k + w_{3J}^k - h_{\min}^k \right) - q \right] p_{J3} + \\ \qquad (W_{J\tau} - u'_{J\tau}) \, p_{J\tau} \\ s.t \quad p_{J3} \geq 0 \quad \left| p_{J\tau} \right| \leq b_J \quad \forall \mathbf{x} \in A_c \\ \qquad A_0 \sum_J^M p_{J3} = P \end{cases} \tag{1}$$

where h_J is the normal gap at the center of element *J,* and $h^k{}_{\min}$ is the minimum normal gap between the wheel and rail. The rectangular element area is equal to $A_0 = \Delta x_1 \times \Delta x_2$, A_0 is that 0.8×0.8=0.64 mm^2 for the case of non-flange contact (on straight line and inner rail), and 1.3×0.1=0.13 mm^2 for the case of flange contact (on outer rail). A_c is the potential contact area; M is the total number of elements, selected as 21 × 21 = 441 in the calculation. The denotations of other symbols in Eq. (1) can be found in (Jin, 2008)..

The modification reflects that at each calculation step, $w^k{}_3$ and h_J are updated since they are different at different contact points. Accordingly, the effect of the wear depth in the previous calculation step is taken into account in the present step, as sketched in Fig. 3, which depicts the contact area moves on the rail running surface and also indicates that the wear depth on each contact area is accumulated along the surface. It should be noted that Fig. 3 is just a schematic diagram indicating the calculation position of rail corrugation. An actual location where the corrugation occurs is determined through the vehicle-track dynamics analysis, i.e. the wheel/rail contact point obtained through the dynamic calculation. The calculation of the corrugation can be carried out on both the rails of the tangent and curved tracks, as shown in Fig. 4. For convenience, the wheels of the vehicle are numbered 1~8 respectively. The wheels on the left hand side are numbered with 1, 3, 5 and 7, and the wheels on the right hand side are numbered with 2, 4, 6 and 8, as schematically shown in Fig. 4. The corrugation calculation length is selected as 1.6m in this paper.



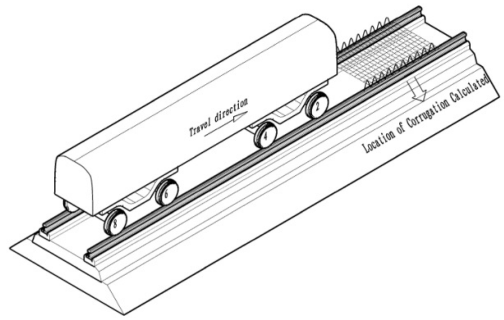


Figure 3 Rail running surface passed by contact area; Figure 4 Location of rail wear analysed on the track

2.4 Material wear model

The material wear model is a friction work model, in which the mass loss of unit area is proportional to frictional work of unit area.

$$\Delta m(x_{I1}, x_{I2}) = C_w f_w(x_{I1}, x_{I2}) \tag{2}$$

In Eq. (2), (x_{I1},x_{I2}) are the coordinates of the center of element I, the $\Delta m(x_{I1},x_{I2})$ and $f_w(x_{I1},x_{I2})$ are, respectively, the material mass loss of unit area and the friction work density at point (x_{I1},x_{I2}), the proportional coefficient C_w=1.0×10^{-9} kg.(N.m)$^{-1}$ (Igeland and Ilias 1997, Jin and Wen 2008).

3 Discussions of Results

In the coupling vehicle-track dynamics simulation, the vehicle speed is 50 km/h. The sleeper pitch is 0.625 m. The vertical stiffness and damping of fasteners system are 12.07 kN/mm and 1.4 kN·s/m, respectively, and the lateral stiffness and damping are 7.6 kN/mm and 0.98 kN·s/m, respectively. The measured roughness of the straight line after grinding is used as a vertical excitation in the dynamic simulation, and the lateral excitation is ignored. The calculation length of the track is 100 m. The integration step in solving differential equations of the vehicle-track is 7.2e-8 s. It takes a longer CPU time in the calculation of the whole feed-back process of corrugation evolution. The calculation length of the corrugation along the rail is 1.6 m. The rail irregularities in the corrugation calculation section are illustrated in Fig. 5, in which the roughness amplitude of the right rail is larger than the left rail. The rail irregularities after grinding indicate the residual corrugations.

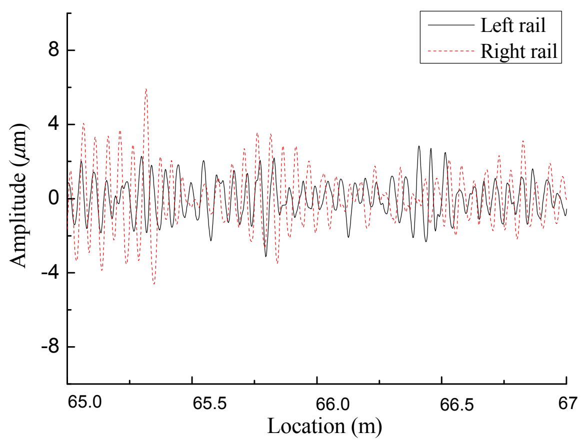

Figure 5. Measured roughness used in the corrugation calculation section

3.1 Dynamic characteristics of track

Through the dynamic simulation, the vertical, lateral and torsional displacements of the rail are obtained when the vehicle operates on the track with the residual corrugations after the grinding. Figs. 6 (a), (b) and (c), illustrate the linear spectra of the vertical, lateral and torsional displacement respectively. It can be observed that the track resonances in the three frequency bands, 160~300 Hz, 500~700 Hz and 900~980 Hz, can be easily excited when the vehicle passes the Cologne egg fasteners track with the residual corrugations. The resonant frequencies in the range of 160-300 Hz nearly match the dominant corrugation wavelength of 40~50 mm, and those in the range of 500~700 Hz match the wavelength of 25 mm. From Fig.6, it can be seen that the maximum amplitude of vertical, lateral and torsional displacement spectrum occurs around 300 Hz. Therefore, the resonances around 300 Hz play an important role in the formation and development of 40~50 mm corrugation on the Cologne egg fasteners track.

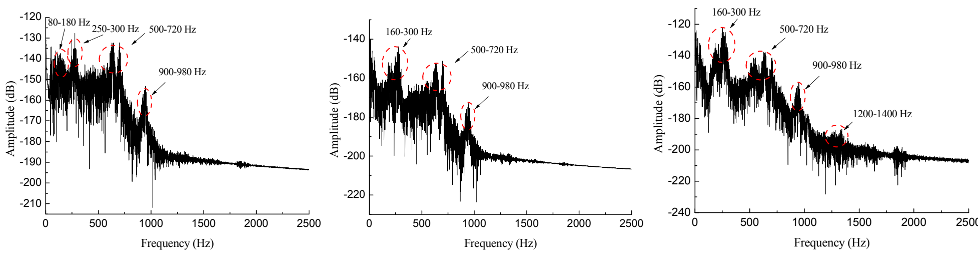

Figure 6. Receptance of the track: (a) Vertical; (b) Lateral ; (c) Torsional

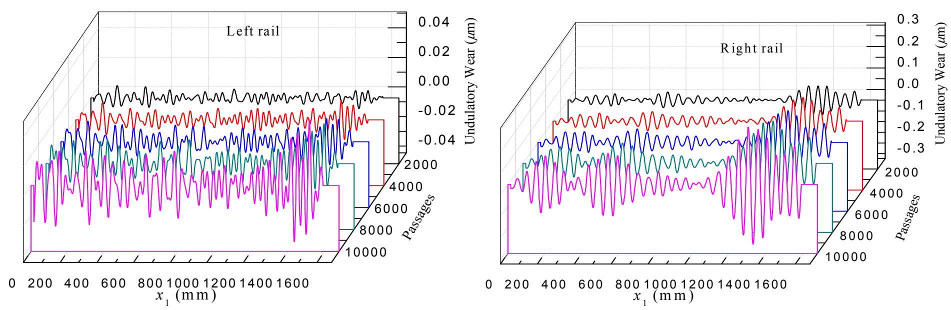
3.2 Rail corrugation evolution

After the dynamic simulation, the non-Hertzian rolling contact code is used to calculate the frictional power and then the material wear model is employed to calculate the wear depth in the contact patch. The wear depth gradually accumulates on the rail running surface with the wheel passage increase.

Fig.7 illustrates the evolution of the profiles of the left and right rails, respectively, due to wear. Each line in these figures represents 2,000 wheel passages increase. Here it is noted that the wear depth does not contain the even wear on the running surface. Namely, the even wear is removed from the calculated results so as to compare the wavy surface after each increment of 2,000 passages.



(a) (b)

Figure 7. Rail profile evolution: (a) Left rail (b) Right rail

It is obvious that the corrugation develops quickly with the passage increase, especially with 2,000~10,000 passages. And it develops slowly after 10,000 passages. This is because the contact condition between the wheel and rail is changed with the passage increase due to the accumulated wear increase on the rail surface. Namely, the wheel gets in a pretty good conformal contact with the rail in a running-in period. Comparing (a) with (b), it can be found that the fluctuated amplitude of the right rail corrugation is approximately 10 times greater than that of the left rail after 20,000 passages. This is because the input irregularity on the right rail is severer than that on the left rail, as depicted in Fig. 5, which results in the greater fluctuant normal load and the larger frictional work between the right rail and the wheel. So the growth rate of the right rail corrugation is much faster than that of the left rail.

4 Conclusions

A numerical model of rail corrugation for the whole vehicle and the slab track and its procedure were put forward and discussed in detail. The model considered a combination of the coupling dynamics model of a whole vehicle and track, the modified Kalker's non-Hertzian rolling contact model for wheel and rail, a material wear model and an accumulated wear model. The procedure is utilized to predict the evolution of the residual corrugation after grinding. The mechanism was analyzed according to the dynamical response of the track. The numerical model can be used to estimate the effect of many concerned factors on corrugation. It plays an important role in the improvement of the vehicle and track dynamical characters to mitigate the initiation and development of rail corrugations.

5 Recommendations for Future Research

The numerical model can be further improved in wheel-rail contact model considering the effect of stick-slip curve, in the material wear model considering the effect of hardening and environment.

Development Regulation of Rutting Deformation Based on an Accelerate Pavement Test

Tianming Zhu

Liaoning Transportation Research Institute, Key Laboratory of Expressway Maintenance Technology, Ministry of Communications (Shenyang), Shenyang 110015. E-mail: zhutianming89@126.com

Abstract: Based on the experimental data of different pavement structure through full scale accelerate pavement test (f-APT), the development regulation of rutting on different pavement structure is analyzed and compared, and the characteristics of rutting depth development trend and rut profile shape is summarized. Based on the test date of several semi-rigid base asphalt pavement structures, a rutting prediction model based on f-APT is achieved by multivariate regression, and the range of uplift coefficient is determined. The axle load and vehicle velocity conversion are also considered in the prediction model. The research result can provide a reference for optimizing the structural design and determining reasonable pavement structural scheme.

Keywords: Development regulation of rutting; Uplift coefficient; Prediction model; Accelerated pavement test.

1 Introduction

The main research methods on the development regulation of rutting deformation including wheel tracking test, accelerate pavement test and the study of long term performance of pavement. While the influence factors of rutting deformation are complex and interactional, the laboratory wheel tracking test cannot simulate the actual road environment and stress states accurately, and the study of long term performance of pavement takes too long and costs too much. By comparison, the full scale accelerated pavement test (f-APT) can simulate the actual environment and stress states of pavement more realistically, and obtain the decay law of pavement performance in a relatively short period of time. Taking account of this advantage, it is widely adopted in the research of pavement materials and structure design.

The domestic and overseas scholars adopted different analysis methods and proposed various rutting prediction models. These prediction models can be classified into three categories: mechanistic methods, mechanistic-empirical methods and empirical methods. Based on the experimental data of f-APT conducted by Liaoning Transportation Research Institute, the development regulation of rutting on different pavement structure is analyzed. By regression analysis of the experimental data, a rutting prediction model based on f-APT is achieved. The uplift coefficient of rutting is also determined, and the axle load and wheel speed conversion of equivalent rutting deformation based on f-APT is preliminary studied.

2 Test Condition and Structure Type

The rut-resistance f-APT test was conducted under two types of temperature condition, i.e. normal temperature condition and high temperature condition. The temperature was monitored by the temperature sensor installed at 2cm depth beneath the pavement surface. The range of normal temperature is 10~40℃, and the test result can revel the development regulation of rutting under normal temperature condition. To stimulate the high temperature condition, 45 and 55℃ were selected as the representative temperature. The temperature controlling is realized by the heating unit accessory to the facility. The axle load is 75kN. Several typical structures are chosen to analyze the development regulation of rutting. The structure types of test road are shown in Fig.1.

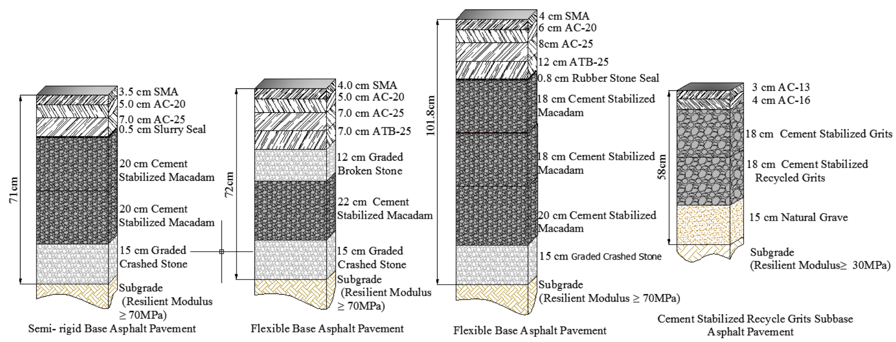

Figure 1. Structure type of f-APT

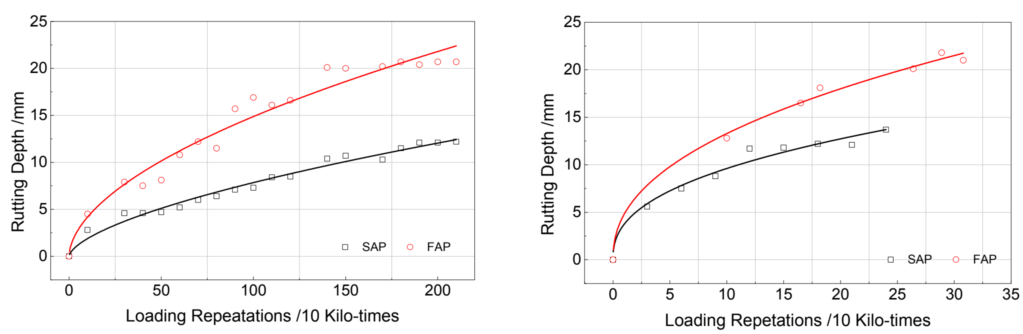
3 Analysis of Development Regulation of Rutting

Owing to space constraints, taking semi-rigid base asphalt pavement (SAP) and flexible base asphalt pavement (FAP) for instance, the development regulation of rutting is analyzed below.

3.1 Development trend of rutting depth

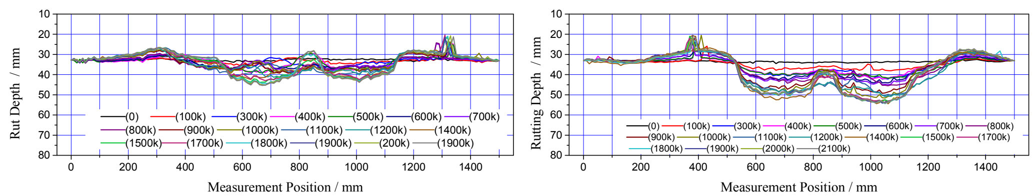


(a) Normal temperature **(b) High temperature**

Figure 2. Development trend of rutting depth

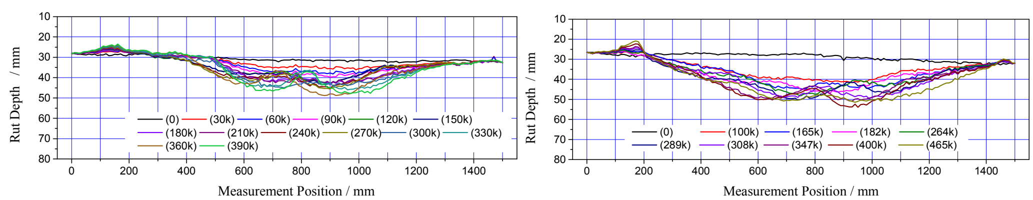
From the development trend of rutting depth under different temperature conditions shown in Fig.2, we can clearly see that high temperature has significant effect on the development of rutting. Compared with semi-rigid structure, the rutting depth of flexible structure increased faster under the same axle load repetitions and temperature conditions. In initial loading stage, the rutting depth of both structures increased rapidly. With the load repetitions increased, the rutting depth increased linearly to final. The inflection point can be easily found in the development trend of rutting depth. The development trend is consistent with the permanent deformation regulation of asphalt mixture in initial stage and steady stage, but the accelerated damage stage did not appear. To analyze the reason, the loading repetitions are limited so that the accelerated damage stage did not appear; or it may be due to the strong lateral constrain of loading section.

3.1 Development of rutting profile



(a) Semi-rigid base structure **(b) Flexible base structure**

Figure 3. Development of rutting profile under normal temperature condition



(a) Semi-rigid base structure **(b) Flexible base structure**

Figure 4. Development of rutting profile under high temperature condition

From the figures above we can clearly see that the degree of deformation under high temperature condition is greater. Under high temperature condition, the vertical permanent deformation is distinct in the initial loading stage. With the load repetitions and temperature increase, the rutting profile formed protuberance at unfixed position and presented W-shape, and the maximum depth of rutting almost kept constant. At this point the shear deformation occurred. Compared with semi-rigid structure, the deformation of rutting profile is significantly more serious.

By analyzing the development trend of rutting depth and rutting profile, the conclusion on developing mechanism of rutting is consistent with the research results that have been generally accepted, that is the permanent deformation of asphalt mixture consists of two parts: compaction deformation and shear deformation, and the shear deformation has significantly effect on pavement performance. The shear deformation is more seriously under high temperature condition.

4 Rutting Prediction Model Based on f-APT

4.1 Regression analysis of experimental data

By analyzing the experimental data and summarizing the achievements of previous researches on effect factors of rutting, the loading repetitions, temperature and thickness of asphalt layer are determined as the main effect factors. Thus, the relationship between rutting depth and main effect factors is achieved by adopting multivariate nonlinear regression analysis. The major type of pavement structure in China is semi-rigid base pavement, thus the prediction model established in this paper just for semi-rigid base pavement structure. The experimental date was selected from several semi-rigid base asphalt pavement structures. The regression results are shown as follows:

$$RDD = (-0.0019h^2 + 0.0650h - 0.0973)\cdot N^{0.4147}\cdot e^{0.0434T} \tag{1}$$

with *RDD* is the absolute rutting depth of asphalt pavement(mm), *N* is the loading repetitions(10 kilo-times), *T* is the representative temperature at 2cm beneath the pavement surface(℃), *h* is the thickness of asphalt layer(cm).

The effect of regression analysis is shown in table 1.

Table 1. Results of regression analysis

Root Mean Squared Error (RMSE)	Sum of Squares for Error (SSE)	Coefficient of Correlation (R)	Coefficient of Determination (R^2)	F-statistics
1.3244	145.5945	0.9440	0.8912	663.3856

From the results of regression analysis shown above, we can see that the coefficient of determination is 0.89, and the coefficient of correlation is 0.94, the results show that the model precision is high theoretically. According to correlation test result, when the level of significance is 1%, the critical value F_{α} is 4.15, less than F-statistics, which reveals that the rutting depth has a significantly linear relationship with loading repetitions *N,* temperature *T* and thickness of asphalt layer *h*.

The relationship between calculated value by prediction model and actual value is shown in figure 5. The calculated value and actual value uniformly distributed on both sides of level curve.

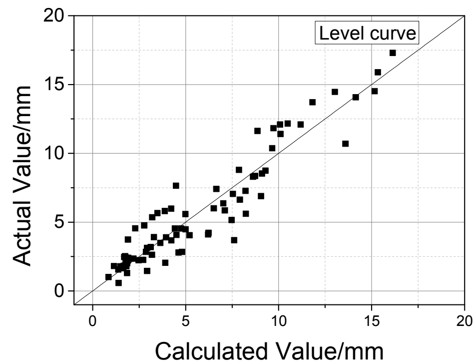


Figure 5.Relationship diagram for calculated value and actual value

4.2 Analysis of uplift coefficient

From the development of rutting profile showed in Fig.3 and Fig.4, we can see that the sides of wheel path bulged compared with the origin profile. Thus, the uplift deformation should be considered in the rutting prediction model. In order to analyze conveniently, uplift coefficient K_L is defined here, which is a ratio of uplift deformation to down concave deformation(*RDD*).

By analyzing the development tendency of uplift coefficient, we can determine that it is relevant to the thickness of asphalt layer. When the thickness of asphalt layer is thinner, the uplift coefficient is smaller, while when the thickness of asphalt layer is larger, the uplift coefficient is greater. The uplift coefficient of long-life asphalt pavement, semi-rigid base pavement of expressway and general asphalt pavement is about 0.53, 0.3 and 0.2 respectively. Thus, the range of uplift coefficient is recommended as 0.2~0.5, the lower limit value should be selected when the thickness of asphalt layer is thinner, and upper limit value should be selected when the thickness of asphalt layer is thicker.

4.3 Axle load conversion of equivalent rutting based on f-APT

Refer to the conversion formulas of deflection equivalent, when taking the standard axle load(100kN) as the conversion benchmark, the relationship between axle load and load repetitions is as follows:

$$k_{ec} = \frac{N}{N_i} = \left(\frac{P_i}{P}\right)^b \tag{2}$$

with k_{ec} is the equivalent coefficient of rutting, N is the load repetitions under standard axle load(BZZ-100), N_i is the load repetitions when the axle load is P_i, P is the standard axle load, i.e. 100kN, P_i is the conversion axle load, b is the axle conversion coefficient.

Refer to the test results of ALF, the equivalent coefficient of rutting is 2.08, according to Eq. 2, the axle conversion coefficient is determined as 1.56

4.4 Vehicle velocity conversion of equivalent rutting based on f-APT

JianFeng Hua deduced the linear relationship between rutting depth and vehicle velocity is shown as follows:

$$\frac{D_{rut}(v)}{D_{rut}(v_0)} = \left(\frac{v_0}{v}\right)^{m+1} \tag{3}$$

With $D_{rut}(v_0)$ is rutting depth at the speed of v_0, $D_{rut}(v)$ is the rutting depth at the speed of v, m is the material parameter related to creep property, the recommended value is 0.5

The wheel speed of the facility is 22 km/h, according to Eq. 3, the vehicle velocity conversion based on f-APT is computed as follows:

$$\frac{D_{rut}(v)}{D_{rut}(v_{22})} = \left(\frac{v}{22}\right)^{-(m+1)} \tag{4}$$

4.5 Rutting prediction model based on f-APT

Considering uplift deformation, axle load and vehicle velocity conversion, the rutting prediction model under standard axle load is shown as follows:

$$RD = (1+K_L)\cdot(-0.0015h^2 + 0.0500h - 0.0749)\cdot N^{0.4147}\cdot e^{0.0434T}\left(\frac{v}{22}\right)^{-0.5} \tag{5}$$

With RD is the rutting depth including uplift deformation.

4.6 Rutting prediction model validation

In order to verify the model accuracy, the author investigated the rutting deformation on several expressways nearby Shenyang, and collected the associated parameters, which is shown in table 2.

As the rutting deformation under low temperature is insignificant, the axle loads below 15℃ are ignored. The representative temperature at 2cm beneath the pavement surface is 25℃，and the reduction factor of axle loads is 0.5, the uplift coefficient is 0.3. Thus, the estimated rutting depth is shown at the last column in table 2. It can be seen through comparison that the estimated value is close to measured value.

Table 2. Estimated rutting depth of actual pavement

Investigated Section	Equivalent Single Axle Loads (10 kilo-times)	Thickness of Asphalt Layer (cm)	Large Vehicle Velocity (km/h)	Actual Rutting Depth (mm)	Estimated Rutting Depth (mm)
SF	1671	16	55	10.5	13.5
BL	677	18	87	5.4	7.3
LL	1505	18	70	12.7	11.4
LX	465	16	60	7.23	7.6

5 Conclusions

Taking semi-rigid base asphalt pavement and flexible base asphalt pavement for instance, the development regulation of rutting is analyzed in this article. The main effect factors of rutting are determined, and the rutting prediction model is achieved by adopting multivariate nonlinear regression analysis. Besides, the range of uplift deformation is determined by analyzing the experimental data of different pavement structure. Finally, a rutting prediction model considering uplift deformation, axle load and vehicle velocity conversion is achieved.

Vertical Vibration Characteristics of a Concrete Sleeper with Cracks in a Heavy-Haul Railway

Dawei Zhang; Wanming Zhai; Kaiyun Wang; and Pengfei Liu

State Key Laboratory of Traction Power, Southwest Jiaotong University, Chengdu 610031. E-mail: dwzhang1230@163.com

Abstract: With the continuous development of heavy-haul transportation, the dynamic interaction between heavy-haul train and track structure has dramatically intensified. Track structures bear repeated and huge loads over a long period of time, and concrete sleeper acting as an important load-bearing component inevitably generates various damages, in which transverse crack in the middle cross section of the sleeper occupies a large proportion. On the basis of the theory of linear elastic fracture mechanics, the concrete sleeper model is established through finite element method to analysis vertical vibration characteristic of damaged concrete sleeper under train loads, including the rail-sleeper forces calculated by vehicle-track coupled dynamics theory. Then stress intensity factor is introduced as an index to investigate the propagation of the transverse crack. The results show as follows: the modal frequencies of damaged concrete sleeper reduce to some extent; under train load, vertical acceleration and displacement of damaged concrete sleeper rise evidently; dynamic response of stress intensity factor in the crack tip shows that the intensity of stress field near the crack tip is controlled by Stress Intensity Factor Type-I.

Keywords: Heavy-haul railway; Concrete sleeper; Crack; Stress intensity factor; Finite element method.

1 Introduction

Freight transportation requires considerably heavier trains than passenger transportation. The static axle load, which reflects the gravity loading of the train, normally does not exceed 170 kN for passenger trains, while for freight trains it may vary between 250 kN and 350 kN. Hence, track structures in heavy-haul railway bear repeated and huge loads over a long period of time. The advantages of concrete technology led to its use for sleepers in the 1950s. Over the last six decades, researchers in different parts of the world have been investigating the failures of concrete sleepers and looking for sustainable solutions. Therefore, greater control over the materials and design of railway track foundations is needed.

(Dyk, 2012) ranked the most common causes of concrete sleeper failures using the results obtained from their North American and worldwide surveys (Figure 1). They indicated that concrete sleeper acting as an important load-bearing component inevitably generates various damages, in which transverse cracking from dynamic loads, center binding and environmental or chemical degradation occupies a large proportion. (Ferdous, 2014) pointed out the main Failures of mainline railway sleepers and suggested remedies. (Oregui, 2014) indicated that the FRF-based statistical method in combination with the non-destructive hammer test measurements had the potential to be employed to identify the characteristic frequencies of damaged conditions in railway tracks in the frequency range of 300–3000 Hz. (Kaewunruen, 2009) constructed a high-capacity drop weight impact testing machine evaluate the ultimate capacity of prestressed concrete sleepers under impact loads. (Zhu, 2012) and (Lin, 2010) studied the vibration characteristics of double-block ballastless roadbed with cracks.

The above studies indicate that the damaged sleeper has a significant influence on the dynamic response of track structure. Therefore, this paper establishes a vehicle－track coupled dynamic model for the heavy-haul freight with double suspension systems to acquire the rail-sleeper forces. In addition, on the basis of the theory of linear elastic fracture mechanics, the concrete sleeper model is established through finite element method to analysis vertical vibration characteristic of damaged concrete sleeper under train load, including rail-sleeper forces acquired from the above model. Finally, stress intensity factor is introduced as an index to investigate the propagation of the transverse crack.

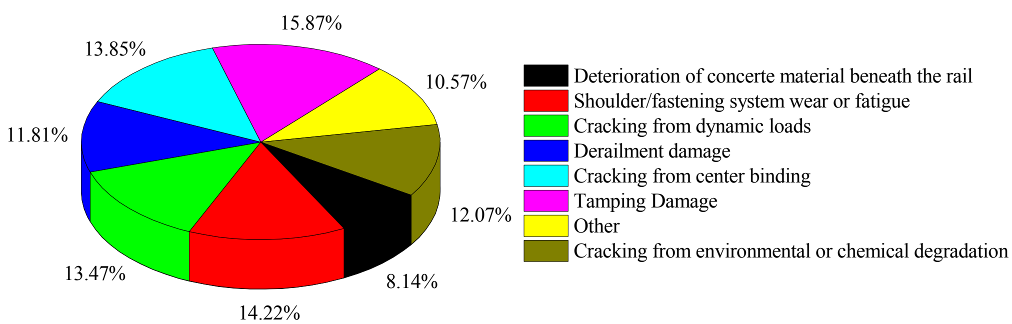

Figure 1. Types of concrete sleepers failures

2. Numerical Model

2.1 Vehicle－Track Coupled Model

The train–track interaction is a classic railway dynamics topic that has been studied for a long time. As shown in figure 2, the paper adopts a freight truck－track coupled model (Zhai, 1996), in which a freight subsystem is modeled as a multi-body system with 47 DOFs running on the track with a constant velocity, and the track substructure is modeled as an infinite Euler beam supported on a discrete-continuous elastic foundation consisting of the three layers of rail, sleeper, and ballast, including completely and incompletely hanging sleepers. Based on the study, the model is built to solve the problems in heavy haul railway.

The equations of motion of the freight car subsystem are regularly derived according to D'Alembert's principle, which are second order ordinary differential equations expressed in the matrix form as follows (Garg et al., 1984):

$$[\mathbf{M}]\{\ddot{X}\}+[\mathbf{K}]\{X\}+[\mathbf{C}]\{\dot{X}\}=\{\mathbf{F}\} \quad (1)$$

where [**M**], [**C**] and [**K**] are mass, damping and stiffness matrices, respectively; and $\{X\}$ and $\{\mathbf{F}\}$ are the generalized displacement and external force vectors, respectively.

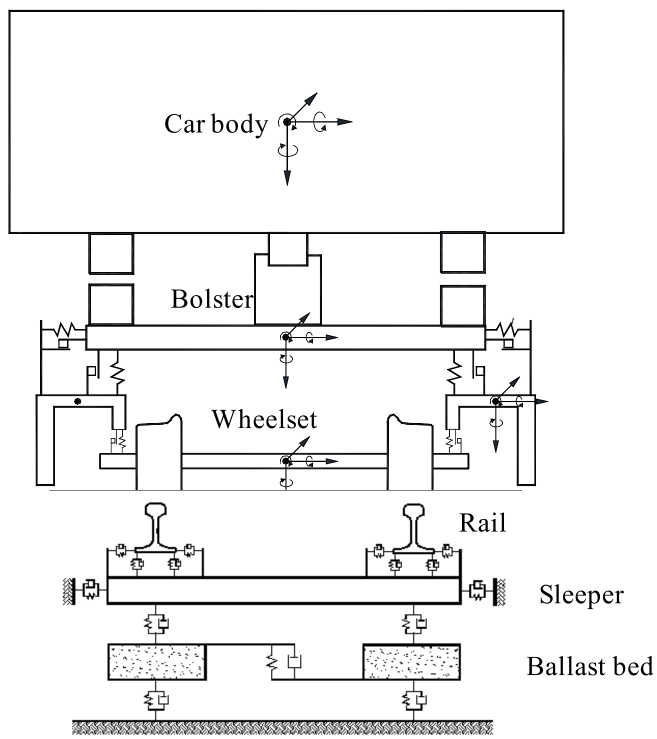

Figure 2. Vehicle－track coupled model

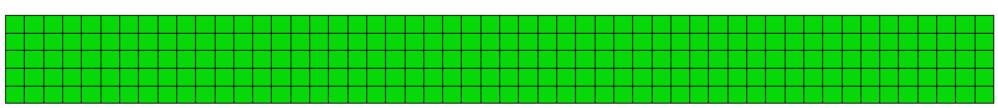
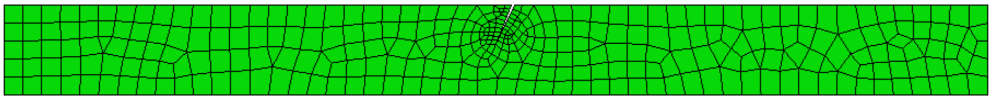
2.2 Concrete Sleeper Model

The finite element method is applied to build the concrete sleeper model though the Abaqus software. Type-III concrete sleeper was selected to study, as shown in figure 3. Its overall dimension is 2.6m×0.23m×0.314m, and CPS4 element was used to mesh for the concrete sleeper.



(a) Normal concrete sleeper



(b) Damaged concrete sleeper

Figure 3. Concrete sleeper finite element model

Stress intensity factor (SIF) is introduced as an index to investigate the propagation of the transverse crack, which can be used to evaluate the stress in the field of crack tip. However, it is difficult to determine the analytical expression of SIF with the complex loads and irregular structure. Thus, a numerical calculation named extrapolation method based on the node displacement is applied to solve SIF with the finite element method. In the software of Abaqus, the displacement is a primary variable and the stress connected by stain and displacement is a secondary variable. So it is a precise way to calculate SIF with the node displacements. The vertical displacement υ can be read directly in the finite element analysis. Therefore, SIF can be expressed as follows,

$$K_{1i} = \frac{2\mu}{\kappa+1}\upsilon_i\sqrt{\frac{2\pi}{r_i}} \tag{2}$$

where $\mu = E/2(1+v)$; $\kappa = (3-v)/(1+v)$; E is elasticity modulus and v is poisson's ratio. The data pair (r_i, K_{1i}) can be structured and the SIF is finally defined by least square method.

3. Model Verification

Based on the concrete sleeper model, the first five order mode frequencies are 125 Hz, 326 Hz, 603 Hz, 934 Hz, 1303 Hz, respectively, as shown in table 1. To verify the concrete sleeper vibration modes, a field test has been conducted in a heavy-haul railway line. Figure 4 describes the test site where the concrete sleeper vibration displacement and acceleration are measured by the tapping test using a hammer.

Table 1. Concrete sleeper modes

Modal frequency	Mode shape	Modal frequency	Mode shape
Mode 1 125Hz		Mode 2 326Hz	
Mode 3 603Hz		Mode 4 934Hz	Mode 5 1303Hz			

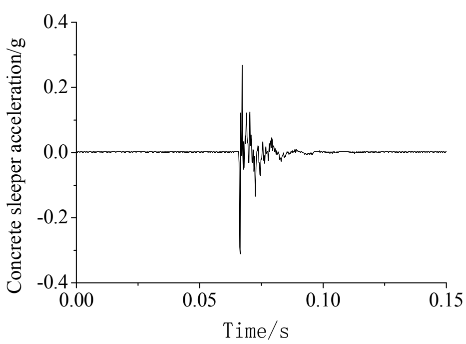
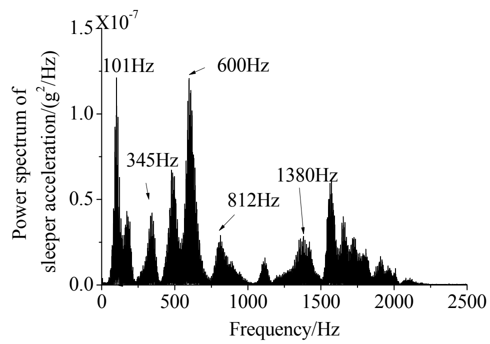
(a) Test site (b) IMC(test instrument)

Figure 4. Field test in a heavy-haul railway line





(a) Sleeper acceleration **(b) Power spectrum of sleeper acceleration**

Figure 5. A typical test data

As shown in Figure 5, the vibration acceleration of concrete sleeper can exceeds about 0.3g in the case of tapping test. In order to acquire the sleeper vibration mode frequencies, FFT of sleeper acceleration is shown in figure 5, in which the first five order bending modes are 101 Hz, 345 Hz, 600 Hz, 812 Hz, 1380 Hz, respectively. Therefore, the bending modes of concrete sleeper calculated by numerical calculation and measured by field test are coincident.

4. Vibration Characteristics of Damaged Concrete Sleeper

4.1 Vibration Modes

Transverse crack in the middle cross section of the sleeper occupies a large proportion. So a damaged concrete sleeper considering transverse crack is built in Abaqus software and the modal analysis is conducted. As shown in table 2, the first 5 order natural frequencies are 124 Hz, 324 Hz, 511 Hz, 914 Hz, 1186 Hz, respectively. Compared with the modal frequencies of normal concrete sleeper, the modal frequencies of damaged concrete sleeper reduce to some extent. The first 2 order modal frequencies of the two different concrete sleepers have little change, whereas the 3rd order frequency and the 5th order frequency have obvious difference, reducing by15.3% and 9.0%, respectively. Therefore, modal frequency of concrete sleeper in high frequency range would decrease clearly when the transverse crack appears in the middle crossing section of the concrete sleeper.

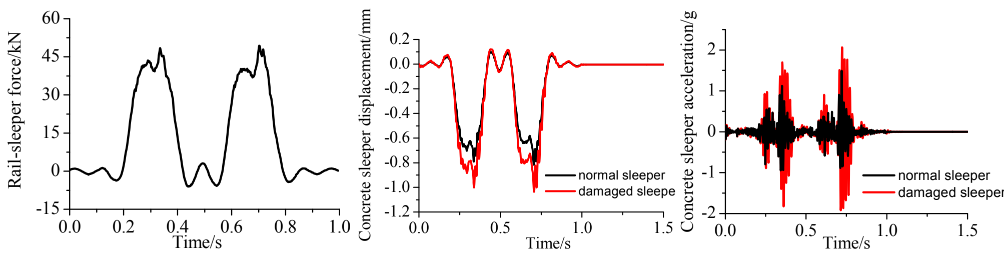
Table 2. Damaged concrete sleeper modes

Modal frequency of damaged sleeper/Hz	Mode shape	Modal frequency of normal sleeper/Hz	Changing rate/%
124		125	-0.8
324		326	-0.6
511		603	-15.3
914		934	-2.1
1186		1303	-9.0

4.2 Vibration Response under Train Loads

In order to simulate the vibration characteristics of the concrete sleepers, the rail-sleeper forces calculated by vehicle－track coupled dynamics theory were applied to the sleeper finite element model. Figure 6(a) gives the rail-sleeper forces which can exceed about 50 kN when a freight car with the axle load of 25 t passes though the track with a constant velocity.

Figure 6(b) and figure 6(c) describes the displacement and acceleration of concrete sleeper in the cases of normal concrete sleeper and damaged concrete sleeper. It can be seen obviously from figure 6(b) and figure 6(c) that the displacement and acceleration of the damaged concrete sleeper are a little higher than normal concrete sleeper. The maximum of normal concrete sleeper displacement is only 0.80 mm while that of damaged concrete sleeper displacement is about 1.04 mm, increasing by 30%. For the acceleration of the concrete sleeper, the two cases are 2.06 g and 1.51 g, respectively. The former increases by 36% compared with the latter. Therefore, the vibration characteristics of damaged concrete sleeper would deteriorate dramatically, which affects the running safety and reduces the track lifetime. It is necessary to control the appearance of crack to ensure the normal traffic.



(a) Rail-sleeper force; (b) Concrete sleeper displacement; (b) Concrete sleeper acceleration

Figure 6. Vibration characteristics of concrete sleepers

4.3 SIF

As shown in figure 7, in order to investigate the propagation of the transverse crack, the stress intensity factor is introduced. It can be seen that ΔK_1 exceeding about 50 $N{\cdot}mm^{-1.5}$ is much larger than ΔK_2. Dynamic response of stress intensity factor in the crack tip shows that the intensity of stress field near the crack tip is controlled by Stress Intensity Factor Type-I. Fracture toughness K_{IC} was usually used to describe the capacity of concrete resisting fracture, which is in the range of 20~30 $N{\cdot}mm^{-1.5}$(Carpinteri et al., 1984). Therefore, crack instability propagation would occur under the train loads and it is important to control the crack size to prolong service life of concrete sleeper.

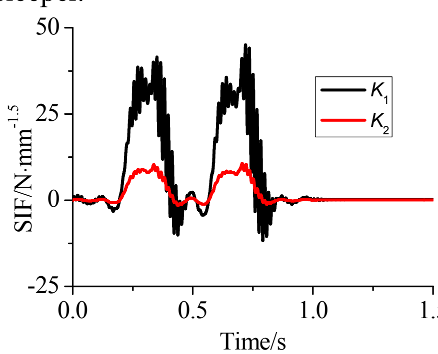


Figure 7. Stress intensity factor (SIF)

5 Conclusions

This paper presents an investigation on the effect of transverse crack in the middle cross section of the sleeper on vibration characteristics of concrete sleepers on the basis of the vehicle—track coupled dynamics. From the above studies, the following conclusions can be reached:

(1) Modal frequencies of damaged concrete sleeper reduce to some extent;

(2) Vertical acceleration and displacement of damaged concrete sleeper increase obvious;

(3)The intensity of stress field near the crack tip is controlled by Stress Intensity Factor Type-I and crack instability propagation would occur under the train loads.

Abstract: Due to growing concerns on the low-frequency box bridge structure vibration-born noise, the noise and vibration reduction design becomes a research focus at present. In this paper, based on the slab ballastless track- box bridge coupling dynamic model developed by the finite element method, the influences of stiffness and damping of the cement asphalt mortar (CAM) layer on the elevated box bridge structure vibration and noise radiation are studied. The results show that: the effect of stiffness of the CAM layer on the sound pressure level (SPL) caused by the box bridge structure vibration is not obvious, but the radiation scope of the box bridge structure noise is expanded by the greater stiffness of the CAM layer; with the damping of CAM layer increasing, the sound pressure of vertical acoustic field decreases, and the radiation scopes above and below the box bridge are also smaller, but the sound pressures of the noise concentration areas near the box bridge increases.

Keywords: Elevated box bridge; Cement asphalt mortar; Stiffness; Damping; Vibration-born noise radiation.

1 Introduction

The elevated bridge structure will become an important noise source, when a train moves quickly on it (Thompson, 2009). The main characteristics of the bridge structure noise are of low frequency, slow attenuation and large radiation area. According to, the previous studies on the bridge structure noise focus on noise radiation laws, spectrum characteristics analysis and test verification. As the research going, the controls of bridge structure vibration and noise are taking more and more attention. The articles found that for the railway box bridge, there are some differences between the low vibration deduction design and noise reduction design due to that the spectrum characteristics of its vibration and noise are different. He also did an optimization design for the box bridge structure noise by changing the thickness of the panels and the inclination of web panels (Zhang, 2013; Zhang, 2013). HAN Jianglong carried out the vibration and noise reduction design for the concrete groove bridge by adding horizontal ribs (Han, 2012). GAO Fei found that the stiffness of bearings has important effects on the bridge structure vibration, but has not obvious influences on bridge structure noise (Gao, 2012). GENG Chuanzhi developed a metro vehicle-elastic fasteners coupling dynamic model to analyze the influence of stiffness of fasteners on the wheel/rail forces (Geng, 2007). LIANG Shangyan established a dynamic model of the floating slab track structure, and studied the influences of the positions of loads, the length of slab and the stiffness and damping of steel springs on the vibration isolation performance of the floating slab track (Liang, 2013). CAI Chengbiao analyzed the effects of the stiffness of CAM layer or rubbers on the dynamic responses of track (Cai, 2011). GUO Yajuan studied the influences of the stiffness of fasteners, the stiffness and damping of steel springs on the dynamic responses of floating slab track structure (Guo, 2006). Nelson J. T. found that fasteners the flexible fasteners of stiffness 10 MN/m, compared to the common fasteners of stiffness 20 ~ 25 MN/m, can reduce the ground vibration noise of more than 30Hz by 5 dB (Nelson, 1996).

In order to study the influences of the stiffness and damping of CAM layer of the ballastless CRTS-I slab track on the elevated box bridge structure noise, the vehicle-track coupling dynamic model is firstly established by the Simpack software, and the vertical wheel/rail forces excited by Germany low interference spectrum is obtained. The track-box bridge coupling dynamic model is secondly established by the Ansys finite element software, and the wheel/rail forces are taken as the load boundary conditions to calculate the bridge structure vibration responses in time domain using the transient analysis method. At last, the bridge structure vibration acceleration responses are taken as the acoustic radiation boundary conditions to calculate the box bridge structure-born noise by the Virtual Lab software. On this basis, the influences of the stiffness and damping of CAM layer on the acoustic field distribution and the frequency spectrum characteristics of the box bridge structure noise are studied, aiming at providing some references to the noise reduction designs for bridge structure.

2 Acoustic boundary element theory of box bridge structure

The noise radiation caused by the vibration of a closed structure in the fluid medium meets the acoustic wave equations, the Neumann boundary conditions for the fluid-structure interface and Sommerfeld radiation condition, expressed as:

$$\nabla^2 \vec{p} + k^2 \vec{p} = 0 \tag{1}$$

$$\frac{\partial \vec{p}}{\partial \vec{n}} = -i\rho_0 \omega \vec{v}_n \tag{2}$$

$$\lim_{r\to\infty}\left[r\left(\frac{\partial \vec{p}}{\partial r} - ik\vec{p} \right) \right] = 0 \tag{3}$$

Where ∇ is the Laplace operator, $\vec{p}$ is the sound pressure, $k=\omega/c$ is the wave number, ω is the circular frequency, c is the sound velocity in the air, $\vec{v}_n$ is the normal vibration velocity vector, ρ_0 is the fluid density, $r=\left|\vec{X}-\vec{Y}\right|$, X is a point on the surface of the structure A and Y is a point in the sound field, A is the surface area of the structure.

Using the Green function of the free space, the Helmholtz integral equation is

$$\vec{p}(Y)=\int_A\left(\frac{e^{-ikr}}{4\pi r}\Delta\vec{v}(X)+\frac{e^{-ikr}}{4\pi r}\left(ik+\frac{1}{r}\right)\cos\beta\Delta\vec{p}(X)\right)dA(X) \qquad (4)$$

Where β is the angle between the point normal vectors of structure surface X and the radius vector r; D is the fluid media area; $\Delta\vec{v}(X)$ is the velocity difference of either side of point X on the boundary surface, and $\Delta\vec{p}(X)$ is the sound pressure difference of either side of point X on the boundary surface, which are expressed as, respectively:

$$\begin{cases}\Delta\vec{v}(X)=-i\rho_0\omega(\vec{v}_{n1}(X)-\vec{v}_{n2}(X))\\ \Delta\vec{p}(X)=\vec{p}_1(X)-\vec{p}_2(X)\end{cases} \qquad (5)$$

Where $\vec{p}_1(X)$ and $\vec{p}_2(X)$ are the pressures of either side of point X on the boundary surface, respectively; $\vec{v}_{n1}(X)$ and $\vec{v}_{n2}(X)$ are the normal vibration velocities of either side of point X on the boundary surface, respectively.

Dividing the structure surface by boundary elements obtain the pressure difference and vibration velocity difference of each node on the structure surface, expressed as

$$\begin{Bmatrix}\Delta\vec{v}(X)\\ \Delta\vec{p}(X)\end{Bmatrix}=C^{-1}F \qquad (6)$$

Where C is the full rank symmetric plural matrix which is also the function of excitation frequency, which is related with the shape of the surface of the structure, the size and the interpolation shape function. F is the vector of external excitation which is determined by the vibration velocities of the boundary surface.

The sound pressure of any point out the structure surface calculated by formula (7), shown as

$$\vec{p}(Y)=B\begin{Bmatrix}\Delta\vec{v}(X)\\ \Delta\vec{p}(X)\end{Bmatrix}=BC^{-1}F \qquad (7)$$

Where $\vec{p}(Y)$ is the sound pressure of any point out the structure surface, and B is the interpolation matrix, which are determined by formula (4).

3 Influences of the material properties of CAM layer on box bridge structure vibration

3.1 Finite element model of track-bridge coupling dynamics

Taking the 32m simply supported concrete railway box bridge as the research object whose height is 3m, poisson's ratio 0.25 and density 2500*kg/m³*.The thickness of the top, web and bottom plates are 0.315m, 0.48m and 0.3m, respectively. The tracks on the box bridge are comprised of CRTS-I slabs, and the length, width and height of slab are 4.93m, 2.4m, 0.2m, respectively. Tab. 1 and Tab. 2 shows the dynamic parameters of the finite element model and the element type, and the element sizes are 0.3m.

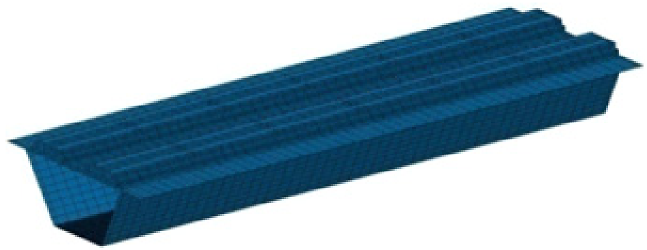

Figure 1.Finite element model of CRTS-I slab ballastless track-bridge coupling dynamics

Table 1. Dynamic parameters of track and box bridge

Dynamic parameter	Value
Stiffness of fastener/(N·m^{-1})	4×10^{7}
Damping of fastener/(N·s·m^{-1})	2.2656×10^{4}
Elastic modulus of slab /(N·m^{-2})	3.6×10^{10}
Poisson ratio of slab	0.2
Density of slab /(kg·m^{-3})	2500
Stiffness of CAM layer /(N·m^{-1})	9.375×10^{9}
Damping of CAM layer/(N·s·m^{-1})	7.5×10^{5}
Elastic modulus of base /(N·m^{-2})	3.3×10^{10}
Poisson ratio of base	0.2
Density of base /(kg·m^{-3})	2500
Elastic modulus of bridge /(N·m^{-2})	3.8×10^{10}
Poisson ratio of bridge	0.25
Density of bridge /(kg·m^{-3})	2500

Table 2. Element types of the element model

Component	Element type
rail	Beam4
fastener	Combin14
slab	Solid45
CAM layer	Combin14
bridge	Shell63

3.2 Dynamic responses of box bridge

For a high-speed train composed of 8 vehicles with a speed of 200 km/h runing on a elevated bridge, the wheel/rail forces excited by the track irregularity are shown in Fig. 2. The parameters of train are listed in reference.

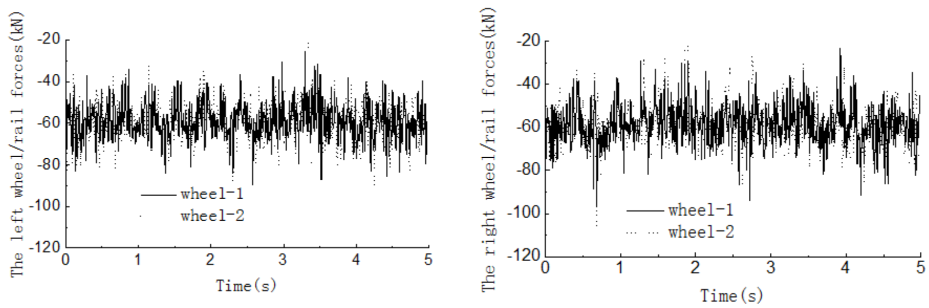

Figure 2.Vertical wheel/rail force

Figure 2 shows that the wheel/rail force fluctuations near 60 kN, wholes maximum value reaches 108.28 kN. Compared to the left wheel/rail force, the right is larger. Those wheel/rail forces are applied on the finite element model of CRTS-I slab ballastless track-bridge coupling dynamics to calculate the bridge structure dynamic responses. The time history and spectrum diagram of the acceleration of the bridge are shown in Figure 3.

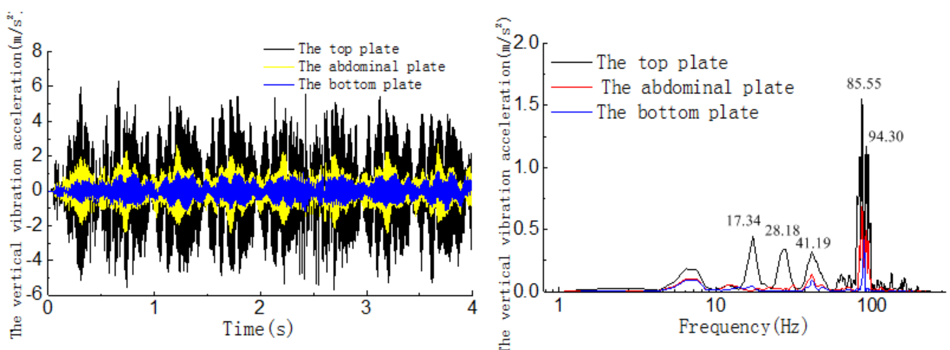

Figure 3.The acceleration responses of the bridge at 1/2 span

From Figure 3, we can find that the box bridge structure vibration are mainly concentrated in 0-200 Hz; the vibration of top plate is most obvious and its peaks appear mostly in 10-100 Hz, and its maximum is at 85.55Hz and it also has some peaks at 17.34 Hz, 28.18 Hz, 41.19 Hz and 94.30Hz.

3.3 Influences of the material properties of CAM layer on box bridge structure vibration

Previous research had shown that the influences of the material properties of CAM layer on the wheel/rail forces are tiny, so the effects of the material properties of CAM layer on the wheel/rail forces are not taken into consideration.

Tab. 3 Selected material parameters

Component	Stiffness/MPa	Damping/N·s·m^{-1}
CAM layer	937.5	75e^4
	750	75e^4
	1250	75e^4
	1500	75e^4
	937.5	37.5e^4
	937.5	150e^4
	937.5	225e^4

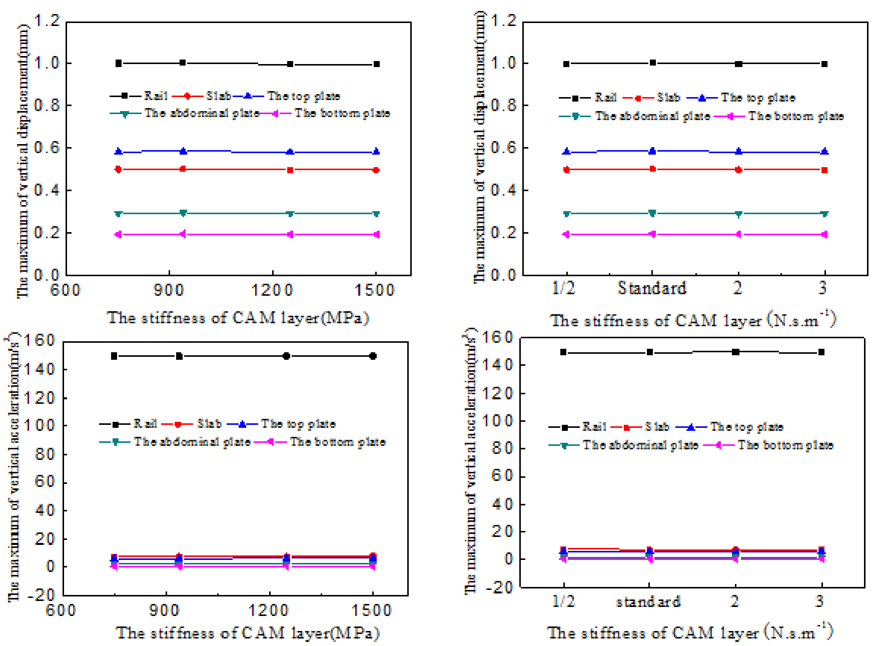

Figure 4.Influences of the stiffness and damping of CAM layer on the vertical displacement and acceleration of rail, slab and bridge

From Fig. 4, we can find that the influence of the stiffness of CAM layer on the vibration displacements of rail, slab and bridge is small; the vibration displacements of slab and bridge have slight increase; the influence of the damping of CAM layer on the vibration displacements of rail, slab and bridge is also small; the greater damping can slightly reduce vibration displacements of bridge.

4 Influences of the material properties of CAM layer on box bridge structure noise

In this paper, we put focuses on the influences of the material properties of CAM layer on box bridge structure noise and taking the effect of the ground reflection will be disadvantage to our analysis, so it is better to neglect the ground reflection.

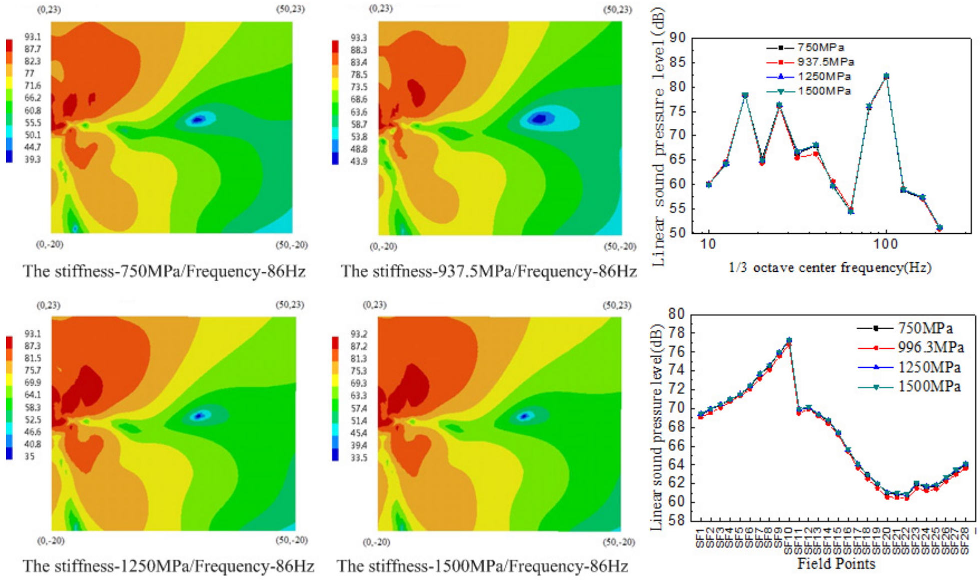

Figure 5.Influences of the stiffness of CAM layer on box bridge structure noise

From the sound field frequency spectrum, we can find that the effect of stiffness of the CAM layer on the SPL caused by the box bridge structure vibration is not obvious, but the radiation scope of the box bridge structure noise is expanded by the greater stiffness of the CAM layer.

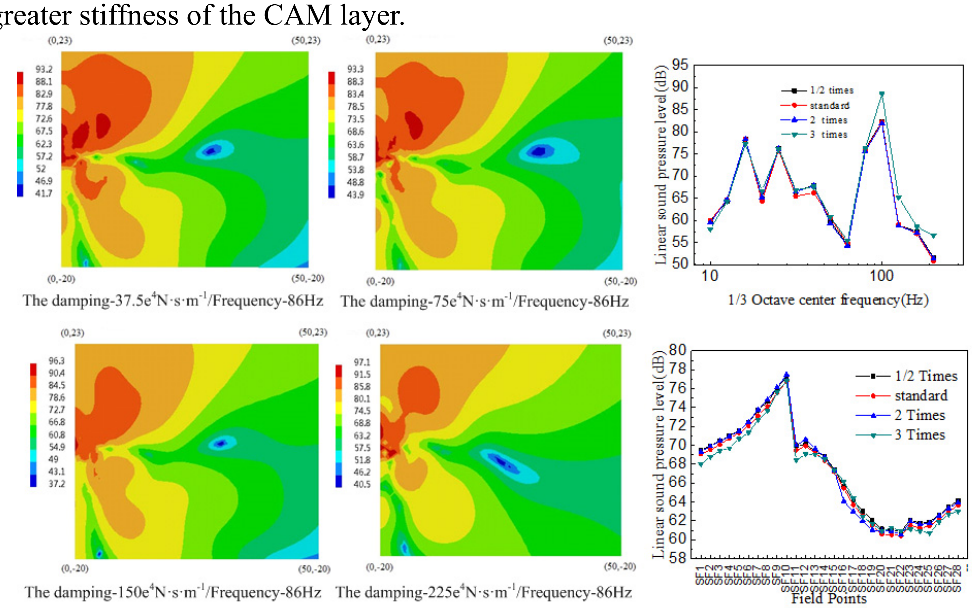

Figure 6.Influences of the damping of CAM layer on box bridge structure noise

From the sound field frequency spectrum, we can find that with the damping of CAM layer increasing, the sound pressure of vertical acoustic field decreases, and the transverse sound field not obviously changes; when the center frequency is above 80Hz, the greater the damping is, the greater the SPL is. From the sound field distribution, we can find that with the damping of CAM layer increasing, the sound pressure of the sound pressure of vertical acoustic field radiation scopes above and below the box bridge are smaller, but the sound pressures of the noise concentration areas near the box bridge increases.

5 Conclusions

(1) The effect of stiffness of the CAM layer on the sound pressure level (SPL) caused by the box bridge structure vibration is not obvious, but the radiation scope of the box bridge structure noise is expanded by the greater stiffness of the CAM layer;

(2) With the damping of CAM layer increasing, the sound pressure of vertical acoustic field decreases, and the radiation scopes above and below the box bridge are also smaller, but the sound pressures of the noise concentration areas near the box bridge increases.

Abstract: This article proposes a bilinear stiffness plastic hinge simplified model , based on the existing experimental research on dry joints fabricated pier; Using of nonlinear time history analysis method, seismic isolation performance of combination system of dry joints fabricated pier with laminated rubber bearing is discussed in the perspective of damping isolation. Results indicate that the dry joints fabricated pier system can reduce the seismic force and energy. The conclusion has some practical significance for the applications of dry joints fabricated pier bridge in high earthquake region.
Keywords: Seismic isolation performance; Fabricated pier; Time history analysis method; Simplified calculation mode.

1 Introduction

The harsh construction conditions or restrictions on traffic interference, promotes the application of precast segmental bridge columns which mainly used as wet seam application form in low seismic intensity areas（LAN, 2012）. Considering of the advantages and application requirement of precast segmental bridge columns on high earthquake zone, seismic performance study on precast segmental bridge columns rises.

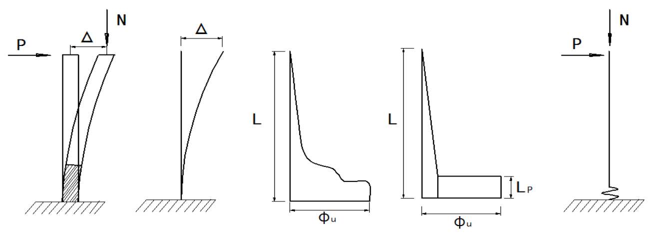
Currently, the scholars have carried out some related researches, including theoretical and experimental studies (WANG, 2009). Theoretical methods includes analytical method, concentrated plastic hinge method, the fiber model method and reinforced concrete solid finite element model (GE,2008). Experimental research regards to component failure mode (Mander, 1997, Hieber,2005). The foundation for the relevant experimental and theoretical studies of Segmental pier was laid. However, the research for the highly seismic performance of precast segmental pier bridge is still in its infancy and mainly component level.

Seismic must be withstood by the bridge structure and seismic isolation philosophy is a necessary means to resist earthquakes. Therefore, the possibility of dry joints pier high earthquake zone applications is explored, with some practical value, in the perspective of the bridge system, combined with seismic isolation measures.

2 Calculation mode for dry joints precast segmental piles

Segmental pier nonlinear factors including analog tendons and mechanical properties of the seam area is much. Calculation of nonlinear seismic response is not realistic using of the precise method. It needs to be simplified. Concentrated plastic hinge method is a suitable, systematic, efficient methods, widely used in the whole cast piers.

Mechanical model of the plastic hinge is to set up a spring in the plastic hinge to simulate the elastic-plastic rotation (Figure 1).



Pier	Deform	Actual curvature distribution	Ideal curvature distribution	Plastic hinge model

Figure 1. Plastic hinge model

Centralized plastic hinge method requires determining the restoring force model for Segmental pier. Restoring force model is an important parameter to reflect the dynamic characteristics of the structure, and indispensable for structural analysis and design. Restoring force model and its parameters reasonable will have a significant impact on nonlinear seismic response of Segmental analysis piers.

2.1 Moment Curvature Analysis

According to quasi-static test result of the dry joint sections pier (GAO, 2011), precast segmental bridge columns occurs through three stages (joints closing, open, the plastic deformation of concrete, prestressed reinforcement yielding process) under cyclic loading (Figure 2). Sectional moment curvature can be calculated by finite method.

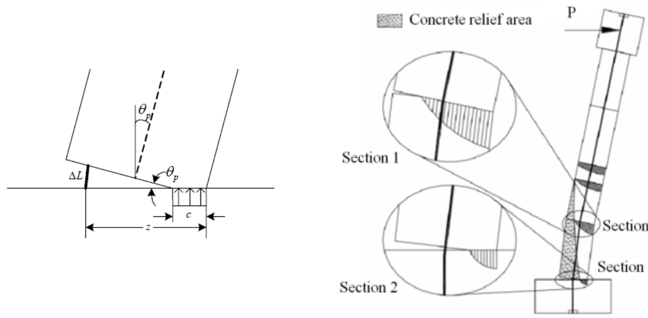


Figure 2. Elastic-plastic analysis

According to the equilibrium condition, relationship between section internal forces and stresses satisfy is as following:

$$N=\int \sigma dA=\int \sigma_c dA+\int \sigma_s dA+\int \sigma_{sp} dA \qquad (1)$$

$$M=\int y\sigma dA=\int y\sigma_c dA+\int y\sigma_s dA+\int y\sigma_{sp} dA \qquad (2)$$

Among, σ_c, σ_s, σ_{sp} Respectively Stress of concrete, steel, prestressing steel.

Concrete material uses Kent-Park model, reinforced using Giuffré- Menegotto-Pinto model, prestressing steel using ideal elastic-plastic models.

2.2 Restoring force model

Restoring force model is necessary to consider the hysteresis characteristics of components, and should also be maximum simplified for the present level of seismic response analysis. Seeing from the existing experimental results (LIU, 1994), skeleton curve of prestressed beams can be simplified to forward and reverse three polylines (Figure 3), reflecting strengthening properties of tendon.

Based on a number experiments (Clarkp,1999), the hysteresis curve of segments pier plastic hinge can be simplified as follows (Figure 4): After the force component exceeds the yield strength, load path along the skeleton curve; Hysteresis loop no stiffness or strength degradation; Unloading stiffness smaller then initial stiffness.

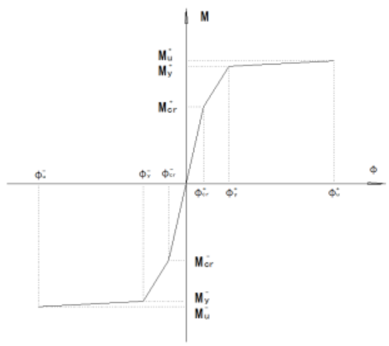

Figure 3. Skeleton curve

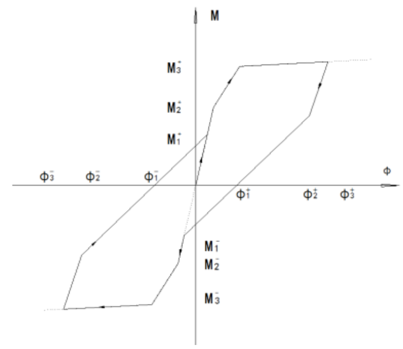

Figure 4. Hysteresis curve

2.3 Plastic hinges number

Prestressed Concrete Segmental piers destruction mainly occurs at the joints. According to the results, according to the joint position, a plurality of plastic hinges is set.

3 Calculate schema validations

In order to ensure the correctness of the analysis method, the calculation results and existing research results of concentrated plastic hinge analysis were compared (Figure 5). The foundation for the analysis of seismic isolation system of precast segmental bridge piers is laid.

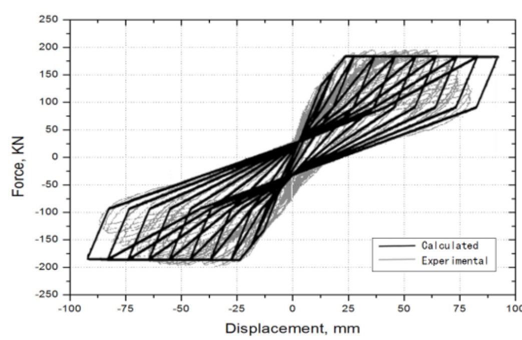

Figure 5. Comparison of Hysteresis curve

Compared with the experimental results (LIU,2008), hysteresis curve of centralized pier plastic hinge analysis resulting is good agreement with experiments, and simulation error can be negligible before its stiffness degradation. The simulation results can be used to meet the bridge seismic isolation system analysis.

4 Isolation Performance Research

Prestressed concrete continuous bridge with 5 spans set as the example engineering shown in Figure 6. Pier height variation makes dynamic response for the isolated bridge is more representative.

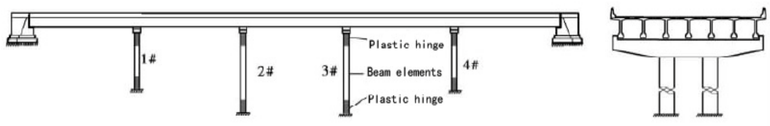

Figure 6. Example engineering

The main beam is simulated by elastic beam elements, and the mass simulated by concentration mass method; Use of centralized plastic hinge method to simulate the pier, each bearing simulated by connection elements. EI Centro seismic waves and Rayleigh damping ratio of 5% damping is used. And compared the precast segmental bridge columns (Normal bearing), precast segmental bridge columns (lead core bearing), the whole piers (lead core bearing) continuous beam bridge seismic performance.

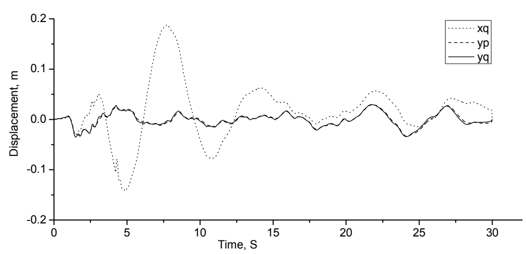

Figure 7. The 1st pier top displacement time history results

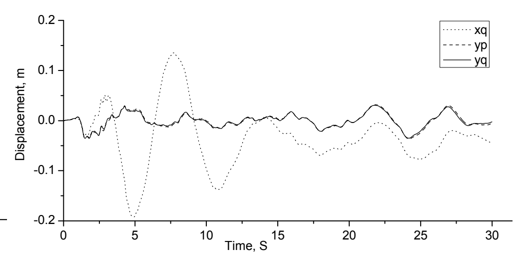

Figure 8. The 2st pier top displacement time history results

Comparison of Pier top displacement time history response (Figure 7, Figure 8) shows: prefabricated bridge pier and overall pier displacement time history during the first 2 seconds is consistent; Thereafter displacement time history response are different, and both frequency components are different. Segmental Piers displacement extreme response is smaller to the corresponding overall bridge pier. The two forms of precast pier bridge bearing displacement process are basically the same. The results proved the possibility of application of precast segmental bridge pier in highly seismic region.

5 Conclusions

Here we may draw the following conclusions.

(1) The simplified calculation method proposed is reasonable, and can be applied to structural analysis.

(2) A meaningful discussion on the application in highly seismic region is made,

and accounts segmental pier with appropriate isolation measures can be applied.

Abstract: Compare to the ordinary road sections, the traffic environment of tunnels is particularly different, especially when considering the visual environment. Due to the black hole effect, the threshold zone is regarded as accident-prone location. But in the engineering practice in China, the greatest change of the illumination in tunnels happened not at the tunnel portal but at somewhere inside the tunnel. This paper aims at discovering the distance range with the highest driving risk in threshold zone of tunnel. A field experiment has been conducted in a typical tunnel in Hunan Province, China. Based on the experimental data analysis, the relationship is built between the target detection distance, the distance from the tunnel portal, and the ratio of illumination, respectively. The results showed that at operating speed of 60 km/h, the distance range with the highest driving risk is 70 m to 109 m from the tunnel portal. The distance range is 50 m to 87m from the tunnel portal for 80 km/h and 42 m to 79 m from the tunnel portal for 100 km/h. Based on target detection distance, the illumination design for tunnel lighting can be optimized.
Keywords: Visual adaptability; The threshold zone; Target detection distance; The ratio of illumination.

1 Introduction

Today there are over 11,359 highway tunnels in China in 2013 while more than 1,337 new tunnels are built each year (China Statistics, 2013). The visual environment in tunnels is quite different from the ordinary road sections, especially the threshold zone, which is the first entrance zone of the tunnel. Due to the "black hole" effect, it is regarded as the accident-prone location.

The driver's visual adaptability in the threshold zone is determined from the ratio between the threshold zone luminance and the access zone luminance. Usually, the illumination of natural light is still high at the tunnel portal. Therefore, the greatest change of the illumination appears not at the tunnel portal but at somewhere inside the tunnel.

In order to assess the driver's visual ability (Bre´mond, 2007), several indicators (illuminance, luminance, Visibility Level, etc.) have been proposed by now. The most popular indicator used is the Visibility Level (VL), which is proposed as a quality index in the American standard (IESNA, 2000) and French standard (AFE, 2002), but not in the European standard (European Norm, 2004–2005). The VL is defined as the ratio between the measured contrast ΔL (between the target and its background, which is, typically the road surface) and the contrast threshold ΔLt (Adrian, 1989, 2004).

This study investigated the target detection performance by conducting a field experiment in a typical tunnel in Hunan Province, China. The detection distance of the target inside the tunnel was obtained at three different speeds. The ratio of illumination was chosen as the visual adaptability indicator. The relationship was built between target detection distance and the ratio of illumination, then the distance range with the highest driving risk in threshold zone of tunnel was found out.

2 Method

2.1 Participants

Ten participants (3 women and 7 men) aged 26–35 years old took part in this study. 8 were drivers and 2 were field operators. All drivers had been driving for at least 3 year with a valid driving license. Their vision was good or good with glasses. And all participants were requested to be familiar with the experiment tunnel where the test drive was to be conducted.

2.2 Apparatus

2.2.1 Experimental Tunnel

A field experimental was conducted in a typical two-lane highway tunnel in Hunan Province, China. The lane width is 3.75m, and the design speed is 80 km/h. The tunnel was not open to traffic and was free of other vehicles during the experiment. (See Figure 1)

Figure 1. The experimental tunnel and target

2.2.2 Equipment

The instrumented vehicle was a 2004 Mazda Premacy. Driving speed and detection distance were collected using a non-contact speedometer (CTM-8C). The illumination photometers were used by the field operators to measure the illumination of two typical places (the tunnel portal and the target surface).

2.2.3 Target specifications

In roadway visibility research, the target specifications were almost consistent. For instance the American standard (IESNA, 2000a, 2000b) used a 20 cm uniform square as the target, with reflectance of 50%. While in Japan, a 20 cm width square flat target with a diffuse reflectance of 9-11% was used in the visibility research (K Narisada, K Yoseoikawa, 1974). In this experiment, the target specifications were the same as mentioned above and the diffuse reflectance was 30%.

2.3 Procedure

The field experiment was conducted on both sunny and cloudy days, for illumination was greatly influenced by natural light. The target was placed in the center of the left lane, while the experimental vehicle drove in the right lane. Several target locations were chosen in order to get relevant illumination values. Each participant completed three drives, one for each of 60, 80, 100 km/h conditions.

Experimenters started to record the non-contact speedometer as soon as they detected the target stimulus placed on the experimental section, and stopped the record when the vehicle drove past the target. The detection distance was recorded by the speedometer in each drive. In each test drive, two field operators used illumination photometers to measure the illumination of the tunnel portal and the target surface at the same time. Thus, the illumination was recorded.

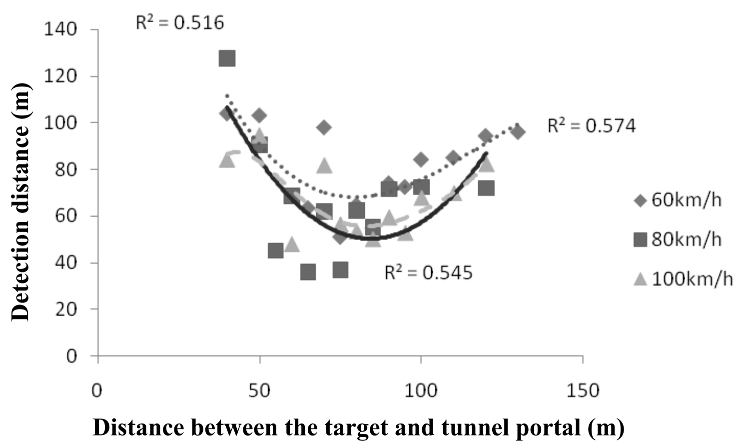
3 Results and Discussion

3.1 Analyses of the distance between the target and tunnel portal

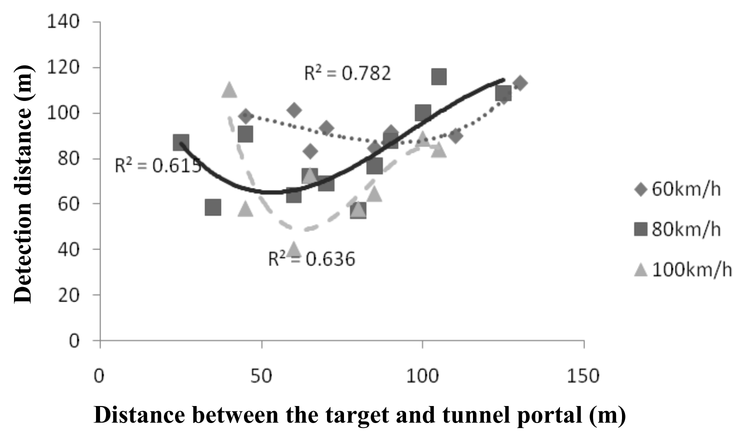
Figure 2 shows how the distance between the target and tunnel portal affects the detection distance on both cloudy and sunny days. As the target distance increases, the detection distance decreases at first and then increases. When the target distance range is between 50m to 100m, the detection distance is smaller than that in the other zones. It is the same at the operating speed of 60, 80, 100 km/h on both cloudy and sunny days.

When the drivers are close to the tunnel portal, the illumination of natural light is still high, so the detection distance is long. When the drivers are far away from the tunnel portal, the dark adaptation has already generated. Thus the drivers have actually adapted to the dark environment, and then the detection distance increases.

The smaller the detection distance, the higher driving risk exists for drivers. Therefore, the distance range with the highest driving risk for drivers is between 50m to 100m from the tunnel portal.



(a) The detection distance on cloudy days



(b) The detection distance on sunny days

Figure 2. The detection distance on different weathers

3.2 Analyses of the ratio of illumination

In order to make the connection between the detection distance and illumination, the ratio of illumination is proposed which can be calculated as following:

$$v = \frac{\left| \lg E_{out} - \lg E_{object} \right|}{\lg E_{out}} \tag{1}$$

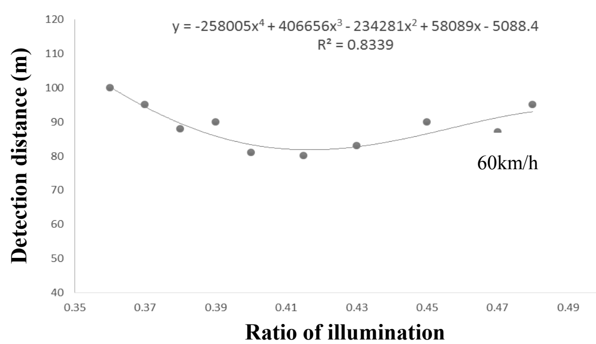
Where,

E_{out} = illumination at the tunnel portal,

E_{object}= illumination on the target surface.

Figure 3 displays the relationship between the detection distance and the ratio of illumination. As the ratio of illumination increases, there is a significant reduction in the detection distance. At operating speed of 60 km/h, when the ratio of illumination is 0.416, the detection distance reaches the minimum of 80.4m. The detection distance decreases to 69.4m for the ratio of illumination 0.425 at 80 km/h and decreases to 51.0m for the ratio of illumination 0.410 at 100 km/h.

Otherwise, for each operating speed, the detection distance doesn't decrease continuously with the increase of the ratio of illumination. As the ratio of illumination continues to increase, the detection distance grows as well. Thus, the ratio of illumination with high driving risk has been found out. At operating speed of 60 km/h, the range of ratio is from 0.391 to 0.449. The ratio is from 0.391 to 0.440 for 80 km/h and the ratio is from 0.380 to 0.440 for 100 km/h. (See Figure 3)



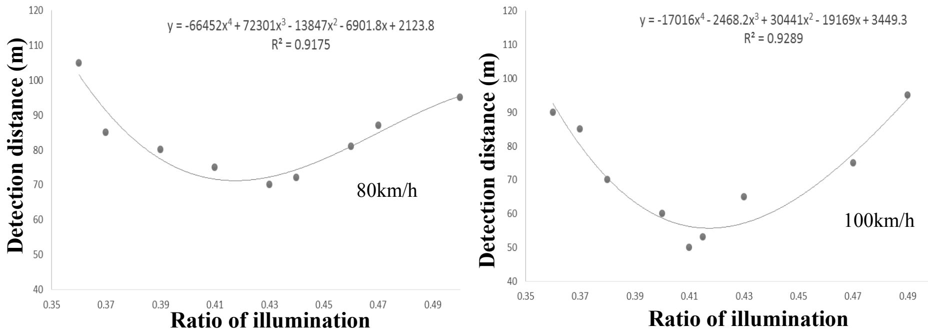


Figure 3. The relationship between the detection distance and the ratio of illumination

Based on Figure 3, the distance range with high driving risk in threshold zone of tunnel has been found out. At operating speed of 60 km/h, the distance range is 70m to 109m from the tunnel portal. The distance range is 50m to 87m from the tunnel portal for 80 km/h and 42m to 79m from the tunnel portal for 100 km/h. (See Figure 4)

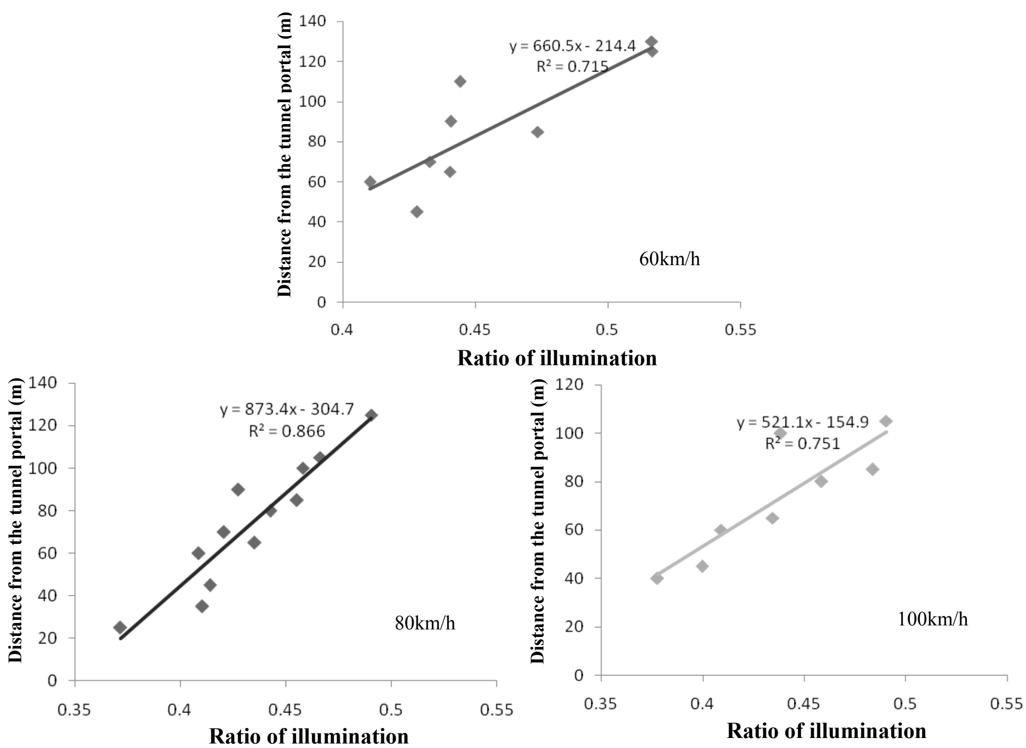

Figure 4. The relationship between the distance from the tunnel portal and the ratio of illumination

4 Conclusions

The following conclusions have been drawn:

The distance between the target and tunnel portal plays an importation role on the detection distance on both cloudy and sunny days. As the target distance increases, the detection distance decreases at first and then increases.

When the target distance range is between 50m to 100m, the detection distance is smaller than that in the other zones. It is the same at the operating speed of 60, 80, 100 km/h on both cloudy and sunny days.

When the drivers are close to the tunnel portal, the illumination of natural light is still high, so the detection distance is long. When the drivers are far away from the tunnel portal, the dark adaptation has already generated. Thus the drivers actually have adapted to the dark environment, and then the detection distance increases.

The impact of increased operating speed is clearly reflected in the results of detection distance. The higher the operating speed, the smaller the detection distance is.

The distance range with highest driving risk in threshold zone of tunnel has been found out. At operating speed of 60 km/h, the distance range is 70m to 109m from the tunnel portal. The distance range is 50m to 87m from the tunnel portal for 80 km/h and 42m to 79m from the tunnel portal for 100 km/h.

Design and Analysis on Rail Anti-Head Check Profile for a Curve Rail of a Heavy-Haul Railway

Yu Zhou[1]; Miao Yu[1]; Tianyi Wang[2]; Jie Zhang[1]; and Junnan Jiang[1]

[1]Key Laboratory of Road and Traffic Engineering, Ministry of Education, Tongji University, No. 4800, Cao'an Rd., Jiading District, Shanghai 201804, China. E-mail: yzhou2785@tongji.edu.cn
[2]Shanghai Tunnel Engineering & Rail Transit Design and Research Institute, No. 1999, West Zhongshan Rd., Xuhui District, Shanghai 200235, China. E-mail: toni1989@126.com

Abstract: Based on the characteristics of the head checks (HCs) in curve rail of a heavy-haul railway, the design method for lower rail profile where the HCs occurred frequently by the cubic interpolation spline curve was presented. The algorithm including control points and the key control parameters in the profile, equations of the curve between adjacent control points and the boundary conditions were discussed. The control parameters was researched by applying the designed profile to a vehicle-track model for simulation of wheel-rail contact patch area and contact stress, wheel-rail lateral force and contact position in the rail. Results show that for curve radius below 800m, the designed 75kg/m rail profiles which lower profile from rail center to gauge side can make the acreage area of contact patch over 100 mm^2 and both contact stress and lateral force smaller when the maximum lower amount of 0.1-0.6mm, the maximum lowering position of 26-30 mm, the start point position 5-8mm away from rail center.

Keywords: Rail; Rail profile; Rolling contact fatigue; Cubic interpolation spline curve.

1 Introduction

The life of curve rail of the heavy-haul railway is seriously affected by the rolling contact fatigue cracks, especially the head checks (HC) in rail shoulder and corner (Zhou, 2014). Ameliorate the rail profile of fatigue cracks prone areas to realize a anti-HC profile was important methods to improve the wheel-rail relationship and prolong the life of HC initiation and propagation in rails. (Olofsson, 2002).

Based on the research by Magel (Magel, 2002), Persson (Persson, 2004), Dollevoet (Dollevoet, 2010) etc., the design method for lower rail profile by cubic interpolation spline curve (Wang T.Y,2014)was presented through field observations of curve rail of a heavy-haul railway in which HCs occurred frequently (Hamid,2008). The multi-body dynamics model of vehicle-track was used to analyze the effect of anti-HC profile and confirm the range of control parameters of the cubic interpolation spline curve (Chongyi,2010).

2 Characteristics of rail RCF crack

From the analysis of static wheel-rail contact on 500 m radius curve of the heavy-haul railway in China it shows that the contact patch of the new wheel -new rail and worn wheel -new rail located at a distance about 10-25mm and 9-31mm away from rail center. The distribution scope was both in gauge shoulder - gauge corner area. In-situ observation found that after about 10 million gross tonnages (MGT), the RCF cracks had initiated and propagated. They mainly distributed in the range 12-33 mm away from the rail center, and shown 20~30 degrees with the lateral direction of rail (Zhou, 2014).

3 The design method of rail anti-HC profile by using cubic interpolation spline curve

The cubic interpolating spline curve for designing anti-HC rail profile should ensure the veracity of lowering rail profile in fatigue crack prone area. Moreover, the designed profile should be continuous, smooth and tangent to the rest parts of the existing rail profile.

Figure 1 show control points and control parameters of the designed rail anti-HC profile. There were n+1 control points, (x_0, y_0), $\ldots$, (x_n, y_n), in the designed profile. The starting point was (x_0, y_0) while the terminal point was(x_n, y_n). The parameters for rail profile optimization are as follows:

(a) The start point position: horizontal distance between the start point to origin coordinate.

(b) The maximum lowering amount “d”: vertical distance between the control point P_m which was the maximum lowering point at the new rail and the same abscissa point at the standard rail.

(c) The maximum lowering position “L”: horizontal distance from P_m to the rail crown center.

(d) The lowering mode of the profile on each side of the maximum lowering point: it required that on the left maximum lowering position (towards rail center), the profile between control points should change slowly. On the right side of the maximum lowering position (towards rail gauge side), the profile between control points should change steeply.

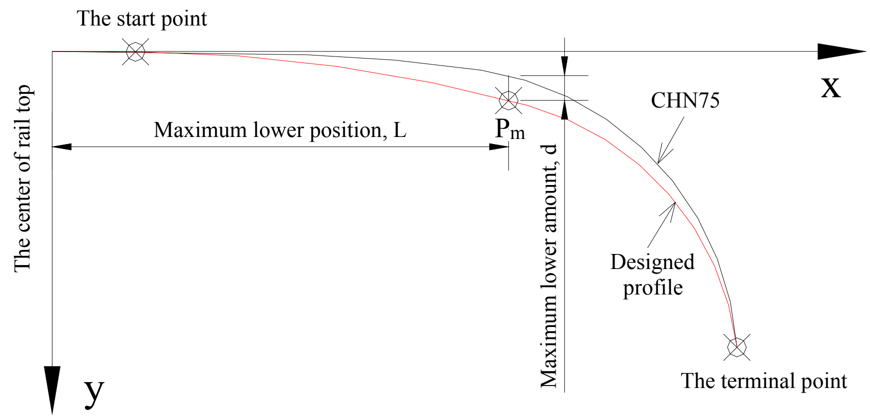

Figure 1.Control points and control parameters of the designed anti-HC rail profile

3.1 The determination of control parameters

(1) The design scope: regarding a point between the coordinate origin and the control point P_m as the start point, the terminal point was located at 16mm below rail crown which on the guage side.

(2) The control point P_m: the position of the maximum lowering point was at 26mm from the rail center.

(3) "d" is change from 0.1mm to 1.5mm with 0.1mm interval in this paper.

(4) The lower mode on each side of P_m: to guarantee the smoothness of rail profile, it should be a continuously gradual changing process of the profile changing from 0 to "d" and then to 0. The lowering function defined as the exponential function of the ratio between the abscissa of each control point and L, as follows:

$$\begin{cases} D_1(x) = \mathrm{d} \times (x/L)^Q, x < L, & Q_1 \quad (a) \\ D_2(x) = \mathrm{d} \times [(36 - x)/(36 - L)]^Q, x > L, & Q_2 \quad (b) \end{cases} \quad (1)$$

Where Q_1 equaled 1,2,3,4 and Q_2 equaled 1,1/2,1/3,1/4 to realize the gentle change of the profile from the start point to P_m and the fast change of the profile from P_m to the end point which can be seen from Figure 1 respectively.

In this way it satisfied that the values of ordinate change along with the increasing abscissa respectively smaller or larger on two sides of the control point.

(4) The density of control point: 1mm interval from 0mm to 34mm, 0.25mm interval from 34mm to 36mm (the horizontal ordinate of the end point in the rail profile).

3.2 Curve equation between control points

The equation between the two adjacent points (Point i and i+1) was derivated by the cubic spline interpolation curve to smooth the designed profile as follows:

$$y = F(x) = y_i + C_{i,1}(x_{i+1} - x_i) + C_{i,2}(x_{i+1} - x_i)^2 + C_{i,3}(x_{i+1} - x_i)^3 \quad (2)$$

Where x and y were the abscissa and ordinate of the control points in Figure 1, $C_{i,1}$,$C_{i,2}$, $C_{i,3}$, were the coefficients.

The second order derivative of the Equation (2) was $S_i = F(\ddot{x_i})$. The relationships between y and its first and second order derivatives were as follows respectively:

$$F'(x) = \frac{-(x_i - x)^2}{2h_i} S_{i-1} + \frac{(x - x_{i-1})^2}{2h_i} S_i - \frac{h_i}{6}(S_i - S_{i-1}) + \frac{y_i - y_{i-1}}{h_i} \tag{3}$$

$$F(x) = \frac{-(x - x_i)^3}{6h_i} S_{i-1} + \frac{(x - x_{i-1})^3}{6h_i} S_i + (y_{i-1} - \frac{h_i^2}{6} S_{i-1}) \frac{x_i - x}{h_i} + (y_i - \frac{h_i^2}{6} S_i) \frac{x - x_{i-1}}{h_i} \tag{4}$$

Since the first derivative of $F(x)$ is continuous as $F'(x_i - 0) = F'(x_i + 0)$, when the distance between the two adjacent points was the same, that is to say, $h_i = h_{i+1} = h$, the equation (3) can derived as:

$$S_{i-1} + 4S_i + S_{i+1} = \frac{6(y_{i+1} + y_{i-1} - 2y_i)}{h^2} \tag{5}$$

Then, the coefficients in Equation (2) can be definited as:

$$\begin{cases} C_{i,1} = \dfrac{y_{i+1} - y_i}{h_{i+1}} - \dfrac{2S_i + S_{i+1}}{6} h_{i+1} \\ C_{i,2} = \dfrac{S_i}{2} \\ C_{i,3} = \dfrac{S_{i+1} - S_i}{6h_{i+1}} \end{cases} \tag{6}$$

3.3 The tangent and continuous between starting/end point and the rest of the curve

In order to guarantee the starting/terminal point (x_0/x_n) to be tangency with the endpoint of existing profile, the first derivative of starting/end point should be succession. The boundary conditions can be available from (2) When $x = x_i$ and $x = x_0$:

$$\begin{bmatrix} 2 & 1 & & & \\ \mu_1 & 2 & \lambda_1 & & \\ & \vdots & \vdots & & \\ & & \mu_{n-1} & 2 & \lambda_{n-1} \\ & & & 1 & 2 \end{bmatrix} \begin{bmatrix} S_0 \\ S_1 \\ \vdots \\ S_{n-1} \\ S_n \end{bmatrix} = 6 \begin{bmatrix} M(x_0, x_0, x_1) \\ M(x_0, x_1, x_2) \\ \vdots \\ M(x_{n-2}, x_{n-1}, x_n) \\ M(x_{n-1}, x_n, x_n) \end{bmatrix} \quad (7)$$

Where the distance between the two adjacent points was the same, $u_i = \lambda_i = 1/2$, $i = 1, \cdots n-1$.

The whole cubic interpolation spline curve just to be confirmed (Chongyi, 2010).

4 Simulated analyses on rail anti-HC profile

A vehicle-track model was established by Simpack, to analyze the effect of the designed anti-HC rail profile. The model parameters: C70 open wagon, with axle load of 23t, worn-type wheel, running speed of 60km/h, friction coefficient between wheel and rail of 0.3, and track with a curve of 800m radius, super elevation of 90mm, and rail inclination of 1:40, both the high and low rails applied the designed profiles that L=26mm. The track geometry irregularity was not considered.

4.1 Wheel-rail contact position on rail surface

The wheel-rail contact position caused by the designed rail profiles with different lowering amount as the high rails was shown in the Figure 2:

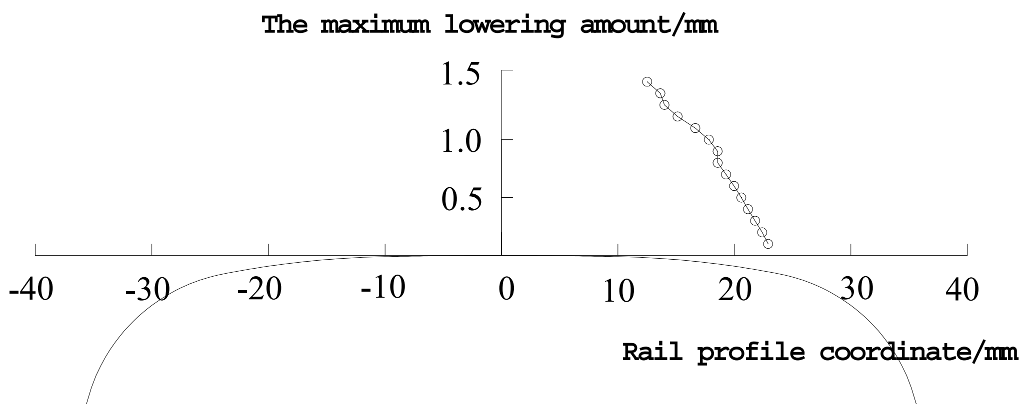

Figure 2.Wheel-rail contact position changes with variation of the maximum lowering amount

From Figure 2, it can be observed that the contact position on the high rail gradually moved from 23mm to 15mm away from the rail center. So we could conclude that the more of the maximum lowering amount, the closer contact point is to rail center.

4.2 The acreage of contact patch

Figure 3 shows variation of contact patch on the high rail by the designed rail profiles with different start point locations and different maximum lowering amount:

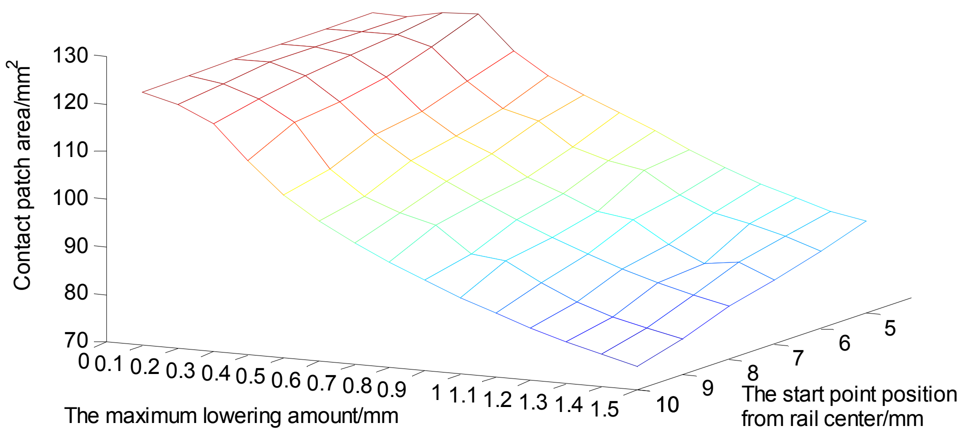

Figure 3.Contact patch on the high rail

It can be seen from Figure 3 that the acreage area of contact patch was over 100 mm^2 when the designed rail profiles with the maximum lowering amount of 0.1-0.6mm, the start point position was 5-8mm away from rail center. At this situation, the wheel/rail contact stress was about 1.5-1.9Gpa. When the start point was 5mm and the maximum lowering amount was 0.4mm, it achieved the maximum area of contact patch. So the acreage area of contact patch decreased when the maximum lowering increased and the start point kept away from rail center.

4.3 The wheel-rail force

The wheel-rail lateral force varied as different lowering amount, seeing in Figure 4:

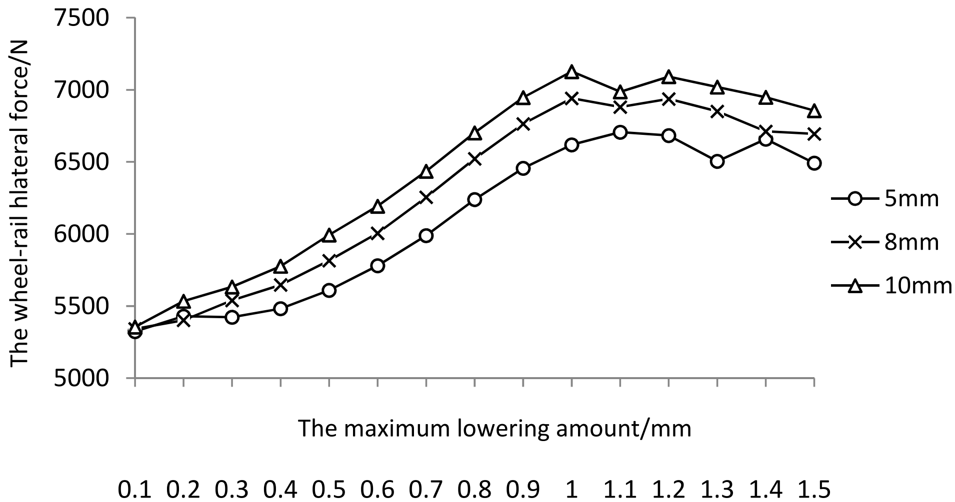

Figure 4.Wheel-rail lateral force changes as variation of the maximum lowering amount

It can be seen from Figure 4, although the start point location was different, the wheel/-rail lateral force increased with the increasing of the maximum lowering amount from 0.1-0.9mm. After the maximum lowering amount was over 1.0mm, the development trend of the wheel/rail lateral force got slowly. Therefore it was the maximum lowering amount “d” of 0.1~0.6mm that the lateral force kept in lower situation of 5.3 kN-6.3kN.

In addition, the effect of the designed rail profile with different maximum lowering amounts on the wheel-rail vertical force was small.

5 Conclusions

(1) Based on the cubic interpolation spline curve, the special designed anti-HC rail profile was realized. The change of rail profile was decided by four control parameters, namely, the start point, the position of the maximum lowering point in the profile, the maximum lowering amount and the lower mode of the profile on each side of the maximum lowering point.

(2) The designed profile could make the wheel/rail contact point move to rail center and the more of the maximum lowering amount, the closer contact point is to rail center.

(3) The special designed anti-HC rail profile can make the acreage area of contact patch over 100 mm^2 and both contact stress and lateral force smaller when the maximum lower amount of 0.1-0.6mm, the maximum lowering position of 26-30 mm, the start point position 5-8mm away from rail center.

[2]Department of Road and Bridge Engineering, Shanxi Conservancy Technical College, Yuncheng. E-mail: ben7731262ben@163.com

Abstract: For the problem what particle size and dosage of crumb rubber powder is best for road concrete, 24 groups of rubber powder concrete were prepared using four kinds of particle size (60,80,100 and 120 meshes) and 6 kinds of dosage (0%, 10%, 15%, 20%, 25% and 30%). And its pavement performance was measured, such as, strength, toughness, crack resistance, frost resistance and permeability. The results showed that: strength of crumb rubber powder concrete decreased with dosage and fineness degree of rubber powder increasing, and it had a higher sensitivity for dosage. Add crumb rubber powder into concrete has a positive effect to improve toughness, crack resistance and permeability of concrete, and the effect can be more obvious when the dosage increasing. However, the ability of frost resistance increased at first, and then decreased when the dosage increasing. The optimum dosage for 60, 80, 100 and 120 meshes rubber powder was 15%.

Keywords: Road engineering; Crumb rubber powder; Pavement performance.

1 Introduction

Crumb rubber powder modified concrete made with discarded tires not only can reduce pollution, is also benefit to development circular economy. Because of a low modulus, good toughness and other characteristics, it has been a major focus of the current concrete science. The strength of rubber powder modified concrete decreased with increasing of rubber powder dosage, but the deformation capacity increased (Zhao Li-yan and Xu Jing, 2009. Li Guang-yu, 2008. PAN Zuan-feng, 2010). A detailed study on cracking, impact resistance, abrasion resistance and permeability and other road performance of rubber powder modified concrete was done. It showed that although added rubber powder into concrete reduced the strength, an appropriate dosage and fineness had benefit to improve the durability (Meng Yun-fang and Guo Can-xian, 2006. ZHOU Lu, 1994.)

In view of this, in order to study the pavement performance of recycled tire crumb rubber powder modified concrete, 24 groups concrete specimen were prepared. The fineness of crumb rubber powder in it was 60, 80, 100 and 120 meshes, and the dosage was 0%, 10%, 15%, 20%, 25% and 30%. Then, a series of experimental was carried out to research the effect law that fineness and dosage of crumb rubber powder to the performance of concrete, such as, strength, toughness, crack resistance, frost resistance and permeability.

2 Raw Material And Test Methods

2.1 Raw Materials

P.O 42.5 cement in this test was made in Witton in Yuncheng. The physical-mechanical properties were shown in Table 1. It meets the requirements in the specification that GB175-2007 "Common Portland Cement".

The fineness of fine aggregate was 2.8 and density was 2.70 g/cm^3.

The density of coarse aggregate was 2.77 g/cm^3, with well graded.

The water in this test was Ordinary tap water.

There were four kinds of crumb rubber powder with different fineness was selected in this test, such as, 60, 80, 100 and 120 meshes. The apparent density was about 1.01 ~ 1.04g/cm^3, and the specific surface area was about 0.47 ~0.55kg/m^2.

Table 1. Physical-mechanical properties of cement

fineness /（m^2/kg）	Setting time /min		Compressive strength /MPa		Flexural strength/MPa		Stability
	Initial setting	Final setting	3d	28d	3d	28d	
350	180	275	30.6	52.8	6.1	9.0	Qualified

2.2 Test Methods

In order to accurately measure the effect of crumb rubber powder fineness and dosage to the performance of cement concrete, the test used univariate analysis method to avoid mutual interference between multiple factors. First, prepare 24 groups concrete specimen using four kinds of crumb rubber powder based on the mix proportion was shown in Table 2. The fineness of the four kinds of crumb rubber powder was 60, 80, 100 and 100 meshes. The dosage of every crumb rubber powder was 0%, 10%, 15%, 20%, 25% and 30%, and it replaced with equal volume fine aggregate in concrete. In order to make the workability of concrete similar, water reducer was added into it to guarantee all the slump of fresh concrete was between 30 to 50mm. Then, carry out the test such as, strength, toughness, crack resistance, frost resistance and permeability.

Table 2. Mix Proportion

Cement / kg	Water / kg	Fine aggregate / kg	water reducer /%	Corase aggregate/ kg		
				0.5cm-1cm	0.5cm-1cm	0.5cm-1cm
370	155	693	0.3～1	246	246	246

In the test, compressive strength, flexural strength and frost resistance was carried out in accordance with the specification JTG E30-2005. The permeability test carried out in accordance with the specification ASTM C1202. The crack resistance test carried out in accordance with the specification GB T50082-2009. The toughness test carried out in accordance with the specification ASTM Cl018.

To facilitate comparison of test results, 24 group of concrete specimen were numbered with following rules. The fineness 60, 80, 100 and 120 meshes was labeled A, B, C and D. Meanwhile, the dosage 0%, 10%, 15%, 20%, 25% and 30% was labeled 0, 10, 15, 20, 25 and 30. So, for 80 meshes crumb rubber powder concrete, when the dosage was 10%, the specimen label was B-10.

3 Test Results And Analysis

3.1 Compressive strength of crumb rubber modified concrete

The 28d compressive strength of concrete specimen with different crumb rubber powder fineness, dosage was shown in Figure 1. Overall, the compressive strength decreased with the crumb rubber powder dosage and fineness increasing. But, it had a higher sensitivity for crumb rubber powder dosage. When dosage of crumb rubber powder was equal, the greater the fineness, the lower the compressive strength; and the effect continued to enlarge when increasing dosage. When the dosage was 15%, the compressive strength of concrete used 120 meshes was lower 19.3% than 60 meshes. When the dosage was 30%, this value was 46.4%.

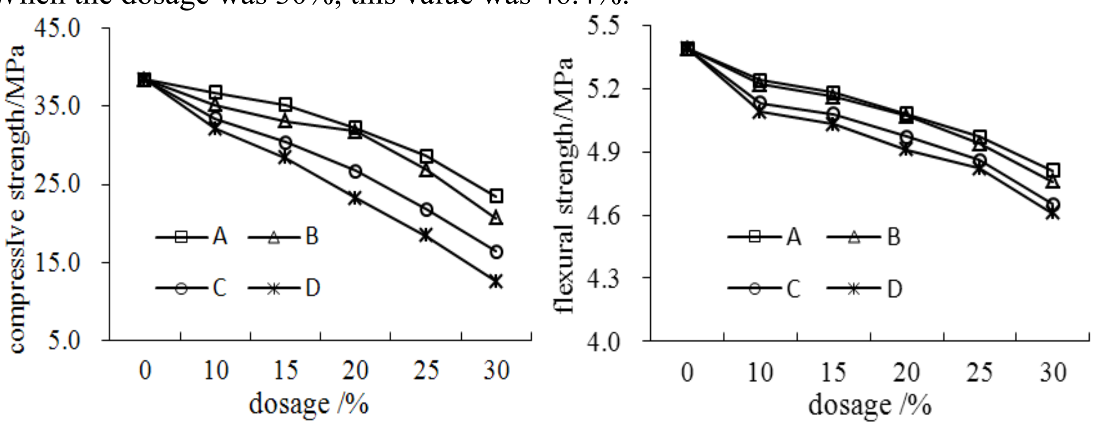

Figure 1. Effect of rubber powder on compressive and flexural tensile strength

In terms of the downward trend of compressive strength, when the dosage was less than 15%, decreased rate was slower. But, when the dosage was more than 15%, the decreased rate increased significantly.

3.2 Flexural tensile strength of crumb rubber modified concrete

The 28d flexural strength of concrete specimen with different crumb rubber powder fineness, dosage was shown in Figure 1. The change law was similar with compressive strength. The flexural strength decreased with the rubber powder dosage and fineness increasing. It had a higher sensitivity for rubber powder dosage. The difference was that the effect of rubber powder on flexural strength of concrete was not significant as compressive strength. When the rubber powder dosage was 30%, the flexural strength of specimen decreased by about 5% to 13%, but, the compressive strength decreased by 30% to 70%.

Furthermore, with increasing rubber powder dosage, the ability resistance to deformation of concrete increased. When the dosage was 30%, the vertical displacement of specimens that used 100 meshes increased about 22%.

3.3 Toughness of crumb rubber modified concrete

For general rubber concrete, the specimen had been destroyed before its vertical deflection has been reached first crack point. Therefore, the toughness index takes the area ratio that the stress-strain curves when the specimen completely fracture and reached first crack point.

The toughness index of concrete specimen with different rubber powder fineness, dosage was shown in Table 3. When the fineness was equal, the toughness index of concrete specimen linearly increased with the increase of rubber powder dosage. When the dosage was 30%, the toughness index of A-30 increased by 28.6%. Meanwhile, D-30 increased by 38.1 %. When the dosage was equal, increasing the fineness can improve toughness, especially when the dosage was small. When the dosage is bigger than 15%, improving toughness by increasing dosage was not effective.

Table 3. Effect of rubber powder on toughness index

Crumb rubber powder fineness	Toughness index			
	A	B	C	D
0	1.26	1.26	1.26	1.26
10	1.31	1.32	1.36	1.34
15	1.38	1.41	1.45	1.41
20	1.46	1.49	1.56	1.52
25	1.53	1.58	1.64	1.64
30	1.62	1.66	1.71	1.74

3.4 Cracking resistance of crumb rubber modified concrete

Effect of crumb rubber powder fineness and dosage on the total cracks area in unit area and the number of cracks in unit area of concrete was shown in Figure 2.

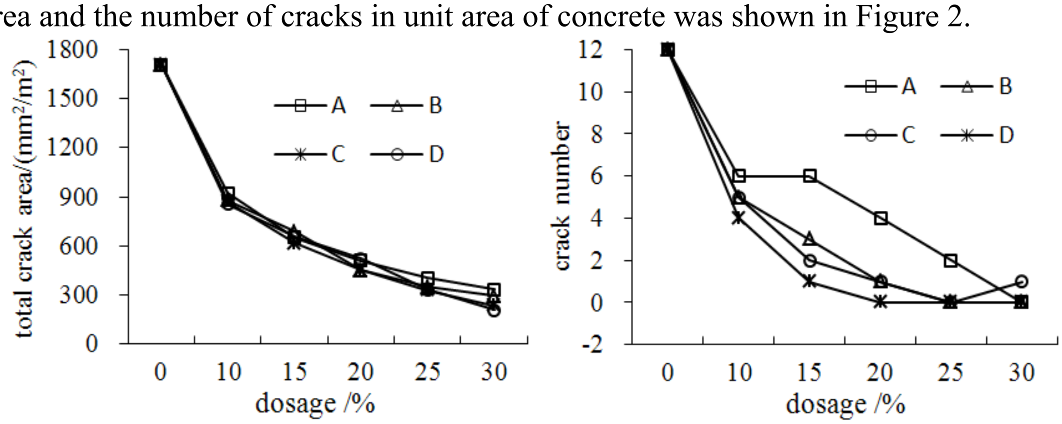

Figure 2. Effect of rubber powder on concrete cracking

Added crumb rubber powder into concrete was benefit to inhibit cracks happened. The total cracks area in unit area and the number of cracks in unit area of concrete specimen declined when the rubber powder dosage increased. When the dosage was 15%, the number of cracks was only 20to 25 present of concrete not use rudder powder. The fineness of rubber powder had little effect on the total cracking area in unit area of the concrete. Even if increased the fineness from 60 meshed to 120 meshed, the total cracking area was basically the same. However, the number of cracks reduced significantly when the fineness increasing. So, when the rubber powder dosage was equal, increasing the fineness can reduce the numbers of cracks.

3.5 Frost resistance of crumb rubber modified concrete

In the test, the freeze-thaw cycles when loss rate of flexural strength reached 40% was called extreme frost resistance cycles. And it was take to evaluate the frost resistance ability of crumb rubber powder concrete. Effect of rubber powder fineness and dosage on extreme frost resistance cycles of concrete was shown in Figure 3.

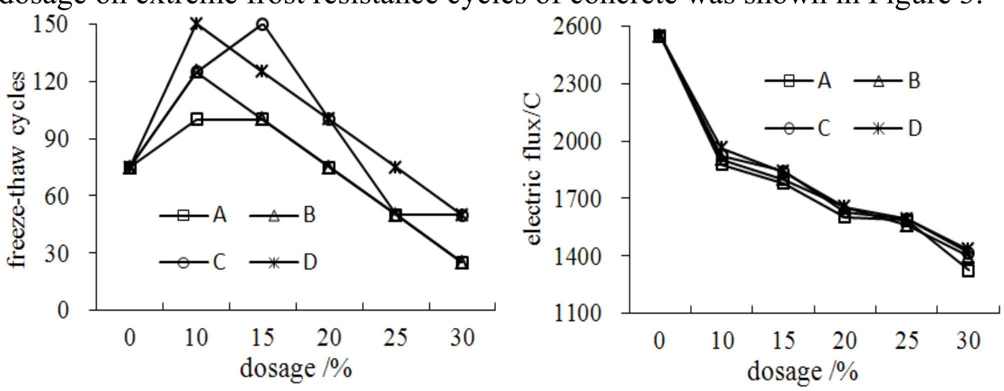

Figure 3. Frost resistance ability and permeability

When the fineness of rubber powder was equal, the extreme frost resistance number presented with increasing trend and then decreased. When the dosage was 15%, the frost resistance ability improved more than 70%. When the dosage was greater than 15%, the frost resistance ability began to decline rapidly. When the dosage was greater than 20%, the frost resistance ability of concrete bad than concrete not used rubber powder. In addition, when the dosage was equal, the frost resistance ability of concrete increased with the fineness increased.

3.6 Permeability of crumb rubber powder modified concrete

Effect of crumb rubber powder fineness and dosage on concrete permeability was shown in Figure 3. Added rubber powder into concrete had significant effect on its impermeability. The impermeability ability of concrete increased with dosage of rubber powder increasing. When the dosage was equal, the impermeability of concrete was slow-growth with the fineness increasing. In accordance with the specification, when the rubber powder dosage was bigger than 15%, the impermeability of all concrete can meet the actual needs.

4 CONCLUSIONS

(1) The compressive strength and flexural strength of crumb rubber powder concrete decreased with dosage and fineness degree of rubber powder increasing, and it had a higher sensitivity for dosage.

(2) Add crumb rubber powder into concrete has a positive effect to improve toughness, crack resistance and impermeability of concrete, and the effect can be more obvious when the dosage increasing. However, the ability of frost resistance increased at first, and then decreased when the dosage increasing.

(3) The optimum dosage for 60, 80, 100 and 120 meshes rubber powder was 15%. In the vicinity of dosage, except frost resistance ability, effect of fineness on other properties of concrete can be ignored.

Abstract: Lightweight aggregate concrete has been widely used due to its excellent performance, such as the light weight, the high strength and the thermal insulation. Ceramsite sand is a kind of artificial fine lightweight aggregate, which could be used as an effective internal curing material for concrete with low water-binder ratio. In this paper, the mechanical properties of concrete with the water to cement ratio of 0.3, 0.35 and 0.4, in which the natural sand was replaced by ceramsite sand at 20%, 40%, 60%, 80% and 100% in volume were studied. The hydration degree of cement in the paste around ceramsite sand particles was also tested. The research results showed that with the increasing of the ceramsite sand content, the compressive strength, the flexural strength and the static elastic modulus of concrete decreased. Ceramsite sand promoted the hydration degree of cement at the interface area, and this effect became more obvious for the concrete with lower water to cement ratio.
Keywords: Ceramsite sand; Concrete; Mechanical property.

1 Introduction

Cement concrete is an important building material widely used in constructions in nowadays. With the history of over a century, the performances of concrete have been improved a lot with the progress of technology, and concrete has been developing towards high quality and high strength. Concrete with low water to cement ratio is more likely to be used in order to improve the concrete strength, leading to the compact structure of concrete. Moreover, the cement particles used in concrete are getting smaller by effective grinding, resulting in the accelerated hydration of the cement. Therefore, the self-desiccation is very common for modern cement concrete, and the risk of cracking of concrete at early ages rises. And then the reliability of structures decreases significantly within the service life.

Ceramsite sand is a kind of artificial porous material with the ability to absorb and release water, which could be used as the fine lightweight aggregates of concrete. When pre-wetted ceramsite sand is mixed into concrete, the water contained in pre-wetted ceramsite sand could be gradually released in the process of hydration of cement, acting as self-curing for concrete. Thus, the cement hydration degree increased and the microhardness at the interface area is improved. The cracking resistance of concrete at early ages is also improved effectively. Meanwhile, the compaction degree at the interface between ceramsite sand and cement increases and the cracking risk under stress at the interface area is reduced, so the impermeability of concrete can be effectively improved. In this work, the effect of ceramsite sand on the mechanical properties and the hydration degree of cement in the concrete with different water to cement ratio were studied.

2 Materials and test program

2.1 Materials

A typical Chinese type P·O 42.5 cement made by Harbin Cement Plant was used in this investigation, and its physical and mechanical properties are shown in Table 1. Locally available natural river sand was used as the ordinary fine aggregate, which has the continuous gradation, the fineness modulus of the 3.0, the apparent density of 2620kg/m^3 and the stacking density of 1500kg/m^3. Shale ceramsite sand produced by Heilongjiang Hegang was used as the lightweight fine aggregate (LWAs). Table 2 provides the details of the properties of LWAs. Crushed basalt with the grain size of 5~26.5 mm was used as coarse aggregates. Polycarboxylate based superplasticizer with a water reducing ratio of 30%, which was produced by Qiangshi Concrete Admixtures Company, was used as the water reducing agent. Tap water in Harbin area was used in the tests.

Table 1. Properties of cement

Name	Water requirement of normal consistency (%)	Setting time (min)		Flexural strength (MPa)		Compressive strength (MPa)	
		Initial set	Final set	3d	28d	3d	28d
P·O 42.5	30	190	250	4.2	6.5	21.7	43.2

Table 2. Properties of ceramsite sand

Particle size (mm)	Bulk density (kg/m^3)	Apparent density (kg/m^3)	Water absorption (%)	
			1h	24h
0~2.36	625	1035	13.0	20.2
2.36~4.75	435	725	11.2	16.4

2.2 Mix proportions and test program

The control concrete mixtures with the water to cement ratio of 0.30, 0.35 and 0.40 were designed, as shown in table 3. On the basis of the control mixtures, the 20%, 40%, 60%, 80% and 100% ordinary fine aggregates in volume were replaced by ceramic sand respectively in each group. The mechanical properties, including the compressive strength, the flexural strength and the static modulus of elasticity were tested on concrete specimen according to the standard test methods. The microhardness of cement mortar at the interface area and the cement hydration degree were also measured. Hardened cement paste was extracted near the interface area by removing the coarse aggregate and the ceramic sand in crushed concrete, and then the paste was put into absolute ethyl alcohol to stop the hydration process. The chemical bond water content of the paste was tested after been ground (particle size <80μm) and drying.

Table 3. Proportions of concrete mixtures

No.	Ceramsite sand content (%)	*W/C*	Cement (kg/m^3)	Water (kg/m^3)	Ordinary sand (kg/m^3)	Ceramsite sand (kg/m^3)	Coarse aggregate (kg/m^3)	Water reducer (%)

C6	100	0.40	486	194	0	628	1117	0.4

3 Results and analysis

3.1 Cement hydration degree

The mechanical properties of concrete are affected by the microstructure, which is mainly related to the cement hydration process and the structure of interface area. In addition, the structure of concrete containing ceramsite sand is more complex. The hydration degree of the cement paste surrounding the lightweight aggregate and the interface area structure would be greatly influenced by the water desorption of the pre-wetted ceramsite sand in concrete.

The chemical bond water content of cement in hardened concrete contained 0%, 20% and 40% ceramsite sand at 28d was tested, and the results are shown in Figure 1. The results showed that with the increasing of the water to cement ratio, the chemically combined water content of the hardened paste around aggregates gradually increased, no matter the ceramsite sand was added or not. For example, the chemical bond water content in the 28d control concrete with the water cement ratio of 0.30, 0.35 and 0.40 were 12.03%, 12.85% and 14.27%, respectively.

Furthermore, when the ceramic sand was added, with the increasing of the content of ceramsite sand, the chemical bond water content of the hardened cement paste also increased. The increasing extent of concrete with lower water to cement ratio was greater than that of concrete with higher water to cement ratio. At the content of ceramsite sand of 40%, the chemical bond water content of concrete with the water cement ratio of 0.30, 0.30 and 0.40 was increased by 24.4%, 20.7% and 15.3% respectively, compared with the control concrete. Therefore, the hydration degree of cement could be significantly improved with the addition of pre-wetted ceramsite sand.

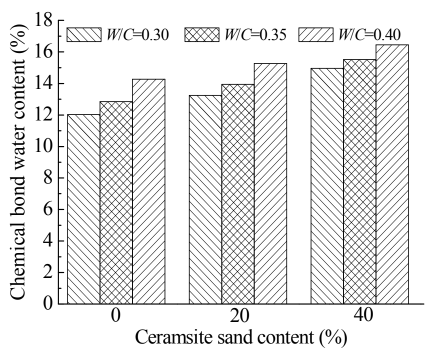

Figure 1. Chemical bond water of harden cement paste in concrete with ceramsite sand

3.2 Mechanical behaviors

3.2.1 Compressive strength

The mechanical properties of concrete were influenced by the addition of the pre-wetted ceramsite sand, along with the hydration degree of cement. The test results of the compressive strength were shown in Figure 2. The results showed that the compressive strength of concrete decreased with the increasing of the ceramsite sand content. For example, at the ceramsite sand content of 40%, the compressive strength of the concrete with the water to cement ratio of 0.30, 0.35 and 0.40 at 28d was 95.3%, 92.3% and 92.2% of the control concrete respectively. However, the ceramsite sand had a more obvious reducing effect on the compressive strength of concrete with higher water to cement ratio.

In addition, with the growth of the age, the increasing rate of the compressive strength of concrete with lower water cement ratio was higher. For instance, for the concrete mixtures A2~A6, of which the water to cement ratio was 0.3, the compressive strength at 28d was increased by 10.9%, 12.9%, 14.0%, 22.1% and 25.3%, respectively, compared to the compressive strength at 7d. For the mixtures with water to cement ratio of 0.40, C2~C6, the compressive strength at 28d was increased by 8.5%, 6.5%, 9.4%, 9.1% and 13.8% from 7d.

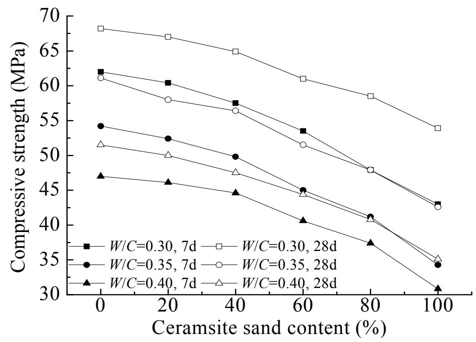

Figure 2. Compressive strength of concrete with ceramsite sand

3.2.2 Flexural strength

The flexural strength of concrete with and without ceramsite sand was shown in Figure 3. Similarly, the flexural strength decreased with the increasing of the ceramsite sand content, while the reducing rate was lower than that of the compressive strength. At the ceramsite sand content of 40%, the flexural strength of concrete with the water to cement ratio of 0.3, 0.35 and 0.4 at 28d was 91.3%, 90.5% and 88.2% of the control concrete, respectively. With the growth of the age, the increasing rate of the flexural strength of the concrete with lower water to cement ratio was greater. The flexural strength of each test group with water to cement ratio of 0.3 at 28d was increased by more than 20% compared to that at 7d.

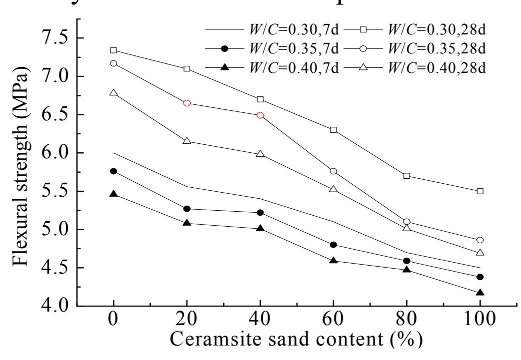

Figure 3. Flexural strength of concrete with ceramsite sand

3.2.3 Elasticity modulus

The results of the static elasticity modulus of concrete with the water to cement ratio of 0.30 at 7d and 28d are shown in Figure 4. The static elasticity modulus of concrete decreased with the increasing of the ceramsite sand content. At the ceramsite sand content of 80% and 100%, the static elasticity modulus of concrete was close. The static elasticity modulus of concrete with the ceramsite sand content of 100% at 7d was 73.4% of that of control concrete, and 82.8% at 28d.

The lower elasticity modulus of the ceramsite sand than that of the ordinary sand resulted in the lower elasticity modulus of LWA concrete. However, when the ceramsite sand content increased, the hydration degree of the cement was increased due to the self-curing effect of the ceramsite sand and the structure of the hardened cement paste tended to be compact. The final static elasticity modulus of the concrete was increased as a result of the combined two actions.

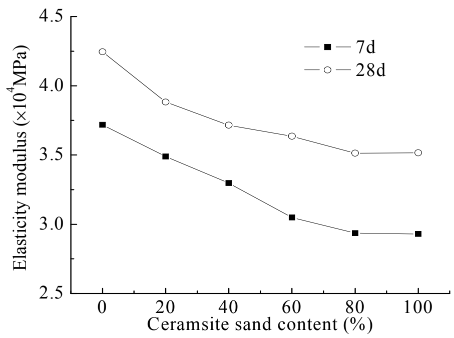

Figure 4. Static elasticity modulus of concrete with ceramsite sand

4 Conclusions

The hydration degree of the cement at the interface area and the mechanical properties of the concrete with ceramsite sand were studied. The following conclusions can be drawn.

The ceramsite sand promoted the hydration degree of the cement at the interface area, and this effect was more obvious for the concrete with lower water to cement ratio. At the ceramsite sand content of 40%, for concrete with the water cement ratio of 0.30, 0.35, 0.40, the chemically combined water content increased by 24.4%, 20.7% and 15.3% respectively compared with the control concrete at 28d.

The compressive strength and the flexural strength of concrete decreased when the ceramsite sand was added. But when the ceramsite sand content was lower than 40%, the strength reduced less than 12% compared with the control group.

The static elasticity modulus of concrete containing ceramsite sand decreased as well. For concrete with the water cement ratio of 0.30, the static elasticity modulus of concrete with 100% ceramsite sand was 73.4% and 82.8% of that of the control group at 7d and 28d, respectively.

Influence of Heavy Axles on the Dynamic Response of the Existing Railway Ballast Track under Freight Vehicle Running

Tianhang Long; Xinwen Yang; and Songliang Lian

Key Laboratory of Road and Traific Engineering, Ministry of Education, Tongji University, Shanghai 201804. E-mail: lth19910309@163.com

Abstract: In order to relief railway transportation pressure in China, the load-raising reform of existing railway lines is paid much more attention. In load-raising reform of existing railway lines process, the most obvious improvement is the increase of vehicle axle load. Using the theory of wheel-track dynamics, The vertical dynamic model for the ballast rail track and heavy haul train interaction could be built. In this model, the heavy haul train is regarded as a subsystem with 10 degrees of freedom, and the ballast track structure is built using finite element method. The two subsystems are coupled using via non-linear Hertz contact mechanism considering the influence caused by track irregularity. This paper analyzes the dynamic response between train and track using the combination method of new rapid explicit integration method and Newmark integration method. And the dynamic response of existing ballast track under heavy haul train of different loads which are 25t, 27t and 30t is specialized analyzed. During the analysis process, the dynamic performance indexes include: rate of wheel load reduction, wheel-rail vertical force, dynamic displacement of the ballast track, vibration acceleration of ballast track, and dynamic stress distribution of ballast track. The research results show that: 1). When heavy haul train are running on ballast track, every dynamic performance index is still within the national standards, and it can meet the dynamic requirement for running heavy haul train. 2). The trends of the dynamic displacement of the track structure under different loads are similar to one another. And the dynamic displacements of the rail under 27t-axle-load and 30t-axle-load increase 16% and 22% respectively, compared with the 25t-axle-load. 3). In general it can be concluded that the growth proportion of the dynamic stress of the track structure is similar to the dynamic displacement. And the dynamic stresses of the rail under 27t-axle-load and 30t-axle-load increase 15% and 22% respectively, compared with the 25t-axle-load.
Keywords: Load-raising reform of existing railway lines; Vehicle axle load; Theory of wheel-track dynamics; Dynamic response.

1 Introduction

In order to relief railway transportation pressure in China, the load-raising reform of existing railway lines is paid much more attention. In the process of the load-raising reform of existing railway lines, we have to recognize that, with the increase of vehicle axle load, the interaction between wheel and rail will get stronger, adding to the wear of vehicle and track, which will increase the pressure of maintenance of track structure and reduce the economic benefits of heavy transport.The development model of load-raising reform of existing railway lines were reviewed by scholars (Du Xusheng, 2013) from line facilities, rolling stock, station layout and train operation, etc. Relatively speaking, the theory of dynamic response for both aspects of the process line in heavy-duty yet to be perfected. Relatively speaking, the theory of the dynamic response in load-raising reform of existing railway lines is still evolving.

Based on the theory of wheel-track dynamics, the vertical dynamic model for the ballast rail track and the heavy haul train interaction is built. This paper analyzes the dynamic response between the train and the track using the combination method of new rapid explicit integration method and Newmark integration method. And the dynamic response of the existing ballast track under heavy haul train of different loads which are 25t, 27t and 30t is specialized analyzed.

2 Numeric Calculation Model

2.1 The Vehicle submodel

In order to study the heavy haul train, the vertical model for vehicle dynamics is deduced in the paper. The vehicle is considered as a multi-rigid-body system running on the track at a steady-state velocity in the longitudinal direction, regardless of the elastic deformation of the wagon body, bogies and wheel sets, etc. Compared with the traditional model of the cargo train, the model of the heavy haul train is built as secondary suspension structure. While the wagon body and bogies are allowed vertical displacement and in-plane rotation (bounce and pitch motions respectively) the wheelsets are allowed vertical displacement (bounce motion) only as shown in Figure 1. The wagon is thus represented by a 10 degree of freedom (DOF) system.

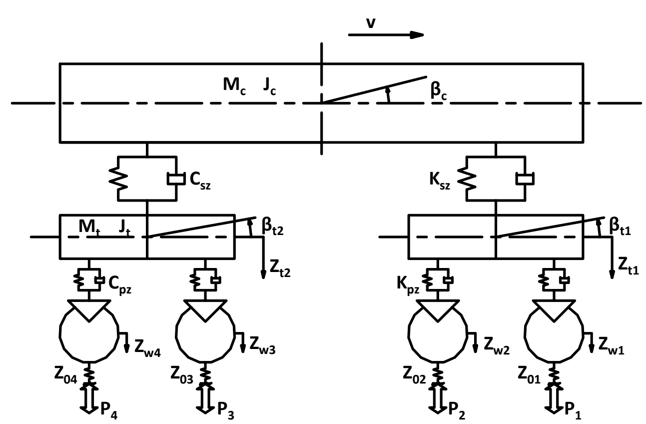

Figure 1. The vehicle submodel

The dynamic vibration equation of each component of the heavy haul freight vehicle system can be obtained from the reference (Zhai Wanming, 2007).

2.2 The track submodel

The track submodel consists of the rail, the pads, the fasteners, the sleepers, the ballast and the subgrade. In this paper, the rail is constructed using beam elements; the pads and fasteners are constructed using spring-damper elements; the sleepers and ballast are constructed using solid elements; the subgrade is constructed using spring-damper elements. The three-dimensional finite element model is shown in Figure 2.

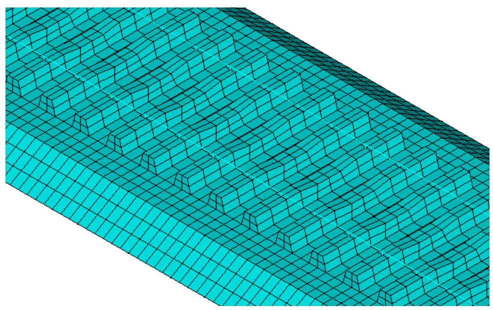

Figure 2. The finite element model

2.3 the numerical integration method

The dynamic equation of the vehicle-track coupling system can be given as

$$[M]\{\ddot{q}\} + [C]\{\dot{q}\} + [K]\{q\} = \{P\} \quad (1)$$

where $[M]$, $[C]$ and $[K]$ are the global mass and the damping and stiffness matrices of the vehicle-track coupling system, respectively; $\{P\}$ is the generalised load vector of coupling system; $\{q\}$ is the generalised displacement vector of the coupling system; $\{\dot{q}\}$ is the generalised velocity vector of the coupling system; and $\{\ddot{q}\}$ is the generalised acceleration vector of the system. Flow chart of the numerical solution of the vehicle and track systemis shown in Figure 3.

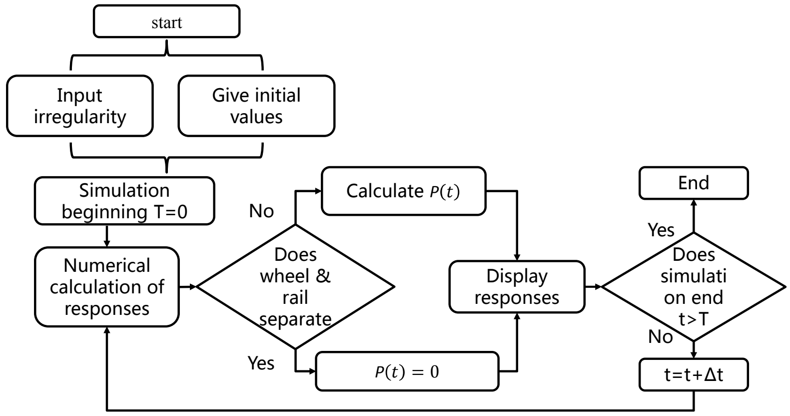

Figure 3. Flow chart of the numerical solution of the vehicle and track system

3 The Influence of Heavy Axles on the Dynamic Response of the Existing Railway Ballast Track under Freight Vehicle Running

3.1 Calculation Parameters of heavy haul trains and the Ballast Track

Calculation Parameters of heavy haul trains of 25t, 27t and 30t load refer to references (Zhai Wanming, 2007; Liu Xinli, 2013).

The elastic modulus, Poisson's ratio and Rail mass per meter of the rail are 2.11×10^5 Mpa, 0.3 and 60kg/m, respectively; the spacing, damp and vertical stiffness of the fasteners are 600mm, 75kN·s/m and 9×10^7 N/m, respectively; Ⅲ concrete sleepers is used, laid spacing 1760 / km.

The elastic modulus, density, Poisson's ratio and thickness of the ballast are 140Mpa, 2500kg/m^2, 0.27 and 0.35m, respectively.

The support stiffness of the subgrade is 180MPa/m, respectively.

3.2 The track irregularity

The harmonic excitation modal is taken as the wheel-rail excitation model in this paper, and the equation of which can be given as

$$Z_0(t) = \frac{1}{2} a \left(1 - cos \frac{2\pi v}{L} t\right) \left(0 \le t \le \frac{L}{v}\right) \quad (2)$$

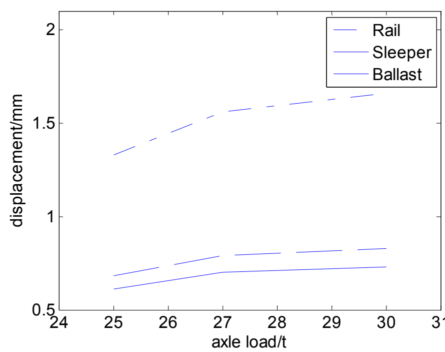
Where L is wavelength(L=1m in the paper) and a is wave hollow(a=0.7mm in the paper).

3.3 The analysis of the response of the wagon and track

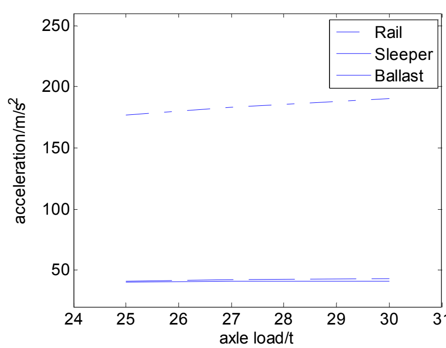
Under the premise of steady-state velocity, the dynamic responses of existing ballast track under heavy haul train of different loads is calculated, which are shown in Sheet 1 and Figure 4.

Table 1. The Dynamic response of the existing railway ballast track under haul vehicle of different loads running at 100km/h

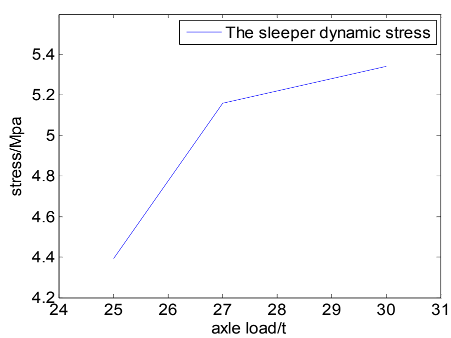
results	units	axle loads of vehicles		
		25t	27t	30t
The vertical displacement of the rail	mm	1.33	1.56	1.66
The vertical displacement of the sleeper	mm	0. 68	0. 79	0. 83
The vertical displacement of the ballast	mm	0. 61	0. 70	0. 73
The vertical acceleration of the rail	m/s^2	177.07	182.84	189.94
The vertical acceleration of the sleeper	m/s^2	41.12	42.50	42.76
The vertical acceleration of the ballast	m/s^2	40.38	40.76	40.93
The sleeper dynamic stress	Mpa	4.39	5.16	5.34
The ballast dynamic stress	Mpa	0.097	0.11	0.12
The Wheel/rail vertical force	kN	165.77	190.21	202.69
The rate of wheel load reduction	—	0.344	0.309	0.279



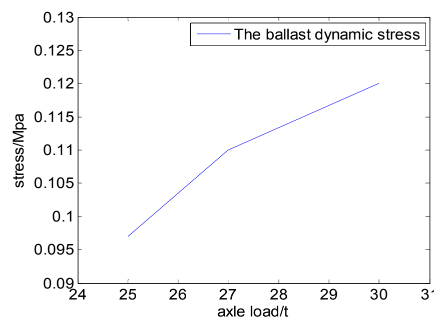
(a) The vertical displacement of the track



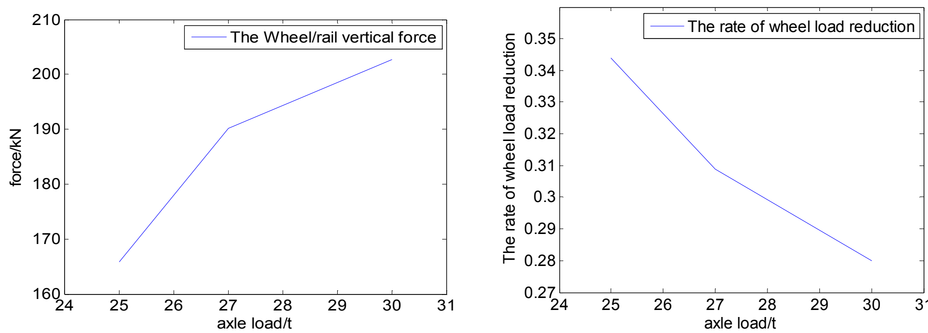
(b) The vertical acceleration of the track



(c) The sleeper dynamic stress



(d) The ballast dynamic stress



(e) The Wheel/rail vertical force (f) The rate of wheel load reduction

Figure 4. The Dynamic Response of the Existing Railway Ballast Track under Freight Vehicle of different loads Running at 100km/h

5 Conclusions

(1) As the vehicle axle load increases, The Wheel/rail vertical force Increases to 202.69kN from 165.77 kN, which is still within the national standards. The maximum of The rate of wheel load reduction is 0.344, 0.309, 0.279, respectively, which does not exceed the safety limit.

(2)As the vehicle axle load increases, every dynamic index of tracks shows a growing tendency. The change of displacement is rather more obvious. And the dynamic displacements of the rail under 27t-axle-load and 30t-axle-load increase 16% and 22% respectively, compared with the 25t-axle-load. The displacements of sleepers and ballasts are more gradual, and that's because the existence of fasteners' damp can make interaction force decays effectively. The change of acceleration is relatively unconspicuous.

(3)As the vehicle axle load increases, the press of tracks also shows a growing tendency. In general it can be concluded that the growth proportion of the dynamic stress of the track structure is similar to the dynamic displacement. And the dynamic stresses of the rail under 27t-axle-load and 30t-axle-load increase 15% and 22% respectively, compared with the 25t-axle-load.

Abstract: This study was conducted in-depth study by doing several more important road performances of asphalt rubber mixture through laboratory tests, firstly, comparing the relationship of the content of mineral powder and asphalt bitumen membrane thickness at different asphalt content, through film thickness to determine the range of gradation and asphalt content in laboratory tests, Grade 1 and grade 4 asphalt content 5.5%, 6.0% and 6.6% are set for the benchmark, then mixes adhesion, anti-damage and fatigue properties of the test are carried out in the established range, the study found that: With the addition of mineral powder, asphalt film thickness decreases, but the adhesion of Modified Cantabro testis influenced little by mineral powder added to the asphalt or not; whatever the grade adding 6.5% mineral powder or not, TSR values were greater than 80%,which meets regulatory requirements, but without mineral powder grade slightly better; fatigue properties of asphalt rubber mixture will reduced, when mineral powder added in, especially when the asphalt content is high.
Keywords: Mineral powder; Asphalt rubber mixture; Mixture; Performance.

1 Introduction

The controversy also exists in Chinese domestic asphalt rubber mixture gradation. Through laboratory test and on the premise of correspond voidage, this study conducted the test on water stability and adhesion of asphalt rubber mixture with and without applying mineral powder, and compared the difference of their performances.

2 Dosage of Mineral Powder and Thickness of Asphalt Membrane

Based on the suggestion from foreign statistics, usually the effective thickness of asphalt membrane in continuous dense gradation asphalt mixture shouldn't be less than 6μm, and the effective thickness of asphalt membrane in dense asphalt macadam mixture shouldn't be less than 5μm. Overall, according to both domestic and foreign experience in research, the asphalt membrane thickness of asphalt concrete should be within 5~8μm. Due to the dosage of asphalt in asphalt rubber is higher, it is required that the maximum value be 8μm.

As for asphalt rubber mixture, since asphalt rubber contains powder particles, there isn't yet definition whether powder particles should be included in the asphalt part or in aggregate part. The gradation design is shown in table 1. In table 1, powder particles are counted in asphalt part and aggregate part individually, coming to the regarding thickness of asphalt membrane, which is shown in table 2. For the accuracy of the test, each group conducted parallel tests for 3 times, and the surpassing mean value 15% tests were rejected and re-conducted.

Table 1. Gradation Applied in Asphalt Membrane Thickness

Sieve Pore Size（mm）	Passing Rate（%）									
	16	13.2	9.5	4.75	2.36	1.18	0.6	0.3	0.15	0.075
Gradation 1	100	94.2	64.5	30.1	19.5	15.5	12.2	9.8	8.1	6.5
Gradation 2	100	94.8	67.8	36.1	26.2	16.2	11.5	6.7	4.2	3.6
Gradation 3	100	94.2	64.5	35.1	25	17.2	14.4	10.9	8.6	1.9
Gradation 4	100	94.5	65.9	39	27.1	16.9	11.9	6.9	4.3	0

Note: all the dust below 0.075 in the test was excluded and replaced by mineral powder, same below.

Table 2. Thickness of Asphalt Membrane

Dosage of Asphalt（%）	Gradation	Mean Voidage（%）	VMA	Thickness of Asphalt Membrane（μm）	
				Thickness 1	Thickness 2
5.0	1	13.1	16.5	6.01	3.57
	2	12.2	15.2	6.90	4.86
	3	11.5	14.6	7.11	6.54
	4	11.0	14.3	7.86	8.68
5.5	1	10.8	15.7	5.54	3.64
	2	9.2	14.5	5.78	4.42
	3	8.5	13.4	6.84	5.18
	4	8.1	12.5	8.83	7.97
6.0	1	9.9	15.8	6.43	4.29
	2	9.0	14.4	7.66	5.64
	3	8.8	13.5	8.60	6.60
	4	7.9	12.3	10.15	8.91
6.5	1	8.1	13.1	7.31	4.99
	2	7.6	12.5	8.16	5.51
	3	7.1	11.4	11.80	7.57
	4	6.6	11.2	13.98	9.68
7.0	1	7.4	13.1	13.43	9.19
	2	7.0	12.2	14.51	10.64
	3	6.3	11.4	14.42	12.70
	4	5.9	10.8	15.12	12.88

Note: asphalt membrane thickness 1: powder particles were counted as part of asphalt; asphalt membrane thickness 2: powder particles were counted as part of padding.

In the system of rubber asphalt, powder particles are partially melted among rubber asphalt, hence, theoretically the thickness of rubber asphalt mixture shall be between value 1 and value 2. From Table 2 we can see that all the thickness of asphalt membrane of gradation 1, 2 and 3 with mineral powder are all below 6~8μm; from the Table, with the same dosage of asphalt, the more we apply mineral powder, the thinner the asphalt membrane will be. And also, the VMA indicated rubber asphalt was absorbed largely, and effective asphalt volume was less, which laterally explained the reason why such a big dosage of asphalt shall be programmed in rubber asphalt. When asphalt's dosage was 5.5%, the asphalt membrane thickness without mineral powder applied in gradation 4 was between 7~8μm, and with the oilstone percentage increased, the thickness of asphalt membrane with mineral powder applied gradation was all above 8μm. Based on the study, when the thickness of asphalt membrane is above 8μm, the asphalt mixture will be free from water damage. Thus for the following study, we chose 8μm as midpoint, and selected the situation that value below 8μm in Thickness 2 and value above 8μm in Thickness 1 for pavement performance research. For this purpose, gradation 1, gradation 4 and asphalt dosage were 5.5%、6.0% and 6.6%.

3 Mineral Powder's Influence on the Adhesive Property of Rubber Asphalt Mixture

The adhesion of asphalt influences mixture's many properties such as water stability, aging stability and fatigue property. And research shows that though the viscosity of rubber asphalt is high, the adhesion was low, and that's due to the application of powder particle had increased the solid content in asphalt, the infiltrating ability decreased and surface porosity of attached aggregated rock. Therefore by applying finer particle mineral powder, this study adopted Cantabro Test for the verifying of rubber asphalt's adhesion. Regarding the test of gradation 1 and gradation 4's rubber asphalt in Table 1, the 5.5%, 6.0% and 6.5% were adopted as dosage of asphalt. Result of the test was shown in Table 3.

Table 3. Cantabro Test Result

Dosage of Asphalt （%）	Gradation	Voidage（%）	Thickness of Asphalt Membrane（μm）	Fly Apart Loss （%）
5.5	1	10.8	3.64~5.54	12.2
	4	8.2	7.97~8.83	11.8
6.0	1	9.9	4.29~6.43	9.0
	4	7.9	8.91~10.15	8.8
6.5	1	8.2	4.99~7.31	6.8
	4	6.5	9.68~13.98	6.8

Required by Chinese standard, modified asphalt's fly apart loss in Cantabro Test shall be below 15%. And in the table showed above, all the fly apart loss for the three dosage conditions were within the standard. With the increase dosage of asphalt, the adhesive property of rubber asphalt mixture increased, and the fly apart loss under both gradations' mixture decreased.

The test showed, however, under the asphalt dosage 5.5% and 6.0%, all the fly apart loss of rubber asphalt mixture in gradation 4 without applying mineral powder was slightly lower than gradation 1 which had applied mineral powder, but the disparity was tiny, and they became same under the value 6.5%. It is thus clear that the applying of mineral powder didn't have major influence on the adhesive property of asphalt fly apart test, and it is not comprehensive to judge the rubber asphalt mixture's water stability performance merely based on the adhesion in fly apart test.

4 Mineral Powder's Influence on Rubber Asphalt Mixture's Water Damage Resistance

By freeze-thaw splitting test, the study evaluated mineral powder's water damage resistance influence on rubber asphalt mixture. The freeze-thaw splitting test was conducted against gradation 1 and gradation 2, and the result was shown in Table 4. It is mentionable that for a better evaluation on the water's function in void and the influence on mixture, Marshall Test out of freeze-thaw splitting test conducted 50 times of two sided compaction instead of 75 times, which increased the voidage with same dosage of asphalt.

Table 4.Result of Freeze-Thaw Splitting Test

Dosage of Asphalt（%）	Gradation	Voidage（%）	Thickness of Asphalt Membrane（μm）	Splitting Value (freeze thaw cycle) KN	Splitting Value (normal temperature) KN	TSR（%）
5.5	1	12.6	3.64~5.54	4.21	5.03	80.7
	4	10.2	7.97~8.83	4.73	5.32	83.9
6.0	1	11.4	4.29~6.43	8.66	10.21	80.8
	4	9.5	8.91~10.15	9.93	11.78	88.1
6.5	1	9.3	4.99~7.31	8.21	9.98	87.8
	4	8.0	9.68~13.98	9.75	10.64	94.1

Under the three dosages of asphalt and by maximizing proper gradation, the voidage of rubber asphalt mixture was maintained, so the freeze-thaw test was conducted. From the result of Table 6 we can see that all the gradation's mixture TSR value were higher than 80%, which met the specifications concerned. Under whatever asphalt dosage, the splitting absolute value of gradation 4 without mineral powder was always higher than gradation 1, and gradation 4's mixture TSR value was also slightly higher than gradation 1, which had applied mineral powder. Thus, when the rubber asphalt mixture applied mineral powder, its asphalt membrane thickness was hard to reach 6~8μm. While if the asphalt membrane was too thin, with the washing of dynamic water pressure, the asphalt mixture would become fragile and cracked, causing early water damage.

5 Mineral Powder's Influence on Rubber Asphalt Mixture's Fatigability

In the present major application and laboratory study, the fatigue life of rubber asphalt mixture is the crucial link. According to the previous study, although the applying of mineral powder can fill in the void of mixture which makes for a lower voidage and furthermore resists fatigue cracking, this meanwhile thins the membrane of asphalt, and the lowed asphalt membrane would not only cause a lower adhesion and water stability but also lead to structural layer's fatigue cracking in an early stage. Based on this contradictory, a balance is needed. Fatigability adopted the gradation in fly off test which is shown in Table 5. And BFA four-point bending test with Nf_{50} of AASHTO method was adopted for this study. When the stiffness modulus decreased to 50% frequency of initial stiffness modulus, it was defined as the fatigue frequency. The test's forming used self-made mold, and then the mold was grinded by roller whose wheel width was 45cm, vibration rate at 4460 times per minute, compacting force 896N, compacting depth 22.86cm. According to calculation and prepressing validation, when the static pressure reached 4 times and vibration rolling was one time, it reached the voidage of Marshall Design (while adjusting voidage, static pressure can be increased or decreased to reach the ideal result). After 24 hours' rest in dry room, it was cut into a 400×63×50mm specimen.

Figure 1. Four-Point Bending Fixture (Left) and Roller for the Test (Right)

Based on current road-vehicle condition, 500με、1000με and 1500με was adopted as load level for simulating of different traffic load.

Table 5. Test Parameter

Loading Method	Loading Waveform	Strain Level	Temperature	Frequency	Intermittence
Strain Control	Half Sine	500、1000、1500με	15℃	10Hz	No Intermittence

Table 6. Fatigue Testing Result

Asphalt Dosage（%）	Gradation	Voidage（%）	Asphalt Membrane Thickness	Initial Stiffness Modulus （MPa）	Strain Level	Fatigue Times
5.5	1	9.7	3.64~5.54	4762	500	32690
				4643	1000	16390
				4752	1500	6010
	4	7.9	7.97~8.83	4428	500	33690
				4329	1000	17720
				4530	1500	6770
6.0	1	8.9	4.29~6.43	4212	500	62670
				4318	1000	36390

				4381	1500	17930
	4	7.3	8.91~10.15	4123	500	72610
				4087	1000	46390
				4007	1500	12040
6.5	1	7.6	4.99~7.31	3760	500	86500
				3649	1000	47230
				3693	1500	10260
	4	6.8	9.68~13.98	3353	500	125430
				3384	1000	76390
				3240	1500	22020

From Table 6 we can directly tell that with the applying of mineral powder, the fatigability of rubber asphalt mixture would have a certain decrease especially with a higher dosage of asphalt. Hence, considering the long-term effects of rubber asphalt, in northern China area where the temperature is low, if rubber asphalt is used for pavement, the dosage of asphalt should be higher, which is supposed to apply less mineral powder or even no mineral powder. Thus, these areas where cold cracking often happens can have a better fatigability.

6 Epilogue

Due to rubber particle's partial reaction which degraded and dissolved in asphalt, the actual rubber asphalt membrane hence is supposed be within the range of higher limit and lower limit. According to domestic and overseas research experiences, in terms of asphalt concrete usually the asphalt membrane should be 5~8μm. because the dosage of asphalt is higher, it is required to adopt the maximum value which is 8μm, and observing the requirement of maximum value, adopting gradation 1 and gradation 4 without asphalt dosage 5.5%, 6.0% and 6.6% as standard for testing research. Results are listed as below:

1.The adhesion relation between mineral powder's dosage and fly off test was not largely relevant, and considering the complexity and comprehension of adhesion test, we shall not judge the water stability property of rubber asphalt mixture simply from the fly off test.

2.Mixture TSR of all gradation were over 80% which was within the required standard. No matter under what dosage of asphalt, gradation 4 which was without mineral powder was higher than that of gradation1, and the mixture TSR of gradation 4 was all slightly higher than gradation which applied with mineral powder.

3.With the applying of mineral powder, the fatigability of rubber asphalt mixture would decrease to a certain extent, especially when the dosage of asphalt is higher.

The application of mineral powder has a disadvantageous influence on the performance of rubber asphalt mixture. Under the condition that leaking and bleeding would not happen, less or no mineral powder should be applied.

Abstract: This paper investigates the influence of tunnel geometry on the capacity of multiple-input multiple-output (MIMO) wireless communication system in underground environment. Due to the geometry of underground tunnels, such as mine and transportation tunnels, there are sufficient scattering objects, and MIMO system can take great advantage of such geometry. Through the experimental evaluations, it is shown MIMO systems in underground tunnel with complicated geometry can achieve an obvious improvement on channel capacities.
Keywords: Transportation tunnels; MIMO wireless communications.

1 Introduction

In underground mine and transportation tunnels, a reliable and efficient wireless communication system is in great demand to improve the safety and productivity. Since multiple-input multiple-output (MIMO) wireless communication system, due to its spatial diversity on both transmit and receive ends, can significantly increase the channel capacity and provide higher link reliability (Foschini, 1998; Telatar, 1999), deploying MIMO systems in underground tunnels is a promising approach to fulfill communications needs.

The propagation of electromagnetic (EM) waves in underground tunnels is different from that in terrestrial environment. According to the geometry of the tunnel, the EM waves are confined in the restricted internal space, and there are always lots of scattering objects (e.g. pipes, brackets, vehicles, machines, and human being). Hence, the underground tunnels are sufficiently rich in multipath components (MPCs), which are yielded by the abundant reflections and diffractions from the boundary walls and scattering obstructions. This "rich multipath" environment, which is considered as a drawback in traditional wireless communications systems, but is a major advantage in MIMO systems (Shiu, 2000). The MIMO system can mitigate the impact of multipath fading and potentially take advantage of it to achieve a preferred performance in underground tunnels.

In this paper, we provide evaluation and demonstration of the influence of the tunnel geometry on the capacity of MIMO system in underground environment. In particular, we firstly review the MIMO system model and channel capacity in Section 2. Then, in Section 3, a sophisticated tunnel model based on physical underground tunnel is developed in Wireless InSite (a 3D ray-tracing software)

(Remcom, 2009), including empty tunnel and detailed tunnel model (with pipes, machines and other obstructions). The experimental scenarios are conducted in the tunnel models and post-analyzed, and the evaluation results are provided in Section 4. It is shown that the MIMO system deployed in the detailed tunnel has obvious improvements in channel capacity than the system deployed in the empty tunnel. Finally, the paper is concluded in Section 5.

2 MIMO Channel Model and Capacity

Figure 1 shows a generic MIMO wireless communication system with N_T transmit antennas and N_R receive antennas, and a variety of approaches to model the MIMO channel have been proposed (Jensen, 2004 ; Almers, 2007).

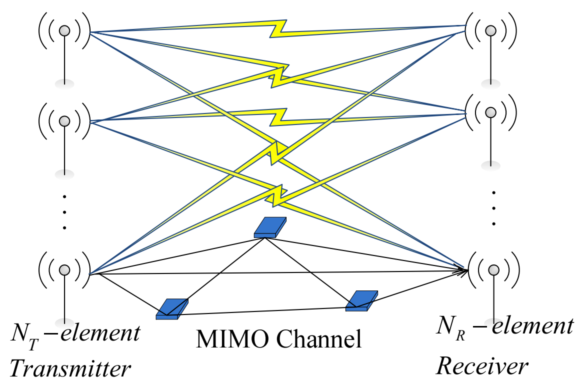

Figure 1. Illustration of a MIMO system

From a system level perspective, the baseband input-output relationship between the length-N_T transit signal vector $\mathbf{s}(t)$ and length-N_R receive signal vector $\mathbf{y}(t)$ can be formulated as

$$\mathbf{y}(t) = \int_\tau \mathbf{H}(t,\tau)\mathbf{s}(t-\tau)d\tau + \mathbf{n}(t) \tag{1}$$

where, $\mathbf{n}(t)$ is Additive White Gaussian Noise (AWGN) at the receive end, and $\mathbf{H}(t,\tau)$ is an $N_T \times N_R$ channel impulse response matrix represented as

$$H(t,\tau) = \begin{pmatrix} h_{1,1}(t,\tau) & h_{1,2}(t,\tau) & \cdots & h_{1,N_T}(t,\tau) \\ h_{2,1}(t,\tau) & h_{2,2}(t,\tau) & \cdots & h_{2,N_T}(t,\tau) \\ \vdots & \vdots & \ddots & \vdots \\ h_{N_R,1}(t,\tau) & h_{N_R,2}(t,\tau) & \cdots & h_{N_R,N_T}(t,\tau) \end{pmatrix} \tag{2}$$

where, $h_{ij}(t,\tau)$ denotes the time-variant complex impulse response between the *j*-th transmit antenna and the *i*-th receive antenna.

Then, the Capacity C of a MIMO system as figure 1 shown, with N_T transmit antennas and N_R receive antennas, is given b

$$C = \log_2\left[\det(\mathbf{I}_{N_R} + \frac{\rho}{N_T}\mathbf{H}\mathbf{R}_{xx}\mathbf{H}^T)\right] \tag{3}$$

where, (T) denotes the transpose-conjugate, $\mathbf{I}$ is the identity matrix, $\mathbf{H}$ is the normalized $N_R \times N_T$ channel matrix in frequency domain, ρ is the average signal-to-noise ratio (SNR) per receiver branch, and $\mathbf{R}_{xx}$ is the correlation matrix of the transmit data (with an assumption, for data at the different antenna elements that are uncorrelated, it is a diagonal matrix with entries that describe the power distribution among the antennas). Thus, if we assumed that all the N_T transmit antenna elements have equal power and are uncorrelated, the $\mathbf{R}_{xx}$ becomes a identity matrix, and we get a simple formula of the capacity of MIMO channel from (6)

$$C = \log_2\left[\det(\mathbf{I}_{N_R} + \frac{\rho}{N_T}\mathbf{H}\mathbf{H}^T)\right] \tag{4}$$

Furthermore, in the case of channel changes into many instances, there are two statistical capacity to evaluate the performance of MIMO channel:

(1) **The ergodic capacity.** This is the mean value (expectation) of the capacity, taken account of overall realizations of the channel.

(2) **The outage capacity.** This is the minimum capacity that is achieved at a certain fraction of the time, for example, 90% or 95%.

3 Description of Experimental Scenarios

With the perspective of measurement campaign in future, we choose an actual site to construct a floor plan model in Wireless InSite now. The chosen underground tunnel, is a suitable site considering its ease of access, long and narrow pathways, and rich infrastructure in mimicking mines or transportation tunnels.

Figure 2. Snapshot of the physical tunnel cross-section

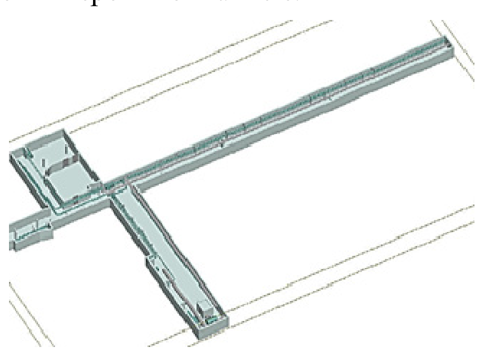

Figure 3. Snapshot of the detailed tunnel floor plan

3.1 Description of the Experimental Tunnel

The entire structure of the underground tunnel resembles a general cross-shape with a total length of 103.1 meters and a width of 55.7 meters. The widths of the tunnel substructure vary from 2.8 to 6.3 meters with almost same height of 2.4 meters. As shown in figure 2, there are a large number of metal pipes and brackets in the tunnel. Additionally, other extensive infrastructures such as the elevator section, steel doors, large scale equipment, also exist in the tunnel.

With the view of distinguishing the geometry of the tunnel on MIMO channel capacity, we construct two version of 3D floor flan in Wireless InSite: empty tunnel and detailed tunnel.

(1) **Empty tunnel**

This floor plan model is designed to incorporate only the basic structure with support pillar and two steel doors.

(2) **Detailed tunnel**

This floor plan model is based on the empty tunnel, and filled with extensive infrastructures such as pipes, brackets, equipment, etc. Figure 3 shows the 3D detailed tunnel floor plan, and we make the shape and property of all infrastructures materials (such as thickness, permittivity, conductivity, reflection and transmission coefficient, etc.) close to the corresponding prototypes in the physical tunnel.

3.2 Setups of Experimental Scenarios

A MIMO system with complete setups is designed in the experimental scenario. Considering a narrow band system, the operation frequency is 2.4GHz with the bandwidth of 1MHz. Ignoring polarization, Omni-directional antennas are chosen to install at both transmit and receive ends, and the radiation powers are equal zero dBm. As shown in figure 4, the transmit route, which consists of 4 transmit points with equal height of 2 meters, is positioned parallel with the tunnel ground; and, the receive grid, which is comprised of 9×9 receive points, with equal height of 1.5 meters, is positioned parallel with the tunnel ground and away from the transmit route. Especially, the spacing distance apart from adjacent points in both transmit route and receive grid, is equal 0.25 meters, i.e., double wavelength of operation frequency (2λ).

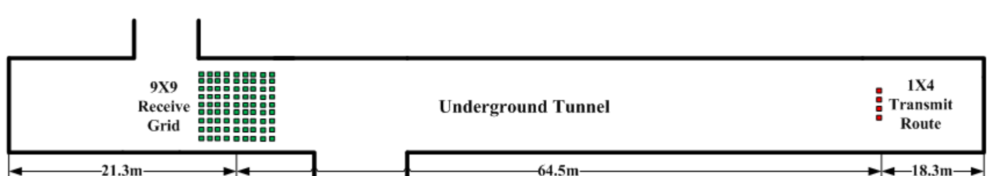

Figure 4. Sky view of MIMO scenario in the tunnel

In order to capture different performance of MIMO channel, the MIMO system mentioned above is deployed in both the empty and detailed tunnel floor plans. Since

EM waves are approximately modeled as optical rays in Wireless InSite, and the EM filed and other outputs dependent on EM filed are obtained by summing the contributions of rays undergoing reflections and diffractions from the tunnel geometry, numerical results are acquired after the time-consuming computation, which dramatically increases as the geometry of tunnel becomes more complicated. In particular, the number of propagation paths is limited to 100 in this experimental scenario. There is no transmission in underground environment, and the upper limit number of reflections and diffractions in each propagation path is set to 6 and 1, respectively.

4 Evaluations

In this section, we present the capacity of MIMO channel in both empty and detailed tunnels to evaluate the influence of the tunnel geometry. The evaluation results are obtained from post-analysis of Wireless InSite numerical outputs.

4.1 Experiment Algorithm

Even through there is a receive grid in the experimental scenario (figure 4), only 4×4 MIMO channel is concerned. In particular, the receive route selected from the receive grid, consists of 4 receive points, and is perpendicular to the tunnel wall with spacing equal 2λ as well as the unique transmit route. Then, there are a quantity of arrangements for receive routes, and numerous instances of 4×4 MIMO channel is realized. Because of the diversity of channel realization, the statistics of capacity can be collected in the post-analysis.

Variety of outputs are generated by the computation in Wireless InSite, and we can employ them to achieve characteristics of MIMO channel, such as capacity, sub-channel complex gains, etc. The H-matrix of MIMO channel in (2) is comprised of complex impulse responses of each possible transmission pair between transmit point and receive point in (5). Since experimental setups in section III are in accordance with the assumption that data at the different antenna elements that are uncorrelated, all the antennas at transmit point have equal radiation power and are uncorrelated, the capacity of MIMO channel is calculated by formula (7).

4.2 Experiment Results

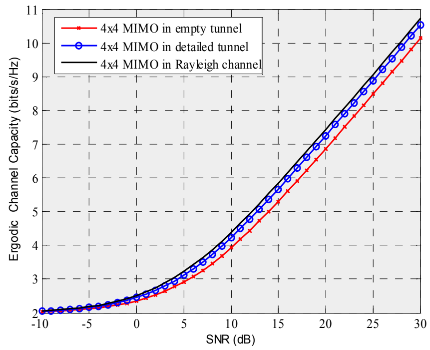

Figure 5.The ergodic capacity of MIMO channel in different tunnel geometries as a function of SNRs within [-10, 30] dB

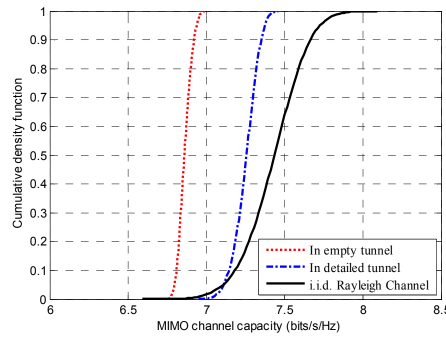

Figure 6. The cumulative density function of channel capacity in different tunnel geometries at SNR=20dB.

In figure 5, the ergodic capacity of MIMO channel in different tunnel geometries as a function of average SNR at each receive point is shown. The capacities of all 4×4 channel realizations are collected, and the mean values of them at different SNRs are plotted. It indicates that the capacity in detailed tunnel is lower than in the ideal Rayleigh channel, but higher than in empty tunnel. With specific SNR at receive route, the cumulative density function (CDF) of channel capacity in both empty and detailed tunnels are shown in figure 6. Through the comparison among the three CDFs of channel capacities, the same result, i.e., the MIMO channel in detailed tunnel has preferable agreement with that in ideal Rayleigh case, is revealed. In a sense, the existence of rich scattering objects in detailed tunnel and its associated MPCs, make the MIMO channel more close to the ideal Rayleigh channel.

5 Conclusions

In this paper, a sophisticated 3D tunnel model based on physical underground site is designed, and experimental scenarios with complete setups are conducted in this model. After analysis of the experimental results, we provide an evaluation and demonstration of the influence of the tunnel geometry on the capacity of MIMO system in underground environment. It is concluded that the MIMO system deployed in detailed tunnel has obvious improvement on channel capacity, and the complicated geometry of the underground transportation tunnel, always with sufficient scattering objects, is a benefit in the context of MIMO system. Therefore, deploying MIMO system in the transportation tunnel is a promising way to construct a wireless communication with substantial improvement on channel capacity.

Abstract: As a massive public traffic, the safety of rail transit system directly concerns the lives and properties of all the passengers. The signal system, playing a crucial role in ensuring operation safety of rail transit, must be evaluated to make sure its safe running. However, it lacks of the comparative research of safety assessment methods that are suitable for the key equipment of rail transit signal system. Based on the signal system of rail transit related research and safety assessment theory, several safety assessment methods, including fuzzy comprehensive method which was explored in the safety assessment of switches, have been analyzed in this paper so as to present the characteristics of these methods and applicable range and conditions.
Keywords: Rail transit; Signal system; Safety assessment methods; Fuzzy comprehensive assessment.

1 Introduction

With some characteristics such as large capacity, high speed and low pollution, rail transit has got rapid development fully in multiple countries around the world. Comparatively perfect rail transit network has been formed in many big cities. Improving the safety of rail transit operation has aroused the public attention. As for the command of safe train plan and efficient operation of rail transit, signal system plays a great role in the operation safety. As a safety-related system, the safety assessment work of signal system is responsible for running.

As it comes to safety assessment methods study, Li Jin , Song Rui et al. used the fuzzy comprehensive evaluation method for rail transit operation safety assessment. The hierarchy structure of evaluation index is established from four aspects, operations management, facilities, staff and external conditions. He Qinghai applied the fuzzy comprehensive evaluation method to the highway traffic safety assessment, putting forward the 'human-vehicle-road-environment' evaluation index. Zhu Wenhai, He Shanshan used the gray comprehensive evaluation method in the study of rail transit passenger satisfaction. Combining qualitative and quantitative analysis and integrating expert experience and scientific computing, the multilevel gray comprehensive evaluation method has very strong practicability, and the results have higher credibility in application examples.

From the literature review above, it can be seen that many experts and scholars have studied safety evaluation of rail transit signal system and put forward many feasible assessment methods. But these methods have their own characteristics and range of application, so in-depth study and comparison of these methods is particularly important in safety assessment of the complex rail transit signal system. In this paper, based on the signal system of rail transit related research and safety assessment theory, several safety assessment methods, including fuzzy comprehensive method which was explored in the safety assessment of switches, have been analyzed so as to present the characteristics of these methods and applicable range and conditions.

2 Concept of transit signal system

Signal means "signal (display), interlocking, block". Made up of all kinds of signs, track circuit and other equipment and ancillary facilities, rail transit signal is a complete system. Signal system mixed with computer, communication and other advanced technology into an organic whole develops in the direction of digital, intelligent, and automatic. Figure 1 shows that rail transit signal system has three parts, the station signal system, wayside signal system and operation control system.

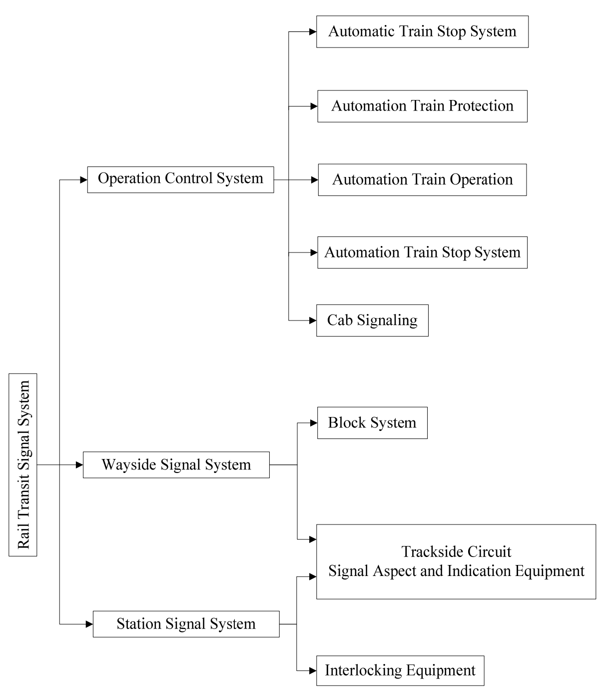

Figure1.Rail transit signal system composition

On the premise of the train operation safety, signal system improves the quantity and efficiency by raising the train speed or shortening the train operation interval or both the two ways. As a part of rail transit signal system, switches play a very important role in the operation safety. So safety assessment of the key equipment, switches is needed. There are many factors that influence the safety of switches, such as operating conditions, operation state, product material, the natural environment and so on. A suitable assessment method should be found out to accomplish the analysis work.

3 Safety assessment and methods research

3.1 Safety assessment content and process

Signal system safety assessment is based on system safety analysis by using various methods to find out the potential danger and weak links that exist in the system, to determine whether the system can meet the safety requirements or not. In the process of safety assessment in rail transit signal system, certain standards needed to judge whether the system meets the requirements and though the assessment or not. The process of safety assessment is shown as Figure 2.

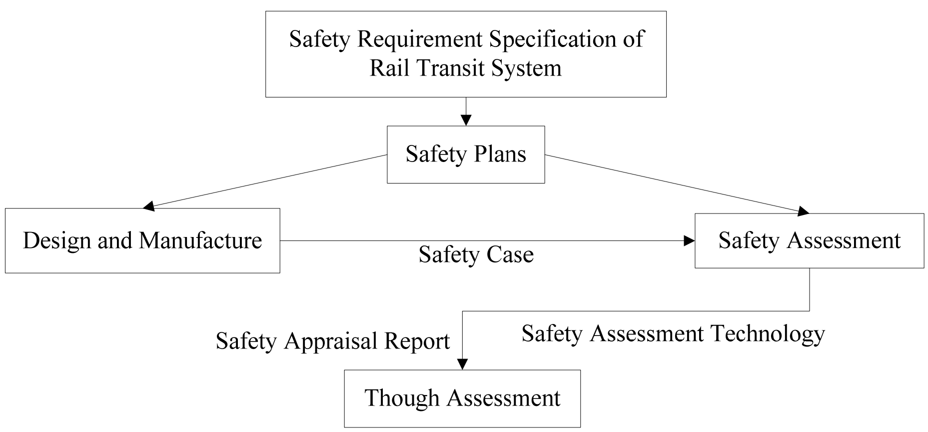

Figure2. Process of safety assessment

3.2 Analysis and research of safety assessment methods

With the development of safety assessment work in various fields, many safety assessment methods emerge, such as fuzzy comprehensive evaluation method and gray comprehensive evaluation method. Choosing appropriate assessment method has significant impact on the final result in safety assessment of rail transit signal system. Because of the complexity of the rail transit signal system, the choice of safety assessment method is demanding, however each method has its own characteristics and scope of use. So how to choose the appropriate method can refer to the following process: preliminary and quantitative analysis is need firstly in order to obtain a qualitative concept, then make detailed analysis according to the risk level and select a appropriate assessment method for a certain object finally. At present, the safety assessment methods can be divided into two main categories, namely, qualitative assessment methods and quantitative ones.

3.2.1 Fuzzy comprehensive evaluation method

Fuzzy comprehensive evaluation comprehensively evaluates the membership of degree from multiple factors using fuzzy set theory and principle of fuzzy synthesis. It can effectively solve the problem of the fuzziness and uncertainty of judgment in two ways, one is evaluating and sorting the object according to the size of the comprehensive scores, the other is evaluating the object according to the value of fuzzy evaluation set.

The advantage of fuzzy comprehensive evaluation is to estimate a system which involves fuzzy factors comprehensively. As a commonly used method of fuzzy mathematics, it is widely used in economic, social and other fields. However, with the continuous application of comprehensive evaluation in economy or society system, it is hard for human beings to make objective evaluation and decision due to complexity of the problem, insufficient information and multiple factors. But fuzzy comprehensive evaluation method can not solve the problem of information overlapping, and there is no systematic method to determine membership function. What's more, the synthesis algorithm also needs to be further discussed. In general, fuzzy comprehensive evaluation is a comprehensive evaluation method based on the subjective information which comes from people's judgment. The reliability and accuracy of this method depends on the reasonable selection of factors, weight distribution and composition operator of comprehensive evaluation.

Fuzzy evaluation method can be used in safety assessment of rail transit signal systems, such as evaluating track circuit or switches. A low class hierarchy assessment model should be built firstly, then determine evaluation index weights, and accomplish the assessment with this method.

3.2.2 Gray comprehensive evaluation

Gray comprehensive evaluation method is a combination of qualitative analysis and quantitative analysis.

In gray correlation analysis, the closer between geometric curves of several statistical sequences, the greater correlation degree between them. Grey correlation coefficient:

$$r_{ij} = \frac{\min_i \min_j \left| x_{oj} - x_{ij} \right| + \xi \max_i \max_j \left| x_{oj} - x_{ij} \right|}{\left| x_{oj} - x_{ij} \right| + \xi \max_i \max_j \left| x_{oj} - x_{ij} \right|} \begin{pmatrix} i = 1, 2, \ldots, m \\ j = 1, 2, \ldots, n \end{pmatrix}$$

Level two minimum differences: $\min_i \min_j \left| x_{oj} - x_{ij} \right|$.

Level two maximum differences: $\max_i \max_j \left| x_{oj} - x_{ij} \right|$.

Resolution ratio: $\xi \in [0,1]$, usually $\xi = 0.5$.

So, the correlation degree between the sequence and the reference sequence is:

$$r_{oi} = \frac{1}{n}\sum_{j=1}^{n} r_{oj} .$$

We can know the degree of correlation between the sequence and the reference sequence through r_{oi}.

If weight of each evaluation index is not equal, weight matrix is: $w_j\ (\mathrm{j}=1,2,\ldots,\mathrm{n})$

Grey correlation matrix is: $A = W \times R^T$

So the degree of correlation between evaluation objects is: $a_i = \sum_{j=1}^{n} w_j \times (r_{ij})^T\ (\mathrm{i}=1,2,\ldots,\mathrm{m})$

We can know the degree of closeness between the evaluation index and the optimal index through a_i.

This method can well solve the problem that evaluation index is difficult to accurately quantified, and eliminate the effects of the human factors, making the evaluation results more objective and accurate. Raw data can be directly calculated and normalization processing of experimental data is no needed. Without a large number of samples, this method just needs a small amount of representative ones. But this method requires the sample data with the characteristic of time series, and calculating the resolution ratio is needed. There is a need to explain that how to choose the object evaluation index system and weight distribution will affect the final evaluation result. In addition, there is a positive or negative correlation relationship between things. But the correlation is always positive using gray correlation degree, so it can not fully reflect the connection between things. The usage of this method should be especially careful in analyzing work.

3.2.3 The analysis of the above methods

Each safety assessment method has its own characteristics. When choosing method, according to the evaluated object's characteristic and needs of evaluation to determine whether the qualitative method or quantitative method should be used. When evaluating rail transit signal system, it’s not to say that can only use quantitative or qualitative methods. At the start of the assessment, purely qualitative assessment can be undertaken and then on the basis of the result of the qualitative assessment to decide whether need to do further work. When quantitative evaluating, two or more than two quantitative methods can be applied in combination according to complex features of the evaluated object.

4 Safety assessment of rail transit switches based on fuzzy comprehensive evaluation method.

From the comparative research above, it can be seen that the fuzzy comprehensive evaluation method is more suitable than the gray comprehensive evaluation method in the safety assessment of the switches, the key equipment of rail transit signal system, as the switches involve fuzzy factors comprehensively and the evaluation index can be quantified by the analytic hierarchy process.

So we choose the fuzzy comprehensive evaluation method to achieve the assessment work, and choose the economic life, physical life and technical life as the evaluation criterion for switches, then we establish the following hierarchy model as Table 1.

Table 1 Comprehensive weight table of switches safety assessment model

<table>
<tr><th rowspan="2">A</th><th colspan="2">B</th><th colspan="2">C</th><th colspan="2">D</th><th colspan="2">E</th><th rowspan="2">Comprehensive weight</th></tr>

					D16	0.216			0.023
					D17	0.431			0.045
					D18	0.248			0.026
			C9	0.149					0.084
	B3	0.281							0.281

A: safety assessment criteria of switches; $B_{1:}$ economic life; $B_{2:}$ physical life;
B_3: technical life; $C_{1:}$ the annual cost; $C_{2:}$ maintenance cost;
$C_{3:}$ operation cost; $C_{4:}$ inherent design; $C_{5:}$ system interface;
$C_{6:}$operating conditions; $C_{7:}$operation state; $C_{8:}$maintenance and management;
$C_{9:}$engineering reform; D_1:product design; D_2:product manufacturing;
D_3:product material; D_4:product inspection; D_5:switches interface; D_6:point switch interface; D_7:relay interface; D_8:the natural environment; D_9:ballast bed environment; D_{10}:practical serviced life; D_{11}:number of times; D_{12}:general failure rate; D_{13}:serious failure rate; D_{14}:dangerous failure rate; D_{15}:management system; D_{16}:periodic replacement; D_{17}:daily maintenance; D_{18}:technical training;
E_1:designed service life; E_2:reliability design; E_3:fault-safety design;
E_4:environmental adaptability design; E_5:ice and snow; E_6:hydrops;
E_7:thunder.

Based on the evaluation model, experts give scores for each layer of influence factors by choosing one level from "excellent, good, normal, bad". Finally count the total number of each element .We can use the frequency of factors as the membership degree of fuzzy evaluation. Then fuzzy comprehensive evaluation can be done by the following the formula.

$$B = A\begin{bmatrix} B_{B1} \\ B_{B2} \\ B_{B3} \end{bmatrix} = \begin{bmatrix} 0.157 & 0.562 & 0.281 \end{bmatrix}\begin{bmatrix} 0.27 & 0.6 & 0.13 & 0 \\ 0.330844 & 0.441804 & 0.183917 & 0.042528 \\ 0.27 & 0 & 0 & 0.73 \end{bmatrix}$$

$$= \{0.304195 \quad 0.342494 \quad 0.123771 \quad 0.229031\}$$

According to the principle of maximum membership degree, the grade of the switches is good.

By comparing the actual operation condition of rail transit lines, it's clear that the evaluation result is coincided with the physical truth. So the method selected in this paper is reasonable and feasible.

5 Conclusions

In order to ensure the stability and safety in the field of rail transit development in our country, from the historical experience shows that the safety assessment of signal system is very important. In the safety assessment, the choice of assessment methods directly affects the whole efficiency and accuracy of results. In this paper, the composition of rail transit signal system and the research status of safety assessment were introduced. On the basis of deep analysis and research the current safety assessment methods, proposed and summarized the advantages and disadvantages and using range of several main methods, accomplished the safety assessment of rail transit switches based on the fuzzy comprehensive method, put forward the basis and reference for safety assessment work in method selection.

Railway Information Sharing Platform Security Management Technologies Analysis

Hongguo Shi[1,2]

[1]School of Transportation and Logistics, Southwest Jiaotong University, Chengdu 610031, China. E-mail: shg@swjtu.cn
[2]National United Engineering Laboratory of Integrated and Intelligent Transportation, Chengdu 610031, China.

Abstract: Railway information sharing platform is the key technology to realize the railway information systems connectivity, integration and optimization of all kinds of information resource in railway companies. Security technologies of railway information sharing platform are the foundation of the long-term stable operation of the platform. Through analysis of security requirements and technical characteristics, the key security technologies are pointed out, mainly including access control technology, single sign-on technology, authentication technology and unified security center technology, etc. The security technologies laid a foundation for safety management implementation of the platform.
Keywords: Railway information sharing platform; Security management technology; Information security.

Chinese railway information systems have been isolated from each other since they are built. In order to solve the problem, railway information sharing platform need urgently to be constructed. The main functions of the information sharing platform include information exchange, cross-system messaging, data format conversion, building a shared database and providing shared services, etc.

On the other hand, the platform will face great security challenge from very different railway applications. In the paper, multiple security technologies are selected and analyzed, laying the foundation for the realization of the railway information sharing system security management and operation.

1 Railway Information Sharing Platform Security Demand

By investigation of current and potential customers of the railway information sharing platform, combined with analysis of platform function and realization technology, it can be summarized that the security requirements include: access control security, information transmission security, data storage security and the safety control center.

1.1 Access control security

Access control security is the primary issue to ensure system safety. It includes global identity management, the customer identity authentication, single login problem etc.

(1) Global Identity Management

Chinese railway information sharing platform uses a service-oriented architecture. Different systems have different set of roles, different permission schemes and different user identities. This will lead to the problem how to identify which are legal customers and which are invalid, which have "A" privilege and which have "B" privilege. So the global identity management technology is needed.

(2) Authentication Problem

Due to the complexity of the shared platform, a large number of access points from in or out of railway system. If the legitimacy of the remote client is not clear and hastily provides services, there will be a big security risk. Meanwhile, legitimate requestors are also needs "identified" to guarantee security. So technology of verification is clearly needed. Making railway information sharing platform authentication is an important part to protect the security interoperability.

(3) Single Sign-on Problem

If one will log in different services in current rail applications, he must enter username and password each time. It is a very tedious problem for people who need to share a lot of services and data. Now single sign-on technology can be used to solve the problem. The technology can reduce login and authentication times, reduce the possibility of loss or forgotten passwords.

2.2 Information Transmission Security

Enterprise Service Bus (ESB) technology is used to realize different systems sharing data and service in the railway information sharing platform. But information security is a basic problem in the transmission process.

Web services is an important means of information sharing platform, and to enhance Web service security is very important. The secure transmission protocol (HTTPS), Transport Layer Security STL/SSL technology will be used in Chinese railway information sharing system.

2.3 Data Storage Security

Data storage security is an important issue to build railway information sharing platform facing. Using technology such as cloud data storage and management of decentralized computing technology can improve the safety of the railway store important data, but also brings a complex system structure, management and complex problems. Therefore, study off-site storage, disaster recovery, data recovery, security technology, response information sharing platform to build the new data security situation.

2.4 Unified Security Prevention Center

Railway Information Security Center can centralized manage globe security services and some important basic globe database. The public railway infrastructure and critical information database backup and recovery management, centralized monitoring and dealing with security threat is its main objective. Information

Security Center realize security control through security audits, intrusion detection, virus analysis etc. On the other hand, scheduling and balancing the entire railway information sharing platform resources, optimize the using of computing, storage system capacity and network bandwidth for the entire railway safety and efficient operation of information systems services.

3 The security technology analysis

According to design objective and security requirements, combination of the technology and infrastructure of the information sharing platform, the security management technology should include service authentication, access control, single sign-on technology, dynamic data encryption technology etc.

3.1 Access control of information sharing platform

The railway information sharing platform users come from companies in and out of railway system. Various types of users having different security risks, should be adopted different access control technology. The users in existing railway system had existed roles. If they will access other application to get shared information they should be deployed other roles from the objective system. For users outside the railway system, they bring higher risks. Require the use of access control technology is the first to carry out a global role and user permissions match, then authentication technology to enhance security control.

Limited to the complexity of railway information system structure and the number of user roles, united access roles and permissions are more appropriate for globally applications. For example, information sharing platform set up three roles : P1, P2, P3, corresponding to different privileges. At the same time, each connected application set up information sharing accessing roles and permissions.

As bellow in figure 1, A and B system are two railway information systems in information sharing platform, each has user roles: A system with A1, A2, A3 and A4, B system with B1, B2, and B3. In order to transform roles between system A and B and others, the information sharing platform will build information sharing roles P1, P2 and P3.Through the information sharing platform to implement A system of shared services system service mode access B, can build A system of information sharing system and B respectively access roles (PA1, PA2, PA3, and PB1, PB2, PB3). When A system user A3 access B system, according to a certain mapping rules, it can be transformed to P2 role, which dedicated PB2 role corresponds to B, so as to realize an A3 system role to PB2 system role.

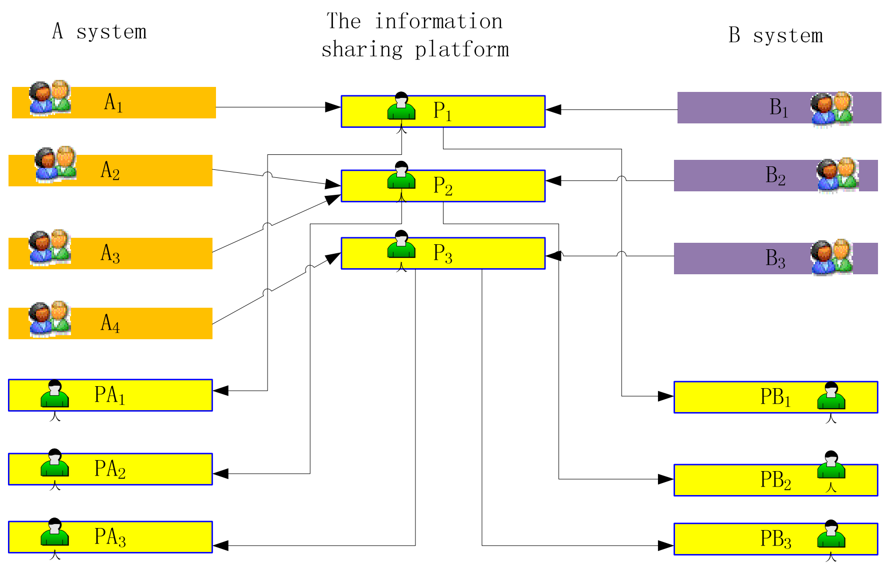

Figure 1. Roles mapping between different applications

Outside railway system users are at highest risk to the platform, this group should be given the most strict access control. Firstly, they need to be identity authentication, Secondly, according to the users categories, when they login, they should be given the lower permissions. For example, for logistics companies even individual users can be given the lowest level, but for government users, can be given a higher privilege. More security technologies should be used such as firewalls, data encryption, VPN and so on.

3.2 Single sign-on technology

Single sign-on technology (SSO), is one of the most popular enterprise integration solutions. SSO is used in multiple application systems. The users need only login once to access all applications by SSO.

By using the SSO technology, the whole railway system users authentication and unified service can be realized. Considering the railway information sharing platform connecting a large number of railway information systems, and theses systems are distributed in the whole country, centralized management for authentication and single sign-on authentication are a higher risk. We can set up the technical architecture based on cloud computing, certification service in a big field. So national certification server and regional certification servers are both needed.

As shown in figure 2, multiple authentication servers are built in different locations, and through the Security Assertion Markup Language (SAML), authentication information can be exchanged by geographically distributed single sign-on service. But there is no difference when customer login. When a user access TDCS system, he get authentication and ticket from the first authentication server. When he visited the SCADA system, the other authentication server (server n) can exchange authentication information via SAML and identify this ticket.

Single sign-on technology will integrate all systems certification services together. And user identity, credentials, login information and other management can use the lightweight directory access technology (LDAP).

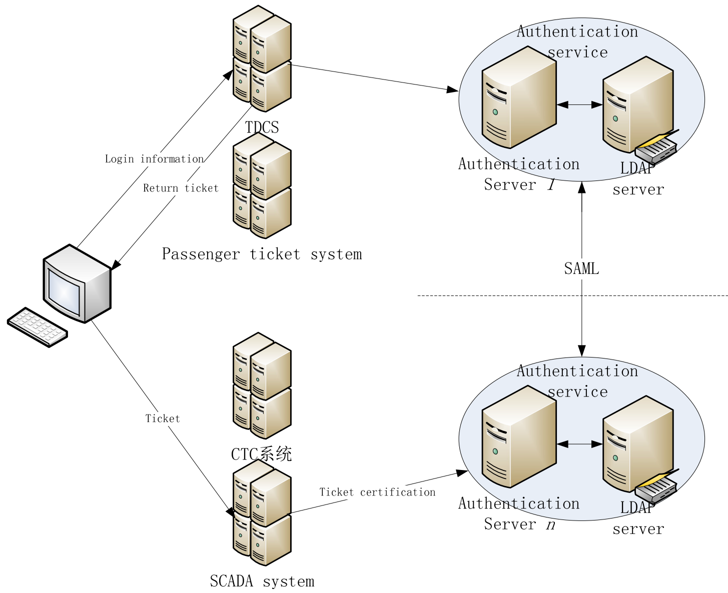

Figure 2. Multi-server distribution of single sign-on technology

3.3 The identity authentication technology

The identity authentication technology is the foundation of the railway information sharing platform. According to the characteristics of the authentication technology, combined with the actual situation of the platform, prospective and standardized authentication PKI authentication system should be used. Complete PKI system includes PKI certification authority (CA), digital certificate library, key backup and recovery system, invalid certificate system, application interface (API) and other basic components.

Railway information sharing platform can first choose certification institution to obtain a digital certificate, such as Chinese electronic certification service industry alliance, or apply for certification bodies, to establish a digital certificate issued, backup, invalid system.in the Center of the Security built the whole way digital certificate libraries, build the digital certificate backup and recovery system, the construction of a digital certificate invalid system, research and development application interface, complete digital authentication system form the railway information system.

3.4 Unified security center technology

Because of the complexity and huge size of the railway information sharing platform, a unified security management center should be built to improve the whole system security. The security center includes national node and regional nodes. The security management center can deploy security technology centrally and uniformly, dispose security threat, strengthen security control in a more rapid mode.

The main security services and technology in security management center include: authentication and single sign-on authentication services, security monitoring, invasion warning, prevention and procession. On the other wise, railway public basic information database and shared business database backup and disaster management are also its functions. Main services in the unified security center can be shown in figure 3:

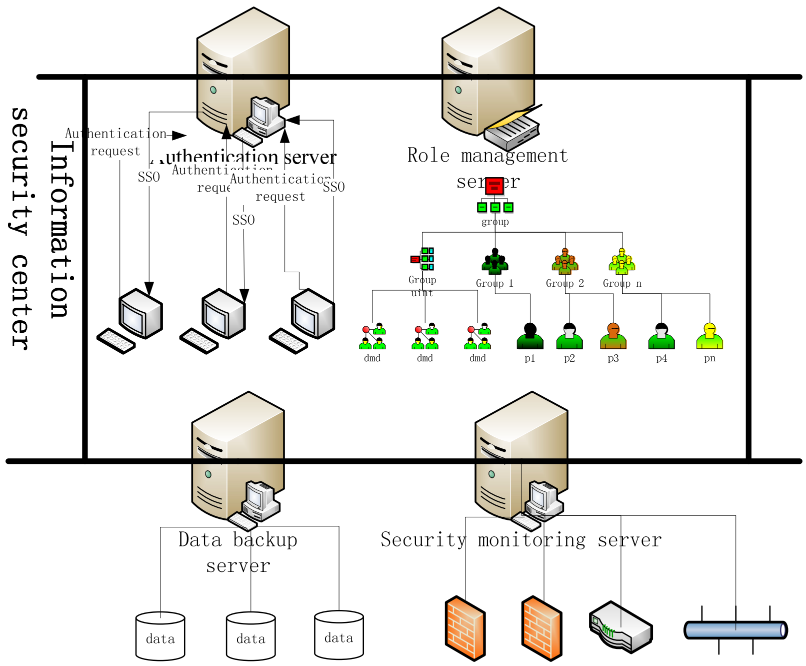

Figure 3. The unified information security control center

4 Conclusion

Railway information sharing platform security technologies are directly related to the system security and stability of operation for a long time. According to information sharing platform security requirements analysis, the security technologies and configuration are put forward. These technologies include access control technology, single sign-on technology, authentication technology, security control center, etc. By using these information security technologies, the railway information sharing platform will gain necessary security and stability. With the construction of the platforms, it will face a more complex security environment, and new security technology also needs to be deployed.

Abstract: Although plenty of models have been proposed in previous researches on bus travel time estimation/prediction, little attention has been paid to the effective usage of the historical travel time. In this research, comparisons on performance of historical travel time estimation model were made among different statistical values, namely the mean, the median and the maximum probability values. The research results show that, to the wholly speaking, when buses are far away from the target stop, the model with input of the mean value performs the best on the estimation accuracy and precision, while the model with input of the median value shows the best performance when buses are near the target stop. During peak periods, the model with input of the maximum probability value is superior to that with input of other estimated values. Finally, a multi-stage usage of statistical values in travel time estimation is suggested on basis of the estimation results.

Keywords: Bus transit; Travel time estimation; Mean value; Median value; Maximum probability value.

1 INTRODUCTION

Bus travel time plays an important role in operation and management, and the accurate prediction of it can help transit agencies take proactive controls on buses to maintain the service regularity or provide bus arrival time information service to transit riders.

Before the equipment of automatic vehicle location (AVL) devices, it was hard for transit agency to acquire the travel time information unless by manual collected data. With the rapid development of Advanced Public Transit System (APTS), AVL devices have been widely equipped by transit agencies all over the world. In 2000, 88 transit agencies in the United States had operational AVL systems, and 142 were planning such system. In China, the document "Suggestions on the priority development of public transit system" issued by the General Office of the State Council on September 23, 2005 promotes the nationwide rapid development of intelligent transit systems. At present, all transit agencies in metropolis have built operational AVL systems, and more and more transit agencies in medium-sized cities, with population over 500,000, have started incorporating such systems, which is supported by both the local governments and the Ministry of Transport.

The construction of passenger information system has been implemented or considered by more and more transit agencies as a method to improve the service quality of bus system. However, the low accuracy of travel time prediction in real application has troubled the passenger information system all the time. The prediction errors of bus travel time can be affected by many factors, to which the input of prediction model is an important source. This research is an extension work for bus travel time estimation on basis of historical data, and a further insight was made into how to efficiently make use of the collected historical data to improve the accuracy bus travel time estimation.

2 LITERATURE REVIEW

Bus travel time is affected by quantities of factors, which have been validated in previous researches. Generally speaking, those factors can be clustered into five categories, which include: (1) Infrastructure, such as number of stops, number of traffic signal lights , length of segment, and whether a low-floor bus or not; (2) Running Environment, such as weather, traffic pattern (time-of-day and day-of-week), congestion, and incident; (3) Operation and Management, such as scheduled travel time, dwell time, and time-check points. (4) Passenger demand and activity, such as boarding and alighting time, passenger arrival rate; (5) Driver Behavior, such as schedule recovery.

In order to explain the relationship between bus travel time and factors, several typical models or algorithms have been proposed in previous researches, like the historical travel time based model, the regression model, the kalman filter algorithm, the artificial neural network model, the markov chains model, the trajectory-based model, and the tendency-based model. Among those models, the accuracy of the historical travel time based model is in general considered to be unsatisfied, but it has an advantage in its scalability to account for other routes. In real application, it is still a favorite method in the passenger information system in China and some other countries, for its easiness for development, the less computation burden on information processing centre and stability in a data missing condition. The principle of the historical travel time model is that it tries to seek the most similar historical bus travel time to predict the real-time bus travel time, which is based on the assumption that bus travel time remains constant under similar condition. Therefore, the performance of the historical travel time model is largely determined by the degree of similarity between the real-time travel time and the historical travel time. Therefore, how to make an efficient usage of the historical data is meaningful for improving the performance of the historical travel time based model. In previous researches, the mean value was much more preferred for estimating bus travel time, and had not been compared with other forms of statistical values.

Focusing on this problem, comparisons were made on the performance of the historical travel time based model with input of different estimated values—the mean, the median, and the maximum probability values respectively. The rest of paper is organized as follows: in the next section, the historical travel time based model was represented, with different estimated values as the input of the model. Followed is an experiment carried out for travel time estimation, and the estimation accuracy and precision was evaluated. Finally, conclusions were addressed and future studies were suggested.

3 MODEL DEVELOPMENT

A historical travel time based estimation model is proposed as a common platform for validating and evaluating its performance on estimation accuracy and precision with different estimated values as inputs of model.

Bus Travel Time Estimation Model

Define Target Stop is the terminal of the estimation zone, and buses are approaching to the target stop after depart from the departure stop. Bus travel time is composed of an inter-zone link travel time (ILTT) and a section travel time (STT) (as shown in Figure 1). ILTT is defined as the time that buses travel from the current position in a link to the end stop of the link, and they are assumed to be running with the uniform velocity; while STT stands for the time that buses travel from the end stop of the link to the target stop.

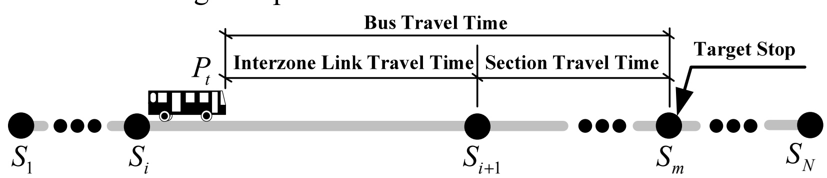

Figure 1. Illustration of the bus travel time estimation model

Thus, bus travel time can be described as the sum of an ILTT and a STT.

$$t_{P_tS_m(t)} = \left(1 - \frac{d_{S_iP_t}}{d_{S_iS_{i+1}}}\right) t_{S_iS_{i+1}}\left(\tau_{S_i}\right) + \sum_{j=i+1}^{m-1} t_{S_jS_{j+1}}\left(\tau_{S_j}\right) \tag{1}$$

Where, $d_{S_iP_t}$ is the traveled distance from the stop S_i to the current position P_t,

$d_{S_iS_{i+1}}$ is the length of the link S_iS_{i+1},

τ_{S_i} is the time-interval when the bus vehicle enters the link S_iS_{i+1}, and

$t_{S_iS_{i+1}}\left(\tau_{S_i}\right)$ is the estimated link travel time on the time-interval τ_{S_i}.

Note that the time-interval τ_{S_i} specifying the link travel time $t_{S_iS_{i+1}}\left(\tau_{S_i}\right)$ is determined by the time when buses arrive at the stop S_i, and the relationship between the time-interval τ_{S_i} and the arrival time t_{S_i} meets the followed equation.

$$\left(\tau_{S_i} - 1\right) \times \Delta T < t_{S_i} \le \tau_{S_i} \times \Delta T \ , \ \ 1 \le \tau_{S_i} \le 24/\Delta T \tag{2}$$

Where, t_{S_i} is the time when the bus arrives at the stop S_i, and

ΔT is the length of the time-interval, which is equal to a quarter of one hour in this research.

Estimated Values of Link Travel Time

The day-of-week pattern of the bus travel time for the experimental route has been validated in a previous research. It was found that the travel time is similar among days among weeks on Tuesday, Wednesday, Thursday, Saturday, and Sunday (for example, travel time on successive Tuesdays among weeks is similar), and similar among days in one week on Monday and Friday (for example, travel time on successive weekdays in one week is similar).

With this consideration, the travel time of last four days with the same day-of-week characteristic was preferred as the historical data needed for link travel time estimation, and used to estimate the link travel time.

The mean value of historical link travel time

The mean statistical value of link travel time is on basis of the travel time samples of previous four days with the same characteristic.

$$t_{S_iS_{i+1}}^{Mean}\left(\tau_{S_i}\right)=\frac{1}{N}\sum_{k=1}^{N}t_{S_iS_{i+1}}\left(k,\tau_{S_i}\right) \tag{3}$$

Where, $t_{S_iS_{i+1}}^{Mean}\left(\tau_{S_i}\right)$ is the mean value of historical link travel time on the time-interval τ_{S_i},

N is the number of trips (four days) on the time-interval τ_{S_i}, and

$t_{S_iS_{i+1}}\left(k,\tau_{S_i}\right)$ is a sample link travel time on the time-interval τ_{S_i}.

The median value of historical link travel time

A percentile is the value of a variable below which a certain percent of observations fall. Firstly, a general definition of the α percentile value of link travel time is given in Equation (4), which is the maximum one that α percent of observations fall below it.

$$\begin{aligned} & t_{S_iS_{i+1}}^{\alpha}\left(\tau_{S_i}\right)=\underset{k=1}{\overset{N}{MAX}}\left\{t_{S_iS_{i+1}}\left(k,\tau_{S_i}\right)\right\} \\ & s.t.\ \frac{\sum_{k=1}^{N}n_k}{N}\le\alpha \end{aligned} \tag{4}$$

Where, n_k is a Boolean variable, and the value is determined by whether a travel time sample is larger than the selected one or not (see equation (5)).

$$n_k=\begin{cases}1, t_{S_iS_{i+1}}\left(m,\tau_{S_i}\right)\le t_{S_iS_{i+1}}\left(k,\tau_{S_i}\right); \\ 0, t_{S_iS_{i+1}}\left(m,\tau_{S_i}\right)> t_{S_iS_{i+1}}\left(k,\tau_{S_i}\right).\end{cases}\left(m=1,2,...,N\right) \tag{5}$$

$t_{S_iS_{i+1}}^{50\%}\left(\tau_{S_i}\right)$ is the median value of historical link travel time on the link.

The maximum probability value of historical link travel time

In travel time estimation, it is always expected that the difference between the estimated value and the true value meets the need of prediction accuracy and precision; in other words, we always wish that the estimated one is within the expected accuracy and precision at the most probability. Therefore, it is reasonable to have a try on estimating bus travel time with input of the maximum probability value, which is determined by the maximum ratio that the deviation between the estimation value and overall observations is within a tolerant range (see equation (7)).

$$\max \quad z = \sum_{k=1}^{N} n_k / N$$

$$s.t.\ n_k = \begin{cases} 1, \left(\dfrac{\left| t_{S_i S_{i+1}}\left(m, \tau_{S_i}\right) - t_{S_i S_{i+1}}\left(k, \tau_{S_i}\right) \right|}{t_{S_i S_{i+1}}\left(k, \tau_{S_i}\right)} \le \phi_{offset} \right); \left(m = 1, 2, ..., N\right) \\ 0, else. \end{cases} \tag{6}$$

Where, ϕ_{offset} is the tolerant deviation range between the estimated value and overall observations. In this research, it was set to be 50% for the reason that an estimation value with deviation larger than 50% is assumed to be unacceptable.

4 MODEL COMPARISONS AND EVALUATIONS

Test Bed and Data Collection

The southbound corridor of the bus route No.49 in Shanghai, which has 20 stops and is 12.17 kilometers long, was selected as the experimental route (as shown in Figure 2). It starts from the Hankou-Road stop and ends at the Shanghai-Stadium stop. The experimental route is frequent-serviced, with the scheduled headway 5 to 8 minutes during the weekday peak periods, 6 to 10 minutes during the weekend peak periods, and 10 to 15 minutes during the weekday and weekend non-peak periods.

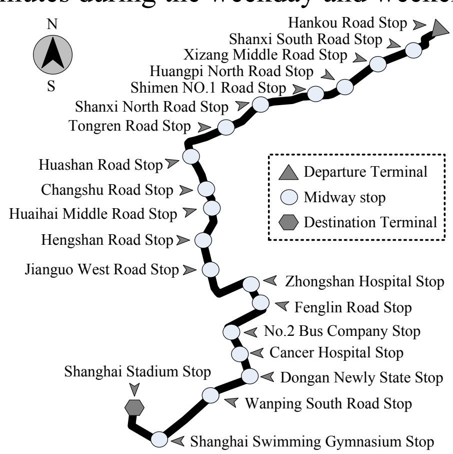

Figure 2. Illustration of the experimental route (Southbound)

AVL devices are equipped on all buses in service, and detailed information can be collected and archived in real time. Three types of location data are collected—the location-at-time data (when buses have traveled for 30 seconds between stops), the location-at-distance data (when buses have traveled 250 meters within 30 seconds between stops), and the location-at-stop data (when buses arrive at a stop or leave it). The status that buses arrive at or depart from the stop is judged by the relative position between the location of buses and two interest-points which are located before and after the stop-point (as shown in Figure 3). If the GPS coordinate of the bus is within a certain range (10 meters) of the interest-point that before the stop-point, the status of the bus is set to be arrival at the stop; while in turn, if within a certain range (10 meters) of the interest-point that after the stop-point, the status is set to be departure from the stop.

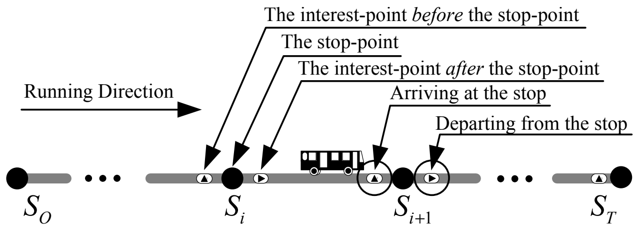

Figure 3. Relationship between two interest-points and the stop-point

The historical AVL data collected for analysis ranges from April 1 to April 30 in 2011, with a total number of nearly 5 million records. The collected raw AVL records were clustered by trips with a self-designed program, and link travel time was calculated by the two AVL records in one trip.

Measures of Performance

All measures developed below made use of the difference between the estimated travel time and the actual travel time, which is known as estimation error.

$$\varepsilon_i = T_{Pi} - T_{Ai} \tag{8}$$

Where, ε_i is the estimation error of sample i,

T_{Pi} is the estimated value, and

T_{Ai} is the actual value.

Accuracy is the degree of closeness of the estimated value to the true value. Mean Error (ME) and Mean Absolute Error (MAE) are chosen as the measures to evaluate the accuracy of models. A lower MAE value and a closer ME value to zero indicate a higher accuracy of the prediction model.

$$ME = \frac{1}{N}\sum_{i=1}^{N} \varepsilon_i \tag{9}$$

$$MAE = \frac{1}{N}\sum_{i=1}^{N} \left|\varepsilon_i\right| \tag{10}$$

Precision is the degree to which repeated measurements under unchanged conditions show the same results. It can be described as the central tendency of the estimated values around the true value. Mean Percentage Error (MPE) and Mean Absolute Percentage Error (MAPE) are chosen as the measures to evaluate the precision of models. The lower the MAPE is and the closer the MPE to zero is; the higher precision of the prediction model is.

$$MAPE = \frac{1}{N}\sum_{i=1}^{N} \frac{\varepsilon_i}{T_{Ai}} \tag{11}$$

$$MAPE = \frac{1}{N}\sum_{i=1}^{N} \frac{|\ \varepsilon_i\ |}{T_{Ai}} \tag{12}$$

Performance Evaluation

172 trips on May 2 in 2011 were estimated with input of the mean, median, and maximum probability values of link travel time respectively, and the performance on the estimation accuracy and precision was compared on basis of the performance measures.

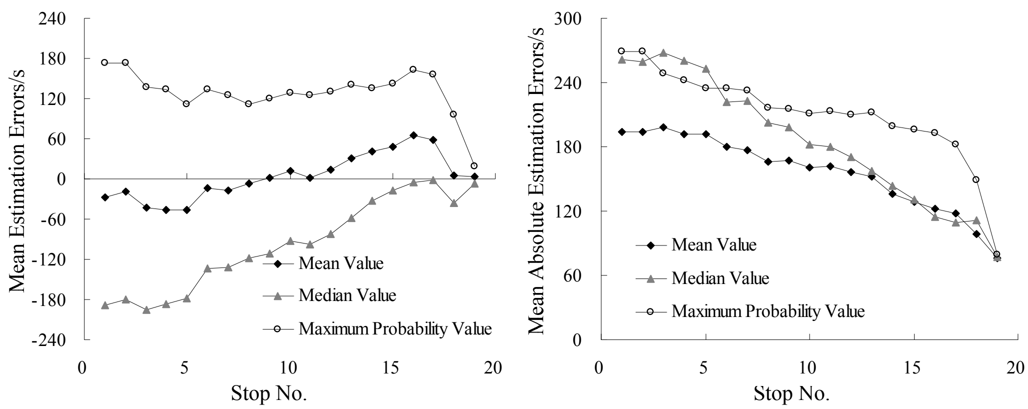
The terminal stop (the Shanghai-Stadium Stop) was chosen as the Target Stop for the reason that it can help make a further insight into the effect of the length of segment on the estimation accuracy and precision when buses are approaching to the target stop. Besides, the estimated trips on May 2, which begin from 5:00AM and end at 23:00PM, help show the effect of time periods on the performance of model with input of different statistical values. With this consideration, the estimation errors were grouped by stops and trips respectively to show the effect of the *length of segment* and *time periods* on the estimation accuracy and precision.

Accuracy Evaluation

The ME and MAE were calculated by stops and trips respectively to show the accuracy of model on different length of segments and during different time periods with input of the mean, the median and the maximum probability values.

Generally speaking, the model with input of the mean value performs the best on the estimation accuracy when buses are far away (more than five stops) from the target stop (No. 49020); while when buses are near (less than five stops) the target stop, the model with input of the median value achieves the best estimation accuracy. (As shown in Figure 4(a))

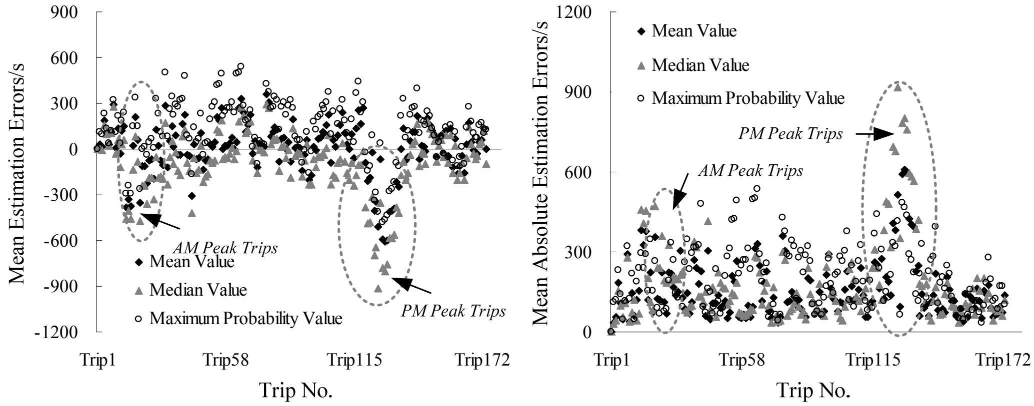
Moreover, it is interesting to be found that the accuracy of the historical travel time based model increases gradually when buses are approaching to the target stop (as shown in Figure 4 (b)), which is reasonable that the value of travel time is decreasing as well when buses are approaching to the target stop.



(a) Mean Errors with different inputs (b) Mean Absolute Errors with different inputs

Figure 4. ME and MAE with different inputs (Grouped by stops)

When the ME and MAE are grouped by trips, it was found that the historical travel time based model with input of the mean and median values performances worse than that with input of the maximum probability value during peak periods (as shown in Figure 5(a) and 5(b)). On the other hand, the model with input of the mean and median values performances better than that with input of the maximum probability value on midday periods. On the early morning and late night, few differences exist on the estimation accuracy and precision between the model with input of the mean, the median and the maximum probability values.



(a) Mean Errors with different inputs (b) Mean Absolute Errors with different inputs

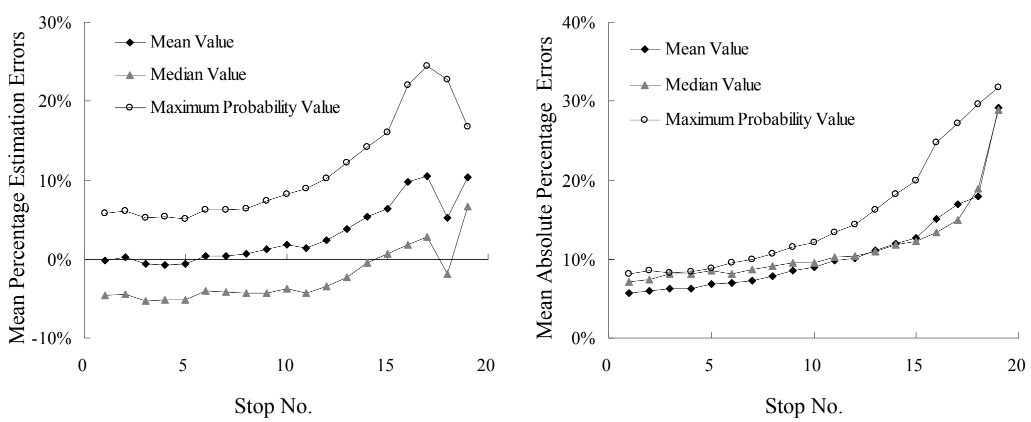
Figure 5. ME and MAE with different inputs (Grouped by trips)

Precision Evaluation

In the same way, the MPE and the MAPE were calculated by stops and trips respectively to show the precision of the model on different segments and time periods with inputs of the mean, the median and the maximum probability values.

In general, the model with input of the mean value shows the highest estimation precision when buses are relative far away (more than six stops) the target stop, while the model with input of the median value perform best on the estimation precision when buses are near (less than six stops) the target stop. (As shown in Figure 6(a))

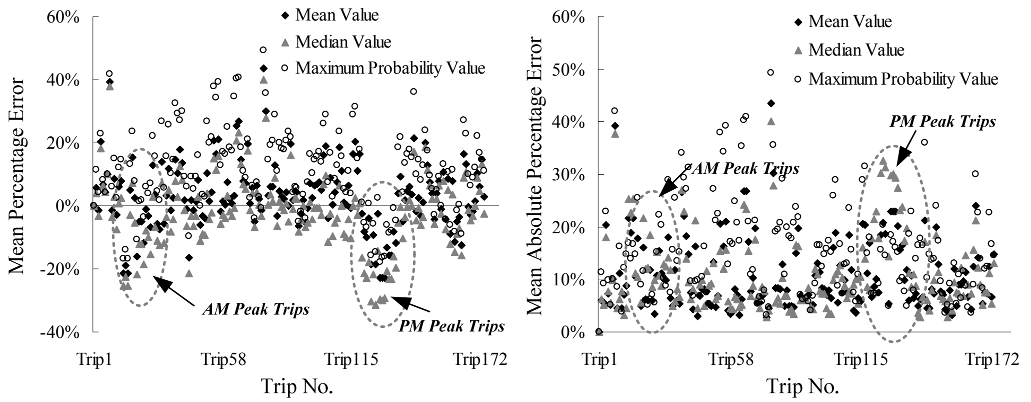
When buses are approaching to the target stop, the precision of the historical travel time based model decreases gradually because the variation of link travel time is larger on a shorter segment. (As shown in Figure 6(b))



(a) Mean Percentage Errors with different inputs (b) Mean Absolute Percentage Errors with different inputs

Figure 6. MPE and MAPE with different inputs (Grouped by stops)

When the MPE and the MAPE are grouped by trips, it was found that the historical travel time based model with input of the mean and the median values performs worse than that with input of the maximum probability value on the estimation precision during peak periods (as shown in Figure 7(a) and 7(b)). During the other time periods, the model with input of the median value performances slightly better than that with input of the mean value, but significantly better than that with input of the maximum probability value.



(a) Mean Percentage Errors with different inputs (b) Mean Absolute Percentage Errors with different inputs

Figure 7. MPE and MAPE with different inputs (Grouped by trips)

5 DISCUSSIONS AND CONCLUSIONS

Plenty of researches have been carried out on travel time estimation/prediction, but seldom of them have validated the effect of different estimated values on the performance of models. In this research, comparisons were made on the estimation accuracy and precision on basis of the historical travel time based model with input of the mean, median and maximum probability values of historical travel time.

The estimation results show that the performance of model varies a great deal with the different estimated link travel times on different lengths of segment and during different time periods. When buses are far away from (more than five stops) the target stop, the model with input of the mean value shows the best estimation accuracy and precision, while the model with input of the median value achieves the best estimation accuracy and precision when buses are near (less than five stops) the target stop. It is not unreasonable why the mean travel time is much more preferred in previous researches, as it does help the proposed model achieve a well comprehensive performance on the estimation accuracy and precision. Although the overall estimation accuracy and precision of the model with input of the maximum probability value is worse than that with input of the mean value and median value during early morning, midday, evening and night periods, it performs the best during the peak periods, which has not been validated in previous researches yet. Therefore, a multi-stage usage of statistical values of historical travel time is suggested in travel time estimation to achieve a better performance on both estimation accuracy and precision; that is to say, for the experimental bus route, it is preferred to use the mean value when buses are far away (more than five stops) from the target stop, while the median value is given priority to when buses are near (less than five stops) the target stop, and the maximum probability value is strongly suggested during peak periods.

Abstract: Based on the traffic impact assessment of construction project, the thesis applied random queuing theory to determine the number of parking spaces in a taxi station. The study calculated the changes of some operational index in queuing system, such as the probability of passengers taking a taxi without waiting, the average waiting time of taxi drivers and taxi leave rates based on the change of taxi arrival rates. Through case analysis, queuing theory was proved to be an effective method in determining the number of parking spaces in a taxi station.
Keywords: Random service system; Construction project; The parking spaces for taxi; Utilization rates.

1 Introduction

Planning the number and the scale of parking spaces in a taxi station scientifically is an important safeguard to regulate drivers and passengers' behavior, reduce the influence of taxi parking on traffic capacity and organize different public transportation mode properly. Current *Taxi Management Approach* only gave principles about the taxi station layout and some factors. It mainly referred to the prediction method of bus stations in real planning, which means that the planning was measured by the distance between the stations or calculated by traffic capacity of bus stations (TRB, 2003). According to the relationship between travel demand and land utilization, Ye Haifei (2013) determined the gross of taxi parking in a traffic zone. As the background of traffic impact assessment in the construction project, this study analyzed the scale of taxi station by traffic demand characteristics based on queuing theory. In addition, the study illustrated the rationality and feasibility of this method by comparing it with the turnover rate of taxi stations in peak hour which was the common method at present.

2 The establishment of queuing model

Queuing theory was widely used in the field of transportation, such as solving problems about optimizing configuration of airport runways design and airport capacity, about optimizing traffic organization in passenger terminals and about highway toll facility design. According to queuing theory, the process of taxi carrying passengers in taxi parking spaces in the construction project could be regarded as a random service system with limited capacity served for passengers getting on the taxi and leaving the taxi station. When an empty taxi arrived at the taxi station or waited there, passengers could get on and leave, finishing the whole service. In order to avoid the influence on traffic led by random parking of taxis, taxis were required to leave the taxi station immediately if there was no empty space upon arrival.

(1) The definition of symbols

N —the demand for taxi parking spaces

n —the number of taxis in taxi parking spaces

P_n —the probability of having n taxis in taxi parking spaces

W_q —the average waiting time of a taxi

L_q —the average number of taxis in parking spaces

(2) The description of queuing system

The usual input process in queuing system including Poisson distribution and Erlang distribution could be used to describe the passenger's arrival law. The choice of distribution should be made after some surveys in analogous projects. Passenger's arrival law usually complied with the Poisson distribution. Assuming the number of passengers in unit time was μ, thus the service capability in the service station in unit time was μ taxis. A service system where taxis were required to leave the parking spaces in accordance with the arrival sequence could be regarded as a queuing system with one service station.

Not considering the influence on taxi's arrival led by passenger's appointment and calling for a taxi by a phone, it was believed that the relationship between passengers' arrival and taxis' arrival was independent. If both passengers' arrival and taxis' arrival complied with Poisson distribution, the process of taxi carrying passenger was a Markov queuing system of M/M/1/N.

(3) The targets of system optimization

Assuming parking was the queuing system of M/M/1, the demand for parking spaces was the capability in queuing system and the demand forecasting of parking spaces was optimization problems in queuing system. It was required to set the targets of optimization. If passengers want to reduce the waiting time as much as possible, the target was the probability of passengers getting on a taxi without waiting. Taxi drivers hoped that there were empty spaces when they came to the station and waiting time was as little as possible. The utilization ration of parking spaces should be taken into consideration due to the limited road resource.

3 The method to optimize the queuing system

Due to the analysis above, when the targets of optimization were different, the demands for parking spaces were different. According to following different targets, the parking spaces in a taxi station were analyzed.

(1) Passengers could get on a taxi without waiting as soon as possible

Passenger getting on a taxi without waiting means that when passengers arrived at the station, there had empty taxis in the station. Therefore, the probability of passengers getting on a taxi without waiting was 1-P_0. Assuming the arrival rate for taxis and passengers were λ and μ respectively and $\rho = \frac{\lambda}{\mu}$, the formulas were

$$P_0 = \begin{cases} \frac{1-\rho}{1-\rho^{N+1}} & \rho \neq 1 \\ \frac{1}{N+1} & \rho = 1 \end{cases} \quad (1)$$

The probability of passengers getting on a taxi without waiting could be set to determine the number of parking spaces in a taxi station.

(2) The taxi drivers' waiting time could be reduced

$$W_q = \frac{L_q}{\lambda(1-P_N)} \quad (2)$$

Among them: $L_q = L_s - (1-P_0)$ (3)

$$L_s = \begin{cases} \sum_{n=0}^{N} nP_n = \frac{\rho}{1-\rho} - \frac{(N+1)\rho^{N+1}}{1-\rho^{N+1}}, \rho \neq 1 \\ \frac{N}{2} \qquad , \rho = 1 \end{cases} \quad (4)$$

(3) There were empty spaces when drivers came to the station

If the parking spaces are not fully occupied when drivers came to the station, the taxis could park. Thus, the probability of having empty spaces when drivers came was 1-P_N.

$$P_n = \begin{cases} \frac{1-\rho}{1-\rho^{N+1}}\rho^n, \rho \neq 1 \\ \frac{1}{N+1} \qquad , \rho = 1 \end{cases} \tag{5}$$

4 Case analysis

The case took the demand for parking spaces in traffic influence analysis of the construction project of a certain hospital as an example. According to the prediction of the project, trip generation of taxis in the evening peak hour μ was 160 pcu/h and trip attraction of taxis in the evening peak hour λ was 90 pcu/h.

(1) The computing method of turnover rate

According to the common method to determine the demand for parking spaces through the turnover rate in peak hour at present, the formula was

$$n = \frac{Q}{\gamma} \tag{6}$$

Among them: Q— trip generation and attraction of taxis in evening peak hour

γ— turnover rate of taxi parking spaces in peak hour

According to taxi operation conditions of the city in this project combined with characteristics of the project itself, it was obtained that the turnover rate of peripheral parking spaces in peak hour was 50 pcu/h and was calculated that the demanding number of parking spaces was 5.

(2) Optimization of queuing system

Three aforementioned optimization targets did not have clear quantitative indicators. Assuming that the number of demanding parking spaces in this project was 5, the taxi operation conditions could be analyzed though the optimization targets above. Using formulas (5), the probability of queuing system could be calculated: P_0=0.4158, P_1=0.2541, P_2=0.1430, P_3=0.0804, P_4=0.0452, P_5=0.0254.

Through formulas (1)-(3), the probability of passengers getting on a taxi without waiting was 0.5482, the average waiting time of a taxi W_q was 23s and the probability of having empty spaces when drivers came was 0.9746.

From the perspective of operational targets, 5 taxi parking spaces could fully meet the demand of taxi drivers and passengers in the hypothetical conditions. Then, it assumed that the number of parking spaces was 1, 2, …, 6 respectively and the operation indexes were compared with each other. The results were listed in table 1.

Table 1. Comparison of related operation indexes

N	The probability of passengers getting on a taxi without waiting$(1-P_0)$(%)	The average waiting time of a taxi W_q(s)	The probability of having empty spaces when drivers came $(1-P_N)$(%)
1	0.3600	0	0.6400
2	0.4678	8	0.8316
3	0.5138	14	0.9135
4	0.5364	19	0.9536
5	0.5482	23	0.9746
6	0.5546	25	0.9859

As the calculation results showed, the more parking spaces it had, the higher probability of passengers getting on a taxi without waiting and having empty spaces when drivers came it might be. However, the average waiting time of a taxi would increase. When N=2, there were 32 taxis could not park per hour. When the number of parking spaces N=3, there were 15 taxis could not park per hour. When $N \geq 4$, the number of taxis that could not park would be less than 8. When $N \geq 3$, more than a half of passengers could get on a taxi without waiting. When N was bigger, the probability of having empty spaces was bigger. When N=4, the probability of having 2 empty spaces was 0.8711 and the probability of having 3 empty spaces was 0.7244. When N=5, the probability of having 2 empty spaces was 0.9293 and the probability of having 3 empty spaces was 0.8489. If there lacked traffic control when it had empty spaces, social vehicles might occupy these empty spaces, influencing the parking of taxis.

The probability of the taxi carrying passengers without waiting P_0 and the probability of passengers getting on a taxi without waiting were exclusive. The model took the small rate of taxi leaving empty as the first target, and the interest of taxi drivers against passengers should be weighed and the utilization rate of parking spaces be considered. Thus, it was believed that it was appropriate when the number of parking spaces was 4.

With the development of the technology of communication and internet, passengers could take a taxi by telephone and some related software applications, increasing the taxi arrival rate. According to the formulas (1) and (2), the function diagram between taxi arrival rate λ and the probability of passengers getting on a taxi without waiting 1-P_0, the function diagram between taxi arrival rate λ and the average waiting time of a taxi W_q and the function diagram between taxi arrival rate λ and the probability of having empty spaces when drivers came 1-P_N could be drew when the number of parking spaces was invariable (N=4). (Figure 1,2,3)

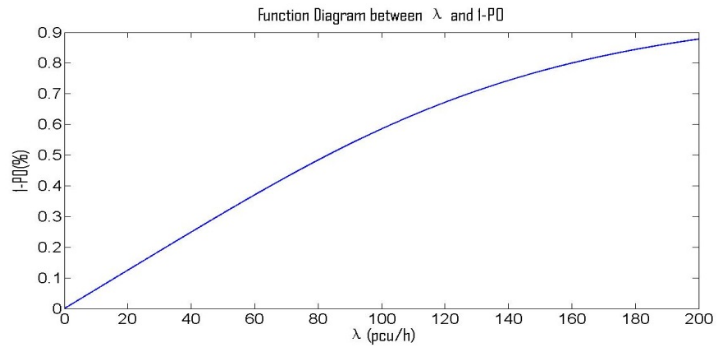

Figure 1 Function diagram between λ and 1-P_0

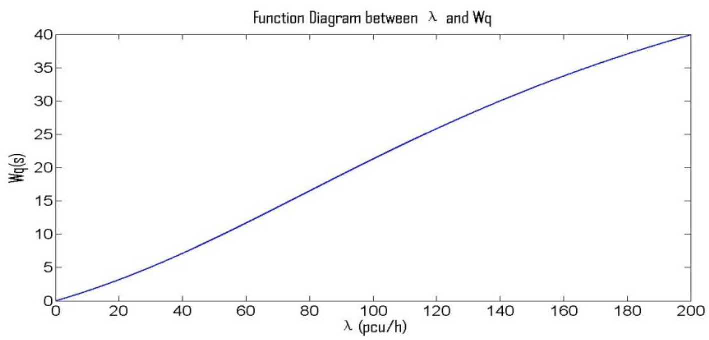

Figure 2 Function diagram between λ and W_q

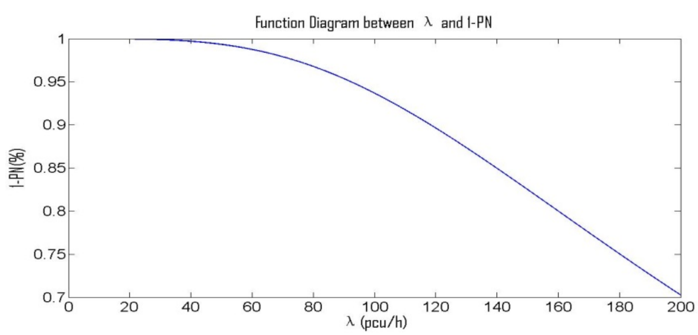

Figure 3 Function diagram between λ and 1-P_N

Obviously, it was beneficial for passengers with the taxi arrival rate increasing but the probability of having empty spaces when drivers came would decrease.

Therefore, more parking spaces were required to meet the demand and when taxi arrival rate increased, the average waiting time of a taxi would increase quickly. To solve these problems, the parking spaces should follow passengers' demand rather than simply increase the parking spaces and the best management method was controlling the taxi rate through effective information transfer.

4 Conclusions

Taxi parking spaces in the construction project could be regarded as a random queuing system due to the independence of taxis and passengers arrival. Passengers and taxis arrival law could be obtained by a lot of surveys and the demand of parking spaces could be analyzed based on queuing theory. This study assumed that passenger arrival rate and taxi arrival rate complied with Poisson distribution and both passengers getting on a taxi without waiting and average waiting time of a taxi deemed as optimization targets. The study also analyzed the change of operation indicators in queuing system with the increasing of taxi arrival rate when the parking spaces were invariable. Distinct characters and locations of construction projects directly or indirectly resulted in the differences of passenger arrival law and taxi arrival law. In practical application, all these influence factors were expected to be taken into consideration in order to analyze the traffic characteristics of passengers and taxis in peak time, determining the appropriate scale of parking spaces in a taxi station. The design standards of case analysis in this study were determined after analyzing multiple optimization targets comprehensively. If the queuing theory was seen as normal optimization method, the requirements of system service, such as utilization rate of parking spaces, the probability of passengers getting on a taxi without waiting and the probability of having empty spaces when drivers came, should be quantified due to specific requirements and standards of the design.

Abstract: A vast ocean of AIS (Automatic Identification System) data broadcast by ships contain characteristic of marine traffic, from which information that reflects latent principles of characteristics of ship movements can be gathered. To extract features of vessels during the berthing phase with as little error as possible, using data mining method and mid-latitude sailing in combination, based on AIS database. Then applying the algorithm to Xiamen Songyu port area and Tianjin Beijiang port area for data of full year 2014 in these two waters. Lastly, in-depth analysis is carried out to discover the berthing speed control law for large container vessels when remaining distance to berth is about 20 times own ship LOA (Length Overall). The research may help competent authority advance the rule of safe speed, while it also provides the basis of speed control during berthing phase for pilot or self-pilot personnel.
Keywords: Shipborne AIS data; Large vessel; Berthing speed; Control law.

1 Introduction

Even if there is tug assistance, personnel who are on large vessel feel stressed while berthing maneuvering is being undertaken. Therefore, it is important to study how to ensure vessels, especially those large vessels or vessels carrying special cargoes, berthing with as little risk as possible.

In recent years, academics at home and abroad carried out research focusing on the field of aids to safe berthing, which includes simulating large vessel maneuvering (Inoue, 2013) (Liu 2014), effect of large-scale vessel on berthing safety (Yang, 2011), critical analysis on piloting vessel berthing safely and so forth (You, 2013). However, there is little research on berthing speed control law for large vessel.

Distributions of ship speed during processes of entering and leaving port have been put forward recently (Xiao, 2014). The study could be better convinced if they have given a deep and comprehensive analysis on speed control. This paper is based on data received by AIS Data Acquisition Subsystem (Shao, 2007), which plays a key part in the VISSEA (Vessel Information Service System based on ECDIS and AIS). In this paper, data mining method is utilized to analyze berthing speed control law for large containers. And it focuses on speed change within range of 20 times own ship LOA (Length Overall) to the berth. We believe that it can both provide valid data and quantitative analysis for competent authority to advance rule of safe speed within the port, and help pilots or ship officers make a berthing plan and ensure safe berthing.

2 Details of Large Vessel Berthing

2.1 Berthing characteristics of large vessel

The large vessel has structural features of a large mass and great hull lines scale. The special structure of large vessel makes it more complicated to complete an already difficult procedure of berthing handling. Large vessel's speed is generally lower than the usual's, while berthing is being undertaken. While berthing, large vessel is seriously affected by wind when it is empty. In contrast, it is affected a lot by currents when it is full loaded. In addition, both shallow-water effects and narrow water do have effects on the berthing vessel. The navigating officer must carefully draw up a berthing plan according to actual conditions, taking the above-mentioned key points into account.

Ship officers should pay more attention to berthing speed, berthing angle and departure between ship and wharf. Generally, in order to avoid keeping engine a long-time astern or frequently changing engine order, it is important to maintain speed within a reasonable range, on the premise of ensuring steerage well performing. The experienced ship master or pilot always estimates the remaining speed of approaching berth by the relatively moving speed of shore-side objects.

2.2 The definition of large vessel berthing speed

In nautical navigation, ship's speed means the speed measured when sailing under the condition without any wind or current effect. Often, the natural factors are inevitable. It is significant to note that there are two kinds of speed used in nautical navigation. Speed over the ground (SOG), also called true speed, is the vessel's speed relative to the surface of the Earth and is calculated empirically by measuring the time required for a vessel to travel a known distance. Speed through the water is measured by instruments that sense the vessel's motion through the water, using some mechanical or electromagnetic principle.

GPS units provide speed readings of the SOG type because they are calculated relative to the Earth's surface and are measured without being affected by the water surrounding the vessel. Considering that the original data used in the research are derived from shipborne AIS, whose speed data are on the basis of GPS receiver, therefore, the speed discussed in this paper is the SOG.

The studies we have performed showed that large container carrier slackens her berthing speed significantly since the moment that the distance between destination and vessel is within about 20 times own ship's LOA. Hence, this research mainly discuss the distribution of berthing speed at the "20 times own ship's LOA" distance stage.

3 Characteristics of Berthing Vessel Extraction Algorithm

Data in the research are based on Microsoft SQL Server AIS information database, which is the main body of Data Analysis Subsystem (Shao, 2007). There are two kinds of information tables in the database, they are dynamic information table and static information table. The data size of the table, especially size of the former, are so huge that picking up those subjects we need is advised.

3.1 Ship arrival distance model design

(1) Confirm the samples we used in the research. They are target vessel, targe berth and range of the longitude and latitude of the pier she locates at. Associate dynamic information table with static information table by using the exclusive MMSI (Maritime Mobile Service Identities) of each vessel. Extract the time point of the first moment when constant zero of Temporary Table A;

(2) Extract the longitude and latitude corresponding to ST by associating the dynamic information table and table A. Define them as berth positions, symbolized by "Berthlong" and "Berthlat". Put the result of berth point into Temporary Table B;

(3) Confirm the start point of calculating according to the circumstances of different harbour water. Then extract the AIS data between the start point and berth point of vessel's track. Insert the result into Berthing table C;

(4) Build a function "CalDist" to calculate the distance between any track point and berth point belong to one ship. And have the function call in Table C. Considering that the distance between start point and berth point are relatively not too far, the method of mid-latitude sailing (Guo, 2005) is put forward to calculate the distance between any two adjacent track points. Then accumulating calculated distances belong to any vessel, her remaining distance is acquired, marked as "DistToBerth". Taking a M/V berthing for instance, calculating the distance between A_i and A_{i+1}:

$$\begin{aligned}\overline{A_i A_{i+1}} = D_i &= \sqrt{D^2\varphi_i + Dep_i^{\,2}} \\ &= \sqrt{D^2\varphi_i + (D\lambda_i \times \cos\varphi_{n_i})^2} \\ &\approx \sqrt{D^2\varphi_i + (D\lambda_i \times \cos\varphi_{m_i})^2} \\ &= \sqrt{(\varphi_{i+1}-\varphi_i)^2 + (\lambda_{i+1}-\lambda_i)^2 \times \cos^2\left(\frac{\varphi_{i+1}+\varphi_i}{2}\right)}\end{aligned} \tag{1}$$

For the sake of convenience, the middle latitude φ_n can be replaced by the mean latitude φ_m. Because sea areas of China locates in the low and middle latitude zone, moreover, the distances to berth are not too far.

Assume that the track of berthing as illustrated in Figure 1, then calculating the distance between start point $A_1(\varphi_1, \lambda_1)$ and berth point $A_n(\varphi_n, \lambda_n)$, so:

$$\overline{A_1 A_n} = D_{sum} = \sum_{i=1}^{n} D_i \tag{2}$$

$$DistToBerth = D_{remaining} = D_{sum} - \sum_{i=1}^{k} D_i (0 \le k \le n) \tag{3}$$

Because the unit of the distances mentioned above is n mile (nautical mile), for the sake of convenience for analyzing data law by using similarity comparison method, using a single dimension to measure the distance, that is the multiple of LOA (Length Overall) which is equivalent to the distance between ship and berth. It is symbolized as D_L, so:

$$D_L = \frac{DistToBerth}{Length} \tag{4}$$

In the course of berthing, because of large container ship has better maneuverability, she always stands by engine when she is about 10n mile apart from the berth (Hong, 2008). Without loss of generality, it is considered as 50 times own ship LOA, namely $50D_L$. Thus, obtain the distance no more than $50D_L$ by further extraction in Berth Table C. Some results of the processed data presents as Figure 2.

Figure 2. Part of berthing table C

3.2 Curve fitting and law mining

Present data for characterized berthing in the form of discrete point on a coordinate plane. Then, using maneuverability characteristics of vessels in conjunction with practical experiences of pilots to analyze relation between berthing speed and remaining distance of the same kind of large vessel under different conditions. After that, do a specific fitting at the stage of reducing berthing speed. Comparing the scatter diagram with curves of given functions, pick up the most similar one to fit it. The studies that have been conducted report that Polynomials Regression Forecast Method (Wang, 2014) based on least square (Xu, 2009) is preferred here. Lastly, regression equation and regression curve are obtained. General form of the equation is described as follow:

$$\hat{y} = a_0 + a_1 x + a_x x^2 + \ldots + b_n x^n \tag{5}$$

Utilize the MATLAB to generate prediction interval with confidence level of 95 percent (Larose 2011), namely, intervals of berthing speed distribution.

4 Algorithm Implementation and Example

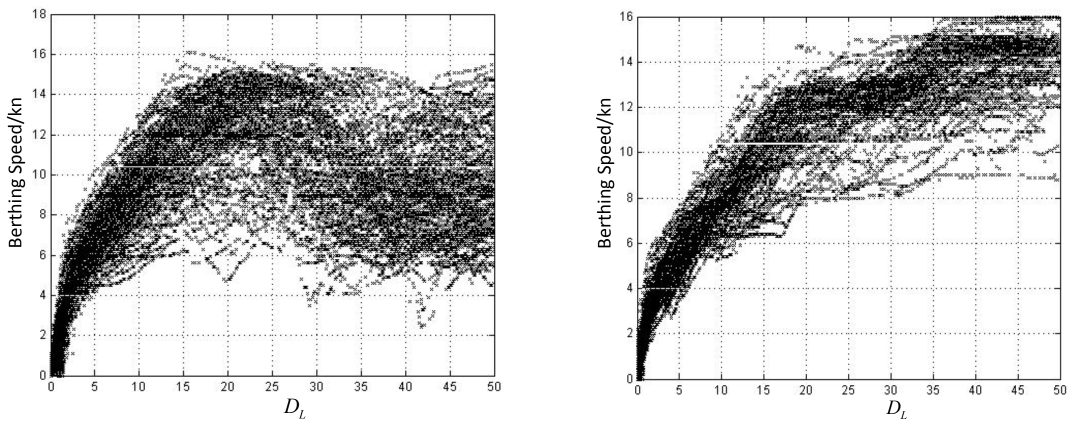
4.1 and data processing

Utilize the established AIS Information Service Platform, gathering data of vessels whose LOA no less than 300m and berthing at pier of Xiamen Songyu and Tianjin Beijiang. The geographical area of Xiamen Songyu confines latitude between 24°26′.48N and 24°27′.03N, longitude between 117°59′.52E and 118°02′.26E. The geographical area of Tianjin Beijiang confines latitude between 38°58′.68N and 39°00′.57N, longitude between 117°46′.36E and 117°47′.38E. And the time range from the first day of 2014 to the last day of the year, totally 365 days. The data processed have been shown in Table 1.

Table 1. Details of AIS data

Time Span	Port Area	Original Data	Processed Data	
			AIS Data	Number of berthing voyage
Whole year of 2014 (365 d)	Xiamen Songyu	70 694 735	25 868	346
	Tianjin Beijiang	98 611 753	20 098	230

4.2 Results of Berthing Speed



(a) Xiamen Songyu **(b) Tianjin Beijiang**

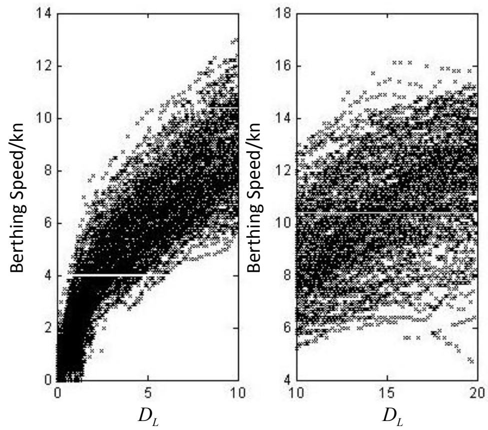
Figure 3. Scatter diagram of berthing details in 2014

The container ship who berths at Xiamen Songyu firstly sails by about $40D_L$ where the pilot embarkation area locate at (The Navigation Guarantee Department, 2009). Then her speed reaches local maximum value when she is about $20D_L$ from the berth. The local maximum value is approximately the upper limit of the water area, namely 15 knots (The Navigation Guarantee Department, 2009). The container ship who berths at Tianjin Beijiang firstly slackens her speed slightly when she is about $33D_L$ from the berth. Then the trend of reducing speed at the range of $20D_L$ is similar to the ship berth at Xiamen Songyu.

4.3 Result Analysis

Based on the similarity of the two port areas mentioned above, distribution of berthing speed is studied in combination. Continue the further analysis on macrosopical law of large container ship at the range of $20D_L$. The results shows as

Figure 4. From this, table for distribution of berthing speed can be deduced, summarized as Table 2.



(a) $0 \sim 10D_L$ **(b)** $10 \sim 20D_L$

Figure 4. Scatter diagram of large container vessels' berthing speed within the range of 20D_L

Table 2. Distribution of large container vessels' berthing speed within the range of 20D_L

D_L	15~20	10~15	5~10	2.5~5	1~2.5	0~1
Berthing speed/kn	10~15	8~13	5~10	4~6	1~4	0~2

Inertial distance of large container ship for reducing full speed to stop-ship state is nearly $9.8D_L$ (Hong, 2004). It's not hard to see that, from Figure 4, the berthing speed is about 8 knots though the remaining distance is $10D_L$. When it is close to about $1.5D_L$, the approaching speed slackens significantly. The berthing speed is approximately 3 knots at that moment. Compared with other kinds of ships, container ship is of small block coefficient, her C_B is smaller than 0.68. Her main engine power per DWT (Deadweight Tonnage) is greater than most of the ships', her $P_{\max} / m_{DW}$ is always greater than 0.60. Her ratio of rudder area to LOA, namely $A_R / L_{PP}d$ is generally greater than 1/55 (Hong, 2004). It is those factors mentioned above that result in the features that container carriers with. They are high stability, good stopping ability and steerability. Furthermore, the displacement of container carrier is so large that she should keep appropriately high speed to ensure efficiency and steerage, with taking safety into account.

Some pilots have commented that they, in the final stage of the berthing maneuvering, are used to undertaking good timing to carry way with engine stopped. It usually takes long time to complete the process of berthing. Therefore, the AIS data in this period is huge and discrete points are especially dense in the interval $0 \sim 2D_L$. In addition, pilots sometimes kick ahead to improve steerage.

4.4 Curve fitting

Considering the above-mentioned, we adopt the data derived from Xiamen Songyu and Tianjin Beijiang for curve fitting in the interval of $0 \sim 20D_L$, which is shown as Figure 5. And the berthing speed distribution in the form of formula is:

$$SOG = 2.25\times10^{-5} D_L^5 - 0.0014 D_L^4 + 0.0316 D_L^3 - 0.3507 D_L^2 + 2.341 D_L + 0.0784 \quad (6)$$

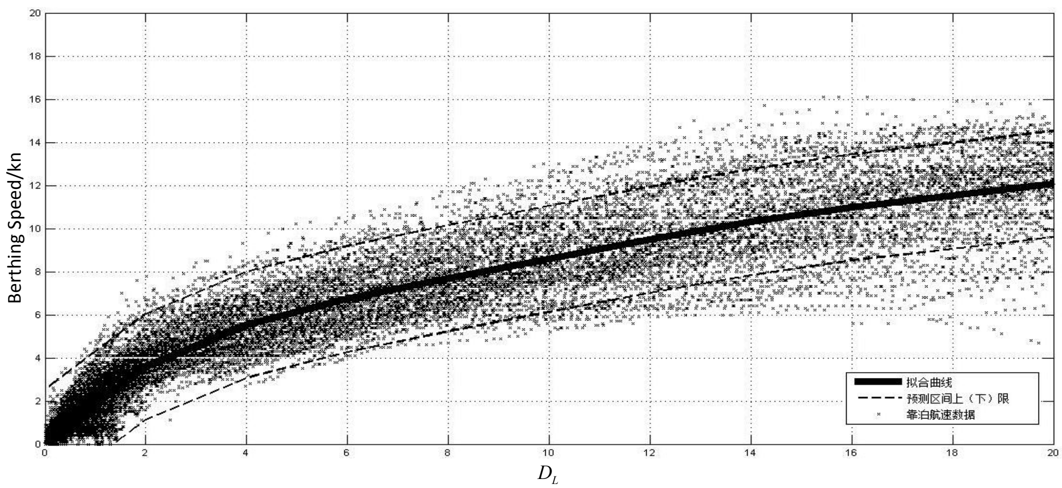


Figure 5. Curve fitting and prediction interval of distribution of LOA>300m container vessel

The recommended speed and corresponding variance for large container carrier berthing can be deduced from the fitting curve and formula 6, which shown as Table 3. The variances display in the table are used to evaluate the deviation between recommended speed and sample speed. As the ship approaches the berth, the difference of different container ships' speed control becomes tiny. Especially when the ship is within the range of $8D_L$, the variance is relatively smaller than the outsides'. It suggests the consistency of most ships' speed control in the range.

Table 3. Recommended speed and corresponding variance for large container carrier berthing

D_L	20	19	18	17	16	15	14	13	12	11
Speed/kn	12.1	11.8	11.5	11.2	10.9	10.6	10.3	9.9	9.4	9.0
Variance	3.458	3.831	3.947	2.783	3.176	3.659	3.529	3.443	3.539	2.994
D_L	10	9	8	7	6	5	4	3	2	1
Speed/kn	8.6	8.1	7.6	7.2	6.7	6.1	5.5	4.7	3.5	2.0
Variance	2.573	2.230	1.721	1.602	1.531	1.417	1.397	1.080	1.096	0.988

5 Conclusions and future work

In this paper, we propose the model of arrival distance for extracting ship berthing features. To get macroscopical law that can reflect large vessel's berthing speed, the experiments on AIS data collected from Xiamen Songyu and Tianjin Beijiang were conducted successfully. The results have been applied on the ship maneuvering simulator developed by Dalian Maritime University and practiced by four experienced masters in simulated Xiamen Songyu port area. The processes of simulative berthing handling were all successful, which shows the ubiquity of the berthing speed law.

The existing provisions of safe speed in harbor regulations were set based on the surveys from experienced ship masters and shore-based personnel, lacking effective support of data. This paper studies the macroscopical law of large container ship berthing speed. It makes a contribution for assisting the competent authorities have a better understanding of the habit of speed control in the water, then effective measurements for advancing rules of safe speed are intended to be raised and launched. Moreover, it is also beneficial to ships' officers or pilots enhance coordination, utilize the aids to berthing like engine, anchor, lines, thruster, tug and so forth with as little mistake as possible.

However, in the future work, the law of berthing angle, the effects of winds or currents or both on the velocity and course should be conducted. Furthermore, correlational researches on other special cargo carriers like VLCC (Very Large Crude Carrier) or LNG (Liquefied Natural Gas) carrier has a practical significance.

Design of Variable Message Signs for Real-Time Berth Guidance in Indoor Parking

Yanxia Yu; Ping Han; and Zhongkai Chen

School of Traffic and Transportation Engineering, Dalian Jiaotong University, No. 794, Huanghe Rd., Dalian, Shahekou 116028. E-mail: jtgc@djtu.edu.cn

Abstract: For the problems with driver's dissatisfaction about cruise and parking in indoor parking, this paper provides some solutions. First, this paper analyzes the current problem of the indoor parking guidance system and the superiority of variable message sign for real-time berth guidance, and then the specific design focuses on the setting mode, location and layout of variable message signs. Finally, taking Dalian Ansheng Shopping Plaza Underground Parking for instance, this paper designs real-time berth guidance information of variable message signs and solves the problem of real-time berth guidance when the optimal berth was occupied.
Keywords: Parking guidance system; Real-time berth guidance; Variable message signs; Layout design.

1 Introduction

Currently, the parking guidance bases on that the driver fully accept the guidance. But When the driver is not satisfied with the parking berth which is provided by the parking guidance system, he may find the parking berth himself. That phenomenon can result in the loss of the best effect of berth guidance. On the contrary, when the traffic environment changes affect the original guidance, the effective guidance system can change the optimal berth and path guidance in real-time.

Variable message sign is a traffic sign which changes display with the change of traffic, road, weather, etc. (LI Junli, 2001) .Because the sign is bright adequately and is not affected by the reflected light, so it is indeed suitable for berth guidance in parking. The sign can provide the right direction for vehicles, and help the driver park in the best berth conveniently, all these advantages will reduce driving distance and save time, and increase the parking efficiency. Meanwhile, due to the sign's lower cost, current parking guidance system's imperfection and the developer's less intention to invest too much, we have many reasons to consider that the variable message sign is the economical and effective method on parking guidance.

2 Variable message sign design for berth guidance in indoor parking

2.1Setting height and position design

Because indoor parking structures and limited space, and also there are many beams and columns inside, so gantry and attachment style are used. Due to the speed in indoor is low and different heights are designed by different architectural , the height design is selected by the height limit of parking.

Generally the road of indoor parking is two-way two-lane or one-way lane road, and also the speed is lower, so the driver do not have to change lanes, accelerate and decelerate, which means action distance is 0. As a result , the long front distance setting is not suitable .

Variable message sign can be set at the intersection of the exit road or entry road, or above the intersection directly. Thus it can be deduced that the distance of reading the end point to screen at the most unsatisfactory state in the actual parking guidance is the reaction distance. The schematic diagram is shown in Figure 1.

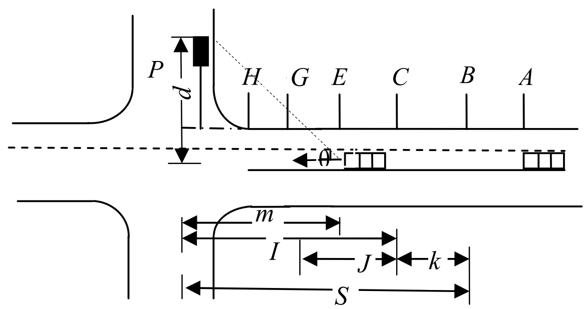

Figure 1. Setting position schematics of variable message signs

Critical point in the figure: *A*—visibility point, *B*—start reading point, *C*—end reading point , *E*—disappeared point, *G*— turning prepare point, *H*—turning point *P*—variable message sign; Key distance in the figure: *S*—distance of visual cognition, *k*—distance of reading sign , *J*—judgment distance, *I*—distance of end reading point to sign ,m—disappeared distance, *d*—the distance between height of the driver's vision field and sign in the roadside or the height between the height of the driver's vision field and the top edge of sign above the intersection, generally, the height of the driver's vision field is 1.2m.

Thus ensure that the driver can fully see the variable message sign and complete the entire decision-making process， following formulas should be met：

$$J \leq I \text{ and } \quad I \geq m \tag{1}$$

In order to make a more detailed and accurate guidance，variable message sign should not only be set up at the main intersection, it should also be set up at the corner of the road. Generally, under normal circumstances the number of signs set as follows: 1 to 2 at the corner, 2 to 3 at T intersection, 2 to 4 at cruciform intersection.

2.2 Layout design of variable message sign for berth guidance

1) Height of layout design

Formula (1) can derive the minimum value and reference values of the height.

$$J = v_s t_0 \le I \quad (2)$$

$$I \ge m = d / \tan\theta \quad (3)$$

v_s— travel speed ,m/s ; t_0— response time,2~2.5s.

θ—the angle between disappearance point and sign in the roadside , generally, it is 15° ,or the angle between disappearance point and sign above the intersection, it is 7° .

In the best case, $J = I = m$, reaction distance equal disappear distance . For sign above the intersection,

$$d = L + H - 1.2 \quad (4)$$

L— the clear height from the bottom of sign to the ground.

Formula (2) (3) (4) can derive the minimum value of the height in the best case.

$$H_{\min} = v_s t_0 \tan\theta - L + 1.2 \quad (5)$$

2) The actual word height of layout design

Word height is calculated by the formula of the word height of the general traffic sign, there is a relationship between I and the actual word height as follows(YANG Jiuling and LIU Xuehui,1999):

$$I = f(h^*) = 5.67 * K_1 * K_2 * K_3 * h \quad (6)$$

h*—the effective word height; h —the actual word height;

K_1—languages correction factor, Chinese is 0.6, Latin alphabet is 1.2;

K_2—word complexity correction factor, Object to the most complex word，value of less than 10 strokes is 1,10-15 strokes is 0.9, more than 15 strokes is 0.85;

K_3—speed correction factor， Values are shown in Table 1.

Table 1.Speed correction factor

speed（*km/h*）	walk	20	30	40	50	60	70	80	90	100
K_3	1	0.96	0.94	0.91	0.89	0.87	0.85	0.82	0.79	0.77

3)Word color and graph design

Basic orange or orange-red is used to display words in color of choice, such as berth number, license plate number, serial number, etc. White should be used to distinguish other messages and highlight the importance in the dark environment of indoor parking .The green guide arrow is used to express the direction information.

The graph of green arrow include turn left “” ,straight “”, turn right “”, U-turn “”.graph include: “”, “O”, “ ”, “P”, among them “ ” stands for “"no parking in front of the road”, it use color of red or orange, “O” stands for “the best berth in front of the road,“ ”stands for “lane dividers”, it use color of white,“P”stands for parking.

4) Concrete berth guidance information design

In this paper, the road between two intersections, is divided into four portions according to the roadway left, right and the distance , five items of berth information are shown in Table 2 . Variable message signs design are shown in Figure 2:

Table 2. Berth information

The optimal berth / Distance from the intersection	Optimal berth in the side of the travel direction	
	On the left	On the right
Short distance		Long distance		No optimal berth at this section		

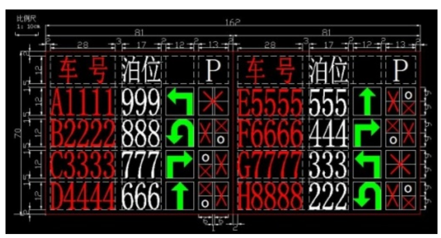

Figure 2. Berth guidance information design

3 Case Analysis

3.1 Introduction of basic information

Taking Dalian Ansheng Shopping Plaza Underground Parking for instance, we suppose that the parking space status is shown in Figure 3 at certain moment. If a vehicle reached parking entrance at this time, there are eight berths available :No. 012, No. 055, No. 087, No. 144, No. 163, No. 185, No. 230, No. 245 .

3.2 Basic setting of variable message signs

L values 2m , by limit of parking height. v_s is 15km / h by the maximum speed limit in the parking, t_0 is 2.5. H_{min} is 47.9cm according to the formula (5). If H of the actual design is 70cm, the disappeared distance m = 12.2m. Considering the following numeric fields :license plate number, berth number, travel direction , “P”, in the worst situation K_1=0.6,K_2=0.85,K_3=0.97, If h is 12cm, according to the formula(6) there are I = 33.7,m> 12.2m, meet the actual.

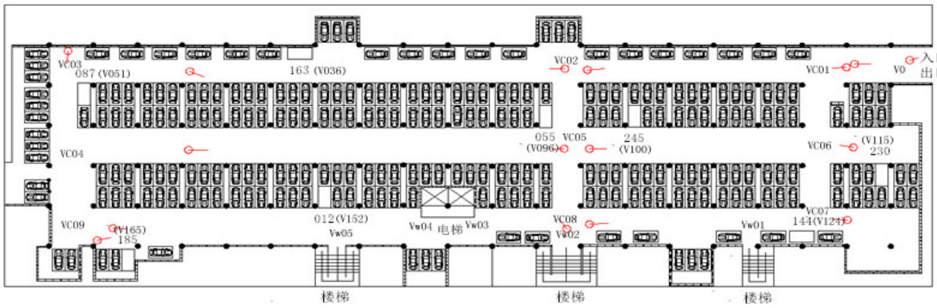

Figure3. Parking Current Situation

3.3 Real-time berth guidance in the best situation

First the optimal berth is calculated according to the optimal berth choice algorithm (FENG Lulu, 2013)for the vehicle A, it is berth No. 230 at node V115, and the optimal path to reach berth 230 is the V0-VC01- VC06-V115. It passes the two intersections VC01 and VC06.The next job is to guide the driver to go to the optimal berth. On this path at least two variable message signs（L11, L62） should be set to provide guidance information for the vehicle A. Assuming the car license plate number is A1234, the guide information display through L11 at the intersection VC01 and L62 at the intersection VC06,they are shown in Figure 4 and Figure 5

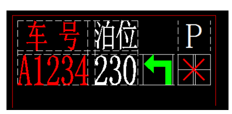

Figure 4. Layout information on L11

Figure 5.Layout information on L62

3.4Real-time parking guidance when the berth has be occupied

Assuming that when the vehicle A drives to the intersection VC06, and No. 230 berth is found to be occupied by the vehicle B , meanwhile No. 219 berth has be vacated at the intersection V104 . At this time the optimal berth and path guidance is needed to supply for vehicle A. The status is shown in Figure 6.

At this situation ,the berth No. 144 on node V124 is the optimal berth .Now, the vehicle's arrival to the berth No. 144 requires the way to via two intersections VC06 and VC07 , and should also be guided by L62 and L72, whose display should be updated to the following information on figure7 and figure8.

Figure 6. The case of berth is occupied

Figure7.Layout information on L62

Figure 8. Layout information on L72

4 Conclusions

The conclusions are as follows:

(1) The condition which the driver can fully see the variable message signs and complete the entire decision-making process is derived.

(2) The height of the variable message sign is derived，diagram of berth guidance information are designed.

(3)Specific examples are given to demonstrate the design of variable message signs during real-time berth guidance.

Abstract: In order to solve the problem of the ignorance of the purpose of resident trips when establishing the bus priority strategy, an BRT signal priority control strategy is presented based on social benefits and exponential smoothing in this paper. Firstly, weights used by G_1 are given to resident trips which are in different period and for different purposes. Secondly, the number of vehicles, the average rate of loading and the travel proportions for different purposes at the intersection are predicted by exponential smoothing, the value of the social benefits are calculated through the indicators above, and the BRT priority strategy is determined by comparing the value of the social benefits. Finally, the feasibility of the model is validated according to the example.
Keywords: BRT signal priority; Purpose on resident trips; G_1 method; Social benefits.

1 Introduction

Giving public transit priority at signalized intersection is an effective means to improve the competitiveness of public transit, generating strategy of public transit access preferentially at intersection is of great importance for reducing residents travel delays and improving operational efficiency together with service level.

Priority strategies of public transit signal are numerous at present, the research achievements can be divided into two categories: The control objectives of one category were to study the priority control strategies on single-point(ZHANG Chun,2011), main line(BIE Yiming,2011) and network(XU Lunhui,2009) based on the delays of per capita and public transit vehicles at intersections(ZHANG Juanzi,2013& ZHANG Weihua,2004); The other kind of research which based on the residents trips were to establish the priority strategies which are subjected to the maximal social benefits of resident trips(ZHANG Zhiliang,2012&ZHAO Bei,2010) through the study of the functional relationship of residents travel time, costs, and the proportion of travel mode.

The methods above have improved the priority strategies of public transit from different perspectives. However problems still exists: (1) The establishment and calculation were complex, the solution of the modes was difficult; (2)The definition of social benefits place particular emphasis on travel mode and time benefits of residents, but ignore the fact that different purposes of residents trip should be taken into consideration when establishing priority strategy. Having realized the shortages above, in order to speed the BRT system, the conception of social benefits of purposes on resident trips is proposed in this paper. And it considers the satisfying of the maximal social benefits of resident trips for different purposes as a goal when establishing priority of BRT system.

2 Travel weight calculation based on social benefits

2.1 Definition of resident travel social benefits

In urban traffic, according to different purposes on resident trips, trips mainly consists of commuting trip and non-commuting trip(PAN Chi,2011): commuting trip mainly includes on and off duty etc, non-commuting trip mainly includes shopping, entertainment, returning home, else etc.

Social benefits of vehicles are based on different purpose on resident trips which means the social benefits achieved by residents for different purposes include social assets and other non-economic benefits, in other words, value, income, satisfying one's own need or additional utility created by the social activities exists by trips for different purposes.

The objective of BRT priority strategy developed in this paper is to maximize the social benefits of trips for different purposes. Therefore, before calculating the social benefits for different purposes, weighting all kinds of travel purposes.

2.2 Weight calculation of travel purpose index

The purposes on resident trips can be influenced by the periodicity of social factors which be with regularity. Generally, going to work, school and other commuting trip have high requirement for time, entertainment and shopping have less demanding on time(ZHAO Shuzhi,2011). Therefore, in different periods, giving different weights to different travel purposes, the principle of weighs given to purposes as follows:

On the morning and evening peak hours at weekdays, weighting greater to going to work, school and other commuting trip; During the holidays, weighting greater to non-commuting trips such as shopping, entertainment and tourist etc;

Giving maximal weight to emergency trip (infinity) such as emergency patients' first aid, traffic accident, firetruck going to firefighting etc.

G1 method is a subjective weighting method which was proposed by GUO Ya-jun, because G1 method can avoid the shortage of AHP, and this method does not require consistency test(Tian Long-hui,2009), give different weights to different purposes of trip at different period by using G1 method. The steps are described as follows:

Step1 Determine travel indexes on different purpose, including m indicators such as going to work, going to school, shopping, entertainment, going home, emergency trip, other non-emergency trip.

Step2 Assign the weight of the indexes by G_1 method.

Firstly, it is necessary to determine the sequence relationship of the every two travel indexes.

If the social benefits importance of travel index X_i is greater than travel indicator X_j,denoted $X_i > X_j$;

If the social benefits of travel indexes $X_1, X_2, \cdots, X_p$ have been determined to

$$X_i > X_j > \cdots X_k \tag{1}$$

$i, j, \cdots, k = 1, 2, \cdots, p$, the sequence relationships of travel inexes have been determined by" > ".

Secondly, determine the relative importance of adjacent travel indexes:

$$r_k = \frac{\omega_{k-1}}{\omega_k} \tag{2}$$

$k = p, p-1, \cdots, 3, 2$, represents the degree of importance (i.e., weight) ratio of two adjacent travel indexes,

Table 1. r_k **Assignment reference table**

r_k	*Description (during the same period)*
1.0	*Travel index* s_{k-1} *and travel index* s_k *are compared with the same importance*
1.2	*Travel index* s_{k-1} *is slightly important than travel index* s_k
1.4	*Travel index* s_{k-1} *is obviously important than travel index* s_k

1.6	*Travel index* s_{k-1} *is strongly important than travel index* s_k
1.8	*Travel index* s_{k-1} *is extremely important than travel index* s_k

Therefore,

$$\omega_p = \frac{1}{1+\sum_{k=2}^{p}\prod_{i=k}^{p} r_i} \qquad (3)$$

$$\omega_{k-1} = r_k \omega_k$$

ω_k—the weight of k-th travel index; $\omega_{k-1} = r_k \omega_k$, $k = p, p-1, \cdots, 3, 2$。

From Equation 3, the weight of every travel index can be calculated by calculating the value of ω_p.

As for emergency trip, giving weight alone, the weight is infinite.

3 Prediction of arriving vehicles at import of intersection

Due to rapid increase of private car, and exponential smoothing method has better timeliness, the changes is more sensitive to recent data in short-term and gain a high accuracy of prediction, so use this method to predict the number of arriving vehicles at every import of the intersection in different period of weekdays and rest day.

First order smoothing formula for exponential smoothing is（Tian Longhui ，2009）

$$Y_{t+1} = \alpha F_t + (1-\alpha) Y_t \qquad (4)$$

Y_{t+1} is predicted value, F_t is observed value (actual value), α is smoothness index, t is time series.

Recursive by recurrence formula,

$$\begin{aligned} Y_{t+1} &= \alpha F_t + (1-\alpha) Y_{t-1} \\ &= \alpha F_t + \alpha(1-\alpha) F_{t-1} + \alpha(1-\alpha)^2 F_{t-2} + \cdots + \\ &\quad \alpha(1-\alpha)^{t-1} F_1 + (1-\alpha)^t Y_1 \end{aligned} \qquad (5)$$

α is determined on the basis of experience, $0 < \alpha < 1$,the more value the smoothing coefficient is, the role of the recent actual value is put more emphasis on, and the reflect on the change of the actual value is more sensitive; Initial value $Y_1 = \frac{1}{n}\sum_{t=1}^{n} F_t$; Error $e_t = Y_t - F_t$.

Take Δt ($10 \le \Delta t \le 30\min$)as interval,detect and investigate the numbers of the arriving social vehicles and the BRT vehicles, average rate of loading, proportions of residents on different travel purposes, The value of Δt should be moderate(if the value is too small, there is no statistical significance, the number of vehicle may fluctuate intensely; If the value is too large, there is no way to statistic the characters of traffic flow at different period).

Statistic the numbers of arriving vehicles $V_{l,m,n}$ （pcu/h） in the j-th period on the the i-th day of all weeks at one year, construct time series $\{V_{1,m,n}, V_{2,m,n}, \cdots, V_{q,m,n}\}$, $l = 1,2,\cdots,q$; $m = 1,2,\cdots,7$; $n = 1,2,\cdots,\frac{1440}{\Delta t}$,the number of vehicles from all directions $\{V_{1,m,n}, V_{2,m,n}, \cdots, V_{q,m,n}\}$ can be predicted in the n-th period of the m-th day in the q+1-th week by Equation 5.

Similarly, the average load ratio $A(N)$, $A(S)$, $A(W)$, $A(E)$ and the proportion of residents on various travel purposes of social vehicles $P_{S_i}(N)$, $P_{S_i}(S)$, $P_{S_i}(W)$, $P_{S_i}(E)$; Average rate of loading $A(N)_{BRT}$, $A(S)_{BRT}$ and the proportion of residents on various travel purposes $P(N)_{BRT}$ 、 $P(S)_{BRT}$ of BRT vehicles can be predicted by Equation 5.

4 Design for priority control strategy at intersection

For example, the intersection has two phases, the direction of BRT lane is north-south. Predict the proportion of residents from different import, period and purposes, weight by G_1 method, calculate the social benefits of all residents from one import in the period of Δt.

As for the direction of east-west, in the period of Δt, the whole social benefits of trips on purposes X_k can be calculated as follows

$$PI(W-E)_k = [A(W)\cdot P_{X_k}(W)\cdot V(W) + A(E)\cdot P_{X_k}(E)\cdot V(E)]\cdot \omega_k \cdot \bar{H}_s \qquad (6)$$

$PI(W-E)_k$ —the whole social benefits of trips on purposes X_k on the east-western direction, （people/ h）; W —western import direction; E —eastern import direction; $\overline{H}_s$ —average rated capacity of social vehicles in the period, （people/ pcu）.

In the n-th period of the day, the m-th day of the week,, the q+1-th week, the whole travel social benefits of the phase can be calculated as follows

$$PI(W-E)=\sum_{k=1}^{p}PI(W-E)_k \qquad (7)$$

Similarly, the whole travel social benefits of the arriving BRT vehicles in the period of Δt

$$PI(o)_{BRT}=\sum_{k=1}^{p}\sum_{z=1}^{r}A(o)_{BRTz}\cdot P_{X_k}(o)_{BRTz}\cdot\omega_k H_{BRT} \qquad (8)$$

r —the number of the arriving BRT vehicles in the period of Δt; H_{BRT} —rated capacity of one BRT vehicle.

At the import which includes BRT lane, the social benefits are the social values of all residents on the social vehicles and BRT vehicles, then the social benefits of all the residents at the import can be calculated as follows

$$PI(o)_{总}=PI(o)_{BRT}+PI(o) \qquad (9)$$

$PI(o)=A(o)\cdot P_{X_k}(o)\cdot V(o)\cdot\omega_k$, $o=N,S$ 。

The social benefits of the BRT phase is

$$PI(N-S)=PI(N)_{总}+PI(S)_{总} \qquad (10)$$

Modeling by indicator function,

$$\phi_{q+1,m.n}=\begin{Bmatrix}1 & if\ PI(N-S)>PI(W-E)\\ 0 & else\end{Bmatrix} \qquad (11)$$

In the n-th period of the day, the m-th day of the week,, the q+1-th week, the value of the function is 1, the whole social benefits of BRT phase is higher than the other phase, open the signal priority strategy to the BRT phase, that is to say turn signal priority to the arriving BRT vehicles in the period; On the contrary, in order to satisfy the whole trip society benefits, do not open signal priority strategy, keep the original signal program.

5 Example Analysis

For example, on the morning 8:00—8:15(during the morning peak, Δt =15 min ,operating hours are 7: 00-22: 00) of one Wednesday, the intersection has two phases.

Step1 In the morning peak, arrange the order relations of trip indexes for different purposes(no emergency travel situations exist);

$$\{X_1\text{=go to work}; X_2\text{=go to school}; X_3\text{=shopping}; X_4\text{=entertainment}; X_5\text{=go home}; X_6\text{=other non}-\text{emergency trip}\}$$

Then $\{r_2 = 1;\ r_3 = 1.6;\ r_4 = 1;\ r_5 = 1.2;\ r_6 = 1.2\}$

Step2 Determine the weights of trips for different purposes;

Calculate by Equation 2,3

$$\{\omega_6 = 0.1034;\ \omega_5 = 0.1241;\ \omega_4 = 0.1489;\ \omega_3 = 0.1489;\ \omega_2 = 0.2383;\ \omega_1 = 0.2383\}$$

Step3 Predict the number of the arriving vehicles, the average rate of loading, the percentage of residents for different purposes;

Predict the data of every import of the intersection, the social benefits of every phase can be calculated by Equation 6-10 which can be shown in the following table(α=0.3) ,

Table 2. Every imported lane's social benefits at the intersection

	N		*S*		*W*	*E*
	Social vehicles	*BRT vehicles*	*Social vehicles*	*BRT vehicles*		
Number of arriving vehicles	*323*	*1*	*329*	*2*	*341*	*336*
Average rate of loading	*0.77*	*1.32*	*0.89*	*1.27*	*0.82*	*0.83*
Rated capacity (average)	*6.56*	*88*	*7.02*	*88*	*5.69*	*7.21*
Proportion of residents going to work	*0.29*	*0.39*	*0.34*	*0.41*	*0.33*	*0.50*
Proportion of residents going to school	*0.36*	*0.31*	*0.30*	*0.23*	*0.27*	*0.23*
Proportion of residents going shopping	*0.18*	*0.12*	*0.11*	*0.20*	*0.15*	*0.09*
Proportion of residents going entertainment	*0.07*	*0.11*	*0.17*	*0.11*	*0.16*	*0.14*
Proportion of residents going home	*0.04*	*0.02*	*0.06*	*0.03*	*0.07*	*0.02*
Proportion of other	*0.06*	*0.05*	*0.02*	*0.02*	*0.01*	*0.02*

residents						
Social benefits PI	*331.67*	*24.24*	*418.74*	*45.70*	*316.39*	*427.79*
	820.35				*744.18*	

Step4 Determine whether the BRT vehicles in the period can be given signal priority strategy.

It can be obtained by comparing the social benefits value that $\phi_{q+1,3,5} = 1$, then giving signal priority to the three arriving BRT vehicles and other social vehicles coming through this intersection on the morning 8:00—8:15 of the Wednesday.

6 Conclusion

In this paper, with the satisfaction of the maximal social benefits produced by resident trips which on different purposes as a goal, the paper established signal priority control strategy model of BRT system. The main conclusions are as follows:

(1) Weighted for travel indexes for different purposes and in different period;

(2) Intersection vehicle indexes needed for calculating social benefits were put forward, and through it the paper predicted the value of these indexes by exponential smoothing method;

(3) The priority strategy of the BRT vehicles were determined by the value of the social benefits at the intersection.

As for this paper, the next job is the perturbation analysis on the influence that the value of period to the priority strategy.

[2]Key Laboratory of Road and Traffic Engineering of Ministry of Education, Tongji University, Shanghai. E-mail: 1059680289@qq.com

Abstract: The headway distribution is a vital foundation for the work of traffic control, capacity calculation, traffic safety analysis, etc. In this paper, based on the analysis of data collected in Shanghai, the statistical features of headway distribution of different road section at the same volume are investigated at weaving section of signalized intersection upstream. The method of $\chi^2 - test$ is adopted to analyze the time headway distribution. The results indicate that in the normal period, headway distributions of three typical sections of the fast lane are fitted well with the negative exponential distribution, and the average headway of the stop line section is the minimum, and the average headway of the weaving section is the maximum. This investigation provides a useful basis for further research on capacity of weaving section of signalized intersection upstream, signalized intersection upstream planning and management.
Keywords: Headway distribution; Weaving area; Typical cross-sections; Mathematical statistics.

1 Introduction

Having a knowledge of vehicle time headway distribution is important for the study of the traffic efficiency and safety. Domestic and foreign scholars made researches of headway distribution on the basic section(TAO etal,2011; Abtahi etal,2011), expressway weaving area(ZANG and ZHOU,2010), ramp connection(PEI and GAO,2007) and so on ,and obtained the negative exponential distribution, shifted negative exponential distribution, M3 distribution, Weibull distribution and so on. Murat analyzed the headway distribution in the off-peak period in signalized intersection, and found it can be described by exponential distribution and Weibull distribution (Murat and Gedizlioglu,2007). Distribution characteristics of headway at weaving section of signalized intersection upstream is important for analysis of traffic flow characteristics of urban road, signalized intersection design and intersection capacity calculation. However, the current research on this part is relatively less. This paper acquired data through investigation, then analyzed the headway distribution of different sections on urban road signalized intersection upstream by the method of mathematical statistics and lay the foundation for further study.

2 Data Acquisition

This paper selected a typical intersection in Shanghai - Tianmu Road Hengfeng Road Intersection. There are three lanes on the south import road of this intersection and two lanes on the road section. The author carried out the survey at 7:00 - 8:30am on July, 10th, 2013(Wednesday). The diagrammatic sketch of invested road and road section is as shown in Fig.1. Respectively, the basic road section is section A, and weaving area section is section B, and stop-line section is section C.

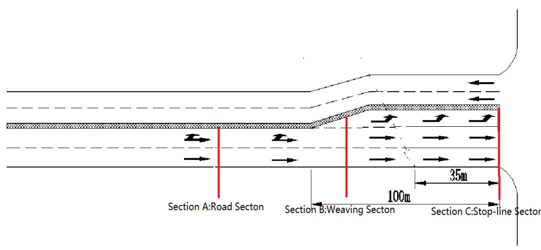

Figure1. Diagrammatic sketch of invested road and road section

Through analysis of collected survey data, the author gets the headway of different sections under the same flow rate (i.e 614vel/h) in the normal period. The value of each section is shown in Table 1 ~ Table 3.

Table 1 Headway of section A on the fast lane

Headway（s）	Median value（s）	Number	Frequency	Cumulative frequency
0~2	1	55	0.447	0.447
2~4	3	48	0.390	0.837
4~6	5	7	0.057	0.894
6~8	7	5	0.041	0.935
8~10	9	1	0.008	0.943
10~12	11	0	0.000	0.943
12~14	13	4	0.033	0.975
14~16	15	3	0.024	1.000
average（s）	3.049			

Table 2 Headway of section B on the fast lane

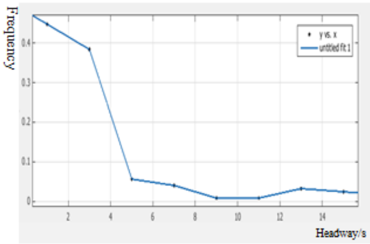
Headway（s）	Median value（s）	Number	Frequency	Cumulative frequency
0~2	1	46	0.404	0.404
2~4	3	40	0.351	0.754
4~6	5	17	0.149	0.904
6~8	7	3	0.026	0.930
8~10	9	2	0.018	0.947
10~12	11	1	0.009	0.956
12~14	13	2	0.018	0.974
14~16	15	3	0.026	1.000
average（s）	3.263			

Table 3 Headway of section C on the fast lane

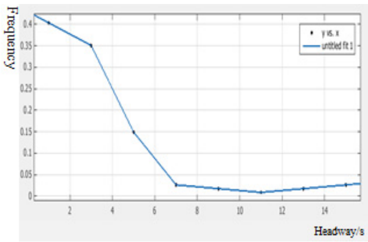
Headway（s）	Median value（s）	Number	Frequency	Cumulative frequency
0~2	1	43	0.457	0.457
2~4	3	28	0.298	0.755
4~6	5	13	0.138	0.894
6~8	7	6	0.064	0.957
8~10	9	3	0.032	0.989
10~12	11	1	0.011	1.000
12~14	0	0	0.000	1.000
14~16	0	0	0.000	1.000
average（s）	2.894			

3 Data Analysis

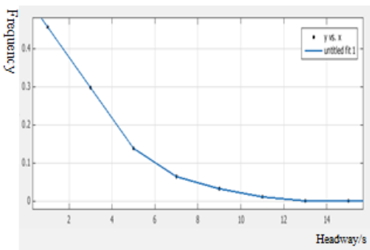
Headway refers to a certain time interval in which when traffic traveling in the same direction, the front two cars passing through the adjacent road section. This paper took the south imports of Tianmu Road-Hengfeng Road Intersection to study the headway distribution in the normal period of the road section, weaving area section and stop-line section. The distribution is shown in Figure 2.



（a） Section A



（b） Section B



（c） Section C

Figure2. Collected data of automobile headway distribution

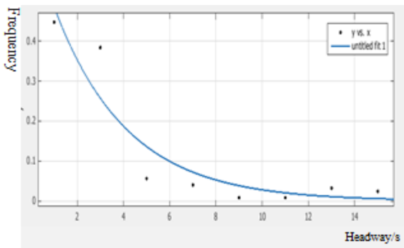
As shown in Figure 2, under the same flow rate, the headway distribution measured in different sections is closer, and this further proved that the headway distribution is closely related to the rate of traffic flow.

Obtained from Table 1~3, the average headway of section A is 3.049s, the average headway of section B is 3.263s, and the average headway of section C is 2.894s.It can be found that the average headway of section C, or the stop-line section is the minimum. There are two probable reasons:

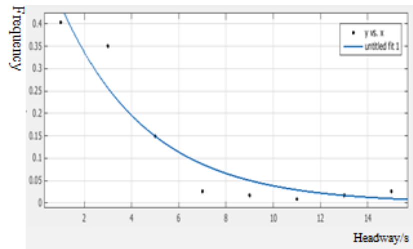
(1) In the actual situation, the stop-line section exists in a queued vehicles because of red light, and most of these vehicles pass the stop-line section with the saturation headway and thus in the stop-line section, the headway distribution is more concentrated;

(2) In the weaving section , vehicles need to slow down to change lane or slow down to provide clearance for the insert car to change lanes, and thus the average headway of section B ,or the weaving section is the maximum.

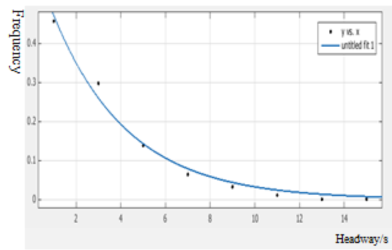
The author used negative exponential distribution to fit the headway distribution of different section and used $\chi^2 - \text{test}$ ($\alpha = 0.05$) to test the goodness of fit of the theoretical distribution. The fitting curve is shown in Figure 3. The χ^2 −test results are shown in Table 4.



(a) Section A



(b) Section B



(c) Section C

Figure3. Frequency curve of different sections

Table 4 Test results of headway distribution ($\alpha = 0.05$)

Section	negative exponential distribution		
	$\chi^2_{observed}$	$\chi^2_{theoretical}$	Fitting results
Road section	0.263	5.991	Recognized
Weaving section	11.585	12.592	Recognized
Stop-line section	1.696	9.488	Recognized

Fitting results show that in the normal period, the headway distribution of each section in signalized intersection upstream obeys negative exponential distribution.

4 χ^2 −Test of Headway Distribution

In traffic engineering, we usually use χ^2 −test to test the goodness of fit of the theoretical distributions. Take the χ^2 −test of section B for example.

(1) the observed parameters of the distribution

$$M = \frac{\sum_1^8 f_i t_i}{\sum_1^8 f_i} = \frac{372}{120} = 3.1, \quad (1)$$

$$D = \frac{\sum_1^8 f_i t_i^2}{N-1} - \frac{\left(\sum_1^8 f_i t_i\right)^2}{N(N-1)} = \frac{2274}{120} - \frac{372^2}{120*119} = 10.433, \quad (2)$$

$$\lambda = \frac{1}{M} = \frac{1}{3.1} = 0.323, \quad (3)$$

f_i——the observed frequency

t_i— —the observed median headway

N— —the number of sample

(2) χ^2 −test

Assume theoretical distribution model as a negative exponential distribution, and use Matlab to obtain the distribution model for fitting.

$$f(t) = 0.5792 * exp\,(-0.2712 * t), \quad (4)$$

t— —the headway

χ^2 −test calculation results are shown in Table 5.

Table 5 Weaving Area Calculation Section χ^2 −test Results

Median Value（s）	Observed Number f_i	Theoretical Number F_i	F_i >5	$\chi^2{}_i = \frac{(f_i - F_i)^2}{F_i}$
1	46	50.34	50.34	0.375
3	40	29.27	29.27	3.935
5	17	17.01	17.01	0.000
7	3	9.89	9.89	4.802
9	2	5.75	5.75	2.446
11-15	6	6.42	6.42	0.027
$\chi^2{}_{observed}$				11.585

DOF = 8-2 = 6, taking α = 0.05, $\chi^2{}_{theoretical}$ =12.592, it can be seen that $\chi^2{}_{observed}$ < $\chi^2{}_{theoretical}$, so the hypothesis is recognized and therefore the headway of section B obays negative exponential distribution. Similarly, examine the observed distribution of headway of section A and section C, the result is shown in Table 4.

5 Conclusion

Here we may draw the following conclusions.

(1) In the normal period, the average headway of the stop line section is the minimum, and the average headway of the weaving section is the maximum.

(2) The above results indicate that in the normal period, the weaving section may become the bottle neck point of signalized intersection upstream.

(3) When traffic flow rate is in the normal period (614vel/h), the headway distributions at different road section are fitted well with the negative exponential distribution.

This investigation provides a useful basis for further research on capacity of weaving section of signalized intersection upstream, signalized intersection upstream planning and management.

6 Recommendations for Future Research

The headway distribution is a vital foundation for the work of traffic control, capacity calculation, traffic safety analysis, etc. So the headway distribution at different flow rate and different lanes at weaving section of signalized intersection upstream can be further studied to provide the theoretical basis for the capacity calculation of signalized intersection, so as to find out the bottle neck point of signalized intersection upstream.

Abstract: Highway without a stop charging system (ETC) is an important subsystem in the field of intelligent transportation. The system has accumulated a large number of charge transaction data, which contains the traffic flow characteristic information and many kinds of feature information of highway users. Based on the analysis of ETC related data, The article did investigation of the ETC user demand investigation. And conducted requirement analysis for the highway travelers which contains transportation information types, information provision methods, service functions and so on. Finally, put forward the application service framework based on data ETC for highway users, highway regulators and highway operation management, covers the analysis of characteristics of highway basal network, the highway customer analysis and management, travel path planning and so on.

Keywords: Intelligent transportation; Highway; Trade data of the ETC; Demand analysis; Application service framework.

1 Introduction

As a new source of traffic data, Electronic Ton Collection system overcomes the defects that traditional artificial charge information can't obtain the vehicle running state. With the improvement of the technology and the promotion, the users of the system will be gradually increased and the volume of trading rapidly growth that will make the ETC system accumulated huge amounts of transaction data. The data not only contains the information of traffic flow characteristics from the traditional coil and video detector data, but it also contains many kinds of feature of the highway users. Xiao et al. (2008) thought that ETC (electronic toll collection) could significantly improve the handling efficiency of the toll station and the capacity traffic ability of toll road because of no parking troll collection.

The ETC system application in China started relatively late, the domestic scholars also less mining research for ETC transaction data. At present. Weng et al. (2010) conducted a preliminary analysis of the ETC data, studied the application method of ETC data. Fu (2008) carried out the exploratory research of ETC data mining. Foreign Levinson (2003) were emphatically studied on the application scope of the ETC data and travel time prediction method based on ETC data, Zarrillo et al. (1997) summarizes the available kinds of traffic information with ETC data. Currently, Myung et al. (2011) could get highway travel time and travel time prediction for the next period. Qian et al. (2012) only from the angle of statistics discussed the extracting, screening and analysis method of ETC trading data, had carried out access the indexs methods such as travel speed, traffic flow and highway station OD distribution and so on. But research for potential information of ETC data had no depth mining, such as the network running status.

The current study is lack of application of ETC data, and ignoring the more depth acquisition of road traffic information that combined with applications and services. Therefore, in this paper, through establishing the ETC data application service framework to provide basis for scientific monitoring highway running state, provide ways for fully excavating the existing system resources. It is also the foundation of the future related objects such as management departments, operating units and the vast majority of traveler and so on, real-time release and apply the monitoring information of highway condition.

2 ETC relevant data base

ETC relevant data includes ETC transaction data, customer information and other basal data, these data laid a foundation for establishing the application and services framework of ETC data.

(1) ETC trading data

The original ETC transaction data table has a total of 74 field and records a large number of trading information, and also details records the vehicle information in and out of the highway. ETC trading data mainly can be divided into two aspects: one is the actual transaction amount, mainly including defined the class of the card by card issuers, the OBU (On board Unit) status, type of payment and the amount of accounts receivable and other fields; Another is the traffic information, mainly including entrance square number, export square number, entry time, export time and vehicle types and other fields. These fields are the main data base of the highway operation monitoring, is also closely related to the main research content of application service requirements. As shown in table 1.

Table 1. ETC raw deal data part of the main content of the field

Field Name	Annotation	Data Sample	
PLAZAID	Export square number	100124	100433
UP_DOWN	1: Ascending 0: Descending	1	0
ENTRY_EXIT	0: Entry 1: Export	0	0
CAR_SERIAL	License plate number	JingPA1234	JingFZ1234
CREATED	Records generated time	2013/9/1 0:08	2013/9/1 0:17
VEHCLASS	Vehicle type	1	1
EN_PLAZAID	Entrance square number	100122	100711
EN_TIME	Export time	2013/9/1 0:01	2013/9/1 0:11

(2) ETC customer information data

ETC customer information data covers the records such as deal and recharge of ETC. And the key information include the customer name, id information, date of birth, contact information and deal with other business transactions. Through the ETC customer information data can identify the identity of the ETC user and make behavior analysis.

(3) Other basic data

Other basic data including name of the toll station, the rate information within the network, the distance between the toll station, toll station routing information, toll station location information, overpass location information, etc.

3 Investigation and analysis for ETC user's requirements

The research take the method of sample survey of the bearer for Beijing ETC users, distributed and recycled effective questionnaire 400.In the sample, the user age mainly concentrated in the range of 30 to 40 years old, the frequency of consumption is focused on the use of 6-10 times a month, accord with typical characteristics of ETC users. In order to grasp the needs of ETC users, this paper analyze the transportation demand and personal information management demand. The proportion of each demand content shown in the following table.

Table 2. Different users demand

Demand content	Traffic Information	Path Planning	Travel Time Prediction	Charging Information	ETC Usage Management	Preferential Information	Social Information
Proportional	68%	94.25%	82%	89%	>50%	91%	82.50%

3.1 Transportation demand analysis

The traffic travel demand analysis for ETC user mainly focused on traffic information, path planning services, travel time prediction, the charge information and so on.

(1)Traffic Information

There are respectively 65.5% and 47.75% of the users want to obtain traffic information through mobile phone text messages and Wechat, and respectively 68% and 53.25% of people want to know the city's congestion information and congestion peak prompt message. The survey results show that the ETC users have urgent request for traffic information services, focusing on global and local road network traffic conditions. The demands of which are not directly affect the information of traffic environment factors such as the construction, the weather are relatively low. Survey for individual users, they prefer to adopt one-to-one directional services such as SMS, Wechat, rather than other widely audiences, weaker targeted or immediacy medium.

(2)Path Planning Services

The questionnaire data show that 94.25% of users are willing to accept the path planning, go around the traffic jam, and respectively 56% and 43.75% of the user wants to obtain path planning information using text messages and phone software. 92.75% of users are willing to accept the guidance of driving and the users prefer to select SMS and Wechat to obtain information; With nearly half of the survey users want to obtain the flow path and information of the next export direction. The results of the survey shows that the ETC users' demand of path planning, traffic guidance is strong, especially the women and less driving experienced investigators. In terms of providing service media, SMS and Wechat, which based on mobile terminal, are the most respected. Respondents also have great interest in the mobile client (APP), vehicle navigation and customer service telephone.

(3)Travel Time Prediction Demand

Survey results show 82% of the users are willing to know the best time to the destination, 92.5% of the users are willing to know the time to the destination, and about half of the users who are surveyed are interested in the time of arrival to the service area, the place of traffic jam and the next exit location. The investigation result indicated that, the ETC users have a strong interest in the prediction of travel time, travel time are required for multiple points of interest, but the arrival time of highway service area is the most attention by respondents.

(4)Charging Information

The questionnaire data show of the users want to see the charge information of road and bridge, and the popularity of the first three methods of obtaining information is: mobile phone, SMS, Wechat, mobile phone client, The demand degree respectively is: 66.5%, 44.5%, 42.25%.

3.2 Personal Information Management Needs Analysis

ETC users not only demand for travel information, also hope to obtain personal information such as ETC usage, ETC preferential information and relevant social information and so on.

(1)ETC Usage Management

Survey data show that more than half of users are willing to know their ETC charge mileage, nearly half of the users want to know their own frequency of using ETC, consumption and mileage and other characteristics. This shows that the respondents have management requirements of use ETC. At the same time, with the gradual lifting of ETC user's awareness of environmental protection, 27.75% of respondents hope to understand their own carbon emission reduction.

(2)The Preferential Information

Survey data shows that ETC users are willing to know the ETC preferential information, and the proportion is as high as 91%, In the investigation to obtain such information channels, SMS and Wechat are still the most popular support rate, accounted for 67.75% and 46.75%.

(3)Social Information

Survey data shows that 82.5% of users are willing to get to know other ETC users and to participate in group activities, and there are 77.75% users want to find the ETC owners who have the same travel habits, and aboard their vehicle in limited number days. For the way of feedback and interaction for experience and problems in the ETC use process, more than half of the survey users choose phone and Wechat. This suggests that ETC users have quite a strong sense of community, hoping to get online and offline social activities through the exchange platform, Limit number day carpooling has also been recognized for most respondents.

4 Application service framework for user requirements

Highway users, highway regulators and highway operation management are the main service objects of ETC data. With the aid of the variable information board, mobile phone terminal, FM radio and other customer service channels, This paper takes highway users as the main service object to achieve the service support for different categories of users, and build ETC data application service framework for user requirements. As is shown in figure 1.

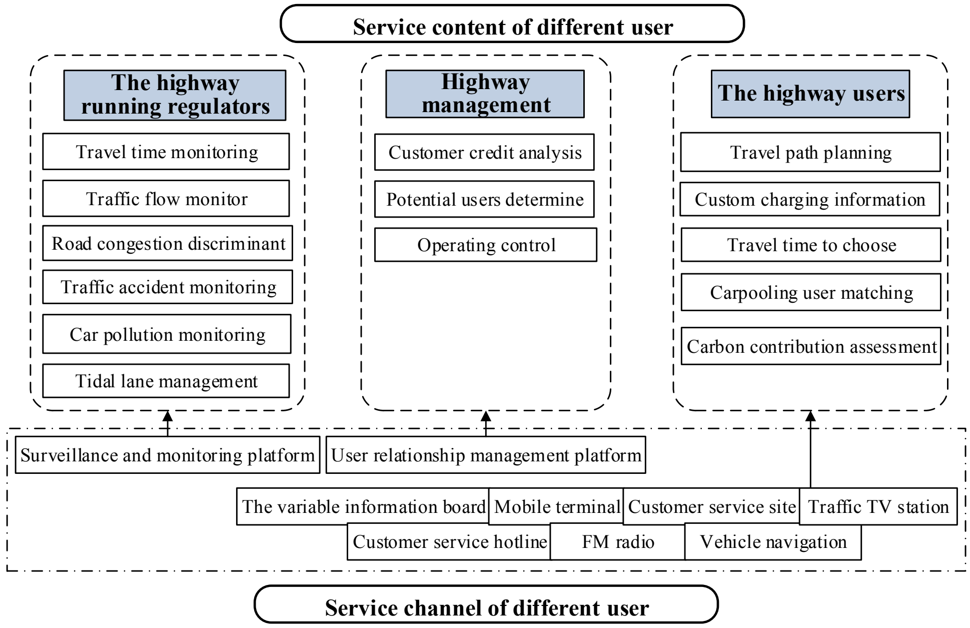

Figure 1. The framework ETC data application service for user requirements

4.1 The Highway Users

The travel satisfaction of highway user in ETC trading data service occupies very important position, providing more abundant travel information service and travel planning services to ETC and highway users .In this way to further improve the highway users satisfaction.

(1) Travel Path Planning

According to the user specified travel origin and destination, and the highway real-time road traffic volume and traffic jam grading discriminant, a proposal is put forward for the users to help users avoid jam and choose the effective path to reach its destination. Meanwhile, When the car drive into the small flow segment or the segment that driving distance is short, to a certain extent, it can also reduce traffic congestion in the entire road network to realize road network traffic assignment.

(2) Charge Information Customization

Road charges information is inherent in every ETC toll station, according to customer requirements, push the ETC charges information ahead for the user. In the way it is convenient for users to know the number, the location, the charging method, charge standard, charge information of road and bridge toll station and so on in advance. If the price of the toll charge change, it is also convenient to notify the user.

(3) Travel Time Choice

Departure time choice can prompt users the morning and evening rush hour to travel, provide a reference for the users to select travel time and reduce the number of users in congestion period into the highway.

(4) Carpooling Users Matching

Some of customers or owners have a need to carpool with others when vehicles are limited. Based on ETC transaction data of individual vehicle information, if users who have a need to carpool with others are matched effectively, it will reduce traffic congestion and benefit the maximum use of transport resources.

(5) Carbon Emissions Contribution Assessment

ETC users want to see their contribution on energy-saving and emission reduction by using the ETC system. According to the information such as models, travel time and so on, the individual carbon emission reduction can be measured.

In order to satisfy the service content of highway users, the application service of ETC data should be effectively explored by the following service approaches such as variable information board, customer service hotline, mobile phone terminal, vehicle navigation, television stations and so on. As shown in table 2.

Table 2. ETC data application service implementation for highway user

Service content	Service channel	Data base	Implementation plan
Travel path planning	1)Variable information board 2)Mobile terminals 3)Customer service website 4)Vehicle-mounted navigation 5)Traffic information television	Travel origin and destination	Traffic jam hierarchical model, cooperate with TGIS auxiliary system, etc
Charging information customization	1)Customer service hotline 2)Mobile terminal 3)Customer service website 4)Vehicle-mounted navigation	Travel origin and destination	Data model of road charges
Travel time choice	1)Customer service hotline 2)Mobile terminal 3)Customer service website 4)Vehicle-mounted navigation 5)Traffic information	Travel origin and destination	Traffic jam hierarchical model, cooperate with TGIS auxiliary system, etc

	television		
Carpooling user matching	1)Customer service hotline 2)Mobile terminal 3)Customer service website	Vehicle information, limit number and commuter interval, traffic habits	Associated with the same properties user, contact to carpool
Carbon emissions contribution assessment	1)Customer service hotline 2)Mobile terminal 3)Customer service website	Travel origin and destination, in and out of the toll station time, vehicle models	Single carbon reduction calculation model

4.2 Highway Running Regulators

Highway running regulators can offer service and improve the governmental regulation and the demand of the public image by using ETC data.

(1) Travel Time Monitoring

Travel time which is got by the record time when vehicles go in or out of the plaza being subtracted each other accurately reflects the running status of road traffic. It can help the supervision department of the highway operation to monitor the travel time of the road network. In addition, the future travel time can be predicted by using a large number of historical data, which provides digital support for the forecasting of traffic congestion, and plays an important role on traffic and logistics planning.

(2) Traffic Flow Monitoring

Traffic flow which is simply obtained according to transaction records of entrances and export is an important index that can reflect the level of road service. And traffic flow OD distribution and the distribution regularity of traffic flow, to a certain extent, reflects the direction of the traffic flow, which build a real foundation for traffic prediction and traffic distribution.

(3) Road Congestion Identification

The degree of urban road congestion is generally characterized by driving speed. In fact, the highway also can imitate the method. Based on the travel speed which is calculated by the section length and the travel time, it can realize the classification of congestion by using the method of classification and assessment of congestion, which facilitates traffic administrative departments to take measures to direct and manage traffic jam.

(4) Traffic Accident Monitoring

An accident on the highway will heavily influence the road traffic. Making predictions on basic feature date- travel time of the road network, and the combination of previous ETC transaction data and travel speed characteristics when accident happened, the corresponding travel time threshold is formulated. Besides, highway road traffic accidents can be effectively monitored by using video information of road monitoring.

(5) Car Pollution Monitoring

Environmental protection is a significant subject that is paid more and more attention by the countries all over the world. In the meantime, exhaust gas released by human into atmosphere is worsening the environment around us. With the growth of cars, car exhaust emissions is increasing dramatically, which is another important factor to influence environment. And by monitoring the highway automobile pollution levels, which can provide support for the relevant departments to develop energy-saving emission reduction measures and make a contribution towards environmental protection.

(6) Tidal Lanes Management

With the development of Beijing highway, the construction of tidal lane is urgent. Combined with ETC transaction data which can count the traffic distribution information in and out of the Beijing at different times and different sections and vehicle travel time distribution, or vehicle models proportion distribution, we can establish tidal lane, adjust the driveway lane number or type, reduce the traffic congestion and improve the service efficiency of lane.

In order to strengthen governmental supervision and enhance the public image, the following measures can be taken: By making full use of the evaluation index from the monitoring and testing platform, analyze the abnormal data from the electronic charge transaction data, then formulate the various index calculation model, and display system users the calculated results in graphical interface.

4.3 Highway Managers

By acquisition and analysis of the transaction data of ETC, highway superintendent need further improve the operational management efficiency, reduce the unfair loss, and provide important support for benefits of scientifically evaluating system.

(1) Reliability Analysis of Users

When ETC system charges, insufficient balance occurs frequently. In order to control the credit sale risk, one step is analyzing users' credit according to the basic information of users, payment information which is got by prolonged exposure to enterprise and customer and other information, the other step is setting the initial credit level and effective credit limits of different customers on the basis of the customer type or level. As a result, it provides decision support for operators to decide to allow overdraft limit and overdraft user and expands the operation benefit.

(2) Judgment of Potential Users

Potential users is the main force of prospective ETC toll lane. Thus, in order to guarantee the construction and development of ETC toll lane in the future, it is necessary to exploit the advantages of ETC toll lane to the full, determine potential users according to the characteristics of the ETC users, find new users, and increase the number of ETC users in the future.

(3) Control of Management Status

ETC lane both bring great convenience to the user, and provide business benefits for the highway construction enterprise. To provide data support for enterprise development in the future, daily / weekly / monthly enterprise accounting statements should be made by using sales data of ETC system and the toll data of toll station, and respective operating conditions and the general trend be analyzed combined with the traffic flow.

Highway managers should integrate users' information from the user relationship management platform and other all kinds of user information which is obtained by other approach, meet their own needs, improve the production efficiency and increase their income.

5 Conclusion and prospect

(1)This study puts forward some service channels and implementation plans for highway users, highway regulators and highway operation management.

(2) This study sets up the application service framework based on ETC data, which paves the way for the application and excavation of ETC dates and the extraction of the highway information.

Of course, in the future, much work need to be carried out around these. Some like: Conduct the related research which is about the extraction and the joint use of ETC data and other types of multi-source data, such as GPS data, detector data, video data and so on. On the basis of ETC dates, to carry out the research about characteristics and preferences of user behavior such as user driving behavior, alternative habits of travel route and so on.

Assessment of Urban Bus Signal Priority Strategy

Da Xu

School of Transportation and Logistics, Southwest Jiaotong University; P.O. Box 610031, Chengdu. E-mail: 411011473@qq.com

Abstract: Current evaluation research of bus signal priority strategy adopting means of traffic simulation, lack of evaluation combined with the actual traffic flow data collected for analysis, based on the common bus priority strategies at home and abroad, on the basis of the current main bus signal priority strategy, including active and passive preference strategy has carried on the analysis and research; Based on HCM method, considering the influence of proportion of buses for intersection saturation flow rate, build the city road bus priority strategy performance evaluation method, On the basis of the traffic data, the urban road bus signal priority control strategies focus on a single point of intersection and compares the implementation of performance evaluation.

Keywords: Bus signal priority; Delay; Traffic capacity; Control strategy.

1 Introduction

This paper in view of the most commonly used bus signal priority strategy in China, based on the study of the control strategy of bus signal priority at home and abroad, using average traffic delay to evaluate the effect after implementation. Analysis signal priority strategies at different times under different proportion of bus transit.

2 Active bus signal priority

Compared with the passive bus signal priority, the active priority control strategy can be based on the specific bus information, the traffic state and the signal control logic, to provide corresponding service for public transport vehicles, it has stronger adaptability.

(Richardson, 1978) and (Heydecker, 1983) consider bus priority signal control may cause phase ignored or jump, but it does not affect the capacity of the intersection, and can be applied to a larger range. (Peter G Furth, 2000) found no signal priority and full signal priority generate more delay than conditional signal priority strategy.

Active priority control strategy generally has the following several control modes: (1) Green Extension, extend the phase of green time. (2) Early Green/Red Truncation, reduce the red light time when vehicles wait for the green light signal. (3) Phase Insertion, add a special phase for bus in the normal phase sequence. (4)Phase Skipping, ignore the green light signal in a certain phase. (5) Phase Rotation: change phase sequence in one phase cycle. (6) Actuated Transit Phase, provide a special phase for bus.

3 Urban road bus signal priority strategy evaluation method

At present the commonly used evaluation index of city road bus signal priority strategy mainly includes: (1)Load factor; (2)Bus travel time on average; (3)Bus stops on average; (4)Intersection queue length; (5)Intersection delay.

In this paper, average traffic delay is the main index to evaluate urban road traffic signal priority strategy, and its estimation method adopts the intersection signal delay model in HCM2000. The estimated value of delay in this model is the average vehicle control delay. During the study period, for a given lane group, the computation formula of average vehicle control delay is as follows:

$$d = d_1 \cdot PF + d_2 + d_3 \tag{3.1}$$

d is control delay of each car;d_1 is uniform control delay, d_2 is increased delay, d_3 is initial queuing delay, if there is no initial queue, d_3=0. *PF* is uniform control delay correction factor of linkage signal, when the traffic flow, PF = 0.95; when the road is slow or congested, PF=1.

Assuming that vehicles arrive uniformly, traffic flow is continuous and at the beginning of the study period without the initial line, according to the first item of Webster delay calculation formula we can find:

$$d_1 = \frac{0.5C\left(1-\frac{g}{C}\right)}{1-\left[\min\left(1,X\right)\frac{g}{C}\right]} \tag{3.2}$$

C is signal cycle, *g* is green time, *X* is the saturation of a given lane, its computation formula:

$$X = \frac{v}{c} \tag{3.3}$$

v is the actual traffic lane group rate; *c* is the capacity of a given lane group, its computation formula:

$$c = s\frac{g}{C} \tag{3.4}$$

s is the saturation flow rate of lane group, its computation formula:

$$s=\sum_{i=1}^{n}s_i \tag{3.5}$$

n is the import lane numbers of lane group; s_i is the saturation flow rate of i import lane, its computation formula:

$$s_i = s_0 f_w f_{HV} f_g f_p f_{bb} f_a f_{LU} f_{LT} f_{RT} f_{Lpb} f_{Rpb} \tag{3.6}$$

s_0 is the flow rate of basic sections, f_w is lane width adjustment factor, f_{HV} is carts adjustment factor, f_g is slope adjustment factor, f_p is the parking adjustment factor of nearby lane group, f_{bb} is the correction factor of bus stop in a intersection, f_a is area type adjustment factor, f_{LU} is lane effective adjustment factor, f_{LT} is turn left vehicle adjustment factor in a lane, f_{RT} is turn right vehicle adjustment factor in a lane, f_{Lpb} is turn left pedestrian adjustment factor, f_{Rpb} is turn right bicycle adjustment factor. f_{HV} can be calculated：

$$f_{HV}=\frac{100}{100+P_{HV}(E_T-1)} \tag{3.7}$$

P_{HV} is the proportion of carts in one direction of traffic, E_T is carts equivalent conversion factor.

Based on actual data collected by microwave vehicle detector in Kunshan, in this paper, its value is 1700 / hour / lane. By formula (3.3), (3.4), (3.5) can be obtained:

$$X=\frac{v}{c}=\frac{v}{s\left(\frac{g}{C}\right)}=\frac{vC}{sg}=\frac{vC}{g\sum_{i=1}^{n}s_i} \tag{3.8}$$

Incremental delay estimation formula is as follows:

$$d_2=900T\left[(X-1)+\sqrt{(X-1)^2+\frac{8klX}{cT}}\right] \tag{3.9}$$

K is incremental delay correction parameter; l is the correction parameter of upstream into the intersection or current-limiting. T is the length of the analysis period. According to HCM2000, in this paper, k=0.5; l=1.0.

In order to facilitate the assessment of bus signal priority strategy, we assume that the implementation of bus signal priority strategy straight on roads in the north-south direction, and the west-east direction will not be considered. Average delay formula is as follows：

$$\overline{d} = \frac{\sum_{i=1}^{n} d_i}{q_1 \times E_1 + q_2 \times E_2} \tag{3.10}$$

d_i is the total delay for the i import lane, q_1 is car traffic flow, E_1 is car traffic equivalent conversion factor, q_2 is bus traffic flow, E_2 is bus traffic equivalent conversion factor.

4 Data description

This paper selects Kunshan city road Kun Tai Road / Changjiang Road intersection as research subjects. Figure 1 shows phase of the intersection.

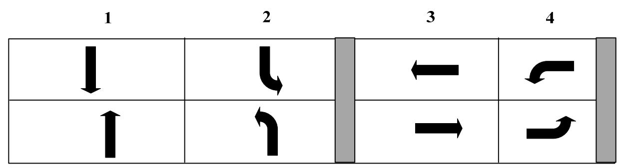

Figure 1. Changjiang Road / Kun Tai Road intersection signal control design phase

Table 1 is the north-south traffic flow data in morning rush hours of the intersection. Table 2 is the east-west traffic flow data in morning rush hours of the intersection. We also have flow data of evening peak hours and flat peak hours.

Table 1. North-south traffic flow data in morning rush hours of the intersection.

Period	Flow							
	North import road				South import road			
	Left	Left	Straight	Straight	Left	Left	Straight	Straight
7:30-7:45	27	23	103	99	58	58	105	71
7:45-8:00	27	23	121	117	55	50	116	73
8:00-8:15	25	22	31	31	27	26	68	47
8:15-8:30	33	36	16	46	36	43	108	89

Table 2. East-west traffic flow data in morning rush hours of the intersection.

Period	Flow					
	East import road			West import road		
	Left	Straight	Straight	Left	Straight	Straight
7:30-7:45	35	42	52	58	95	66
7:45-8:00	45	44	51	50	72	51
8:00-8:15	27	36	67	26	119	88
8:15-8:30	29	42	53	43	92	72

5 Bus signal priority strategy evaluation analysis

In this paper, all buses through the intersection were reduced to the buses with a constant frequency, and assuming their frequencies were 30veh/s, 40veh/s, 50veh/s, 60veh/s.

(1)Total delay

Figure 2 shows the total intersection delay after bus signal priority strategy implementation.

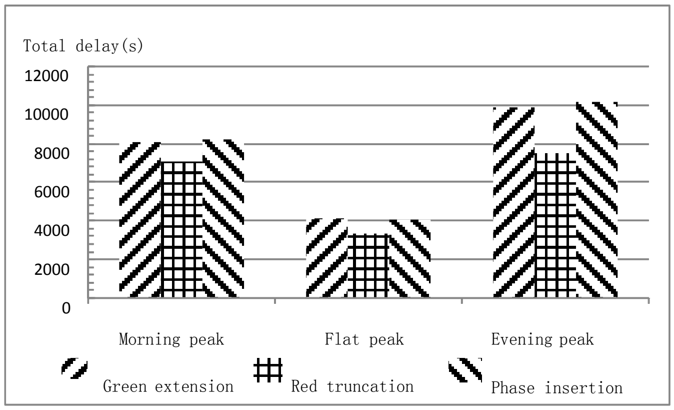

Figure 2. Total intersection delay

(2)Average vehicle delay

Morning peak hours, when the bus arrived frequency is 30 seconds, 40 seconds, 50 seconds and 60 seconds, the proportion of buses were 17.54%, 13.50%, 11.32% and 9.62%. Figure 3 shows average vehicle delay in morning peak hours.

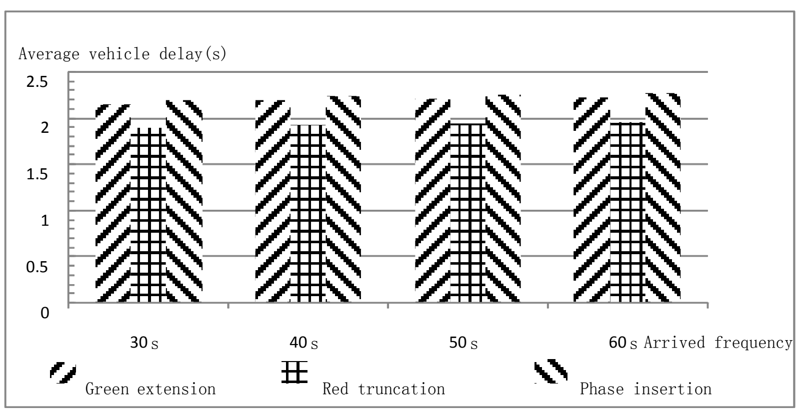

Figure 3. Average vehicle delay in morning peak hours

Flat peak hours, when the bus arrived frequency is 30 seconds, 40 seconds, 50 seconds and 60 seconds, the proportion of buses were 13.71%, 10.44%, 8.71% and 7.36%. Figure 4 shows average vehicle delay in flat peak hours.

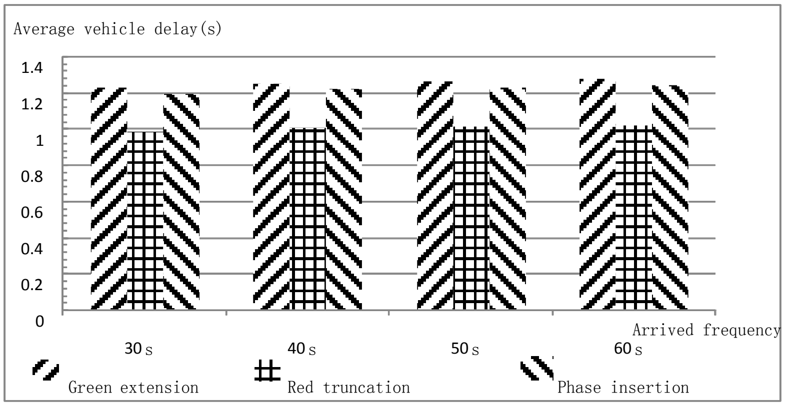

Figure 4. Average vehicle delay in flat peak hours

Evening peak hours, when the bus arrived frequency is 30 seconds, 40 seconds, 50 seconds and 60 seconds, the proportion of buses were 10.44%, 7.88%, 6.54% and 5.51%. Figure 5 shows average vehicle delay in evening peak hours.

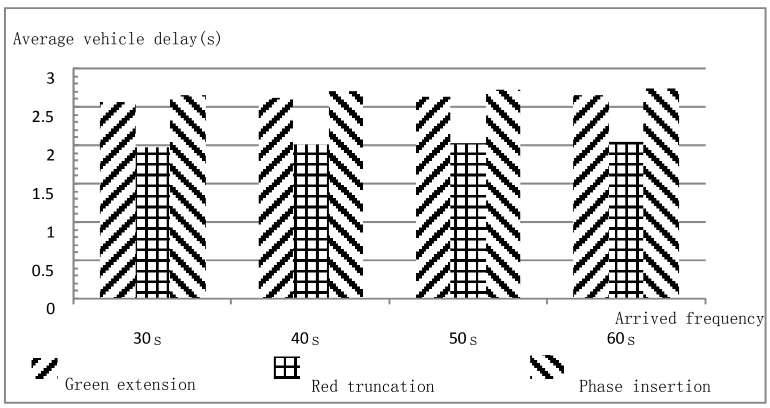

Figure 5. Average vehicle delay in evening peak hours

6 Conclusions

To adopt average vehicle delay as the primary assessment index to measure the bus signal priority strategy, the main findings of the study are as follows:

(1) Study the current major urban road transit signal priority control strategy, clear out the implementation methods and applicable conditions of all kinds of strategies;

(2) Based on HCM method, considering the influence of the proportion of bus for intersection saturation flow rate, and build the city road bus priority strategy performance evaluation method;

(3) Compared to green extension and phase insertion, red truncation strategy can reduce the total intersection delay and average vehicle delay, in addition, when

the proportion of bus become higher, all kinds of bus signal priority strategy can effectively reduce the total intersection delay and average vehicle delay.

Calculation Model of Variable Parking Lots in Urban Synthesis

Qing Zhang[1] and Lingke Wei[2]

[1]School of Transportation and Logistics, Southwest Jiaotong University, Chengdu, Sichuan, China. E-mail: 498480734@qq.com
[2]School of Transportation and Logistics, Southwest Jiaotong University, Chengdu, Sichuan, China. E-mail: 405365189@qq.com

Abstract: The construction of urban synthesis, which combines business, working, living, dining and entertainment in an overall, is an important part of China's urbanization process. The urban synthesis needs to provide enough parking lots to meet the rigid parking demand and the elastic parking demand, etc. Based on the principle that the parking demand of commerce and working alternates with living and the limitation of the surrounding road network's capacity, this paper puts forward calculation model of variable parking lots. By applying it into a case about the calculation of a new urban synthesis' parking lots, this paper finds out that the prediction result of calculation model of variable parking lots is obviously smaller than that of traditional calculation method, which further shows the new calculation model has some kind of reference and guiding meaning when reasonably determining the number of a urban synthesis' parking lots.

Keywords: Urban synthesis; Parking demand; Rigid demand; Elastic demand; Variable parking lots; Road network's capacity; Peak hour of parking.

1. Introduction

Urban synthesis will cause a lot of parking demand in urbanization process. Traffic impaction evaluation in the computing to the parking berth of newly-built urban synthesis, the traditional way (AN S, WANG J, 2001) is to predict according to demand analysis, which does not consider alternating characteristics between office parking demand in urban commercial synthesis with residential parking demand and urban synthesis surrounding road network capacity restriction (ZHANG J, 2005). So in this paper, we put forward a variable parking berth calculation model using the example of checking the number of one new-built architecture synthesis parking berth in the city KunMing and correct the calculation results of traditional method.

2. Analyzing the urban synthesis parking demand characteristics

Parking demand refers to the amount of park attracting amount of the given parking areas during the specified time (NIE T T, 2012). Its randomness is not only difficult to constraints, in some degree but also have the controllability, which can be called the duality of parking demand. On the one hand, it must provide the necessary parking facilities to meet current parking demand.On the other hand it can take advantage of the controllability of parking demand to set up enough and reasonable number of parking garages.

According to different travel purpose, the urban context of parking demand can be divided into two categories:

(1) Rigidity demand. Engaged in commercial activities, office (work) and living (home) of parking demand, this kind of parking demand time is long, commercial, office, and other general parking demand occurs during the daytime, live commonly occur in the evening, more regularity.

(2) Elastic demand. Attracted to the integrated body and its nearby engaged in shopping, dining and entertainment, such as the parking demand, this kind of length of parking demand uncertainty, randomness is larger, general rules.

3. Introduction of road network capacity

Urban road resources consists of time and space resources, any traffic individual travel will occupy a certain amount of time and space resources used by the road. Road network capacity can be known through the lanes space resources, divided by single traffic space and time consumption (BAI Y, XUE K, YANG X G, 2004).

$$C=\frac{L_e\times T_e}{S_a\times T_a} \tag{1}$$

In the formula:

C——road network capacity of the architecture synthesis,

L_e——effective length of the vehicle lane (m),

S_a——the space by the units vehicles (m),

T_e——the road network's peak amount continue time (h),

T_a——unit vehicle's travel time (h).

4. Variable parking berth calculation model

(1) Traditional parking number calculation method

Traditional parking number calculation method uses Parking demand forecasting method, its computation formula just like the formula (2).

$$P=S_0\times\tau+W\times T/(60\times\alpha) \tag{2}$$

In the formula:

P——Synthesis required parking garages (Ind),

S_0——Total number in the synthesis (Include individual business people, workers and residents),

τ——Researchers use proportion of motor vehicle travel in the synthesis,

W——The number of the synthesis allure in the peak time (Not contain taxi)

T——The number of the motor vehicle which alluredby the synthesis's (Not contain taxi) average parking time (min),

α——The utilization rate of the synthesis's parking garages ，about 0.8-0.9.

(2) The paper proposes a variable parking number calculation method like this:

$$P = \min(P_1, P_2) \tag{3}$$

$$P_1 = C \times Los \times \gamma / f \tag{4}$$

$$P_2 = \begin{cases} N \times \tau_n + W \times T / (60 \times \alpha), 当 N \times \tau_n > S \times \tau_s \\ S \times \tau_s + W \times T / (60 \times \alpha), 当 N \times \tau_n < S \times \tau_s \end{cases} \tag{5}$$

$$f = N_{\max} / (N_{15\max} \times 4) \tag{6}$$

In the formula:

P 、W 、T 、α which definition just as the formular (2),

P_1——Based on the Parking garages which calculated by the road network capacities around the road (Ind);

P_2——Based on the Parking garages which calculated by the synthesis's parking demand(Ind),

Los——Synthesis's surrounding road network service level,

γ——Parking behavior proportion in the traffic flow around the road network,

f——Synthesis's parking peak hour coefficient,

S——Staff number in the synthesis (Commercial and office),

N——The number of residents in the synthesis,

τ_n——Per capita vehicle ownership in the synthesis (Mg/peson),

τ_s——Staff（Commercial and office）motor vehicle travel in the synthesis,

N_{max}——Number of parking during peak hours of the synthesis (Mg),

N_{15min}——The largest number of parking within 15 min of the number of parking during peak hours of the synthesis (Mg).

The conception "variable" of Variable number calculation model of parking berthrefers to the combination of parking areas for commercial, office vehicle parking during the day, night due to the residents of private car parking, its USES variable, so can greatly improve the utilization rate of car garages. Formula (6) is parking peak hour coefficient definition.

Formula (5) shows synthes having two kinds of demands. Elasticity parking demand is parked vehicle number drawn to the synthesis during peak period. Rigid parking demand for residents in synthesis parking requirements and business, office needs, in view of the alternant sex is generally occurs in non-working time (night), while the latter is generally occur in the working time (day). Rigid parking lots number selcets the larger value of both. The final parking lots number of synthesis uses the smaller of P_1 and P_2.

5. Case Analysis

5.1 Basic Introduction

Taking a new city synthesis project of KunMing for an example, it takes a net land area of about 1116.33 acres, which includes the ground buildings area of 596740 m^2 and 2870 planning households. The buildings are mainly constituted of low-rise dwelling, supporting commercial, high-rise office and so on. The kind statistics of the synthesis is shown in Table 1.

Table 1. Area and number of different category of the new synthesis

Category	Business	Office	Living	Total
Building area	20660	17310	558770	596740
People's Number	258	577	11175	12011

To the construction project which has clear quantitative thresholds, its impact assessment should be under the range of Table 2. (CJJ/T141-2010)

Table 2. Range of research on construction project

Project scale index/Start threshold(R)	Range of research on construction project
R<2	Enclosure range of urban trunk road nearby the project
Megacity 2≤R＜5， Other city 2≤R＜3	Enclosure range of urban trunk road or freeway nearby the project
Megacity R≥5， Other city R≥3	Enclosure range of urban second trunk road nearby the project

According to the case, R=5.97, which determines the scope of the synthesis study area is shown in blue figure.

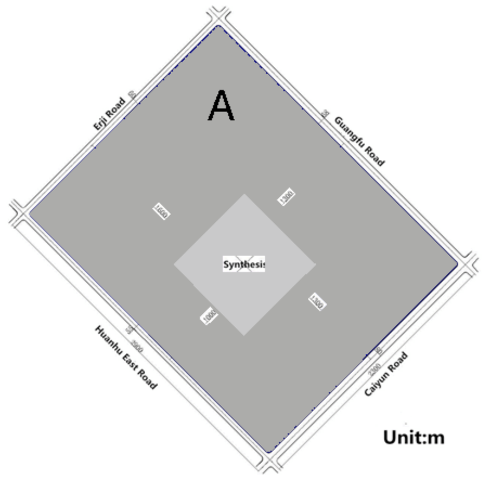

Chart 1. Scope of the study area of new city synthesis (area A)

According to known parameters and scope of the study area as shown, surrounding road network capacity of the synthesis is calculated as Table 3.

Table 3. Surrounding road network capacity of the synthesis

	Huanhu East Road	Guangfu Road	Caiyun Road	Erji Road
Effective Length L_e	2900	2900	2300	2300
Space occupation of each car S_a	8	8	8	8
Duration of rush T_e	1	1	1	1
Transit time of each car T_a	0.121	0.121	0.096	0.096
Road capacity	3000	3000	3000	3000
Road network capacity C		12000		

5.2 Calculate the Number of Berths

(1) By traditional way

Table 4. Calculation of the number of berths (by traditional way)

Parameters	Value
Total number of people in the synthesis S_0	12011
Percent of people going out by car τ	0.31
Car number in rush hours W	1909
Average parking time T	70
Parking utilization rate α	0.9
Parking number required P	6198

(2) By variable parking model

Table 5. Calculation of the number of the berths (by variable parking model)

Parameters	Value
Surrounding road network capacity C	12000
Surrounding road network service levels Los	0.6
Proportion of parking behavior in the traffic flow γ	0.45
Coefficient of rush hours f	0.8
Residents number N	11175
Rate of vehicle ownership per people τ_n	0.3
Number of employees S	835
Proportion of workers traveling vehicle τ_s	0.47
Number of peak hour vehicle attracted W	1909
The average vehicle downtime T	70
Utilizaton of parking lots α	0.9
Based on the surrounding road network capacity Calculated the parking lots P_1	4050
Based on parking demand Calculated the parking lots P_2	5827
Parking number required P	**4050**

(3)Conclusion

① The conclusion in Table 4 and Table 5 shows the results: It considers more comprehensive factors in the variable parking spaces, which reflects actual parking demand better and saving 34.7% parking space. ② commercial synthesis in the evening parking demand daytime parking demand and live with each other alternately office features, plus restricted synthesis surrounding road network capacity, making the combined effect of both reducing the number of parking spaces, indicating a variable number of parking spaces using computational model can effectively improve the efficiency of land use synthesises, urban construction, resource conservation. ③With simplification, we only optimized the calculation for parking place, and did not consider the number of non-motorized vehicles parking spaces. So it needs further study before spreading the calculation model. ④ Many parameters should be considered in the variable parking calculation model, including some ones (such as T_e、γ、f) need further investigation by traditional method, which means that its efficiency of implementation needs to be improved.

6. Summaries

Reasonable foreseeability and science estimate the parking demand of new urban context can provide parking planning and parking policy with reliable quantitative basis. The determination of reasonable parking number can effectively manage urban traffic demand, to alleviate urban traffic congestion produce immediate results. In this paper, the variable parking number calculation model applied to synthesis new city parking for certain instances show that the model can be more scientific and reasonable forecast needed by new urban synthesis parking number, this also for the parking demand research provides a practical and feasible new way of thinking. Variable parking number calculation model to calculate the efficiency of a non-motor vehicle parking demand and implement is the next research direction.

Appropriate Volume on the SHUMA Roundabout

Yan Shao and Ping Han

Traffic & Transportation School, Dalian Jiaotong University, No. 794 Huanghe Rd., Dalian, Shahekou 116028. E-mail: jtgc@djtu.edu.cn

Abstract: The operation of roundabout is not only affected by its geometric characteristics and operation rules, but also mainly affected by traffic distribution of inlet and outlet flow. To explore the suitability of roundabout traffic under the condition of various distributions from the view of running efficiency will benefit to planning and design of the roundabout, and also benefit to traffic organization in peak. In this paper, based on the field data at SHUMA roundabout, the appropriate traffic under the various kinds of influence volumes was analyzed by using VISSUM simulation.
Keywords: Roundabout; Appropriate volume; Traffic distribution; Operation efficiency.

1 Introduction

The capacity of roundabout has several expressions, such as the entry capacity, the total capacity. The entry capacity is applied widely, but it is changeable by the circulating volume and distribution based on the gap acceptance theory (FHWA, 2000). The total capacity is not the simple sum of the entry capacity or volume, because the entry flow is affected by the circulating flow and exit flow（Guo Ruijun, 2006). Based on above mentioned, the two capacities could be calculated on the operation of existing roundabout, also then the capacity's practicability becomes much less on side of the design and operation. The appropriate volume is put forward to replace the capacity based on the operation efficiency. In this paper, based on the field data at SHUMA roundabout which has four entries, the appropriate traffic under the various volumes was analyzed by using VISSUM simulation.

2 The Appropriate Volume

The operation of roundabout is not only affected by its geometric characteristics and operation rules, but also mainly affected by influence of inlet and outlet flow traffic distribution (Hanping, 2011, 2012). The traffic flow enters roundabout and becomes the circulating flow and exit flow, which also affected the entry flow for the weaving conflict. The sum of volume entering the roundabout is crucial and important to organization and design for less congestion and more efficient self-organizing. The efficiency of operation is used by the LOS generally. So the appropriate volume is defined as the sum of the entry volume based on the acceptable LOS.

3 Method and parameters

3.1 LOS criteria

The level of service (LOS) is a qualitative measure to characterize operational conditions within a traffic stream and their perception by drivers. Control delay is used to define level of service at intersections, as perceived by users. In addition to control delay, roundabout causes drivers to incur geometric delays which increase with the expansion of radius. In this paper, only the control delay is considered at the same roundabout, the level of service as followed (table 1) bases on HCM2000 (TRB, 2000). The level "E" could be perceived for drivers in the peak, so it is defined as the acceptable los for the roundabout and 50s is the max criteria.

Table 1. LOS criteria for un-signalized intersection

Level of service	Average control delay(s/veh)	Level of service	Average control delay(s/veh)
A	0-10	D	>25-35
B	>10-15	E	>35-50
C	>15-25	F	>50

3.2Field data

Field data was collected on SHUMA roundabout in Dalian by the manual and video survey in peak. The speed distribution is the normal distribution, the average is 4.95m/s(figure1). The volume distribution among the entries was analyzed as shown in figure2. The sum of entries volume is changing from 3700 to 4800 pcu/h.

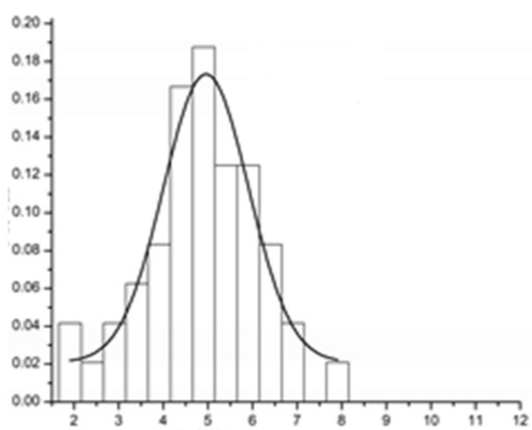

Figure 1. Speed distribution of the SHUMA roundabout

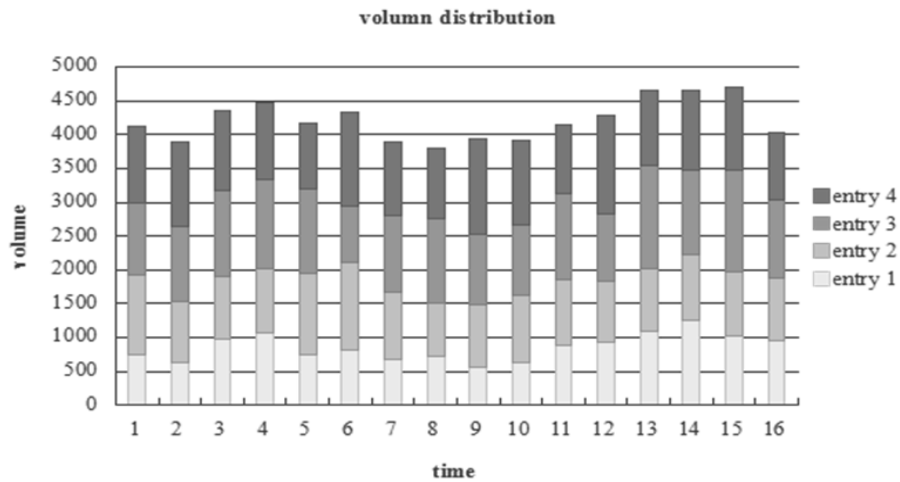

Figure 2. Volume distribution of entry of the SHUMA roundabout

3.3 Parameters in VISSUM soft

The VISSUM model (figure 3) was made according to the map on the video. The conflict rule was the priority of circulating and exit flow. The average speed was 18km/h and the sum volume changed from 1000 to 4500 according to the field data. The five volume distributions of entries were adapted based on the field data. The output of the delay was obtained three times every 500 increasing volumes.

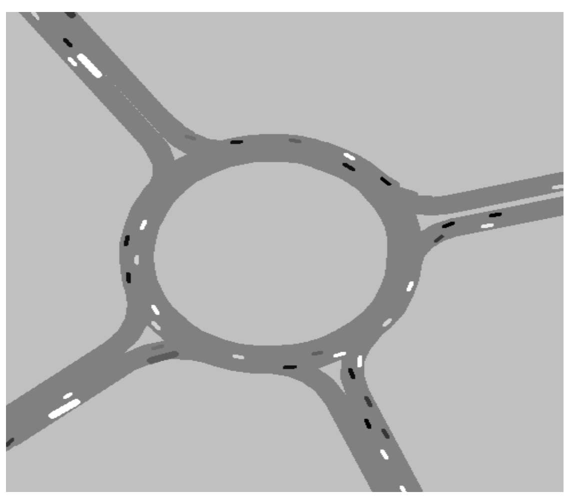

Figure 3. The VISSUM model of SHUMA roundabout in Dalian

4 Discussions of Results

4.1 Relation between volume and delay under the distribution 1:1:1:1

According to the output of VISSUM, the relation between sum of entries volume and control delay is analyzed as following.

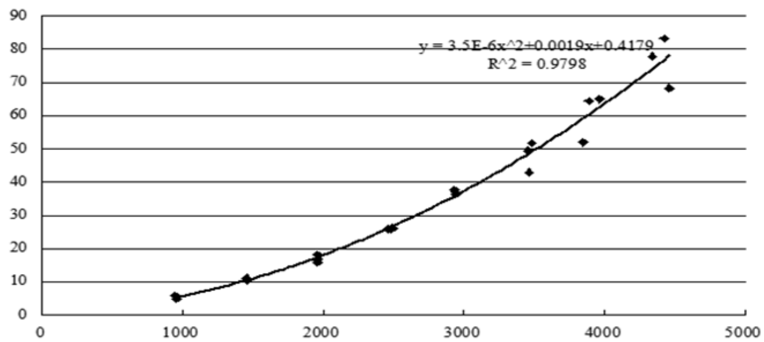

Figure 4.Relationship between the volume and delay on 1:1:1:1

$$y=0.0000035x^2+0.0019x+0.4179 \quad (1)$$

When the acceptable delay is 35-50s,the appropriate volume is 2903-3502 pcu/h based on the formula 1.

4.2 Relation between volume and delay under the distribution 1:2:2:2

When the distribution of the entry volume is 1:2:2:2, the figure 5 could be obtained by the output of VISSUM. We found

$$y=0.0000059x^2-0.0029x+2.7532 \quad (2)$$

When the acceptable delay is 35-50s, the appropriate volume is 2694-3086 pcu/h based on the formula 2.

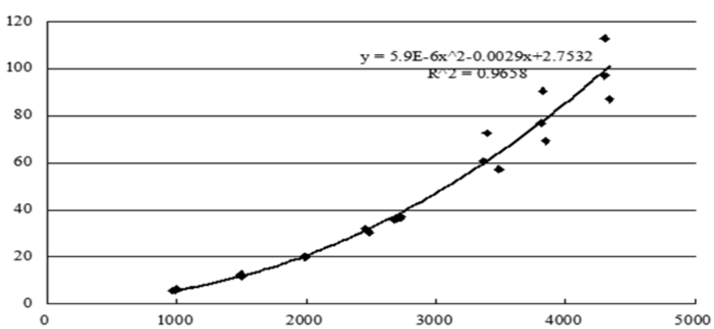

Figure 5. Relationship between the volume and delay on 1:2:2:2

4.3 Relation between volume and delay under the distribution 1:2:1:2

When the distribution of the entry volume is 1:2:1:2, the figure6 could be obtained by the output of VISSUM. We found

$$y=0.0000052x^2-0.0041x+5.156 \quad (3)$$

When the acceptable delay is 35-50s,the appropriate volume is 3018-3357 pcu/h based on the formula 3.

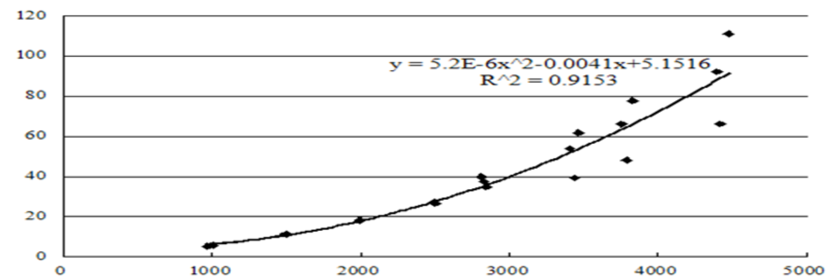

Figure 6.Relationship between the volume and delay on 1:2:1:2

4.4 Relation between volume and delay under the distribution 1:2:2:1

When the distribution of the entry volume is 1:2:2:1, the figure 7could be obtained by the output of VISSUM. We found

$$y=0.000005x^2-0.0028x+3.4193 \tag{4}$$

When the acceptable delay is 35-50s,the appropriate volume is 2940-3345 pcu/h based on the formula 4.

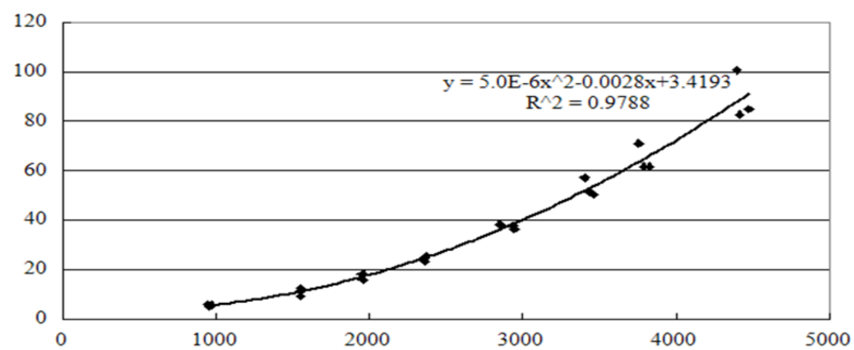

Figure 7.Relationship between the volume and delay on 1:2:2:1

4.5 Relation between volume and delay on the distribution 1:1:2:2

When the distribution of the entry volume is 1:1:2:2, the figure 8 could be obtained by the output of VISSUM. We found

$$y=0.0000049x^2-0.0018x+2.7455 \tag{5}$$

When the acceptable delay is 35-50s, the appropriate volume is 2863-3295 pcu/h based on the formula 5.

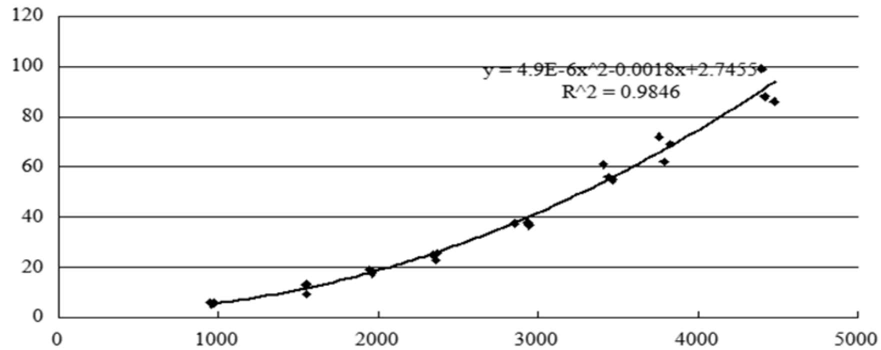

Figure 8. Relationship between the volume and delay on 1:1:2:2

5 Conclusions

Here we may draw the following conclusions.

(1) It is observed that the total volume of the roundabout is changing with the distribution of entry volume.

(2) It is also observed that the delay of the equilibrium distribution is minimum and total volume of the equilibrium distribution is maximum.

(3) It is also observed that appropriate volume of SHUMA roundabout is 2700-3500pcu/h.

6 Recommendations for Future Research

To explore the suitability of roundabout traffic under the condition of various distributions from the view of running efficiency will contribute to planning and design of the roundabout, and contribute to traffic organization in peak. The appropriate volume concluded was lower than the field data, because the VISSUM model based on the absolutely priority rather than sharing priority of field survey. In the future, the sharing priority and more distribution should be taken into consideration to obtain the more practical result.

Multi-Period Signal Control Methods at One Single Point

Jingang Gu[1,2]; Jian Lu[1,2]; Leilei Dai[1,2]; and Qiang Fu[1,2]

[1]Traffic Management Research Institute of the Ministry of Public Security, Wuxi 214151, P.R. China. E-mail: insky01@163.com
[2]Jiangsu Province Collaborative Innovation Center of Modern Urban Traffic Technologies, SiPaiLou #2, Nanjing 210096, P.R. China.

Abstract: The multi-period signal control method at one single point is optimized. The changing situation of every 15 minutes in 24 hours of the different dates is analyzed, and the time division methods aiming at the different intersections and different date are studied. The control phase and phase sequence of traffic control in the different traffic operating characteristics are determined, and the corresponding determination methods of the red clearance time and the pedestrian green time are studied. By recording the control effect parameters on the existing scheme, the practical and easy establishment method of signal time scheme is studied, and the control model of the turning-right vehicle according to the existing standard is defined.
Keywords: Signal control at one single point; Multi-period; Control time division; Red clearance time; Control model of the turning-right vehicle.

1 Introduction

The current traffic signal control method usually divided into a single point of signal control, line coordinated signal control and regional coordinated signal control three kinds of control mode. Line coordinated signal control mode is mainly used in the range of main and minor road in cities. Its application scope is less, but plays an important role in the speed range of traffic; Regional coordinated signal control method at present is still in the theoretical research level. It has little actual application and the practice effect remains to be demonstrated. At present, the most of the road intersection is the single point of control mode. Along with the expansion of the city, single-point signal control intersections are increasing. Therefore, to improve the traffic capacity of urban road intersection, the primary task is to improve the traffic capacity of single-point signal control intersection.

Timing signal control is based on a single intersection's road conditions and intersection traffic flow and traffic direction to determine the signal timing scheme. Equipment requirement is simple, least investment and convenient maintenance is a kind of most basic control mode, the technical principle is the foundation of other control ways and has wide range of applications.

Timing control of single points' basic content including: control period, phase, phase sequence, the green light interval time, full red time, pedestrian green light time, turn right control mode and timing plan, etc.

2 Control Time Division

Along with the increase of urban traffic management pressure, extensive traffic management pattern has already could not adapt to the needs of traffic management. An elaborate traffic management needs to aim at different dates, (holidays and working days) and different times of the traffic running state, set different control objectives and adopt different traffic control strategy, to achieve targeted traffic management mode.

The signal control scheme of time division is to select 15 minutes during weekdays and weekends as traffic statistical units to calculate 24 hours flow. Through the analysis of traffic data, this method uses artificial judgment and the method of clustering analysis to determine the time division. Based on the selection of Jiaxing city, this paper focus on three typical intersections, which are the intersection of Zhongshan East Road-Zhonghuan West Road, central, Hexing Road-Zhongshan Road in central business district, Fanggong Road-Nanxi Road in peripheral city. Through the analysis of traffic data, divide the traffic control time of the weekday and weekend respectively.

2.1 Classification principles

Time division should follow the following principles:

(1) Hospitals with high trip attractions, the intersection time division around schools can be adjusted according to specific flow appropriate division.

(2) Same control area should take the same time, which is easy to take consistent traffic control strategy.

(3) Because controlling scheme needs 10 to 15 minutes to go on transformation process, division of time should guarantee the time interval in more than 30 minutes.

2.2 Workday time division

According to the 15 minutes of Monday to Friday road traffic data line chart, as shown in the figure below, for 24 hours a day, analyze traffic characteristics of each period to develop targeted traffic management measures.

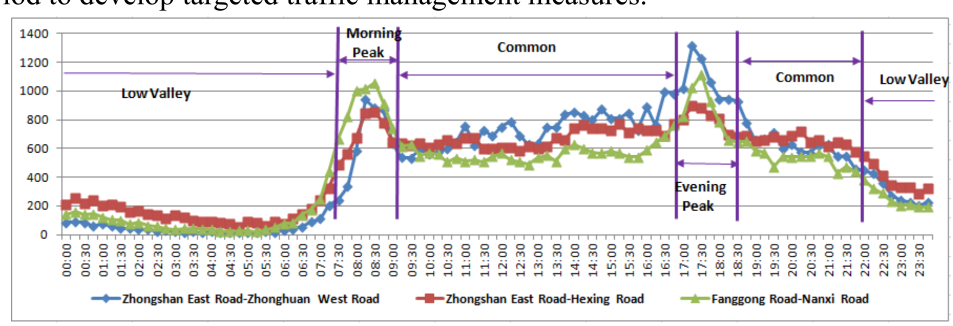

Figure 1. working day 15 minutes traffic flow line chart

Working days (Monday to Friday) classification results are shown in table below.

Table 1. working day (Monday to Friday) classification results

	Session name	Time frame
1	Midnight trough	22:00—07:30
2	Morning peak	07:30—09:00
3	Day time flat peak	09:00—17:00
4	Evening peak	17:00—18:30
5	Flat peak at night	18:30—22:00

2.3 Weekend time division

Use the 15 minutes flow line chart on Saturday and Sunday to compare with working situation. Fanggong Road-Nanxi Road 15 minutes traffic flow line chart at weekend are shown below. There was no peak in morning and evening rush hour traffic flow data and similar to working days flat peak period, which can adopt the same control strategy.

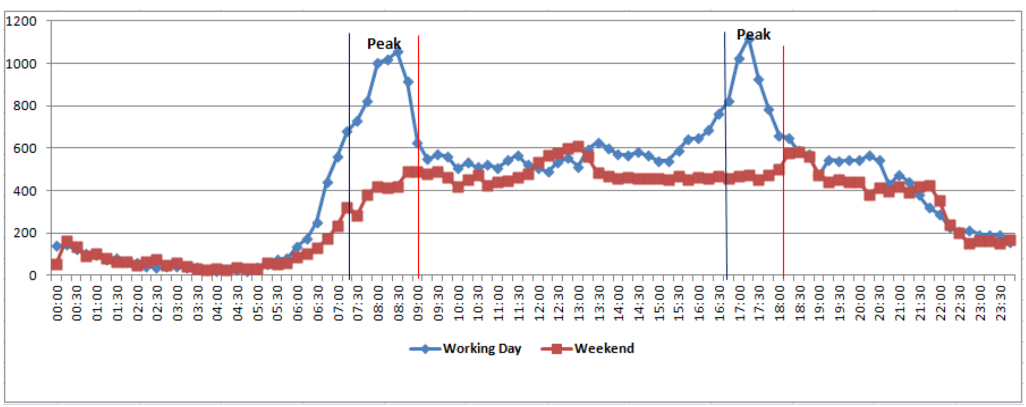

Figure 2. traffic flow line chart 15 minutes at the weekend

Weekend time division results have been shown in the following table.

Table 2. Weekend time division results

	Time frame name	Time frame
1	Low ebb	22:00—07:30
2	Plat peak	07:30—22:00

For weekend traffic flow concentration areas, commercial districts such as 15 minutes traffic flow analysis of Zhongshan Road-Hexing Road intersection, 07:45 08:45 session's traffic flow and working day flat peak period are on same level. 08:45-20:30 session's traffic flow is slightly higher than flat peak period and slightly lower than the rush hour on working day.

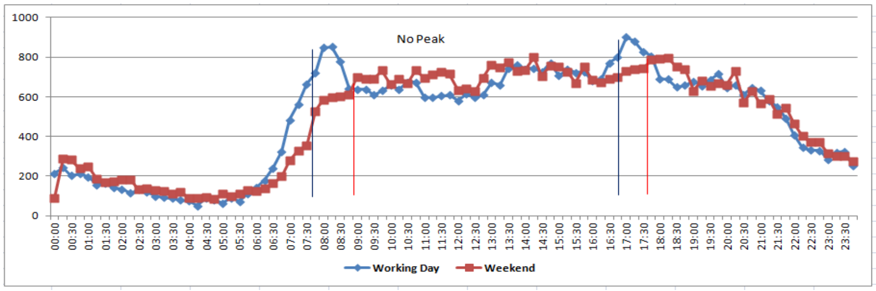

Figure 3. The15 minutes traffic flow line chart at weekend in business areas

Results of business area during the weekend are shown in the following table.

Table 3. Weekend time division results in business area

	Time frame name	Time frame
1	Low ebb	22:00—07:45
2	Morning transition section	07:45—08:45
3	Daytime peak	08:45—20:30
4	Night peak	20:30—22:00

2.4 System time Settings

According to the results of the time division, coordination scheme will be adopted during the beginning time 10-15 min in advance. In the process of transformation, green time and cycle is determined by the signal system. Artificial process is unable to intervene, which is often prone to a phenomenon that certain phase of green light time is too long or too short. When the phase difference is set, this phenomenon is more obvious. Domestic signal typically takes 3-5 cycle adjustment in place and needs 1, 2 cycles to dissipate the impact of the adjustment process. Specific operation is general proposal that start before the peak of the 10-15 min. Ensure that when peak time signal is coming, control scheme has been performed in place.

Implementation plan is that when there is a solution in the process of adjusting individual phase length too long or too short, the start time plan execution could be early or late for 1 minute. Then, observe the changes in the process of green time, which can effectively alleviate traffic impact of scheme transformation.

3. Phase scheme

3.1 Phase design

Phase designers design the first step of signal. Signal phase directly influences the operation of traffic flow operation's safety and intersection traffic capacity and determines the process of signal phase. In fact, it determines the different direction of vehicles or pedestrians' order allocation right of way. In the design of intersection signal timing, because the influence of left turn to traffic intersection operation is very large, in most cases the phase digits, the types of phase and phase sequence is often based on the requirements of left turn traffic flow.

(1) If left traffic flow is small, there is no need that each cycle has left traffic green time. It is reasonable to consider two cycles per running, which should be considered is that at the same time of left turn traffic queue time should not be too long.

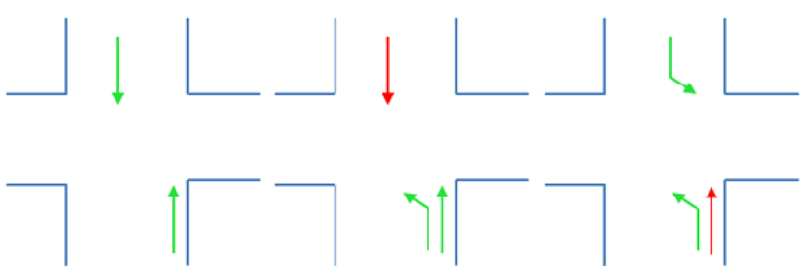
(2) If the green light time of the opposite direction traffic flow is staggered, the system could start left green time early or late. The left turn vehicles go through the intersection before or after the opposite direction straight flow.

(3) As long as the traffic flow is not in line or takes traffic obstruction from vehicles with priorities traffic obstruction, it is suggested that give priority to two phase signal control method. The intersection traffic capacity can be the largest. The green light interval time needs for two phases combined less than three phases for the total green light interval time.

(4) On flat peak the intersection uses two phase control. At the peak it can be adjusted to four phase control, which could reduce the number of traffic conflict and improve the traffic efficiency.

(5) Part of the peripheral regions' signal intersection can be controlled by traffic lights during the day. When night traffic flow drops, it can be considered to adjust to the yellow flash control.

(6) Using the classic four phase control, when given symmetric direction's (south and north, east and west) the traffic flow is asymmetric phase, it can be considered to set the overlapping phase. Close the smaller flow early and open bigger flow direction early.



The traffic flow of south entrance driveway is more than the one of north.

Figure 4. Lap phase setting method

3.2 Determine the phase sequence

Phase and phase sequence design are very close to intersection traffic flow characteristics of each phase, the intersection of geometry and space design factors, etc. In the design of signal phase sequence, it is needed to follow the following principles:

(1) From the viewpoint of safety and efficiency, accord with the driving habits and help drivers to understand;

(2) At an import all the direction of the traffic flow release in the continuous phase;

(3) Set turn left waiting area and set straight phase before the left phase;

(4) When turn left queue length longer than left expand driveway, turn left phase should before straight phase to avoid straight lane was blocked by left flow;

(5) When the import or export direction exist bottleneck intersection, phase sequence should be redesigned or consider to run the phase import (export) the bottleneck section 2 times in a cycle. Raise the time utilization ratio of the bottleneck section.

4. The signal control parameters

Intersection signal control scheme including green light interval, full red parameters and pedestrian green time, etc. Finally timing scheme should satisfy the constraint conditions of these three parameters.

4.1 Full red time

The role of full red time is to ensure that, in the last 1 second yellow light, the vehicle come into the intersection can smoothly through the conflict point. In view of the common combination of three kinds of intersections' shape and control mode, the red light time setting is as follows:

(1) When using classic 4 phase, it delimits the left turn to the big crossroads. The conflict distance between turn left phase and straight phase is shorter, where should set 1s full red time after each straight phase.

(2) When two phase control is adopted, it is suggested to set 1 to 2 s full red time at the end of each phase, which is depended on the left turn traffic flow dissipation time.

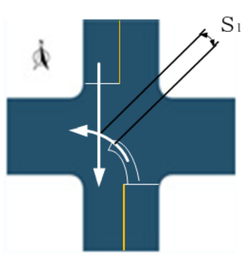


Figure 5. Left turn area conflict point distance

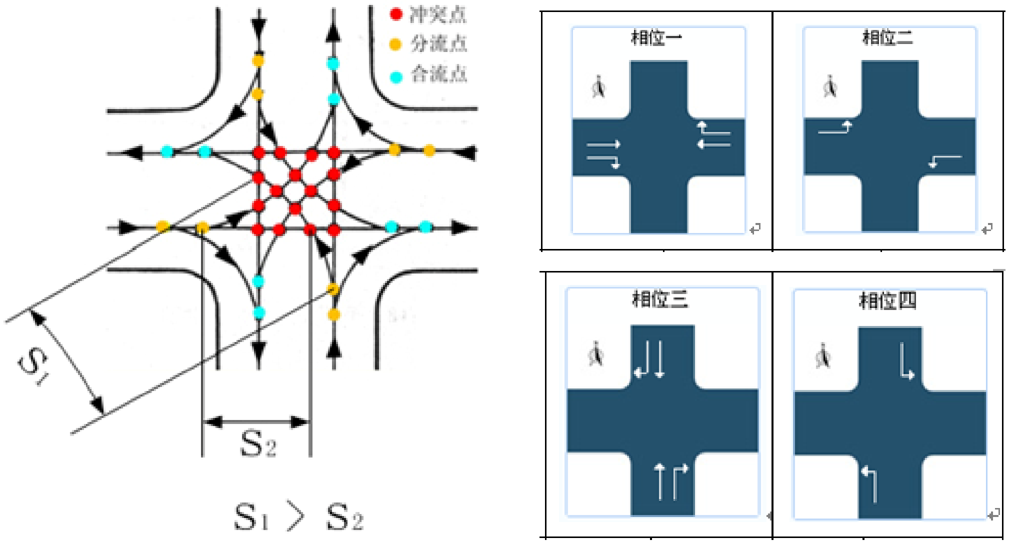
Figure 6. Conflict distance during phase control

(3) Using the classic four phase control, in view of the small corner (no turn waiting area), turn left phase and cross direction's conflict distance is short, should turn left at the end of each phase after full red set 1 second.



Note: S1 is when phase 3 transfers to phase 4, the distance between conflict points.
S2 is when phase 4 transfers to a phase 1, the distance between conflict points.

Figure 7. No left turn waiting area's distance between conflict points

4.2 The pedestrian green time

Motor vehicle shortest straight release time depends on the pedestrian minimum the green light time crossing the street. Pedestrian crossing time is calculated through the pedestrian crossing distance divided by walking speed.

Based on previous accumulation of multiple projects, the elderly, children's average walking speed is 1.0 1.2 m/s and adults' speed is generally 1.5 1.8 m/s. Generally, average pedestrian walking speed is from 1.2 to 1.5 m/s.

Pedestrian the minimum crossing distance usually could be the straight distance between sidewalks and motor vehicle non-motor vehicles separator. In special circumstances, it can be considered to use distance between 2 motor vehicle non-motor vehicle separators.

At present, traffic lights green generally follow the parallel direction motor vehicle lights to start. In the wide cross section road, pedestrian crossing needs a long time, which can be considered to open the traffic lights earlier. In parallel vehicle direction, the previous phase of straight phase (left phase of cross direction) is performing a tail lights that will turn on traffic lights early. Usually arrive 6 s early, namely green flash + yellow flashing time (3 + 3 s). Walking distance at least crosses the non-motor vehicle lane, right lane and a straight line. Walking distance is at least 9m and takes the maximum walking speed 1.5 m/s, which means the pedestrian arrival of the conflict point needs at least more than 6 s. Pedestrian green light turns on 6 seconds earlier, which can avoid motor and non-motor conflict and also can fully ensure the pedestrian crossing time.

5. Timing plan formulation

Single point optimization of intersection's the green time is to look at each phase's the status quo green time and to record the number of vehicles pass through. The presence of stranded vehicles or empty time is recorded

Optimizing green light time could through the following formula.

Optimal green time = green time at present + number of stranded vehicles * the headway

Or = green time at present - empty time

Each phase's green time after measuring is put into signal control system. After scheme's implementation is in place, the result can achieve the optimal by observing and measuring 2-3 times repeatedly.

Commonly used the headway parameter values is as shown below:

(1) Go straight's headway is generally 2s. When pedestrians and non-motor vehicles are crossing facilities, interchanges take 1.8s. Because in the intersection large cars have higher percentage, appropriate correction can be made according to proportion of large cars and large cars twice the parameters of the small cars.

(2) The average headway of turn left is 3.5-4 s.

(3) The headway of turn round is usually 3.5-4 s. When the head cars turn round and after cars turn left, there is 4 seconds time leading car effects following car, which are unaffected in the remaining time. The mixed lanes with higher percentage of turning vehicles could calculate the headway according to the proportion of the car turn round.

In jiaxing city's Zhongshan East Road – Zhonghuan West Road intersection, for example, after 4 times' adjustment, the final signal control plan was made, which is shown in the following table.

Table 4. Zhongshan east road signal timing scheme

Period of time		Phase sequence 1		Phase sequence 2		Phase sequence 3		Phase sequence 4	
	phase	Straight and right of east-west		Left of East-wes		Straight and right of south-north		Left of of south-north	
	Release direction	2，6		1,5		4,8		3,7	
	Cycle, time difference	min	max	min	max	min	max	min	max

Period of time		Phase sequence 1		Phase sequence 2		Phase sequence 3		Phase sequence 4	
Working day									
22:00—07:20	inductive control	16	40	16	24	16	40	16	26
07:20—09:00	C160，0s		48		32		45		35
09:00—16:50	C130，0s		40		24		40		26
16:50—18:30	C160，0s		48		32		45		35
18:30—22:00	C130，0s		40		24		40		26
Weekend									
22:00—07:20	inductive control	16	40	16	24	16	40	16	26
07:20—22:00	C130，0s		40		24		40		26

6. Right turn signal lamp control method

(1) At present, part of the city's right turn vehicles' releasing is following opposite direction's left turn and same direction's straight turn. Take the intersection of four entrances' south import as an example. The change of light has been shown in the figure below. In the entire process of signal transformation, the right direction indicator lights are never bright.

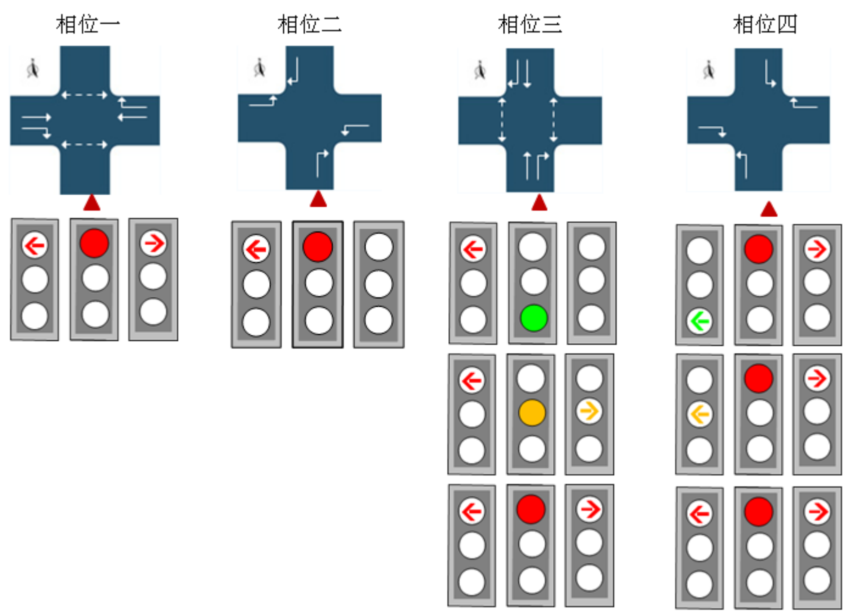


Figure 7. Traffic lights diagram of right turn vehicles release with left turn of opposite direction and straight of same direction

(2) Part of intersections with big right turn flow take a completely open right turn traffic control mode. Under the premise of avoiding pedestrian right turn vehicles run full-time. The following lights can be considered to set up. There is no need to set the right direction indicator lights.

(3) Right direction indicator's green light turned on only on the condition there is no motor vehicles and non-motor vehicles. Two kinds of circumstances are set which are setting stereoscopic pedestrians facilities or right turn vehicles release only on the left turn vehicles release.

7. Acknowledgement

This kind of signal control method is based on given the designated period of time and the arrival rate of default control period is the same. Reasonable design of signal control phase, control effect through the field observation of existing schemes and the real-time of green time adjustment, are used in several rounds of repeated optimization to get the best solution. Confirm that fully satisfy what class key constraints and form the final signal control plan. This method does not need an extensive investigation traffic data and do not need complex formula calculation. The operation method is simple, effective and easy for grassroots polices to adjust and optimize the intersection quickly.

Abstract: The analytic studies of bus IC card and GPS data integration belongs to the important part of Intelligent Transportation. It has much great development potential and brings much convenience and hitherto unknown change to transportation and planning. This paper analyses and summarizes the technical principle, the current situation of application, research status at internal and abroad of bus IC card and GPS data integration. This article points out the deficiency of the current studies and puts forward the direction of later research, application and development.
Keywords: Bus IC card; GPS; Data integration; Bus passenger information; Traffic management.

1 Introduction

Bus passenger flow information is the basis for transit planning, capacity allocation and real-time scheduling. Bus management is based on the flow information collection. The information provides reference for daily schedule and network optimization. Bus IC card records the information such as travel time and route of the passengers. Bus IC data is the analytical object, combines with other kinds of bus operation's schedule information, including routes, site layouts, bus schedules. With the help of date analysis, we can reduce complexity and improve the accuracy.

GPS data integration technology has the characteristics of all-weather, high precision and automatic measurement. As the advanced measurement method, GPS data has integrated into the national economic construction, national defense construction and social development of all application fields. GPS data integration technology in the field of traffic are mainly used in car navigation system, route planning, information search, emergency rescue, etc.

2 Analysis of Data integration principle and its merit and demerit

2.1 Bus IC card and GPS data integration principle

Bus IC card is refers to the integrated circuit card, it consists of large scale integrated circuit, and has the function of repeated access encrypted data. The Global

Positioning System uses GPS satellite, makes the real-time positioning and navigation come true.

The sites passengers get on, transfer or not and the sites passengers get off is the three key question of the IC card data analysis. We should filter and collect the raw data and set up a data storage at first, and according to the analytical content, we can extract relevant data sets to data query, analysis and data mining. The system architecture of Bus IC card data analysis platform is in the Figure 1 below.

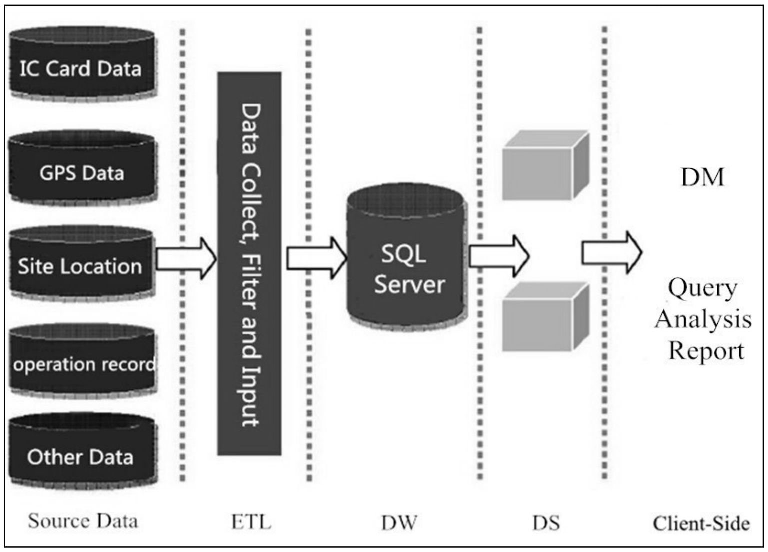

Figure 1. The system architecture of Bus IC card data analysis platform

GPS is a navigational system involves satellites and computers that can determine the latitude and longitude of a receiver on Earth by computing the time difference for signals from different satellites to reach the receiver. GPS system structure is as follows:

Space Segment: Composed of 24 GPS satellites, Each GPS satellite's signals are used for navigation and positioning, they launch navigation message constantly.

Control Segment: Consist of several tracking stations and monitoring systems in the global. According to their different roles, the tracking station is divided into the master station, monitor station and injection station.

User Segment: Consist of the GPS receiver, data processing software and the corresponding user equipment. Its function is receive GPS satellite signals, and use these signals to navigation and positioning, etc.

2.2 Merit and Demerit analysis

2.2.1 Merit and Demerit analysis of Bus IC card data integration technology

Compared with the traditional bus data investigation method, analysis method of the bus IC card data has the following advantages:

(1) Large sample size

(2) Continuous recording of samples

(3) Acquisition cost is low
(4) Data processing can realize automation

Although the method has many merit, but there are also some demerit:

(1) Due to the lack of bus passengers' personal attributes, it can't associate the travel behavior characteristics and passengers' personal attribute together.
(2) Bus IC card data can't get users' evaluation of the system service level.
(3) Bus IC card data can't fully embody all the bus passengers' characteristics
(4) IC card don't record the start sites, so the data can't show the passenger flow volume of each site directly.

2.2.2 The characteristics of GPS data integration

(1) All-weather positioning in the world
(2) High positioning accuracy
(3) Short observation time
(4) Without the visibility between stations
(5) Instrument is easy to operate
(6) Can provide three-dimensional geocentric coordinate globally
(7) Widely application
(8) Drawback of GPS system:

Some questions like the electromagnetic interference of the city, signal reflection, building block signals still need to solve. Blocking satellite signals leads to positioning misalignment, which is the GPS's deadly weakness.

3 Research Status

3.1 Overseas Research Status

Foreign study of data integration of bus IC card can be divided into the following several aspects:

3.1.1 Intelligent bus data integration

Department of Transportation of Florida set up ADAMS（APTS Data Archiving and Mining System）in 2007. It's a part of the intelligent transport system of the research plan. ADAMS use the data of AVL(Automatic vehicle location), APC(Automatic Fare Collection) and EFC(Automatic Passenger Collection). It takes the advantages of the business intelligence technology, set data warehouse and analytical model.

3.1.2 Bus transfer problem

Markus Hofmann studied transfer behavior of passengers in 2005, and he divided all the passengers into single travel and transfer travel. He used the iterative classification algorithm to judge the transfer's assumption continuously.

Ka Kee Alfred Chu took the Gatineau for example in 2008, he used the relationship of twice travels' time and space to judge travel records, and confirm the transfer records.

3.1.3 Bus transit OD prediction

Janine M.Farin took the St. Paulo's data for example in 2006, he calculate buses' OD Matrice between every traffic zone. The research uses the AVL system data to judge the site which passengers get on the bus, and make them the start point of travel. On the basis of two hypotheses below, we can calculate the origin of each trip.

(1) A travel destination is the start point for next trip.

(2) The destination of last trip always end up with the first trip on the same day.

3.2 Domestic Research Status

With the wide implementation of bus IC card system, our country also started the research of data mining. Zhang Wei proposed to use buses' GPS and passengers' IC card information to obtain the buses' OD amount.

About the data integration, Wei Yun introduced a bus regional scheduling method to solve the problem of real-time monitoring to operating vehicle With the help of GPS PPP(Precise Point Positioning), we can improve the accuracy.

4 Research Summary

4.1 Overseas Research Summary

(1) Foreign bus card develop to involve crossing transportation and other businesses. Data analysis includes four aspects: intelligent bus data integration, determine bus transfer, calculate bus OD matrices and analyze the characteristic of the bus passengers' behavior.

(2) The United States, Britain and other developed countries use the technology of traditional bus and subway site to take sampling survey for OD has been relatively mature.

4.2 Domestic Research Summary

4.2.1 Bus IC card research summary

(1) There is little research that is application of actual data in our country, we lack of deep research for intelligent transport system data storage, cleaning, mining, operation and other problem.

(2) There was some differences of internal and overseas intelligent transport system. We haven't analyzed the applicability and accuracy of clustering method of getting on site.

(3) Domestic transit OD prediction research is the OD calculation between sites on a single line. There is no related research of bus network level OD prediction problem.

(4) In the aspect of determining passengers' sites, we have the judge method based on the site which passengers get off the bus. By analyzing the individual credit data, the results are accurate, and we can get passenger's bus travel path. The analysis of characteristics of urban public transit has very important significance.

Overall, the bus IC card data analysis technology is a new research field both at home and abroad, the theory and method are still not mature.

4.2.2 GPS data integration research summary

(1) Traffic data collection and management. GPS should equipped in the City cars, the management's system can collect each hour's traffic flow of any road, and these accurate data is the basis for traffic management and planning.

(2) GPS joint map matching technology to provide real-time scheduling method for traffic controllers. Enable the regionalization of bus dispatching. But to display and map matching has larger error.

(3) Use GPS to help bus operation scheduling can solve the problem of vehicle real-time information collection. Through real-time adjust the frequency, can not only decrease operating cost, but also improve people's satisfaction.

5 Future Direction

(1) Adopt a new data fusion technology or a new model to determine the passengers' get-off site.

(2) By bus IC data analysis, we can grasp the nature of the urban land, function layout, climate characteristics, passengers' travel purpose, travel distance and social characteristics.

(3) Bus IC data analysis needs further study on the data warehouse construction method and get-on or get-off site judgment method.

(4) The combination of GPS data integration and GIS

(5) Higher levels of survey technology

(6) GPS data integration application of dynamic differential GPS.

6 Epilogue

Bus IC card record the important information of the bus passenger flow. Based on bus IC card data mining and combined with the corresponding data of the model calculation, we can get many important data from public transport planning, the capacity allocation and real-time scheduling.

GPS data has the characteristics of all-weather global positioning, higher positioning accuracy, short observation time, without the visibility between stations and widely used, which makes GPS data integration become advanced measuring method and the new productive forces.

This paper analyzes merit and demerit of the bus IC card and the GPS data integration technology, and also introduced the use in the field of transportation. This article summarizes the two kinds of data integration technology research status, research deficiency and the research direction.

The Design of a U-Turn Lane Right Set and Its Control Mode at an Intersection

Zhijian Wang; Liang Li; and Chaofeng Ma

Beijing Key Lab of Urban Intelligent Traffic Control Technology, College of Electrical and Control Engineering, North China University of Technology, Beijing. E-mail: wzjian0722@163.com

Abstract: Aiming at the problem of low efficiency and poor security of u-turn traffic at intersection, the project carry out an analysis of operation characteristic, conflict and design on u-turn traffic, and take the u-turn traffic conflict and influence factors in consideration. For an actual signalized intersection, we design a scheme of u-turn lane right set, and give the corresponding traffic signal control mode, which effectively avoids four kinds of conflict between u-turn traffic and other traffic in time and space, and improves the efficiency and safety of u-turn traffic. Finally, operate the status quo intersection and designed intersection with VISSIM based on actual survey data of the intersection, and collect corresponding traffic data to analyze traffic evaluation. Result shows that, the implementation of u-turn lane right set and the improvement of control mode can effectively avoid conflict points between u-turn traffic and other traffic; delay time, stop time and queue length have been reduced significantly, and traffic flow capacity at intersection has also been greatly improved. In the field of traffic engineering design, it is worthy of in-depth study and innovation on right set of u-turn lane.
Keywords: U-turn lane; Right set; Control mode; VISSIM simulation.

1 Introduction

The intersection is where the bottleneck of traffic network located. According to statistics about 80% of the traffic delay and congestion occurred in the intersection. As one of the common running forms of urban vehicles, u-turn traffic at intersection is one of the influencing factors which can not be ignored.

Aiming at the design of u-turn lane, there are mainly three kinds of design patterns: u-turn in the internal intersection, u-turn in front of the stop line, u-turn at the transition section of the inlet channel. It is more based on engineering experience when setting u-turn lanes in the domestic, and there is no content about u-turn lanes setting in road design standard. In US Highway Capacity Manual in 2000, u-turn vehicles are regarded as left-turn vehicles to estimate saturation flow rate of traffic flow. However the running state of u-turn vehicles and left-turn vehicles are different. The foreign research on u-turn traffic at signalized intersection is mainly discriminated by historical accident data based on MUTCD. The related research includes the internal conflict points and what affects left-turn traffic has on u-turn traffic. But the research mode is single, at the same time it takes less pedestrians and non-motor vehicles for consideration.

As can be seen, the current design of the u-turn lane is lack of system, inefficient and poor safety.

2 The text part

2.1 Design ideas

Aiming at the problems of low efficiency and poor security of u-turn traffic at intersection, this project carry out an analysis of operation characteristic and conflict on u-turn traffic. And for an actual signalized intersection, we design a optimal design of u-turn lane right set, and give the corresponding traffic signal control mode. This design can not only increase the turning radius of the u-turn vehicles to ensure the efficiency of u-turn traffic, and also can effectively avoid conflict points between u-turn traffic and other traffic.

2.2 Design analysis

2.2.1 Analysis of operating characteristics

We analyze the characteristics of u-turn traffic at intersection from 2 aspects: traffic efficiency and security. Traffic efficiency is mainly reflected in time that u-turn traffic pass through intersection, while safety is reflected through conflict points.

At the intersection, the radius of u-turn vehicles is less than the radius of left-turn and right-turn vehicles. The vehicle speed is relatively slow, and it is vulnerable to be interfered in internal traffic at intersection. If u-turn vehicles pass through the intersection with low efficiency, it will directly reduce the efficiency of inlet and outlet channel. If u-turn vehicles and left-turn vehicles share one lane, it will cause great restrictions on left-turn vehicles that follow u-turn vehicles, and even cause serious queue in left turn road.

At general signalized intersection, u-turn vehicles usually share one lane with left-turn vehicles, and it make use of left-turn temporal gap to achieve u-turn. There are conflicts with other traffic, and the diagram of conflict analysis is as Figure 1.

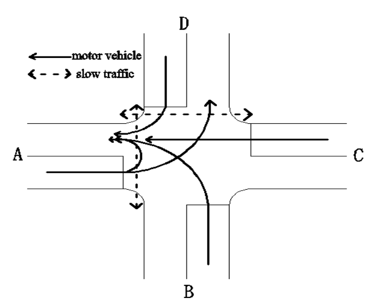

Figure 1. Conflict analysis of U-turn traffic at intersection

There are multiple conflict points in Figure 1 between an import u-turn traffic and the following traffic: (1) respectively other motor vehicles: left-turn traffic (diversion point with left-turn traffic of A and confluence point with left-turn traffic of B), straight traffic of C, and right-turn traffic of D; (2) conflict points with the bicycle, pedestrian traffic.

2.2.2 Influence factors

In the optimal design of u-turn lane at signalized intersection, we need to consider the following influence factors:

(1) Type of u-turn vehicles: The structure and operating characteristics of vehicle will affect its u-turn performance, such as turning radius and speed. So it's necessary to take the composition of traffic flow models in consideration to design.

(2) U-turn space: It refers to the space range that u-turn vehicles run. Whether there is hard isolation or green isolation in the center road has an important influence on u-turn time and space. It would obstruct the vehicles in the opposite if the exit lane were occupied. So we should try to reduce the number of occupied exit lanes.

(3) U-turn Lane sharing: It will cause a lot of restriction or queue on left-turn vehicles that follow u-turn vehicles. So if there are too many u-turn vehicles, we should try to separate out a u-turn lane.

2.3 Design scheme

According to a junction in Jin Zhong city, as shown in Figure 2 is the intersection of Zhong Du Road and Shun Cheng Street which is T type. In the status quo, there are fences on Zhong Du Road and Shun Cheng Street, and there is no u-turn opening on the road. There are many shops and offices on both sides, so it exits a lot of u-turn demand. And it has great influence on traffic efficiency of the whole intersection. So, this intersection design is optimized based on u-turn traffic, and we give the channelization design and signal control scheme.

2.3.1 Traffic channelization design

It should take the running orbit of u-turn traffic and import channel, median strip and export channel in consideration on design of u-turn traffic at intersection.

(1)Through the investigation of the status intersection, the u-turn vehicles at intersection are mostly compact cars. According to Table 1, the turning radius of the cars' axle should be no less than 6m. Because there is no hard isolation in middle of the road and the width of status lane is 3m, the u-turn lane needs to be right set at least two lanes in order to make u-turn vehicles use the inside lane of the export.

Table 1. Table of u-turn vehicles radius

Vehicle type	vehicle length /m	Wheelbase /m	Shaft radius /m	Moving radius /m
Standard car	4.9	3.35	5.8	7.3
Heavy-Duty Vehicle	12	7.32	12.4	13.7

(2)In order to reduce delay caused by shunt between u-turn vehicles and left-turn vehicles in the same direction on Zhong Du Road, we need channelize u-turn lane and left-turn lane separately, and set a u-turn lane alone.

(3)Reducing traffic conflict between u-turn traffic and left-turn traffic, right-turn traffic: In order to make the u-turn vehicles enter the inside lane of the export, we make the separately designed u-turn lane right set on Zhong Du Road.

(4) Reducing conflict between u-turn traffic and slow traffic: There are fences on pedestrian trails in the status, so pedestrian cross the road mainly through the underground passage, which can effectively avoid collisions between pedestrians and u-turn traffic. However, there are still conflicts between non-motor vehicles and u-turn traffic. This design will put the stop line in import backwards in order to avoid such conflicts. The concrete backwards distance should be no less than 7.3m according to moving radius in Table 1.

(5)In order to ensure u-turn vehicles pass the intersection orderly, we design guide line for the u-turn lane in north and east.

In accordance with the design ideas above, the design of traffic channelization is shown in Figure 3.

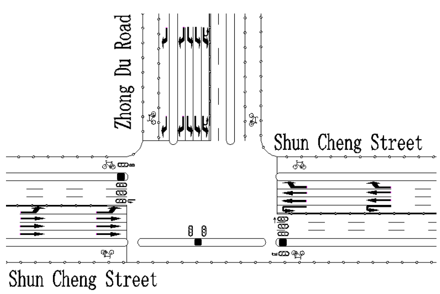

Figure 2. The T intersection of Zhong Du Road and Shun Cheng Street

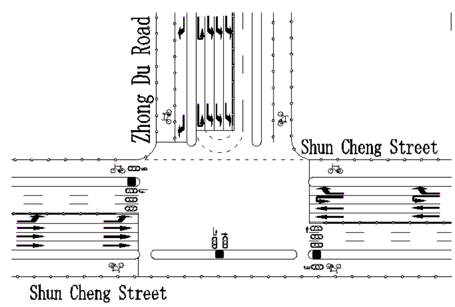

Figure 3.Optimal design of channelization at intersection

And lane channelization sign should be placed in the east side and the north side after 60-80 meters away from the stop line. The layout diagram is as follows:

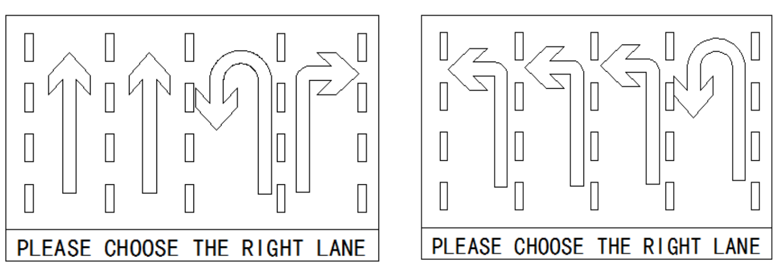

Figure 4. The lane channelization sign on east and north side

2.3.2 Design of traffic control scheme

It can effectively avoid the conflict points of traffic flow through the traffic signal scheme from the time, such as conflict between u-turn traffic on east and straight traffic on west, and conflict between u-turn traffic on north and left-turn traffic on west. The designed signal control scheme of the intersection according to status traffic flow is as follows:

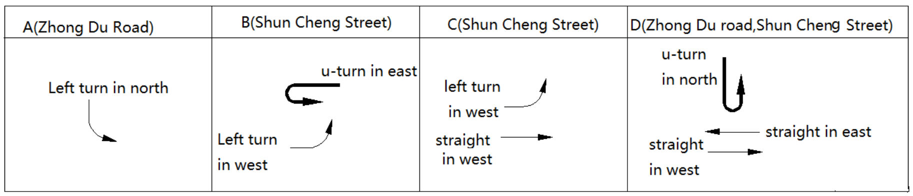

Figure 5. Diagram of intersection signal phase

2.4 VISSIM simulation

Verify the program by VISSIM: First, we should build status intersection simulation on the basis of actual survey data. Then make the simulation comparison with the designed intersection scheme, and analyze the data.

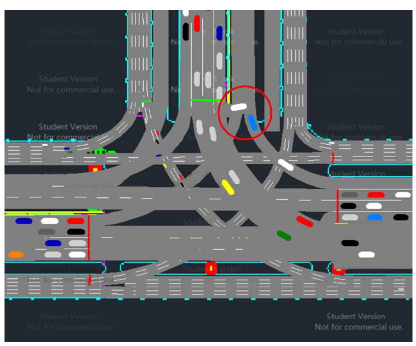

Figure 6.Status simulation

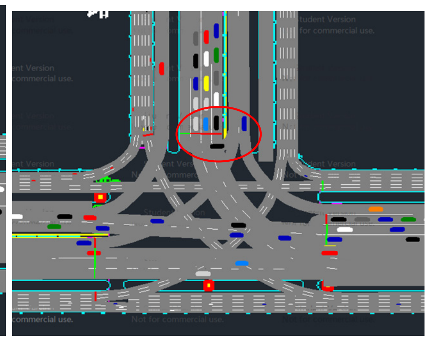

Figure 7.Optimized simulation

As can be seen in Figure 6, because the need of turning radius, the u-turn vehicles on north would access to the outermost lane of the export. And it causes great delay of right-turn vehicles on east. However after u-turn lane right set, as in Figure 7, these two kinds of traffic conflict have been well settled.

Taking advantage of designed traffic control scheme, but maintaining the same cycle of status, we respectively collect status and designed simulation data during peak period and flat period. And traffic evaluation data on u-turn lane on north, right-turn on east and left-turn on west is respectively compared as follows:

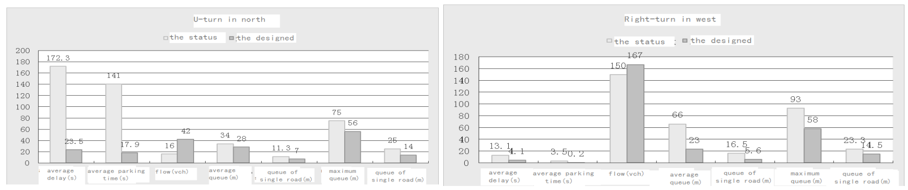

Figure 8. Traffic evaluation data under flat periods

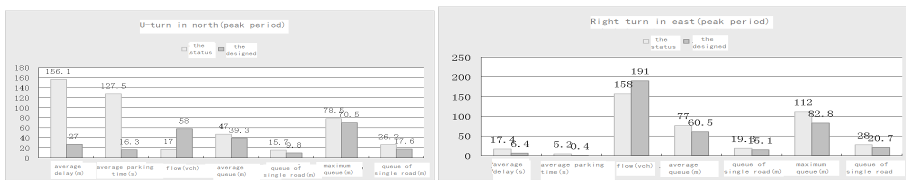

Figure 9. Traffic evaluation data under peak periods

As can be seen from the above figures:

(1)The design virtually eliminates the conflict between u-turn traffic and straight traffic, conflict between u-turn traffic and left-turn traffic (on the north and west side), conflict between u-turn traffic and slow traffic from space and time;

(2)U-turn traffic has been prevented from right-turn traffic. Compared with operating data of current situation, the delay time, stop time and queue length have been obviously reduced, and the traffic flow capacity has also been greatly improved;

(3)Comparing the data in the flat period and peak period, we can see the designed scheme can still work well, and the efficiency of current situation traffic has been greatly improved.

3 Conclusion

Aiming at the problems of low efficiency and poor security of u-turn traffic at intersection, we design a u-turn lane right set and make a simulation by VISSIM software. The result shows that the optimal design has a good sense of the promotion. It has a good reference of the intersection with a lot of u-turn demand but with no central isolation. And it also has a strong reference in the design of other type of intersection or left-turn lane right set. For example, the left-turn lane can be right set in oblique cross to increase the turning radius in order to ensure the security and efficiency of traffic. So, the research of lane right set is still worthy of further study.

Specification for the Construction of Traffic Information Backbone Network Interconnection

Dan Wu

Information Engineering Institute, Jilin Engineering Normal University, Kaixuan Rd. 3050, Changchun. E-mail: 196549@qq.com

Abstract: In this paper, study report and solutions of the interconnection and interworking of voice, video and data transmission of traffic network nodes in Jilin Province by researches on network construction of transport sectors and the visiting and investigational study of relevant network equipment manufacturers and operators in Jilin province are carried out. On this basis, technical standards of Jilin traffic information backbone network construction, traffic communication information transmission including network data, voice and video, grading protection construction of traffic information network security, construction standards of traffic information network IT room, and test standards of traffic information network acceptance have been developed. The study aims to promote the construction of Jilin traffic information network and network security level, and improve the efficiency of its transportation network interconnection, network construction and operation and maintenance from the perspective of technical support, playing an exemplary role in traffic information backbone network interlinking of other provinces and regions.
Keywords: Traffic; Network interconnection; Technical standards.

1 Significance

It aims to achieve standard system of traffic informatization according to the Five-year Development Program of Jilin highway and waterway transportation informatization. It provides a unified standard for booming construction of traffic information network of units around China nowadays, to achieve the goal of provincial bureau and city bureau proposed for the interconnection and interworking of traffic information network. Moreover, it standardizes communications of networks, and ensures effective communication among traffic backbone networks, in order to allow traffic informatization to play its due role in decision making and management at all levels of transport administrative sections.

2 Research process

(1) Survey of network construction of Jilin transport sectors

Combined with the existing network construction of all traffic departments in Jilin Province, investigation and survey has been thoroughly conducted on network construction of various sectors by the questionnaire of provincial transportation affiliated units, and site visit and study has been carried out on provincial affiliated units. Drafting group went to Jilin Province Transport Authority, the Authority of the provincial bureau, Jilin Highway Bureau, Metropolitan Transit Authority, Transit Authority and units directly under to investigate, and visited their computer rooms, toll stations, overload control stations, and passenger stations, following the presentations and recommendations of Information Centers of regional units for network construction.

(2) Research on network equipment manufacturers and ISP operators

Drafting group carried out detailed investigation on device manufacturers, operators. On one hand, they knew the most advanced communication equipments and relevant technology products from equipment manufacturers. On the other hand, they understood equipment room constructions and equipment usages from operators, providing great technical support for the establishment of this standard. Specification drafting group referred to a lot of technical information and relevant norms of our country, industries and regions, with discussion during the conference and in-depth communication with traffic information centers of other provinces, and exchanged work experience on network building mutually, to determine the framework of Jilin Province transportation information backbone network interconnection regulatory.

(3) Develop of Security Standards of Jilin transportation industry and traffic information backbone network interconnection construction

Safety standards of Jilin transportation industry have been developed through researches on units in other provinces which have undertaken informatization level safety construction of transportation departments, and reference to Jilin level security standards. According to needs and requirements of Jilin highway and waterway transportation informatization and relevant researches, specification drafting group determined a number of contents including Jilin traffic information network structure and network technology, network security, the level of information protection. By building a network simulation environment, the interconnection and interworking of voice, video and data transmission of traffic network nodes in Jilin Province have been achieved and feasible report and appropriate solutions have been proposed. After needs analysis, field research, checking and experiments, drafting group prepared rough draft of norms initially. In addition, experts were organized for consultation and demonstration, to further improve the specification, making it a formal exposure draft. The draft was sent to all levels of network nodes in provincial transport sectors for technical feedback and suggestion from various units. The technical standards after feedback were demonstrated, organized and improved again, to prepare system documentation of "construction norms of traffic information backbone network interlinking in Jilin Province".

3 Main content

The system documentation of "construction norms of traffic information backbone network interlinking in Jilin Province" is composed of five parts, involving the technical standards, construction standards and acceptance test standards, such as to form multi-level polyhedral vertical structure (see figure 1) :

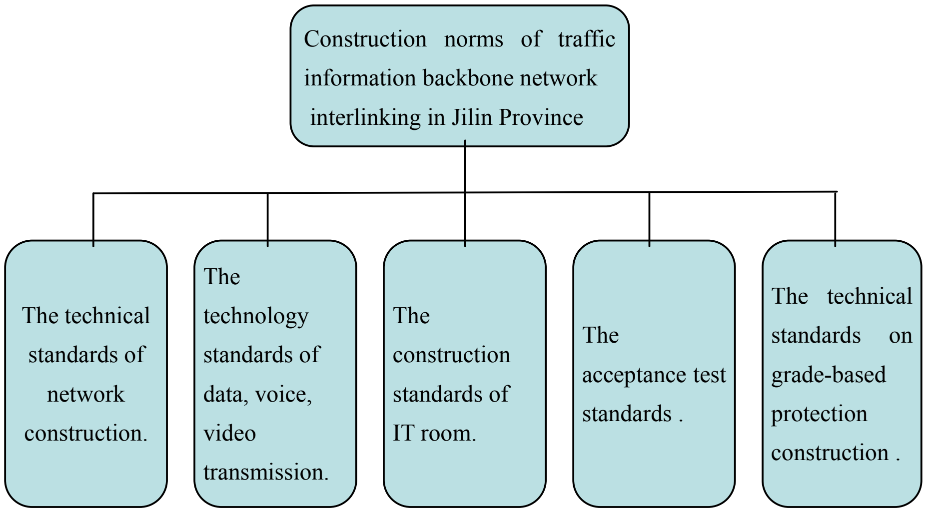

Figure 1 the structure of the system documentation of "construction norms of traffic information backbone network interlinking in Jilin Province"

(1) The development of technical standards of Jilin traffic information backbone network construction

Develop applicable scope, technical route and definition explanations of norms. Standardize guiding principles of network construction, the basic process and traffic information backbone network bandwidth and equipment standards, and prepare IP addresses and domain plans.

(2) The development of technology standards of Jilin traffic information communication network data, voice, video transmission

Data transmission technology standards standardize network selection, network interface devices, network switching equipment, and network server on network platform, with regulations on the selection of network storage devices, and specifications on network generic cabling and network security platform. Voice technology standards standardize basic technologies, protocols and standards and functions of Voice of Internet Phone (VOIP). Video technology standards standardize basic provisions and main technical indicators of video surveillance services. Transmission methods and technical standards of wired and wireless signals, construction standards of multimedia services have been also regulated.

(3) The development of construction standards of Jilin traffic information network IT room;

Formulate standards on the building, environment, UPS, air conditioning systems fire control, lightning in computer room.

(4)The Development of acceptance test standards of Jilin traffic information network;

Develop standards on test range, test methods, test items, performance testing requirements, and test documentation requirements.

(5) The development of technical standards on grade-based protection construction of traffic information network in Jilin;

Standardize security assurance level and grading methods of information system, basic requirements for all levels, basic principles and process of hierarchy protection on information system, as well as engineering management of information system security.

4 Popularization and application prospects

This standard is applicable to information network construction of Jilin Department of Transportation, city (state) Department of Transportation and ministry units directly under. Units directly under district-level or county-level transportation departments can also implement the standards. Results of this specification can guide the province's transportation and communication information network construction into normal construction, so as to improve the efficiency of interconnection, network construction and operation and maintenance of transportation departments in the province.

Results of this specification can enhance application scope of traffic information network, network construction, and ensure the scientificity and consistency of network construction, so that the interconnection and interworking of traffic information network among units in the province can be achieved, to play its role in the protection of the network infrastructure of traffic information data transmission, and a crucial role in emergency treatment and disposal of abrupt environmental accidents. At the same time, it also provides as a basic platform for unified and efficient supervisor-subordinate information sharing of transport sectors.

This specification determines the technical standards for security assurance level of Jilin traffic information systems, serving as reference bases of security assurance level construction of each network node in transport sectors of the province, to avoid the duplication of grading, high grading standards and other issues, while saving a lot of funds in safety grade construction.

Results of this specification can provide technical support to promote the Jilin traffic information communication network construction and network security level construction, making reference to interconnection construction of traffic information backbone network for other provinces and regions.

China Railway Special Line Information Management System Framework Design

Longting Yuan and Yinying Tang

School of Transportation and Logistics, Southwest Jiaotong University, Chengdu 610031, China. E-mail: yinyingtang@swjtu.cn

Abstract: This article describes the problems of railway special line management; put forward the idea of establishing an information management system to standardize the management of railway special line; analysis the demand of special line information management system in security management, operation management and other aspects of daily operations; according to the system functional demands, appropriate discussion are made to obtain the system functional framework, logical framework and physical framework.
Keywords: Special lines; Information management system; Framework design.

1. Existing problems of railway special lines management

Railway special line is designed to serve the industrial enterprises and other units of rail transport facilities. As an important part of the railway network and freight, the special lines play an important role in China's railway freight transport. However, many problems are existing in China's railway special line management, which are seriously affect the transport efficiency and safety, mainly in the following aspects.

Table 1. Existing problems of special line management

Special line management problems	The main performance of the problem
Security Management Problems	1.1 Policy cannot be executed leads to human negligence 1.2 The aging of equipment leads to overload and partial load; 1.3 The lack of on-site monitoring equipment and emergency rescue plan;
Operations Problems	2.1The truck stop time is too long to lower the work efficiency; 2.2 The lack of shunting system leads to take longer delivery vehicles work time; 2.3The loading and unloading machine is generally obsolete which leads to lower efficiency;
Property management Problems	3.1 Illegal conduct of special lines affect the safety of transportation; 3.2 The change of property right can not be recorded promptly, which resulting in unclear responsibility for the accident.
Management systems are not compatible	4.1Mutual exchange of information between special lines and local railway bureau is difficult to achieve.

Those problems mentioned above resulting in improving transportation costs and the responsibility for accident is unclear, etc. It is necessary to establish an information management system that promotes special line to rail freight yard line, standardization and institutionalization. With the application of this system the efficiency and safety of special line transportation can be improved, in which way the special lines could make its due contribution to national economic development.

2. Demand and function analysis

2.1 Special line information management demands analysis

Special Line Information Management System is a multi-system, which can complete various functions to maintain efficient operation of a special line, in general, there are daily operations management demands, operation security demands, customer management demands, property management demands. Specific demands is shown as below table 2.

Table 2. Special line information management demands analysis

Functional demands module	Demand for specific content
Daily operations management demands	1.1 The demand of vehicle arrival prediction and confirmation timely delivery; 1.2 Shunting operation demands; 1.3 Detection work demands; 1.4 Statistical operations demands; 1.5 Resource management operations demands.
security demands	2.1 Working field real-time monitoring demands; 2.2 The demand for establishment of the emergency rescue plan; 2.3 Equipment safety testing demands.
Customer management demands	3.1 Statistical and analysis of traffic volume demands; 3.2 Safety assessment demands.
Property management demands	4.1 Property right management demands; 4.2 Online processing demands.

2.2 The function analysis of dedicated line information management system

According to the above knowable, we can get design of information systems function modules as follows based on causal method.

Table 3. Special line information management functions analysis table

Modules	Functions
Operation Management Module	1.1The establishment of information exchange network; 1.2 Function of efficient organization of vehicle sheeting; 1.3 Function of uploading information for every position in each day.
	2.1 Function of Working field real-time monitoring;

Security Management Module	2.2 Function of emergency safety plan; 2.3 Function of mastering the running state of the equipment. 2.4 Function of Mastering the vehicle load
Resource Management Module	3.1Loading and unloading machine and Handling appliance management; 3.2 Function of financial managemen; 3.3 Function of HRM (human resource management).
Property Management Module	4.1 Function of online application; 4.2 Function of Property information update and record.

According to statistical data, the loading income from special lines account 30% of the whole railway freight transport income. Therefore, we must regard the special line property unit as big customer, which means customer management should be taken into consideration. With the special line information management system, we can get a variety of special line management data, and then we can accurately grasp the status and the laws of send cars, so it will be simply to comprehend the needs of special line transport.

3. Design of special line information management system function framework

Railway Special line information management system is a complex system which include resource management, security management, customer management and other business areas. Therefore, it is necessary to establish the information management system in accordance with the method designed at railway freight station. Only in this way, can we lead the special line toward to standardization, modernization.

3.1 Special Line Information Management System Framework

The functional framework of the information management system is the basis for logical framework and physical framework design, which identifies functionality required to meet the various demands of users. In the following content, we will focus on "high-quality service, high security, and high efficiency management", and then design a system function framework consists of seven sub-system as shown in Figure 1.

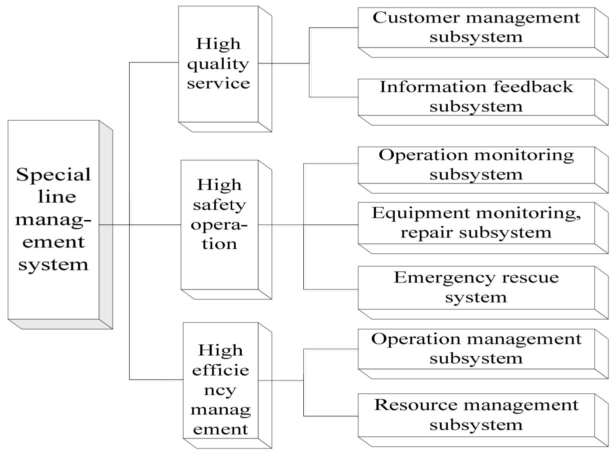

Figure 1.The system function framework

Meanwhile, the function framework can be subdivide into 20 specific subsystems as shown in Table 4.

Table 4. Subsystem functional division

Classification Subsystem	Subsystem functions
Customer management subsystem	1.1 Special line customers in volume, income statistics; 1.2 Special line station stopping statistics; 1.3 Special line in accident statistics; 1.4 Special line dedicated railway property change management.
Information feedback subsystem	2.1 Feedback the irregular operation information to the Railway Bureau; 2.2 Upload statistical data to the Railway Bureau every year; 2.3 Feedback the results of device checks to local railway bureau.
Operational monitoring subsystem	3.1Timely pick-up and recording vehicle status; 3.2 The weighing result record; 3.3 Stop line detection, vehicle stop recording time; 3.4 Safety monitoring in the workplace routinely.
Device Management Subsystem	4.1 System records the state of equipment, service life, the use of the scientific method to predict equipment failure and early warning; 4.2 System Administration and regularly reminded local railway line unit organization dedicated equipment inspection car, recording equipment status.
Emergency Rescue subsystem	5.1 Emergency rescue plan; 5.2 Traffic safety and maintenance decision support; 5.3 Security protection.
Resource management subsystem	6.1Transportation Resource Management; 6.2 Financial Management; 6.3 HRM Management.
Operations Management Subsystem	7.1 Operation management; 7.2 Operating efficiency statistics; 7.3 Employees technology assessment organizations

Logical framework mainly show the relationship between the unit system features and functions through the data stream. According to the functional demands above, the top-down model is employed to simulation the process in which the system deal with problems, and then the system logic framework map systems is established, as shown in Figure 2:

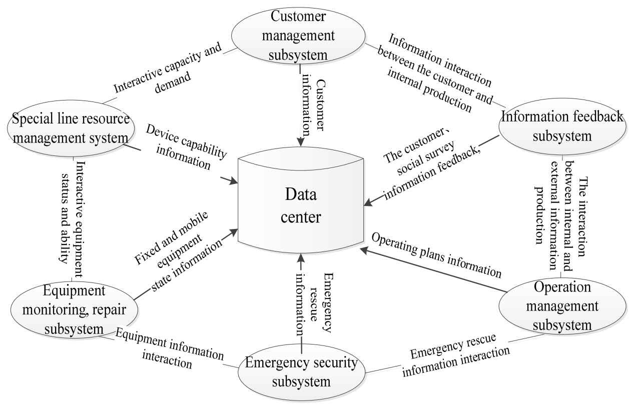

Figure 2.The system logic framework

Physical framework is the concrete embodiment of the logical framework, which describes the relationship between system functions and function and relationship of the way data transfer between divided modules by a system configuration diagram, and then we find out the realization function method through the figure. Combining the above analysis and the present situation of special line management in our country, we can establish the physical framework of the system, based on SSD (system sequence diagram) method, as shown in Figure 3.

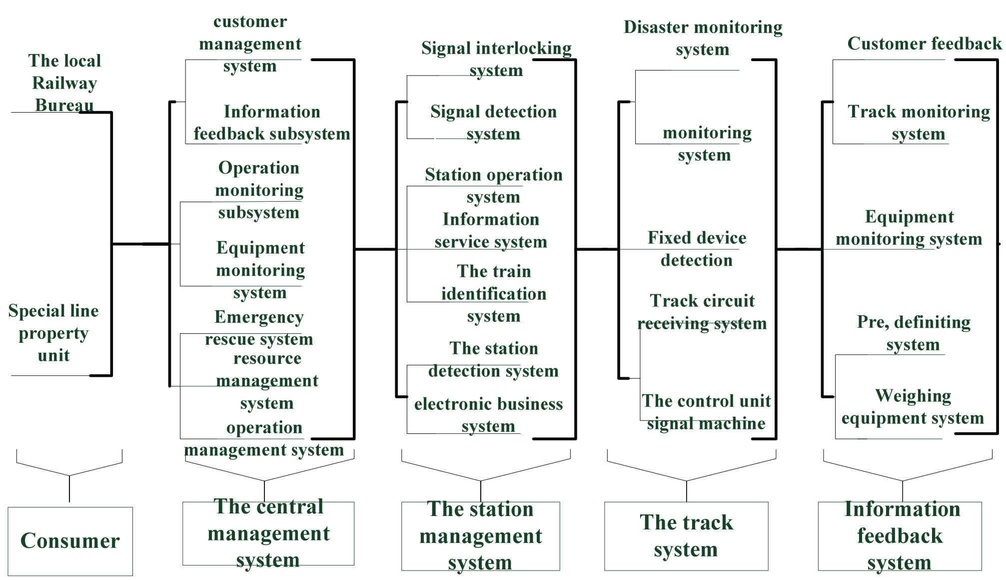

Figure 3.The system physical framework

3.2 System functional advantages

1. The system propose the reform direction of the freight yard in operation management module, establish interconnection between railways bureau Information Systems and special line information management system. In this way, we can improve the operating efficiency and safety protection in special line;

2. The system can automatically detect truck stop time, so we can accurately know the stop time, which helps us to calculate the rent from Trucks instead of warehouse;

3. The system can check the status of real-time monitoring of pounds equipment, and records data automatically, so the overload can effectively avoid;

4. The use of information systems can the scientifically guide the staff work and clarify the responsibilities of employees.

5. The system argument the online application function, which can accept the application of property change and update timely after the change of property. So we can clear responsibility and avoid unsafe factors such as overloading and irregular loading.

4 Conclusions

Firstly, this article describes the existing problems in railway special lines management, and then with the method of system engineering, the concept of information management system was put forward on account of current situation in special lines management. Finally, we establishes function framework, logic framework and physical framework. In recent years, fast freight is rapidly develop, while special lines paly a importation role in it ,so this article may has certain guiding significance to standardize the management of special lines and improve work efficiency. However, the management of railway special line is a tough task, an information management system is barely enough to solve the problems. The cooperation between special lines property units and railway bureau is the fundamental demand to promote the healthy development of special lines.

Abstract: OD matrix is one of the most important research fields in intelligent traffic, it's the key data of microscopic traffic simulation, city traffic planning, management and control etc…In this article, through the multipath search algorithm based on point and punishment method and modified Logit model to determine the distribution of matrix, according to the structure of OD deviation state space model and combining with polynomial trend based on information fusion Kalman filtering, put forward the dynamic OD matrix estimation algorithm based on information extraction. Finally, combining with the example of analysis and calculation, verify the validity and feasibility of the presented method in this paper.
Keywords: Information extraction technologies; Dynamic OD matrix estimation; Distribution matrix; Kalman filter.

1 Introduction

The precise dynamic OD demand, accurately reflect the running status of urban road network, is the data base to develop effective traffic management measures, is important input of ATI and ATMS in ITS, directly influence ITS effectiveness of real-time system.

At present, OD matrix estimation method mainly has the maximum entropy model method, minimum model method, the method of maximum likelihood, generalized least squares method and Bayesian statistics. In recent years, through the efforts of the researchers, the dynamic OD matrix estimation research with some new results. Cascatta put forward two dynamic OD estimation models: one step and iterative method. It's lack of computational effectiveness, and without considering the inherent constraint model. Hazelton solves the problem of uncertainty of OD matrix estimation, using two order statistical information flow between sections to estimate the OD matrix, and illustrates that the model is feasible and effective combining with the example. Li Jueyou analyzed the insufficient of successive iterative algorithm for least squares model adopted to solute OD matrix estimation, proposed the filled function method to find global optimal solution of the model. With the acceleration of the information process, acquiring traffic information using mobile phone positioning information has become feasible. But the current research on the mobile phone positioning information is also limited to theoretical modeling stage, and travel recognition technology is not yet mature. Li Junwei introduced the unscented Kalman filter (UKF) algorithm for fast road network dynamic OD matrix estimation, but it needs to be calculated all the lag influence OD until the present stage, significantly improved the computing complexity. Kalman filtering algorithm can linear estimate dynamic OD based on real-time observation data, it has been widely used. Okutani will be the unknown OD flow as the state vector, using autoregressive process set up the state equation, using Kalman filtering algorithm estimate the real-time OD of a small road network. Chang introduced the advanced extended Kalman fitler (EKF) algorithm to solve the model. In addition, the scholars also studied other dynamic OD matrix estimation algorithm includes genetic algorithm.

Now, according to the traffic of multi-source data, massive, heterogeneous, time-varying, non-intuitive significant feature extraction, advanced traffic information extraction technologies including information fusion, data mining and granular computing, emerge as the times require. The excellent characteristics of the extraction technology has obvious advantages, it greatly improves the level of traffic information extraction, promote the development of ITS. So, the related research technology of information extraction, this paper puts forward the dynamic OD estimation algorithm based on information extraction.

2 Dynamic OD estimation algorithm based on information extraction

As a key parameter in the model to estimate the dynamic assignment matrix OD, reflects the dynamic relationship between OD flow and the traffic volume of time variant. The accuracy of the parameters greatly affect the dynamic OD estimation effect. Therefore, this paper was to explore distribution matrix, on the basis of research on dynamic OD estimation algorithm based on information extraction.

2.1 Extraction of assignment matrix

At present, the parameter acquisition method mainly has the dynamic traffic assignment model and traffic simulation. The dynamic traffic assignment model is a very complicated problem, and spatial and temporal complexity of city road network and the influence of travel behavior leads to traffic simulation cannot get the desired results. The model described traffic network is more complex, the sensitivity of algorithm more weaken, solving more complex, error of omission in the calculation larger. These will reduce the accuracy of the model, and if the model cannot satisfy the real-time requirements, no matter how it's effect will not be accepted. Based on the literature of the particles travel cost, by the multipath search algorithm based on point and punishment method and modified Logit model, combining $\alpha_{i,t}^{r,\tau}$ calculated $\theta_{i,t}^{r,\tau}$.

In the travel route choice, people generally do not consider all connected path, and will only consider travel cost within the scope of sustainable path. Therefore, defining the path impedance within the shortest path impedance 1+H times (H to stretch coefficient path) path and there is no loop as a valid path. Let $l_{r,j}$ be OD r article j dissimilar shortest path, length is $f_{r,j}$, V_j is the set of the through point of $l_{r,j}$, v_b^j is the j time for the shortest path time delay in point b. E_j is the set of the through path of $l_{r,j}$, w_i^j is travel cost of link i, in j-th time for the short circuit. Effective path set of OD r can be obtained, as follows:

Step 1: $v_b^l = 0, \forall b \in V; w_i^l = C_{r,\tau,j}^g; E_j = \varnothing, V_j = \varnothing; j = 1$

Step 2: Using the Dijkstra shortest path algorithm to obtain any shortest path(the path through point v_b to add the corresponding v_b^j), length is denoted by $f_{r,j}$, folding the path through edge into E_j, through point into V_j.

Step 3: Given point penalty factor α', penalty factor β', and the right side and the vertex delays in $l_{r,j}$. And use the right side of w_i^j and v_b^j to replace the corresponding time weight and vertex delay in G. The punishment function as follows:

$$v_b^{j+1} = \alpha', \forall v_b^j : v_b \in V_j \tag{1}$$

$$w_i^{j+1} = (1 + \frac{\beta'}{f_{r,j}}) w_i^j, \forall w_i^j : i \in E_j \tag{2}$$

Step 4: if $l_{r,j} \geq (1+H) l_{r,j}$, the algorithm terminates; Otherwise, $k = k+1$, go to the Step 2.Combined with the travel cost and effective path set, $\gamma_{r,\tau,j}$ can be determined using the improved Logit model. As follows:

$$\gamma_{r,\tau,j} = \frac{\exp(-\theta C_{r,t,j}^g / \bar{C}_{r,t}^g)}{\sum_k \exp(-\theta C_{r,t,k}^g / \bar{C}_{r,t}^g)} \tag{3}$$

Combined with Cascetta's "vehicle package" hypothesis and Dr. Lin Yong's improved "vehicle package" hypothesis, Assume that all vehicles traveled along j-th path composed of a package (j,τ) within the interval time τ(H in length),the headway vehicles in the package always uniform distribution, and can be stretched or squeezed with the same proportion. Making the time interval package (j,τ) through the detector of the link i is $\Delta_j = \left[\delta_{1,\tau}^{i,j}, \delta_{2,\tau}^{i,j}\right]$, $\delta_{1,\tau}^{i,j}, \delta_{2,\tau}^{i,j}$ is time the first and tail car in package (j,τ) through the detector. The duration of H accounts for the time interval $\Delta_j = \left[(h-1)H, hH\right]$, so

$$\alpha_{i,t}^{r,\tau} = \left|\Delta_j \cap \Delta h\right| / \left|\Delta_j\right| \tag{4}$$

In the formula, $|\bullet|$ is operator of interval length. Although the assumption of headway uniform distribution in a particular case may be incorrect, because we are concerned about the variation rule of large flow rate. As long as the estimated time length of H is large enough, statistically, the formula (4) still is practical value. Thus, distribution matrix unit of $\theta_{i,t}^{r,\tau}$ can be obtained by the formula (5).

$$\theta_{i,t}^{r,\tau} = \sum_j \alpha_{i,t}^{r,\tau} \gamma_{r,\tau,j} \tag{5}$$

2.2 **Dynamic OD matrix estimation algorithm based on information extraction**

According to the structure of OD deviation state space model and combining with polynomial trend based on information fusion Kalman filtering, put forward the dynamic OD matrix estimation algorithm based on information extraction, as follows:

Step 1: Initialization, $\hat{E}_{0.0} = E(E_0), P_{0.0} = Var(E_0), k = 1$.

Step 2:Toextractcongestion particles $A_{i,t}$ in link i within t, particles of traffic safety $B_{i,t}$, then extract the travel cost particles $C_{i,t}^{g}$.

Step 3:To extract distribution matrix $\theta_{i,t}^{r,\tau}$.

Step 4:Combined with the conventional Kalman filtering, forecast OD structure deviation value of k-1 to k stage and variance matrix, as follows:

$$\hat{E}_{k,k-1} = A_k \hat{E}_{k-1,k-1} \tag{6}$$

$$P_{k,k-1} = A_k P_{k-1,k-1} A_k^T + W_{k-1} \tag{7}$$

Step 5:Combined with information fusion theory, estimate filter error and estimate of k stage OD structure deviation. If $\left| \frac{\hat{E}_{k,k} - \hat{E}_{k-1,k-1}}{\hat{E}_{k-1,k-1}} \right| \le \varepsilon$ (ε is a critical value of the predetermined precision), go to the Step 4, otherwise, go to the Step 6.

$$P_{k,k}^{-1} = P_{k,k-1}^{-1} + B_k^T V_k^{-1} B_k \tag{8}$$

$$\hat{E}_{k,k} = P_{k,k} \left[P_{k,k-1}^{-1} \hat{E}_{k,k-1} + B_k^T(k) V_k^{-1} Y_k \right] \tag{9}$$

Step 6:According to the composition of OD, estimate dynamic OD matrix combined with $\hat{\mu}_{r,\tau}$, as follows

$$X_{r,\tau} = E(X_{r,\tau}^H + \mu_{r,\tau} + \eta_{r,\tau}) = X_{r,\tau}^H + \hat{\mu}_{r,\tau}, \quad \tau = k\lambda, k\lambda+1, ..., (k+1)\lambda - 1 \tag{10}$$

$$X_{\tau} = E(X_{\tau}^H + \mu_{\tau} + \eta_{\tau}) = X_{\tau}^H + \hat{\mu}_{\tau}, \quad \tau = k\lambda, k\lambda+1, ..., (k+1)\lambda - 1 \tag{11}$$

Step 7:Update database, $k = k+1$, go to the Step 6.

3 Implementation

This chapter selected part of Liuzhou-yufeng old airport road network as the research object in Guangxi autonomous region development zone, the network diagram as shown in figure 1, including 24 sections (article 17 a two-way road, 7 one-way road), 16 nodes, graph edge Numbers beside road number, which nodes are included in the 5 to hair, point 3, 5, 12, 14, 16, a total of 25 OD pairs. There're a total of nine sections of the road network device induction coil, section 5, 6, 14, 15, 16, 17, 18, 24, 25, induction coil, and the remaining sections of the devices under assumed section to install detector are located the position of the nodes in a third section length. At the same time, the actual OD demand and corresponding road traffic information have been collected from 9:00 to 14:00 on July 5, 2007.Assumes that the current maximum of the flow of time interval number is equal to 4, then the observation time interval and the departure time intervals are 10 min. Each time for 30 min, each time interval number equals 3, and each set out the observation interval time interval number n equals 1.

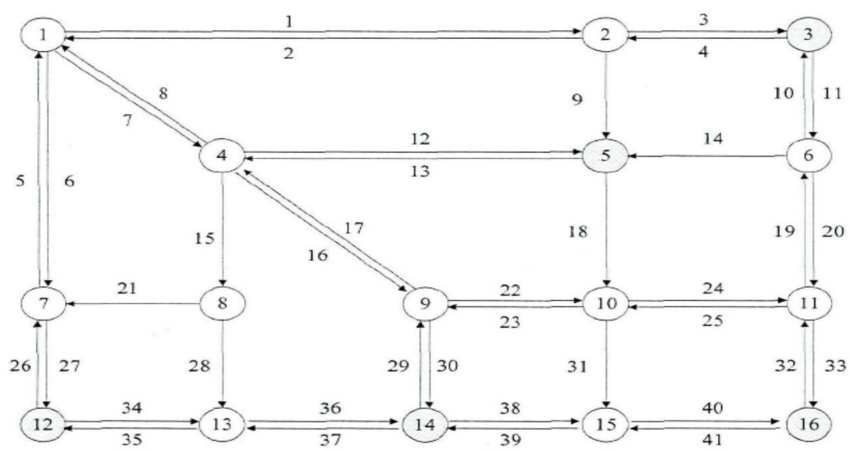

Fig.1 Network diagram

Model history needs the optimal value of OD matrix. Considering the actual system, traffic demand has a certain similarity in different day, so we adopt the method of traffic simulation under the condition of similar input to generate historical value. In practice, collect data in the same day from different weeks or different month, and get the optimal value of history.

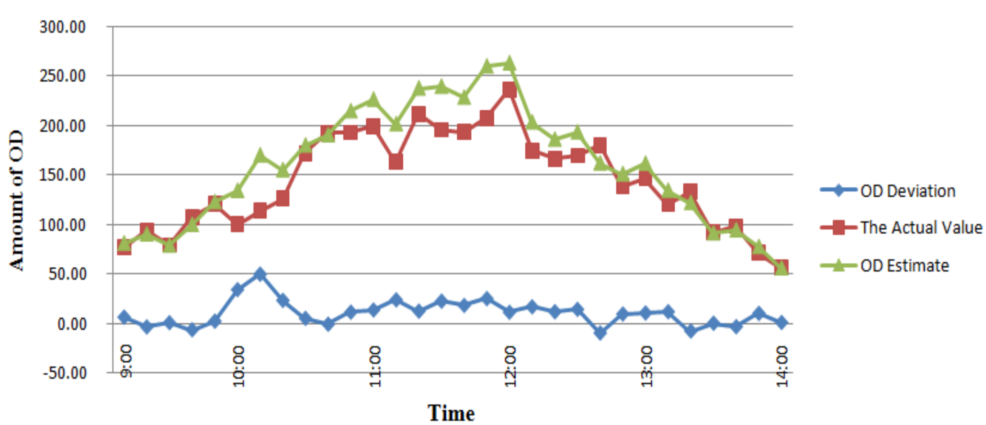

Fig.2 (3, 14) results contrast figure

We used conventional Kalman filtering method to estimate regression simulation of dynamic OD matrix by combining the method of dynamic OD matrix, and got fig.2and fig.3.From the overall, due to the good robustness of polynomial trend model, in terms of accuracy, Kalman filtering method based on the polynomial trend of information fusion is higher than conventional Kalman filtering method. Especially, when great changes have taken place in the OD matrix, polynomial trend Kaiman filtering method based on information fusion of robustness significantly is more than the conventional Kalman filter method.

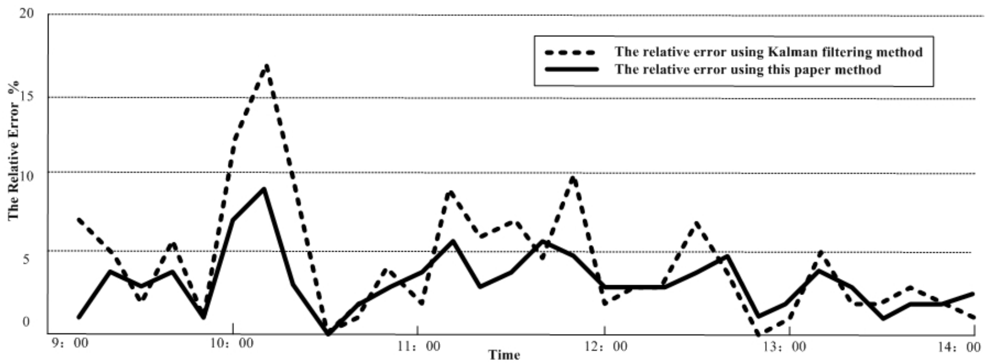

Fig.3 Relative error comparison chart in different methods

4 Conclusions

Dynamic OD matrix is indispensable information in city management, is one of the hot topics in the field of transportation research, but the calculation method of the dynamic OD matrix estimation is still in the primary stage, related research needs to be further. Distribution matrix reflects the dynamic relationship between time-variable OD flow and the traffic volume, the parameter accuracy greatly affects the dynamic OD estimation results, so this paper first puts forward the extraction algorithm of distribution matrix. On this basis, according to the OD structure deviation state space model, combined with the polynomial trend of Kalman filtering method based on information fusion algorithm, proposed dynamic OD matrix estimation based on information extraction. Finally in the instance analysis, respectively use conventional method and the presented method to estimate analysis, the results verify the effectiveness of the presented method.

[2,3]School of Transportation and logistic, Southwest Jiaotong University, Chengdu 610031, China. E-mail: 839029841@qq.com

Abstract: Customized shuttle bus is a new service pattern of public transportation which can meet the personalized travel demand. In the article, we used discrete choice model to analyze the factors affecting commuters travel mode choice, with the investigation which is about Beijing commuters' travel characteristics and transportation mode choice under different scenarios. Binomial Logit model has been built to the population characteristics and probability of commuters who chose the customized shuttle bus, thus it provides the reference to adapt to the characteristics of customized shuttle bus business strategy for the bus companies to determine.
Keywords: Commuters; Customized shuttle bus; Way to travel; Traffic model.

1 Foreword

Bus priority is one of the city's major transport development strategy. The emergence of customized shuttle bus, which is one person one, one-stop direct and personalized service to meet the commuters, adds a new attraction for the public traffic. In the past year, since Beijing took the lead after the opening line of custom bus, in a number of cities in Fujian, Tianjin, Shenzhen, Chengdu, Xiamen, etc. have been popularized. Although the response of customized shuttle bus is active in the market, but the occupancy rate is still low.

In order to attract more commuters to choose customized shuttle bus, we must deeply analyze the population characteristics and the influence factors of travel mode choice behavior of commuters who chose to take the customized shuttle bus. Current research on customized shuttle bus is still in its infancy exploration, existing research focuses on customized shuttle bus line layout, model selection and price. In this paper, we establish binomial Logit model, which is based on the travel behavior of commuters, costs and travel time, to clearly reflect the determinant of commuters' travel mode choice behavior, at the same time, this model can also provide the operator decision basis to promote the new bus service mode customized shuttle bus.

2 Commuters Travel Mode Choice Analysis

2.1 Travel mode investigation

Taking the RP/SP survey as an example, which is about car travelers' behavior in the commuting time in Beijing. The survey sites including office parking lot, large residential area, industrial area parking lots. The main content of RP survey as shown in Table 1:

Table 1. RP survey content

Property	Content
Personal characteristics	gender, age, marital status, income, occupation, driving experience, car ownership situation
Traffic Characteristics	transport, travel distance, travel time, travel costs, the number of days per week car trip, The number of trips together

In the SP survey, assuming the respondents could choose cars or customized shuttle bus to work, the time and cost required for each of the two modes of transportation as follows:

car travel time=walk to the parking lot of time + driving time + walk to the company time

car travel costs= fuel costs+ road toll+ parking fee+ impairment charges

(*fuel costs*=(trip distance* fuel consumption/ kilometer)* prices)

customized shuttle bus travel time=walk to station time + running time walk to the company time

Customized shuttle bus travel cost= trip distance* price/ kilometer

Because customized shuttle bus can use the bus lane or highway, commuting time regarded as a smooth running, so we assume the travel time is 60min, and customized shuttle bus fares can be divided into normal and preferential two cases; however, because the car may appear congestion, car travel is divided into normal and delayed for two cases. The above situation can be composed of 4 scenarios, as shown in Table 2:

Table 2. Classification of travel situation

Situational	Situational brief
1	Car travel is normal, take customized shuttle bus with no preferential
2	Car travel is normal, take customized shuttle bus with preferential
3	Car travel is delay, take customized shuttle bus with no preferential
4	Car travel is delay, take customized shuttle bus with preferential

2.2 Data Analysis

The basic situation of the respondents is shown in table 3:

Table 3. The basic situation of the survey respondents

Category	Actual situation
Gender	60% men, 40% women
Age	To the youth, middle-aged, mainly concentrated in between 26 to 42 years of age
Marital status	76% of the respondents are married
Income	Most respondents monthly income above 4000, the proportion reached 84%
Occupation	The vast majority of respondents personnel for enterprises
Driving experience	75% of respondents in six years or less driving experience
Possession of the car	78% of respondents own a car

Table 4. The results of travel mode choice

Travel situation	Car		Customized shuttle bus		Select the customized bus ratio %
	Time/min	Fee/yuan	Time/min	Fee/yuan	
Situation1	40	25	60	12	17.3
Situation2	40	25	60	10	19.6
Situation3	55	38	60	12	72.2
Situation4	55	38	60	10	75.4

We can see from Table 4: In the context 1 and 2 the respondents chose customized shuttle bus travel is only 17.3% and 19.6%; In the context 3 and 4 the respondents chose customized shuttle bus travel is 72.2% and 75.4%; Thus the difference travel time and cost between cars and customized shuttle bus is the key factor that whether commuters choose the customized shuttle bus.

3 Cars and Customized shuttle Bus Choice Relation Model

3.1 Model establishment

In recent years, There are many travel options for travelers research. For example, Cherchi E (Cherchi E.2002) according to RP / SP surveys of residents in Cagliari, Italy travel Nested Logit (NL) model. In literature (Central Transportation Planning.1997) MNL model using travelers commuting travel mode choices, focuses on the impact of the transfer amount select travelers commuting and travel mode. In Mcfadden DL (Mcfadden D L.2000) article Mixed Logit model using travel mode choice modeling and the results obtained. Yang Liya (Yang,2012) select features travelers, travel features, travel mode and level of service as a utility variable Logit model to build a hierarchical way to travel and departure times union choice. In Guan Hongzhi (Guan, 2008) article Beijing downtown area, for example, the parking fee payers are divided into individual units of payment and reimbursement categories, the establishment of private cars, buses, taxis targeted way to travel for the two types of samples and all the sample selection Logit model.

In this paper, we use binomial Logit model to quantitatively analysis travelers' choice behavior in the commuting time (Liu, 2008; Jia, 2007; Guan, 2004). Based on the principle of random effect theory and maximize effect, assumptions are as follows:

$$\mathrm{P}(i) = \frac{\exp V_i(X)}{\sum_{i=1}^{n} \exp V_i(X)} \quad (1)$$

Among them: *P (i)* as the selection probability of the i travel mode; *Vi (x)* for the selection of the utility function of the i travel mode, i=0、1,i=0, i = 0 represents select customized shuttle bus travel; i = 1 represents choose car travel; n for the number of travel mode.

In the article we regard commuter' car trip as a reference item, its utility equation is 0. The variables of the model and the way we choose its corresponding values as shown in Table 5. We use the chi square detection estimation results, with 95% confidence, the gender variable was not significant, and so it did not enter the model variables. The Nagelkerke R Square (coefficient of determination) is 0.368, more than 0.3, indicating that the accuracy of the model is high. Our model is calibrated as shown in Table 6 with the survey data and the calculated parameters.

Table 5. model variable parameters and values the way

Variable	The value of the variable		
Age(A)	A≤25：1	26≤A≤35:2	36≤A:3
Income (S)	S≤3000：1	3000＜S≤10000:2	1000≤S:3
Marital status (M)	YES：1 NO：0		
Enterprise staff (W_1)	YES：1 NO：0		
Self-employed households (W_2)	YES：1 NO：0		
Driving experience (Y)	Y≥3（年）：1 Y＜3（年）：0		
Car ownership situation (O)	YES：1 NO：0		
Take customized shuttle bus commute time≤40min(T_1)	YES：1 NO：0		
Take customized shuttle bus commute time 40~60min(T_2)	YES：1 NO：0		
Car travel days / week (D)	1、2、3、4、5		
Travel time difference (T)	Car travel time—Customized shuttle bus travel time		
Travel fee difference (F)	Car travel fee—Customized shuttle bus travel fee		
The number of peers (N)	1、2、3…		

Table 6. Model parameter calibration results

Select mode	Variable	Parameters	χ^2	Sig
Customized shuttle bus	Constant term	0.734	14.652	0.001
	A	-0.237	16.234	0.000
	M	-0.034	11.734	0.001
	S	-0.104	6.287	0.008
	W_1	0.052	9.372	0.002
	W_2	0.054	10.843	0.002
	Y	-0.024	16.528	0.000
	O	-0.095	25.753	0.000
	T_1	-0.042	17.436	0.000
	T_2	-0.046	12.264	0.001
	D	-0.005	8.114	0.005
	T	0.047	124.62	0.000
	F	0.057	76.24	0.000
	N	0.009	12.471	0.001
The coefficient of determination	Chi-square		396.000	
	-2 Log likelihood		1.692	
	Nagelkerke R Square		0.368	

According to the parameters of each of the variables in Table 6 the calibration can get utility function for customized shuttle bus ride:

V_0=0.734-0.237*A-0.034*M-0.104*S+0.052*w_1+0.054*w_2-0.024*Y-0.095*O-0.042*T1-0.046*T_2-0.005*D+0.047*T+0.057*F+0.009*N

Using the formula (1) we can be calculated for each commuter time travelers in different contexts probability of selecting a different way to travel. For example, the traveler is 37years old married with a private car. His income is 11,000 yuan a month. He rode the customized shuttle bus was 55 minutes commuting time. However, Private car commuting time is 35 minutes. Two kinds of transportation cost difference of 25 yuan. the traveler selects customized shuttle bus to travel for 2.4% probability, but he choose private car to travel for 97.6% probability.

3.2 The results of the model solution

Based model calibration parameters analyzed commuters choose the law as follows: (1) *A* parameter is negative, indicating that young people more likely to choose to customized shuttle bus travel; (2) *M* parameter is negative, indicating that a single person with respect to the married person is more likely to accept customized shuttle bus travel; (3) *S* parameter is negative, indicating that as incomes increase people more inclined to choose travel by car; (4) *Y* parameter is negative, indicating the shorter driving experience are more likely to change the habits of the past, to choose a new way to travel; (5) *O* parameter is negative, indicating that people of owned car are more willing to choose a car to travel; (6) *T1, T2* parameter is negative, and the T1 <T2 descripts commuters do not want to pay too much time to take the customized shuttle bus, and when the customized shuttle bus save more time, more and more people will choose it; (7) *D* parameter is negative, indicating that as commuters increase the number of days weekly to be more dependent on car travel, selecting the customized shuttle bus is more difficult; (8) *T* parameter is positive, indicating that is the more time cars saved, the more commuters choose using cars; （9）*F* parameter is positive, indicating that the relative cost of car is lower than the customized shuttle bus costs, commuters prefer to choose the customized shuttle bus trip; (10) *N* parameter is positive, indicating that the more people travel together, the more likely people choose the customized shuttle bus travel.

4 Conclusions

In this paper, we established a binomial Logit model based on the actual choice behavior of commuters, travel time and travel expenses. Because of we considered the personal and traffic characteristics of commuter, the model are more reasonable and more precise. The main results are as follows:

(1) Unmarried young commuters prefer customized shuttle bus as a commuter tool;

(2) Relatively low income commuters prefer to choose customized shuttle bus;

(3) The more the number of counterparts, the more commuters likely to choose customized shuttle bus.

At the same time, we can make the following suggestions for the promotion of customized shuttle bus mode through the analysis of model parameters:

(1) Customized shuttle bus mainly aimed to serve the young and middle-income people;

(2) Due to travel time for commuters is sensitive, we can attract car commuter by optimizing bus lines and reducing travel time;

(3) We can formulate preferential fares policies for those who ordered at the same time to attract more potential commuters who may take customized shuttle bus , so that to improve the occupancy rate of customized shuttle bus, let the bus service model innovation, provide more convenient and comfortable way to travel for commuters.

Abstract: In order to explore the driving behavior characteristics of vehicles which across the line of multi-lane freeway diverging areas, the paper selected Hu-Ning multi-lane freeway interchange (groups) as a field observation engineering, and extracted diverging and merging locations, speed and other traffic behavior from the drivers and the vehicles. The test results showed that: a multi-lane freeway diverging area motorcycle type difference and diverging location with low correlation under free-flow condition, and the vast majority of drivers choose merging locations advance under medium and low flow conditions, the locations merging behaviors of heavy vehicles and cars are broadly similar, but when the traffic conditions change, the merging locations between the two appears discrepancy and so on.

Keywords: Multi-lane freeway; Diverging and merging areas; Locations of lane-changing; Traffic behavior; Safety design.

1 Introduction

The research on traffic behavior of multi-lane freeway diverging areas is a new content and hot. The behavior of a driver driving is a process of information exchange and control. The state of the automobile and the state information of the environment are the decision-making basis of the driver driving behavior (Guo Zhongyin, 2012). Driving behavior characteristics of diversification of multi-lane freeway interchange diverging areas directly affects road traffic safety and traffic efficiency. Researchers are working on the multi-lane freeway diverging areas' efficiency and security and exploring vehicle characteristics, in order to establish the most safe and effective design criteria (Fisher. R.L, 1948). Olsen and Hostetter found that the confluencebehavior and the length of speed change lane is related by research of three entrance ramp (Olsen, R.A., 1976). Kou and Machemehl found the unobvious statistical laws between level of traffic flow, vehicle speed near the ramp, enter and delayed into the main line's vehicle speed parameters and vehicle confluence position by collecting four entrance ramp data9 (Kou, C.C., 1997).

2Test Equipment

It can be used with three cameras to shoot sub- confluent area of the vehicle operating conditions, each shot time is 2 hours .Selected one of the 10 minutes time video to analyze, the speed was measured with radar gun . When car out of the main line of diverge spot, mainly has the following several types:

(1)In or before the gradual change section,

(2)A third stage in front of the deceleration lane,

(3)A third stage in the middle of the deceleration lane,

(4)In the final stage of the deceleration lane 1/3,

(5)Out of compositenasal discharge.

3Experimental Design and Data Collection

With Google Map view of the powerful features and full reconnaissance visits Shanghai-Nanjing Expressway road type , Suzhou north and Zhengyi interchange junction located in Kun shan City is taken as a centralized object of study.

Figure1.The map of Zhengyi Interchange

Figure2.The map of Suzhou North Interchange

Firstly specific distance marking along the deceleration lane need to be done to assess the diverge spots at site .and then these point positions of vehicles streaming Need to be statistics during 10minutes.Simultaneously, recorded on the book with classification , and drew data analysis chart, through video analysis software Corel Video Studio Pro X4 processing. vehicles speed data acquisition could be acquired with the radar gun.

4 Lane-changing Position Data Analysis

4.1 Diverging Lane-changing Position Analysis

Selecting the diverging position reflects the way the driver diverge intention to achieve. Vehicle needs a certain critical points in the diverging area before the completion of their diversion lane change behavior, but decide whether it makes the most direct factor that a person produces diversion lane change intent is the distance between the vehicle and the key point(Li Li, 2011).

Driving is a complex intelligent behavior(Li Yingfeng, 2008).For diverging area and exit ramp, vehicle is along the line the outside lane in theory .when driving a certain position in the area , between the deceleration lane and the exit ramp. Vehicles begin steering into the deceleration lane change lane and exit ramp .However, due to the mutual influence of subjective and objective factors, traffic location showed differences, in multi Lane freeway diverging areas. Based on the safety design concept of man-machine engineering, road design should be people-oriented (Zhao Cui, 2012).

Because the expressway entrance region exists straight and the confluence of the traffic flow, traffic behavior becomes more complex than other roads. When the vehicle is accelerating or decelerating to enter or leave the lane, it will produce many conflicts, easily leading to accidents(Wang Xiaofei,2011).from the respect of microscopic traffic safety research, Many scholars at home and abroad established the models by analyzing the relations among the geometric road design , operating characteristics of the vehicle , the driver of the psychological and physiological responses , environmental factors and traffic safety (Yan Ying Sheng, 2011).

All vehicles are divided into five types according to its shunt position characteristic: transition section and the upstream, the deceleration lane of 1/3 segment, deceleration lane middle 1/3 segment , the deceleration lane 1/3 segment , Painted (delta end).the way of Shunt spot collection was used of both artificial field recording and video software review combination .Ten minutes as the basic unit of time at scene, staff recorded vehicles in accordance with the above five kinds of distribution. Indoor the point information could be analyzed through Video analysis software Corel Video Studio Pro X4 diversion, with the help of the radar gun, the speed of the vehicle can also be measured .

Firstly, the analysis that different models effecting Vehicle shunt positions in multi-lane freeway diverging areas could be got. Information in figure3, the heavy duty truck shunt positions are similar to passenger cars' under the condition of free distribution, namely the shunt position mainly concentrated in the range of the gradual stage ,While the shunt degree point decreased from the deceleration lane of

1/3 segment of anterior to the middle1/3segment, the percentage is not significantly different. Due to analyze the internal mechanism of the vehicles, it could be concluded that the headway distance between vehicles are such large under free flow conditions, that mutual interference effects little, and lane changing flow behavior can be chosen arbitrarily , thus drivers usually choose to change diversion into the deceleration lane early. The behavior choice no matter from the aspects of driving safety or comfort are reasonable.In the process, because of the large degree of freedom of choice, small interference factors, the physical properties of different models of vehicles differences reduce,furthermore,under the condition of free flow,the degree of correlation between different models of vehicles and shunt position is low in multi-lane freeway diverging areas.

Secondly, it could be analyzed vehicle shunt positions in multi-lane freeway diverging areas from the point of view of traffic flow environmental differences. figure3 shows that, under restrictive conditions shunt ,there is a great differentiation phenomenon between heavy trucks and passenger cars diverge position, that the primary focus of heavy goods vehicles shunt position are lane of 1/3 segment of anterior , followed by the middle third of the deceleration lane section , However , in binding position it contains the last section of 1/3 the deceleration lane shunt , the analysis can be found in figure3 bottom bar ,diverge position with heavy goods vehicles and buses tends close to shunt nasal discharge with intention from the free flow of traffic diversion to restrictive conditions diverge.

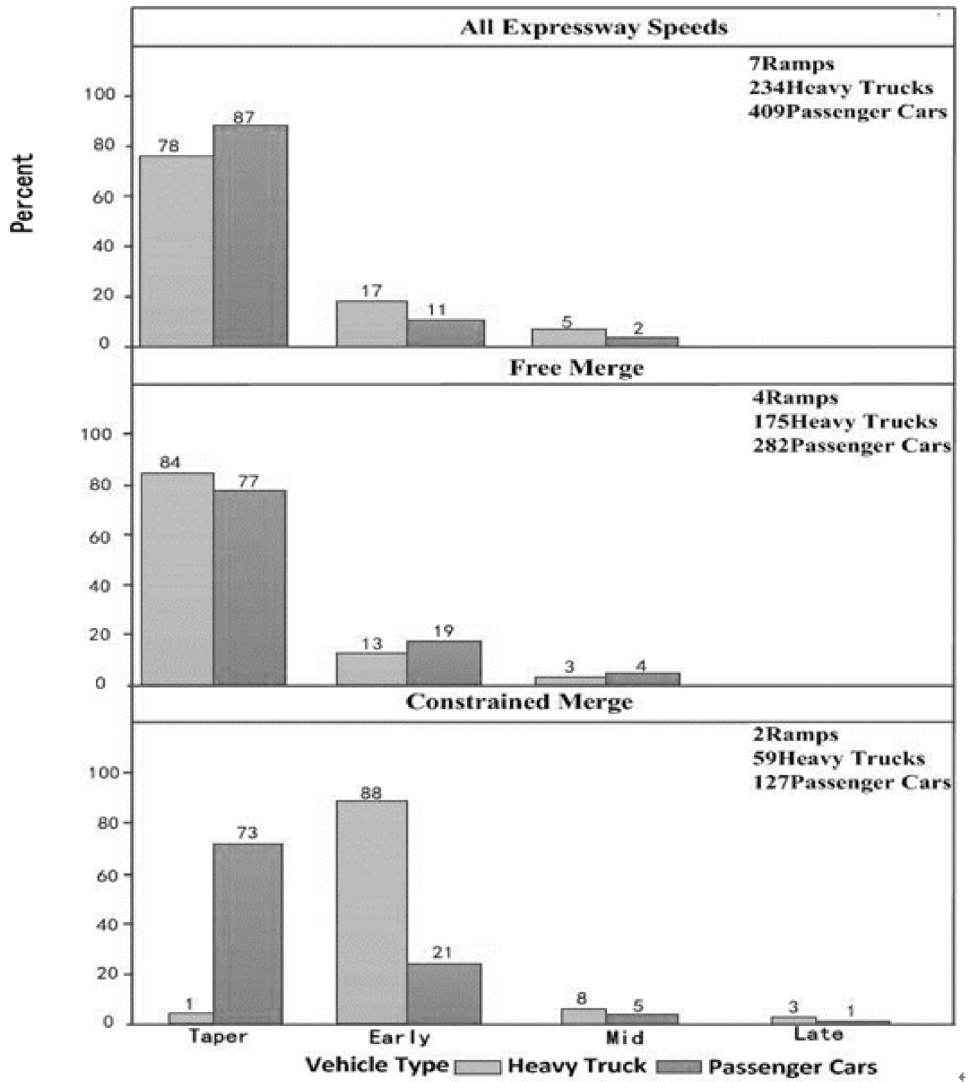

Figure2. Diverging Positions of Vehicles

4.2 Merging Lane-changing Position Analysis

For the multi-lane freeway entrance ramp, in theory, the combined vehicle should be along the confluence of the acceleration lane and in which a position change merge, that is done out of the confluence nose and before the transition section. According to the analysis of the live video and radar gun data, the combined position in figure 4 is statistical analysis in the conditions of all types of the ramp, types of the vehicle and freeway speed.

Analysis of figure4 can be obtained, for free and constrained merge conditions, most of the vehicles in the early or middle position is combined, but for forced merge conditions, most vehicles combined late even in the transition section.

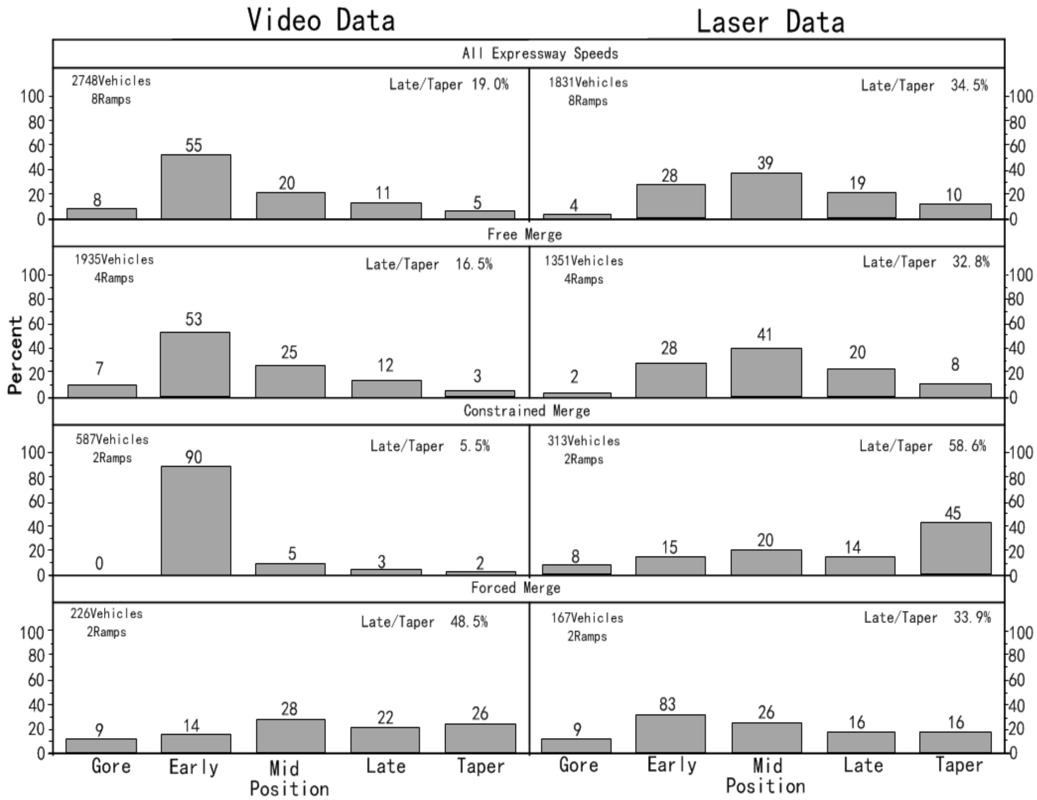

Figure3. Merging Positions of Vehicles(All ramps、Vehicle types、Speeds)

The gap acceptances did not appear frequently in the mandatory confluence condition, but the combined behavior may occur in a certain order and quantity at the same time, because the freeway operation speed is small in this condition, combined vehicle without acceleration too much can reach earlier comfortable confluence speed; in the constraint conditions of confluence, due to the insufficient clearances which can be inserted into and the of traffic flow is not sufficient to provide slow, orderly merging process, so it is difficult to find the gap acceptances.

Figure5 shows the heavy trucks and passenger cars combined driving behavior is similar, however, with the changes of the traffic flow conditions, the two combined position become differences of differentiation.

Analysis of Figure4 can be obtained, in the constraint conditions of merging, most heavy trucks merge in transition section or after transition section, but a few bus also confluence in transition section or after transition section, the situation may be caused by the following reasons, the first is the difference of dynamic characteristics between the heavy trucks and the large passenger vehicles, the second is the traffic flow density, the third is the confluence of space squeezed caused by the length of the acceleration lane restrictions.

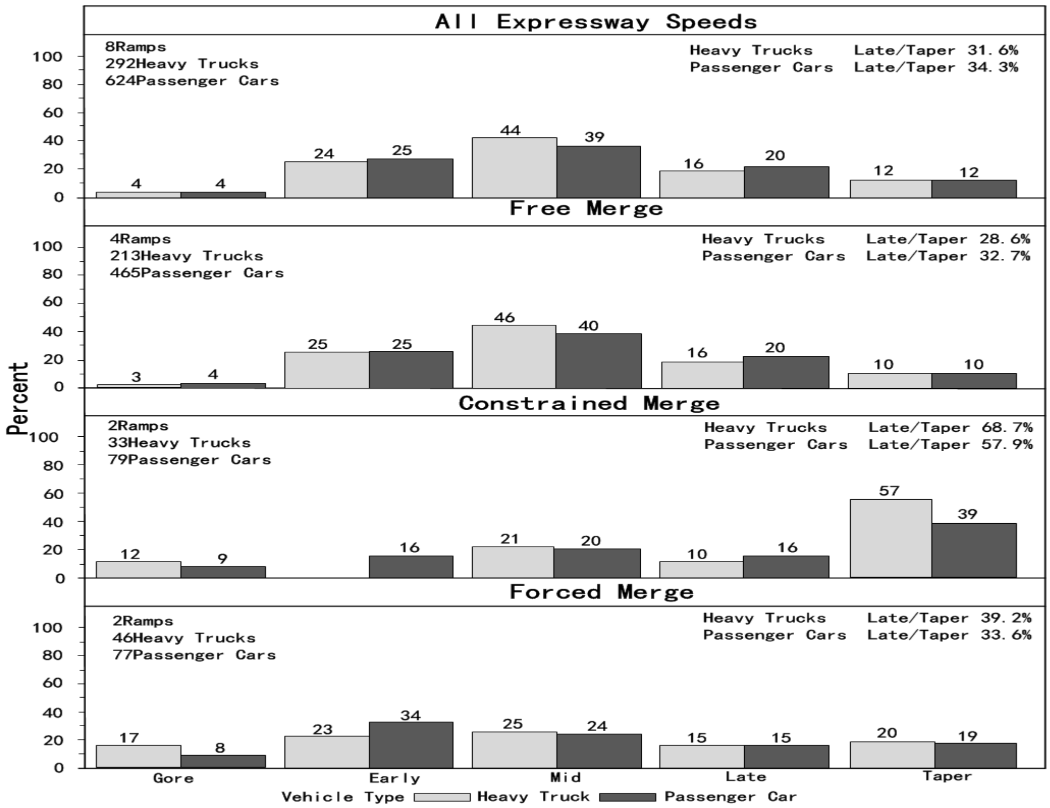

Figure4. Merging Positions of Vehicles (Heavy Trucks and Passenger Cars)

5 Conclusion

This paper get a lot of useful conclusions by far field observation experiment in the Shanghai Nanjing Freeway Interchange (Group) from the drivers and vehicle groups in divert, confluence position , speed and other traffic behaviors. The research into the behavioral characteristics of traffic conditions on multi -lane which explore the design concepts and practice of the people, vehicles and environmental harmony and adapt in the divided and confluence areas of the freeway, for (widening) the divided and confluence areas of the multi-lane freeway safety design and operation management to provide realistic basis.

Abstract: In order to explore and research the characteristic of vehicles' speed driving behavior in a multi-lane freeway interchange diverging area, and provide realistic basis for safety design of diverging area, this paper choosed Hu-Ning multi-lane freeway interchange (groups) as a field observation engineering, and used MC5600 vehicle type pneumatic tube system statistics and field velocity data and SPSS Statistics software processing data. Tests showed that: the relationship between the frequency and the velocity of cars and trucks are the normal distribution. Two-lane ramp terminal average speed of cars is 75~85 km/h, and the operating speed (V85) of cars is 90~100 km/h; the single lane average speed of cars is 60~70 km/h, and the operating speed (V85) of cars is 80~95 km/h. Two-lane ramp terminal average speed of trucks is 70~80 km/h, and the operating speed (V85) of trucks is 80~90km/h; the single lane ramp terminal average speed of trucks is 60~85 km/h, and the operating speed (V85) of trucks is 65~100 km/h.

1 Introduction

China is entering into a multi-lane freeway and the new period of expansion. Studies have shown that the freeway interchange has the highest possible area of accident frequency and severity (McCartt, A.T., 2004). Some researches of multi-lane freeway interchange diverging areas design standards shows that diverging areas is an area of high accident rates , but currently it can be hardly provided clear and updated geometric design standards to the designer (El-Basha, R.H.S., 2006). Domestic and international statistics show that accident rates of multi-lane freeway interchange diverging areas reached about 40% in the entire interchange area (Li Guang, 2012). The vehicle speed characteristics directly affect traffic safety and operational efficiency in multi-lane freeway interchange diverging areas. Reports (The First Highway Survey and Design Institute Co. Ltd.,

2012) showed two-way four lane Expressway merge area and ramp vehicle speed behavior observation test, and achieved to the vehicle running speed of V85, then analyzed The velocity gradient analysis of vehicle. AASHO recommended on an average speed of main line as interchange ramp design speed, the main line design speed of 1/2 is as minimum ramp design speed; Canadian recommendations to the main line design and left some room(Jia Li,2003).Abdel-Aty(Abdel-Aty,M.,2006) studied the road safety performance enhancement effect on different limited speed conditions in Orlando and Florida by experiment, and it was concluded the speed limit has a specific effect on freeway diverging areas upstream, downstream traffic accident.

Tennessee Department of Transportationat (TxDOT) (Fitzpatrick,K.,2006) project research provided different design standards when design speed is greater than 80mi / h freeway.

Vehicle needs a certain critical points in the diverging area before the completion of their diversion lane change behavior, but decide whether it makes the most direct factor that a person produces diversion lane change intent is the distance between the vehicle and the key point(Li Yingfeng,2008).Driving is a complex intelligent behavior. For diverging area and exit ramp, vehicle is along the line the outside lane in theory .when driving a certain position in the area , between fluence into the deceleration lane and the exit ramp. vehicles begin streaming into the deceleration lane change lane and exit ramp .However, due to the mutual influence of subjective and objective factors, traffic location showed differences in multi-lane freeway diverging areas. Based on the safety design concept of man-machine engineering, road design should be people-oriented(Zhao Cui,2012).

Because the freeway entrance region exists straight and the confluence of the traffic flow, traffic behavior becomes more complex than other roads . When the vehicle is accelerating or decelerating to enter or leave the lane, it will produce many conflicts, easily leading to accidents(Wang Xiaofei,2011).From the respect of microscopic traffic safety research. Many scholars at home and abroad established the models by analyzing the relations among the geometric road design, operating characteristics of the vehicle , the driver of the psychological and physiological responses , environmental factors and traffic safety（Yan Ying Sheng，2011）.

In summary, due to the driver's driving process is a process of information exchange and control , while vehicle status and environmental status information is a fundamental basis for the driver's decision to drive behavior（Guo Zhongyin，2012).Given the reality both of accident happening frequently and the lack and differentiation of shunt vehicle driving behavior in Multi-lane Freeway Interchange Diverging Areas , this article through technical means far-field observations triage area for multi- lane freeway vehicle speed operational phase behavior depth exploration. This paper further explores the vhicles speed driving behavior by far field observation techniques.

2 Test instruments and equipment

MC5600 vehicle type pneumatic tube can be used to text the data of two-way two-lane , and the motorcycle types are divided according to the wheel base . When the vehicles pass sensor of pneumatic tube, it can produce a signal , conduct to the unit by the side of the road , and form an axle electrical signal to collect the speeds of different motorcycle types when they pass the section . Figure 1 is MC56500 traffic data analysis and management and the schematic diagram of MC5600 is showed in the figure 2.

Through testing the field observations speed characteristics of different models , we Analyzes the internal mechanism and reveals the influence on road traffic safety . Figure 4 is MC5600 data acquisition platform . Figure5 is MC5600 data output.

4 Analysis of Experimental Data

4.1 The Bus Speed Analysis of Multi-lane Freeway Diverging Area terminal

4.1.1 Bus Speed Analysis of Two-lane ramp Diverging Area Terminal

Two-lane ramp is a kind of important form to be adapted to high density multi-lane freeway ramp traffic diversion,which often is applied in the junction of Interchange . Respectively, table 1and table2 are the Suzhou North and Zhengyi interchange speed statistics of bus.Figure7 and Figure 8 are buses speed chart in two-lane ramp diverging area terminal.

Table 1 shows that it has been measured the effective speed of 1166 bus as a sample which average is 86.53km/h in two-lane ramp diverging area terminal of Zhengyi interchange .In accordance with the determination of the 85th percentile speed driving speed as the operating speed (V85), its operating speed (V85) of 101.2km / h in two-lane ramp diverging area terminal of Zhengyi interchange .

Table 2 shows that it has been measured the effective speed of 982 bus as a sample which average is 75.30km / h in two-lane ramp diverging area terminal of Suzhou North interchange.According to statistical analysis of the measured data, its operating speed (V85) of 86.72km/ h in two-lane ramp diverging area terminal of Suzhou North interchange.

Contrastivly analyze the table 1 and table 2 , from the terms of the mean value, variance and the number and the maximum , Suzhou North Junction is smaller than Zhengyi Junction , but difference between them is about 10 km/h. For speed in the diverging area driving behavior are objective and representative , and can meet the requirements of analysis in the terms of ration and changing trends .We investigate its reason , analyzing the term of diverging area ramp , in the test of Suzhou North Junction , we choose the diverging area ramp of Suzhou and Hangzhou directions , while the test of Zhengyi Junction is Zhengyi diverging area , so the former traffic volume and heavy duty truck scale is larger than the latter , which is the main reason of otherness . Analyzing from the geometric forms of diverging area ramp , they both locate in the plains , but the plane curve radius of the main line in the Suzhou North Junction is obviously smaller than it in Zhengyi Junction , having effects on the sights , while Zhengyi Junction diverging area is located in the straight line and have a good sights . So the difference of geometric linear in the diverging area play a significant part in the influence of diversities in speed .

Table1. Speed statistics of bus in two-lane ramp diverging area(a)

Effective Sample	1166
Average Value(km/h)	86.53
Median(km/h)	86.30
Plural(km/h)	92
Standard Deviation	14.347
Variance(km/h)	205.831
Skewness	-0.199
Standard Error of Skewness	0.072
Kurtosis	0.619
Standard Error of Kurtosis	0.143
Full Distance(km/h)	107
Minimum(km/h)	20
Maximum(km/h)	126
Percentile 25(km/h)	77.07
50(km/h)	86.30
75(km/h)	96.10
85(km/h)	101.20

Table2. Speed statistics of bus in two-lane ramp diverging area(b)

Effective Sample	982
Average Value(km/h)	75.30
Median(km/h)	75.70
Plural(km/h)	69
Standard Deviation	11.772
Variance(km/h)	138.574
Skewness	-0.681
Standard Error of Skewness	0.078
Kurtosis	3.370
Standard Error of Kurtosis	0.156
Full Distance(km/h)	95

Minimum(km/h)	15
Maximum(km/h)	110
Percentile 25(km/h)	68.65
50(km/h)	75.70
75(km/h)	82.20
85(km/h)	86.70

From the analysis of the table, bus speed and frequency can be adopted between the normal distribution curve fitting, in which average speed is among 75~85km/h and operating speed (V85) is 90~100km/h in two-lane ramp diverging area terminal.

4.1.2 Speed Statistics of Bus in Single-lane Ramp Terminal

Table 3 described the speed statistics of bus in single-lane ramp terminal of Suzhou North junction in the direction of Hangzhou.And table 4 is the speed statistics of bus in single-lane ramp terminal of Suzhou North junction in the direction of Suzhou.

Table 3 Speed statistics of bus in single-lane ramp terminal（a）

Effective Sample	291
Average Value(km/h)	69.50
Median(km/h)	66.70

75(km/h)	72.80
Effective Sample	78.91

4.2TheTrucksSpeedAnalysisofMulti-lane Freeway Diverging Area Terminal

4.2.1 The Speed of Trucks in Two-lane Ramp Terminal

Two-lane ramp is a kind of important form to be adapted to high density multi-lane freeway ramp traffic diversion ,which Often is applied in the junction of Interchange . Respectively, table 5and table 6 are the Suzhou North and Zhengyi interchange speed statistics of trucks at Hu-Ning multi-lane freeway ,which was analyzed with the software of SPSS Statistics.

Table 5 Speed analysis of trucks in Zhengyi interchange diverging area

Effective Sample	525
Average Value(km/h)	77.73
Median(km/h)	76.40
Plural(km/h)	65
Standard Deviation	13.354
Variance(km/h)	178.340
Skewness	0.458
Standard Error of Skewness	0.107
Kurtosis	0.230
Standard Error of Kurtosis	0.213
Full Distance(km/h)	84

Minimum(km/h)	43
Maximum(km/h)	126
Percentile 25(km/h)	67.80
50(km/h)	76.40
75(km/h)	86.30
85(km/h)	91.91

Table 6.Speed analysis of trucks in Suzhou North interchange diverging area

Effective Sample	181
Average Value(km/h)	68.41
Median(km/h)	68.70
Plural(km/h)	71
Standard Deviation	10.410
Variance(km/h)	108.377
Full Distance(km/h)	66
Minimum(km/h)	35
Maximum(km/h)	101
Percentile 25(km/h)	62.00
50(km/h)	68.70
75(km/h)	74.80
85(km/h)	79.62

Table 5 shows that it has been measured the effective speed of 525 trucks as a sample which average is 77.73km / h in two-lane ramp diverging area terminal of Zhengyi interchange .In accordance with the determination of the 85th percentile speed driving speed as the operating speed (V85), its operating speed (V85) of 91.91km/ h in two-lane ramp diverging area terminal of Zhengyi interchange .Table 6 shows that it has been measured the effective speed of 181 trucks as a sample which average is 68.41km / h in two-lane ramp diverging area terminal of Suzhou North interchange.According to statistical analysis of the measured data, its operating speed (V85) of 79.62km / h in two-lane ramp diverging area terminal of Suzhou North interchange.

The buses' speed and frequency can be adopted between the normal distribution curve fitting,in which average speed is among 70~80km/h and operating speed (V85) is 80~90km/h in two-lane ramp diverging area terminal.

4.2.2 Speed Statistics of Trucks in Single-lane RampTerminal

Table7 described the speed statistics of trucks in single-lane ramp terminal of Suzhou North junction in the direction of Hangzhou.And table 8 is the speed statistics of trucks in single-lane ramp terminal of Suzhou North junction in the direction of Su zhou.

Table 7 shows that it has been measured the effective speed of 141 trucks as a sample which average is 85.01km / h in single-lane ramp diverging area terminal of Suzhou North interchange . its operating speed (V85) of 91.91km / h in single-lane ramp diverging area terminal of Suzhou North interchange .Table 8 shows that it has been measured the effective speed of 40 trucks as a sample which average is 58.47km/h in single-lane ramp diverging area of Suzhou North interchange.According to statistical analysis of the measured data, its operating speed (V85) of 64.96km/ h in single-lane ramp diverging area terminal of Suzhou North interchange.

Table 7. Speed analysis of trucks in single lane ramp diverging area(a)

Effective Sample	141
Average Value(km/h)	85.01
Median(km/h)	84.90
Plural(km/h)	102
Standard Deviation	17.943
Variance(km/h)	321.937
Skewness	0.048
Standard Error of Skewness	0.204
Kurtosis	-0.912
Standard Error of Kurtosis	0.406
Full Distance(km/h)	76
Minimum(km/h)	48
Maximum(km/h)	124
Percentile 25(km/h)	70.25
50(km/h)	84.90
75(km/h)	101.80
85(km/h)	104.58

From the result ,bus speed and frequency can be adopted between the normal distribution curve fitting,in which average speed is among 60~85km/h and operating speed (V85) is 65~100km/h in single-lane ramp diverging area terminal.

Table 8 Speed analysis of trucks in single lane ramp diverging area(b)

Abstract: Considering urban residents in peak period, the residents can choose by way of car, bus, subway travel network composition of three kinds of travel way to travel. There are bus lanes in the urban road, constitute the travel cost function with urban residents by considering the main factors in the process of travel mode choice. The travel mode choice equilibrium model was established that the bus lane conditions in the peak travel period, on the basis of the User equilibrium theory. Obtain the maximum delay time, the number of trips and travel costs in travel costs equilibrium state. The rationality of the model was verified by a simple numerical example, the next was further discussed that subway fares impact on travel division of three ways. The results showed that: On the one hand, the Subway travel mode by most people's choice, because this way is travel time stability, this is also consistent with the actual situation. But also be launched from the side to avoid the uncertainty of residents during the trip. On the other hand, the subway fares effects of urban travelers' travel mode choice.

Keywords: Bus lane; Rush hour; Travel mode; Travel cost equilibrium.

1 Introduction

In 1952, the famous scholar Wardrop proposed user equilibrium (UE) principle and system optimization (SO) theory (Shao Chunfu, 2004). User equilibrium principle can be described as: road traffic distributes in such a way that travel costs are the same in the path actually used and less than any unused path.

This paper analyzes the problems of travel mode choice equilibrium in the rush hour. This problem can be simply described as follows: Suppose there are N residents travel from living areas to workspaces every morning, in relatively stable travel process, N can be regarded as constant. Every morning peak, N_1 residents choose cars, N_2 residents choose buses, N_3 residents choose subways, the number of each travel mode is unknown. Assuming cars and buses share a road, buses drive on the bus lanes on the very outside, there is a bottleneck at the end of the road. The capacity of the bottleneck is s, when the road vehicles exceeds s, people have to queue up and wait to pass the neck.

The author in the process of establishing processing on the bottlenecks problem and model also draw on research results related to traffic bottleneck theory (Vickrey, 1969; Arnott et al, 1988, 1990, 1993, 1998; Tabuchi, 1993; Lin Zhen, Yang Hao, 2003, 2004). In the condition of bus lanes, travel mode of buses will not affected by the bottleneck. Travel time of buses can be regarded as a definite value. Of course, due to the decline of capacity in the bottleneck, cars have to queue up and wait to pass the neck. Travel mode choice equilibrium is the balance of residents' travel costs, this paper will establish equilibrium model of travel mode choice, focus on the connection of subway fares, travel cost and the number distribution of residents.

2 Symbol definition

Symbols are defined as follows:

t ——Departure time of car mode and the time that arrive at the pick-up point of bus and subway;

t^* ——The time of arriving destination on time;

$C_j(t)$ ——The cost of mode j;

T_j^c ——General time of travel mode j in off-peak;

$T_j^e(t)$、$T_j^p(t)$、$T_j^l(t)$ ——When being early, on time or late, queue waiting time at the bottleneck of mode j;

T_2^o、T_3^o ——The time of walking to the bus and subway, assuming constant;

$T_2^d(t)$、$T_3^d(t)$ ——The time of residents waiting at bus station and subway station;

t_j^e、t_j^p、t_j^l ——For cars, they refer to earliest departure time, departure time when arrive on time and latest departure time; For buses and subways, they refer to earliest arriving time, arriving time when arrive on time and latest arriving time at bus station or subway station;

θ_1、θ_2、θ_3 ——Residents travel cost per unit time, the unit cost of penalty for early and late;

P_j ——The fare of mode j;

π_j ——uncomfortable cost function produced by crowded inside of mode j;

α、β——uncomfortable cost coefficient produced by crowded outside in the rush hours of bus and subway;

Among them： $j = 1,2,3$; represent cars mode, buses mode and subways mode.

3 Establishing equilibrium models

3.1 Equilibrium of cars travel cost

N_1 residents travel by cars in the rush hour. Cost for car mode: travel time cost (off-peak time, bottleneck delay time), penalty cost for early or late, fixed monetary cost (mainly refers to the fuel surcharge, parking fees, etc.). Residents can be divided into three categories respectively: early, on time and late. Residents bear the penalty cost for early or late.

Therefore, the cost of all residents that choose car mode can be expressed as:

$$C_1(t)=\begin{cases}\theta_1[T_1^c+T_1^e(t)]+\theta_2[t^*-t-T_1^c-T_1^e(t)]+P_1 & t\in[t_1^e,t_1^p)\\ \theta_1[T_1^c+T_1^p(t)]+P_1 & t=t_1^p\\ \theta_1[T_1^c+T_1^l(t)]+\theta_3[T_1^c+T_1^l(t)+t-t^*]+P_1 & t\in(t_1^p,t_1^l]\end{cases} \quad (1)$$

When car mode is at equilibrium, whether residents arrive early, on time or late, their travel costs are the same. Suppose in the earliest and latest departure time, there is no delay time at bottleneck. It means residents set out at $t\in(t^e,t^l)$ that have to queue up and wait. So in the station of equilibrium, the expected travel costs of residents that set out at $t=t_1^e$, $t=t_1^p$, $t=t_1^l$ are the same. Therefore, following is the equation:

$$E[C_1(t)]=\begin{cases}\theta_1 E[T_1^c]+\theta_2 E[t^*-t_1^e-T_1^c]+P_1 & t=t_1^e\\ \theta_1 E[T_1^c+T_1^p(t_1^p)]+P_1 & t=t_1^p\\ \theta_1 E[T_1^c]+\theta_3 E[T_1^c+t_1^l-t^*]+P_1 & t=t_1^l\end{cases} \quad (2)$$

Rush hours at the bottleneck starts at t_1^e and ends at t_1^l, so queue waiting duration in the rush hours is $T=t_1^l-t_1^e$. The capacity of a path is determined by the bottleneck, so based on the related theory of traffic engineering （Wang wei, 2000） ,we know $T = nN_1/(n-1)S$, therefore：

$$t_1^l = t_1^e + N_1 / \frac{(n-1)S}{n} \quad (3)$$

When cars travel cost is at equilibrium, according to equation (4) and (5),we can get：

$$\begin{cases} t_1^e = t^* - T_1^c - \frac{\theta_3}{\theta_2+\theta_3} \cdot \frac{nN_1}{(n-1)S} \\ t_1^l = t^* - T_1^c + \frac{\theta_2}{\theta_2+\theta_3} \cdot \frac{nN_1}{(n-1)S} \\ t_1^p = t^* - T_1^c - \frac{\theta_2\theta_3}{\theta_1(\theta_2+\theta_3)} \cdot \frac{nN_1}{(n-1)S} \end{cases} \quad (4)$$

$$T_1^p = \frac{\theta_2\theta_3}{\theta_1(\theta_2+\theta_3)} \cdot \frac{nN_1}{(n-1)S} \quad (5)$$

$$C_1(t) = \theta_1 T_1^c + \frac{\theta_2\theta_3}{\theta_2+\theta_3} \cdot \frac{nN_1}{(n-1)S} + P_1, \quad t \in [t_1^e, t_1^l] \quad (6)$$

3.2 Equilibrium of buses travel cost

Under the condition of bus lanes, there are N_2 residents that choose to travel by buses, cost for bus mode include: travel time cost (including walking time, queue waiting time and bus travel time), penalty cost for early or late, uncomfortable cost produced by crowded inside and bus fare. Uncomfortable cost produced by crowded inside is associated with travel time and number of passengers, the coefficient associated with number of passengers is α, so uncomfortable cost produced by crowded is $\pi_2[\alpha T_2^c(t)]$.

Same to the cars mode, the expected travel costs of residents are the same in the station of equilibrium.

So, we can get:

$$\begin{cases} t_2^e = t^* - T_2^c - \frac{\theta_3}{\theta_2+\theta_3} \cdot \frac{N_2}{S_2} \\ t_2^l = t^* - T_2^c + \frac{\theta_2}{\theta_2+\theta_3} \cdot \frac{N_2}{S_2} \\ t_2^p = t^* - T_2^c - \frac{\theta_2\theta_3}{\theta_1(\theta_2+\theta_3)} \cdot \frac{N_2}{S_2} \end{cases} \quad (7)$$

$$T_2^d = \frac{\theta_2\theta_3}{\theta_1(\theta_2+\theta_3)} \cdot \frac{N_2}{S_2} \qquad (8)$$

$$C_2(t) = \theta_1(T_2^o + T_2^c) + \frac{\theta_2\theta_3}{\theta_2+\theta_3} \cdot \frac{N_2}{S_2} + \pi_2(\alpha T_2^c) + P_2, \quad t \in [t_2^e, t_2^l] \qquad (9)$$

3.3 Equilibrium of subways travel cost

Similar with buses, we can get:

$$\begin{cases} t_3^e = t^* - T_3^c - \dfrac{\theta_3}{\theta_2+\theta_3} \cdot \dfrac{N_3}{S_3} \\ t_3^l = t^* - T_3^c + \dfrac{\theta_2}{\theta_2+\theta_3} \cdot \dfrac{N_3}{S_3} \\ t_3^p = t^* - T_3^c - \dfrac{\theta_2\theta_3}{\theta_1(\theta_2+\theta_3)} \cdot \dfrac{N_3}{S_3} \end{cases} \qquad (10)$$

$$T_3^d = \frac{\theta_2\theta_3}{\theta_1(\theta_2+\theta_3)} \cdot \frac{N_3}{S_3} \qquad (11)$$

$$C_3(t) = \theta_1(T_3^o + T_3^c) + \frac{\theta_2\theta_3}{\theta_2+\theta_3} \cdot \frac{N_3}{S_3} + \pi_3(\beta T_3^c) + P_3, \quad t \in [t_3^e, t_3^l] \qquad (12)$$

3.4 Equilibrium model of travel mode

When travel mode reaching equilibrium station, residents set out in rush hours have same travel cost no matter which mode they choose. A resident cannot reduce his cost by unilaterally changing his travel time or mode. That is to say, in the equilibrium condition of travel modes, meet the formula (13):

$$\begin{cases} C(t) = C_j(t) & N_i > 0 \\ C(t) \le C_j(t) & N_i = 0 \quad i = 1、2、3; j = 1,2,3; \\ N = \sum N_i \end{cases} \qquad (13)$$

$C(t)$ is the travel cost in the equilibrium condition of travel modes.

In practical situation, it is impossible that any travel mode is not selected in rush hours. So, formula (13) can be converted into formula (14):

$$\begin{cases} C(t) = C_1(t) = C_2(t) = C_3(t) \\ N = N_1 + N_2 + N_3 \end{cases} \qquad (14)$$

Total number of residents N is known already, $C_1(t)$、$C_2(t)$ and $C_3(t)$ have been calculated respectively. Bringing formula (6),(9) and (12) into（14）:

$$\begin{cases} C(t)=C_1(t)=\theta_1 T_1^c+\dfrac{\theta_2\theta_3}{\theta_2+\theta_3}\cdot\dfrac{nN_1}{(n-1)S}+P_1 \\ C(t)=C_2(t)=\theta_1(T_2^o+T_2^c)+\dfrac{\theta_2\theta_3}{\theta_2+\theta_3}\cdot\dfrac{N_2}{S_2}+\pi_2(\alpha T_2^c)+P_2 \\ C(t)=C_3(t)=\theta_1(T_3^o+T_3^c)+\dfrac{\theta_2\theta_3}{\theta_2+\theta_3}\cdot\dfrac{N_3}{S_3}+\pi_3(\beta T_3^c)+P_3 \\ N=N_1+N_2+N_3 \end{cases} \quad (15)$$

We can get C and [N_1, N_2, N_3] by solving formu la (15):

$$\begin{cases} N_1=\dfrac{(n-1)(A^1+B^1+SN)}{[nS_2+nS_3+Sn-S]} \\ N_2=\dfrac{nS_2(B^1+SN)-A^1[nS_3+nS-S]}{S[nS_2+nS_3+nS-S]} \\ N_3=N-N_1^1-N_2^1 \end{cases} \quad (16)$$

$$C=\theta_1(T_2^o+T_2^c)+\frac{\theta_2\theta_3}{\theta_2+\theta_3}\cdot\frac{nS_2(B^1+SN)-A^1[nS_3+nS-S]}{SS_2[nS_2+nS_3+nS-S]}+\pi_2(\alpha T_2^c)+P_2 \quad (17)$$

In formula(16)and(17):

$$\begin{cases} A^1=\dfrac{SS_2(\theta_2+\theta_3)}{\theta_2\theta_3}[\theta_1(T_2^o+T_2^c-T_1^c)+\pi_2(\alpha T_2^c)+P_2-P_1] \\ B^1=\dfrac{SS_3(\theta_2+\theta_3)}{\theta_2\theta_3}[\theta_1(T_3^o+T_3^c-T_1^c)+\pi_3(\beta T_3^c)+P_3-P_1] \end{cases} \quad (18)$$

4 Example analysis

According to the equilibrium model of travel mode, set up relevant numerical parameters, assuming the subway fare (P_3) is variable. A numerical example set parameters are shown in table 1 and table 2.

Table 1. parameters 1

Parameters	N	T_1^c	T_2^c	T_3^c	T_2^o	T_3^o	P_1	P_2	q
Value	20000	1.0	1.5	1.2	0.1	0.15	12	2	0.025

Table 2. parameters 2

Parameters	θ_1	θ_2	θ_3	α	β	S	S_2	S_3	n
Value	15	10	20	0.8	1.2	6000	4000	10000	4

When travel cost is under equilibrium condition, assuming $\pi_2(\alpha T_2^c) = \alpha T_2^c, \pi_3(\beta T_2^c) = \beta T_3^c$, fitting formula of P_3 about residents travel distribution and travel cost can be solved as follows by formula (16), (17) and (18):

$$\begin{cases} N_1 = 2956.6216 + 364.8648 * P_3 \\ N_2 = 2508.1081 + 324.3243 * P_3 \\ N_3 = 14535.2707 - 689.1891 * P_3 \\ C = 31.3802 + 0.5405 * P_3 \end{cases} \quad (19)$$

According to formula(19), $P_3 \in [0, 21.09]$.

Draw formula (19) in the reasonable range of P_3 by Matlab, the result is as follows:

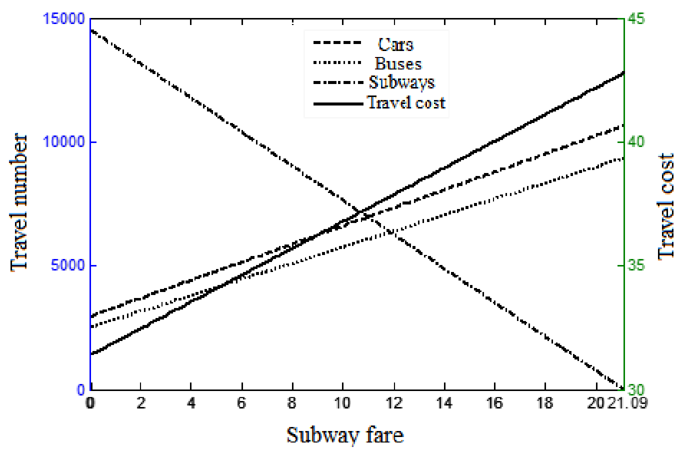

Figure 1. Subway fares relationship with travel number distribution and travel costs under the condition of bus lane

We can get following conclusions through above chart:

(1) When the city subway fare is lower than 11, subway is most popular.

(2) The relationship between subway fares and the number of residents is negative, when fare tends to 0, the number of residents choose subways reaches the maximum value of 14535, when the number tends to 0, subway fare reached the maximum value of 21.09.

5 Conclusion

In order to study the macro situation of urban residents travel mode choice in the rush hour, this paper consulted user equilibrium thought and bottleneck theory, establishing equilibrium model of travel mode choice under the condition of bus lane, the example analyzed the relationship between subway fare, distribution of residents and travel cost. The results show that: (1) subway is most popular because of its stability, large volume and relatively fast speed; (2) the example analysis indicates the applicability and rationality; (3) starting from the subway fare setting angle, equilibrium model of travel mode choice can provide relevant reference for the formulation of subway fare, and put forward a new theory and research method for the relationship between subway fares and the number of residents take subways.

Forecast Model of Conventional Public Transit Passenger Volume in Small- and Medium-Sized Cities Based on the IHGA-LS-SVM with Grey Correlation Analysis

Li Shen; Tong Zhang; and Xiaohui Ji

School of Transportation and Logistics, Southwest Jiaotong University, Chengdu. E-mail: shenli0927@163.com

Abstract: Based on the principal factor analysis of conventional public transit passengers' volume in small and medium-sized cities, the forecast model of passengers' volume on the basis of IHGA-LS-SVM with Grey Correlation Analysis is proposed. By applying Grey Correlation Analysis between the influencing factors of passenger' volume, the input variables of LS-SVM were screened. Then an Improved Hybrid Genetic Algorithm (IHGA) is applied to optimize the selection of model parameters. When applied to forecast the conventional public transit passengers' volume in a city of Sichuan from 1999 to 2011, the results shows that compared to other forecast methods this model improves forecast accuracy, shorten the convergence, is a feasible and effective forecast model of conventional public transit passenger' volume in small and medium-sized cities.
Keywords: Urban traffic; Forecast model of passengers' volume; Grey correlation analysis; Least squares support vector machine; Improved Hybrid Genetic algorithm.

1 Introduction

With the accelerated process of urbanization in China, the total economy and the size of the population continues to expand in recent years, and development of public transit in small and medium-sized cities is closely related to the economy and convenience of residents' trips. So scientific and accurate forecast of public transit passengers' volume is an important reference to planning and management of urban public transport. However, the traditional statistical analysis and forecast methods that predict public transit passengers' volume are mostly based on large sample data which due to various limits in actual circumstances, are quite difficult to be collected. So for solving this problem, the least squares support vector machine (LS-SVM) (J. A. K. Suykens, J. Vandewalle, 1999), which is a reformulation to SVM (V. Vapnik, 1999) and suited for small sample data, is adopted to build the model to forecast public transit passengers' volume in small and medium-sized cities. For the regression accuracy and generalization ability of LS-SVM are extremely dependent on two hyper-parameters, the regularization parameter C and the kernel parameter σ, advanced meta-heuristic approaches are necessary to be used for optimization.

Based on the principal factor analysis of conventional public transit passengers' volume in small and medium-sized cities, the forecast model of passengers' volume on the basis of IHGA-LS-SVM with Grey Correlation Analysis is proposed. By applying GCA between the influencing factors of passenger' volume, the input variables of LS-SVM were screened, then an improved hybrid genetic algorithm (IHGA) is applied to optimize the selection of model parameters. When the model is applied to forecast the conventional public transit passengers' volume in a city of Sichuan, the results shows that compared to other forecast methods this model can effectively improve forecast accuracy, shorten the convergence. It's a feasible and effective forecast model of conventional public transit passenger' volume in small and medium-sized cities.

2 IHGA-LS-SVM Model with Grey Correlation Analysis

2.1 Grey Correlation Analysis

With Grey Correlation Analysis, the uncertain relative situation during objects or the relative situation of system factors can be explained quantitatively(Deng Julong,2002).GCA can analyzes and confirms the influence degree of factors according to the geometry approach degree of behavior factor list and data list, so taking the similar degree of curves as the weigh yardstick of correlation degree(Luo Youxin,Zhang Longting,Li Min,2001).There are many factors which influence the result of public transit passengers'volume forecast, and these factors have different influence degree to volume forecast, so the grey correlation among these factors must be analyzed with qualitative analysis(Chiang YuMin,Hsieh HsinHsien,2009). And initial value processing(Yao Tao,Wang Pengcheng,2004)is adopted to make the equal weight among factors(Zhang Yongjuan,Zhang Xiong,2007).Then setting the factors corresponding numbers as the original data series, which is presented by $x^0(k)$ ($k=1,2,\cdots,n$). The initial value processing is as below:

$$x(k)=x^0(k)/x^0(1)\,(k=1,2,\cdots,n) \qquad (1)$$

Then isopolarity processing of data series obtained from formula (1) can delete the negatives and reserve positive numbers of the data series. Isometric processing can transform the initial data, which makes the new variation tendency reflect the interaction levels of each factor, and moderate-effect measurement is adopted in this paper. The system takes factor sequences screened out as the element points of factors space, and takes those numbers of influencing factors as the part coordinate of this point(S.W.Zhang,T.X.Lan,etc,2010). So the factor sequence can be shown as follows:

$$x_i = [x_i(1), x_i(2), \cdots, x_i(k)] \tag{2}$$

Setting x_0 as the element points of reference factor, and $\eta_{0,i}$ as the grey correlation degree of factor sequence i ($i = 1,2,\cdots,N$) to the reference sequence:

$$\eta_{0,i} = \eta(x_0, x_i) = 1/n \sum_{k=1}^{n} \eta[x_0(k), x_i(k)] \tag{3}$$

The correlation coefficient of factor k on sequence i to the factor of reference sequence, which is denoted by $\mu_i(k)$, is calculated as follows:

$$\mu_i(k) = \eta(x_0(k), x_i(k)) = \frac{\min_{i\in N}\min_{k\in n}|x_0(k) - x_i(k)| + \mu \max_{i\in N}\max_{k\in n}|x_0(k) - x_i(k)|}{|x_0(k) - x_i(k)| + \mu \max_{i\in N}\max_{k\in n}|x_0(k) - x_i(k)|} \tag{4}$$

Where μ ($0 < \mu < 1$)represents resolution coefficient. By replacing $\eta[x_0(k), x_i(k)]$ of formula (3) with $\mu_i(k)$, a new formula of correlation degree is obtained as below:

$$\eta_i = 1/n \sum_{k=1}^{n} \mu_i(k) \tag{5}$$

The weight value of each factor sequence will be obtained after the normalization processing of μ_i, and the main factors can be sorted out.

2.2 IHGA-LS-SVM Model

2.2.1 LS-SVM Model

Compared with SVM which is a machine learning algorithm (J.A.K.Suykens, etc,2002)providing better generational ability than the empirical risk minimization used by traditional methods, the least squares support vector machine(LS-SVM) applies linear least squares criteria to the loss function to replace the inequality constraints with equality constraints. The optimization problem is defined as follows(J.A.K.Suykens,J.Vandewalle,1999):

$$\min_{\omega,\theta,\gamma} J(\omega,\gamma)=\frac{1}{2}\omega^T\omega+\frac{1}{2}C\sum_{i=1}^{N}\gamma_i^2 \tag{6}$$

Subject to $S_i=\omega^T\varphi(a_i)+\theta+\gamma_i$, $C>0$, $i=1,2,\cdots,N$.

The Lagrangian function can be set up by the formula below:

$$L(\omega,\theta,\gamma_i,\lambda_i)=J(\omega,\gamma)-\sum_{i=1}^{N}\lambda_i\left(\omega^T\varphi(a_i)+\theta+\gamma_i-S_i\right) \tag{7}$$

where λ_i is the i th Lagrange multiplier. The Karush–Kuhn–Tucker (KKT) conditions for optimality are described as follows(Fletcher R,1987):

$$\begin{cases} \dfrac{\partial L}{\partial \omega}=0\rightarrow\omega=\sum_{i=1}^{N}\lambda_i\varphi(a_i) \\ \dfrac{\partial L}{\partial \theta}=0\rightarrow\sum_{i=1}^{N}\lambda_i=0 \\ \dfrac{\partial L}{\partial \gamma_i}=0\rightarrow\lambda_i=C\gamma_i, i=1,2,\cdots,N \\ \dfrac{\partial L}{\partial \lambda_i}=0\rightarrow\omega^T\varphi(a_i)+\theta+\gamma_i=S_i \end{cases} \tag{8}$$

After eliminating variables ω and γ_i, the optimization problem could be transformed into the following form:

$$\begin{bmatrix} 0 & \vec{1}^T \\ \vec{1} & \varphi^T\varphi+C^{-1}I \end{bmatrix}\begin{bmatrix} \theta \\ \lambda \end{bmatrix}=\begin{bmatrix} 0 \\ S \end{bmatrix} \tag{9}$$

Where $S=[S_1,\cdots,S_N]^T$, $\lambda=[\lambda_1,\cdots,\lambda_N]^T$, $\varphi=[\varphi(a_1),\cdots,\varphi(a_N)]$, $\vec{1}=[1,\cdots,1]^T$,and I is the identity matrix. The solution of λ and θ can be obtained by solving Eq.(9). Then according to Mercer's theorem, the output result could be calculated as follow:

$$S_i=\sum_{i,j=1}^{M}\lambda_i K(a_i,a_j)+\theta \tag{10}$$

$$K(a_i, a_j) = \exp\left(-\|a_i - a_j\|^2 / 2\sigma^2\right) \tag{11}$$

where σ is the Gaussian kernel, and the kernel function $K(a_i, a_j)$ which is widely adopted is selected as the radial basis function (RBF) (J.A.K.Suykens,J.Vandewalle, 2000)in this paper for less numerical difficulties when implementing nonlinear mapping.

2.2.2 IHGA optimization

After the structure of LS-SVM is determined, the optimal penalty factor C and kernel parameter σ need to be searched while the appropriate selection of these two parameters will affect the learning performance of LS-SVM.In this paper, an improved hybrid genetic algorithm (IHGA) with better convergence speed and accuracy is proposed for parameter optimization. Its basic thought is taking the Levenberg-Marquardt optimization algorithm as an operation operator of GA. So IHGA which consists of four basic operators as selection, crossover, mutation and Levenberg-Marquardt optimization has both advantages of global searching of GA and local optimization ability of Levenberg-Marquardt optimization algorithm.The optimization process of LSSVM by IHGA is shown as follows:

(1)Coding mode. Initialize the population size and maximum iteration. The real coding method is selected to code C and σ to generate initial population.

(2)Fitness function. IHGA is introduced to search the optimal parameters so as to improve the classification precision. And the reciprocal value of root-mean-square error is chosen as the fitness which evaluates the performance of individuals.

(3)Selection. Based on the fitness, the roulette method and the optimal individual preservation strategy are adopted to ensure IHGA converging to the global solution.

(4)Adaptive crossover. Improved arithmetic crossover is proposed to generate new individuals.And the adaptive adjustment of p_c (Srinivas M,Patnaik L M,1994)is illustrated to improve the global search capability as follows:

$$p_c = \begin{cases} p_{c1} - (p_{c1} - p_{c2})(f_a - f_{avg}) / (f_{max} - f_{avg}), & f_a \geq f_{avg} \\ p_{c1}, & f_a < f_{avg} \end{cases} \tag{12}$$

$$p_c' = \begin{cases} p_{c1} - (p_{c1} - p_{c2})(f_b - f_{avg}) / (f_{max} - f_{avg}), & f_b \geq f_{avg} \\ p_{c1}, & f_b < f_{avg} \end{cases} \tag{13}$$

$$a_1' = (1 - P_c)a + P_c b, f_a < f_{avg}$$
$$a_2' = (1 - P_c)b + P_c a, f_a \geq f_{avg} \tag{14}$$

$$b_1' = (1 - P_c')b + P_c' a, f_b < f_{avg}$$
$$b_2' = (1 - P_c')a + P_c' b, f_b \geq f_{avg} \tag{15}$$

where $p_{c1} = 0.9$, $p_{c2} = 0.6$.

(5)Adaptive mutation. Nonuniform mutation is chosen in the paper. And the mutation probability p_m is also adaptively selected according to population fitness:

$$p_m = \begin{cases} p_{m1} - (p_{m1} - p_{m2})(f - f_{avg})/(f_{\max} - f_{avg}), & f \geq f_{avg} \\ p_{m1}, & f < f_{avg} \end{cases} \tag{16}$$

where $p_{m1} = 0.1$, $p_{m2} = 0.001$ .Set $x_{k,i}$ as the value of individual x_k corresponding to i th individual population, $\Delta x_{k,i+1}$ as the changing quantity of x_k when updating to $i+1$ th individual population, $x_{k,i+1}$ as the updating value of x_k , $x_{\max,k}$ as the optimal value of x_k , $x_{\max}$ as the known optimal value of all the populations, $r_1, r_2 \in [0,1]$.Then updating process of mutation operator is as below:

$$\Delta x_{k,i+1} = r_1(x_{\max,k} - x_{k,i}) + r_2(x_{\max} - x_{k,i}) \tag{17}$$

$$x_{k,i+1} = x_{k,i} + \Delta x_{k,i+1} \tag{18}$$

(6)Levenberg-Marquardt optimization(D.W.Marquardt,1963).After the updating operations above, Levenberg-Marquardt algorithm(Guo Xianghong,Sun Xihuan,Ma Juanjuan,2009) is applied as an operator to optimize the value of individuals.

(7)When the optimization process is finished, the global optimal solutions of C and σ are assigned to LS-SVM for the training and testing of sample data.

3 Analysis of case and validation

3.1 Data collection and variables selection

To testify the validation of IHGA-LS-SVM model with Grey Correlation Analysis, the relevant data of a city in Sichuan from 1999 to 2011 are collected to forecast the conventional public transit passengers' volume. Ten items of data as GDP, permanent resident population, urban built-up area, annual per capita disposable income of urban households, bicycle&electric bicycle ownership, motorcycle ownership, bus amount, total mileage of bus lines, total coverage area of bus stops (300m radius), conventional public transit passengers' volume are illustrated in table 1 (from Sichuan Statistical Yearbooks 1999-2011 and actual traffic surveys).

Table 1 Relevant data of a city in Sichuan from 1999 to 2011

Year	GDP (100 million Yuan)	PRP (every 10,000 people)	UBA (sq.km.)	AIH (Yuan)	BEO (10,000 units)	MO (10,000 units)	BA (standard transit bus)	TML (km)	CAS (sq.km.)	PV (10,000 person-time)
1999	63.4	20.2	18.0	3776	4.03	1.01	45	45.9	3.42	464.4
2000	71.6	21.5	18.8	3991	4.44	1.25	45	47.5	3.57	487.7
2001	82.8	22.7	19.7	4280	4.82	1.61	63	57.8	3.94	703.2
2002	95.9	23.6	21.0	4644	5.31	1.97	63	59.6	4.41	735.9
2003	111.8	24.9	22.3	5159	6.03	2.35	90	70.1	5.05	1081.8
2004	130.4	26.3	23.9	5716	6.56	2.68	97	81.3	5.85	1216.3
2005	156.1	28.2	25.6	6371	7.43	3.18	109	93.4	6.72	1427.8
2006	187.0	30.0	27.1	7415	8.43	3.61	123	108.9	8.09	1679.5
2007	227.3	31.9	28.3	8714	9.65	4.33	138	126.4	9.20	1962.8
2008	281.8	33.7	31.5	10125	10.74	5.06	145	128.8	10.44	2164.1
2009	349.0	35.3	36.0	11620	11.58	5.70	162	136.7	12.32	2398.3
2010	418.2	36.6	38.0	12977	11.65	6.00	175	150.0	14.82	2658.1
2011	492.4	38.2	41.2	14495	11.83	6.37	195	164.4	17.30	2892.5

For the selection of main variables, GCA is adopted to verify the correlations between passengers' volume and other influencing factors. By formula (1) and (2), the results of correlations are illustrated in table 2.

Table 2 Correlation analysis results

forecast index	GDP (100 million Yuan)	PRP (every 10,000 people)	UBA (sq.km.)	AIH (Yuan)	BEO (10,000 units)	MO (10,000 units)	BA (standard transit bus)	TML (km)	CAS (sq.km.)
correlation	0.76	0.60	0.64	0.81	0.77	0.75	0.82	0.82	0.80

We can see that four index as annual per capita disposable income of urban households,bus amount,total mileage of bus lines, total coverage area of bus stops (300m radius) exceed 0.8. So, the four corresponding influencing factors are chosen.

3.2 Parameters selection optimization

IHGA is applied to optimize the hyper-parameters selection. The overall process of optimized hyper-parameters is illustrated in Fig.1. The root-mean-square error of the training samples and the fitness function is defined as follows:

$$RMSE = \sqrt{1/N \sum_{i=1}^{N} \left(S_i - \hat{S}_i \right)^2} \tag{19}$$

$$Fitness\ (i) = 1/\left(RMSE\ (i) + 0.00001\ \right) \tag{20}$$

Where $RMSE(i)$ is RMSE of fast leave-one-out of i th individual population, 0.00001 on denominator is empirical value for avoiding $RMSE(i) = 0$.

3.3 Simulation result

The data set is split into training and testing sets. The training set includes 9 groups of data(1999-2007), and the testing set includes 4 groups of data(2008-2011).

The training set is used to establish LS-SVM model for forecasting volume ,and the testing set is used for checking the performance of LS-SVM. After ten times of data simulation with IHGA to get optimal value of C and σ, two LS-SVM models are validated by respectively choosing the four influencing factors with correlations exceeding 0.8 and all nine influencing factors. And, to further test the reliability of the IHGA-LS-SVM model, two methods as multiple regression model and BP-neural networks model are built based on the four influencing factors to carry out the forecast results comparation with LS-SVM.When applying the four models to forecast passenger' volume from 2008 to 2011, the comparation result is illustrated in table 3.

From the results illustrated above, first we can see that the maximum&minimum relative error of forecast values of LS-SVM I is 1.891% and 0.938%, and the maximum&minimum relative error of LS-SVM II is 3.017% and 1.486%. Meanwhile, the modeling speed of LS-SVM I is less than LS-SVM II. So, LS-SVM model with Grey Correlation Analysis is more effective than normal LS-SVM.And the average relative errors of the four models are 1.318%,2.254%,3.081% and 2.523%,the relative errors of LS-SVM I is obviously less than the other models. So, it proves that IHGA-LS-SVM model with GCA has high feasibility, effectiveness and precision when forecasting public transit passenger' volume in small and medium-sized cities.

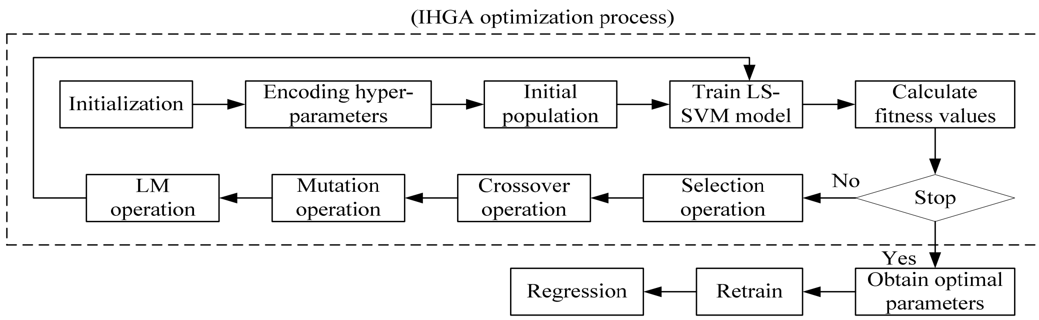

Figure1. Flowchart of IHGA-based hyper- parameter algorithm

Table 3 Forecast results confrontation based on different variables and models

Year	PV(10,000 person-time)	LS-SVM I(four factors)		LS-SVM II(all nine factors)		multiple regression model		BP-neural networks model	
		Forecast value	relative error	Forecast value	relative error	Forecast value	relative error	Forecast value	relative error
2008	2164.1	2195.3	1.442	2229.4	3.017	2219.6	2.565	2236.6	3.350
2009	2398.3	2420.8	0.938	2456.1	2.410	2346.4	-2.164	2464.2	2.748
2010	2658.1	2631.5	-1.001	2618.6	-1.486	2611.7	-1.746	2704.3	1.738
2011	2892.5	2947.2	1.891	2953.3	2.102	2985.1	3.201	2957.8	2.258

4 Conclusion

In this paper, LS-SVM model with Grey Correlation Analysis based on IHGA hyper-parameter selection is established to forecast conventional public transit passenger' volume in small and medium-sized cities. And the proposed IHGA has not only the advantage of global searching of GA, but also the advantage of local optimization ability of Levenberg-Marquardt optimization algorithm.When using the relevant data of a city in Sichuan from 1999 to 2011 to verify the IHGA-LS-SVM model with Grey Correlation Analysis, after comparing the forecast results of four models as LS-SVM I,LS-SVM II,multiple regression model and BP-neural networks model,the analysis of the results indicates that IHGA-LS-SVM model with Grey Correlation Analysis is a more feasible, effective and accurate forecast method for conventional public transit passenger' volume in small and medium-sized cities.

Technical Methods and Application Modes of Lancang River Waterway Modern Management

Xue Wang; Dongsheng Li; and Muhan Deng

China Waterborne Transport Research Institute, Beijing 100088.
E-mail: wangxue@wti.ac.cn

Abstract: Lancang River is an important navigable river in Yunnan province, at the same time it is a cross-border international river in southwest China, however, compared to other rivers such as Yangtze River, the waterway management and maintenance level is relatively backward, and modernization and information lever is lower. Therefore, according to the characteristics of the Lancang River, we need to achieve the modernization and efficient of Lancang River waterway management by means of information, so that the Lancang River waterway management and maintenance can reflect the unique pattern of the Lancang River shipping, and promote the development of the Lancang River shipping.

Based on analysis of the current situation and needs of the Lancang River waterway management, the article put forward the suitable advanced, modern management and maintenance mode for Lancang River, which is based on the building principles of conducting top-level design, constructing the overall framework, improving infrastructure, achieving breakthroughs in key business systems by small strides.

This study is an important foundation of constructing the Lancang River intelligent waterway, and realizing full coverage, all-weather operation and rapid response modern waterway management system. It is helpful to improve the management and maintenance level of the Lancang River waterway, and promote the shipping economic development and international shipping Exchanges development of the Lancang - Mekong River. It can accelerate the Lancang - Mekong international shipping development and construction, improve the status of the Lancang River shipping, and have important significance in promoting economic and social development in Yunnan Province, developing international trade, establishing a good international environment on the neighboring countries.

Keywords: Lancang river waterway management; Means of information; Application modes; Intelligent waterway.

1 Introduction

1.1 Background and Significance

Lancang River is an important navigable river in Yunnan Province and also a cross-border international river in southwest China (Wangtao, 2009). During the "Eleventh Five-Year" period, the first phase of Grade V waterway project was put into operation in 2007. The 71 km long navigable waterway from King Hung to the 243th Sino Burmese Boundary landmark of China and Burma reached the goal of perennial navigation for 300-ton ships. The domestic waterway infrastructure construction tends to be perfect, which laid a foundation for its further development in "the 12th Five Year Plan" period.

In recent years, the Lancang River waterway management and maintenance has gotten high attention of Yunnan government and its transportation department. Thus, the related study is pushing forward gradually. However, compared with other rivers such as Yangtze River, the overall technical level of the waterway management and maintenance is relatively weak. Especially, in comparison to the waterway infrastructure, modern management system in Lancang River and even in Yunnan has not been built, information technology supporting is obviously inadequate, information system construction such as integrated waterway management and public service are lagging behind, which are limiting Lancang River shipping development. If we want to give full play to the ability of Lancang River waterway infrastructure, we need to improve the level of informatization and modernization according to the characteristics of Lancang River, so that the system can reflect the unique pattern of Lancang River shipping, and promote the development of the Lancang River shipping.

This study will improve systematization, scientificalness and effectiveness of waterway management, and improve the efficiency of waterway management, and ultimately promote the overall modernization of Yunnan transportation.

1.2 Overview of domestic and foreign research

The waterway is an important part of the national transportation infrastructure, is the basis for the existence of water transportation. To improve the navigation conditions, and ensure the smooth and safe navigation play an important role in national economy and national defense construction (Ren Bobu, 2007). The main way to achieve modernization of waterway management is informatization construction.

In recent years, with the development of computer technology, network technology, database technology, geographic information system technology and so on, a variety of management systems have been appeared in different countries, the waterway informatization construction improve rapidly. Such as electronic navigational chart (ENC), automatic identification system (AIS), SOA architecture application system, these systems solve some resource integration problems to a certain extent, also improve the efficiency of waterway management, and make the waterway management modernization having technical support.

2 Lancang River Waterway Management Situation and Needs Analysis

2.1 Lancang River Waterway Construction Situation

Lancang River is a 1289.5 kilometers long, typical mountain river in Yunnan

Province, which has been covered by a 40 percent valley area. Most of the river valley has a poor navigation condition. Since 1975, the river has been constructed as national defense waterway, in which 191 km from Nandeba to Jinghong reaches the sixth waterway standard and 100-ton ship is allowed to pass by; 71km from Jinghong to the China-Burma border pillar No. 243 reaches the fifth waterway standard, and 300-ton ship is allowed to pass by; 64km from Nandeba to Jinghong bridge is substandard without renovation, which has not yet been opened officially.

Lancang River's open waters area is 293 kilometers with 290 navigation marks along this area. One of the waterway regulation projects was completed in 2007, which has been equipped with 657 navigational aids and 2 signal stations. Currently, the waterway has not been equipped with night flight navigation aids. Thus, the night flight is not allowed.

Generally speaking, the Lancang waterway construction starts relatively late, investment is inadequate and shipping facilities construction lags behind. To get full play to Lancang River shipping advantage, we must further increase the intensity of waterway regulation and navigation facilities construction to achieve connection of the Lancang - Mekong River shipping.

2.2 Present waterway management situation

In recent years, with the development of computer technology, network technology, database technology and GIS technology, Yunnan Province navigation administration have built electronic navigational chart (ENC))system, network system, Yunnan shipping and Maritime integrated service platform, data storage system, hydrological system and navigation mark remote sensing and control system. The ECN system refers to the Yangtze River ENC production standards, which covers 360km and 5km on both sides from Jinghong Port to Chiang Saen port. China Maritime Safety Administration, provincial maritime bureau and 16 states (city) local maritime bureau are connected through intranet, extranet, private network, cable, wireless, etc. Yunnan Province Harbor Marine Integrated Service Platform enables document exchange, coordination office, daily communication and online communication by the private network for the province 16 states (city) local maritime bureau. The data storage system stores data in a single unified management for several servers. There are 10 hydrological ruler enables remote hydrology report, while navigation mark remote sensing and control system has have pilot.

Although these systems solve some Lancang River management problems to a certain extent and improve the efficiency of waterway management, they still cannot meet the needs of modernization and informatization.

Therefore, studying technical methods and application mode of Lancang River waterway modern management to construct the Lancang River waterway management information, has an important significance to enhance the quality and overall ability of waterway management, improve the electronic navigational chart comprehensive service level, and better serve the coastal economy and the shipping industry .

3 Suitable technical methods analysis for Lancang River waterway management information construction

3.1 Technologies for Digital Waterway

Digital waterway system based on inland electronic navigational chart (IENC) is an excellent platform to implement navigation mark monitoring, spatial query, simulation navigation and other functions. Multiple techniques including IENC, GIS, GPS, database, information transmission, RS and so on will be applied to waterway management in this system. The system will be the major trend of domestic and international waterway management, and also it will be an important mean of information construction of Lancang River waterway management.

3.2 Realize the comprehensive management of waterway by SOA system frame

Lancang River digital waterway should be based on IENC to realize the functions such as navigation mark remote sensing and control, waterway maintenance and management, dynamic management of working ships. It should provide efficient, stable, configurable coordination and linkage among systems based on the requirement of waterway comprehensive management.

According to difficult coordination across multi-system, unease process extension, and difficult coupling across traditional integrated middle ware,the large information construction projects which involve multi-department and multi-domain must rely on good design framework. Currently, there are two methods to achieve system integration including EAI (Enterprise Application Integration) and SOA (Service Oriented Architecture).Essentially, EAI is a message-based integration, having a bad expansion and reusability. SOA is independent of operation system, programming language and hardware platform. Actually, SOA is a flow-based integration and has good expansion, reusability and compatibility. So, SOA will be used as the whole frame of this system.

4 Informatization construction and application mode analysis for Lancang River waterway management

4.1 System construction model

Based on the analysis of the Lancang River management requirements, applicable technology, and the specific characteristics and information construction situation of Lancang River waterway, we suggest that the construction should take the waterway management objectives proposed in Yunnan waterway transportation "Twelfth Five Year Plan" as the overall direction, the management needs of Lancang River waterway management needs as the basis, , "top leading, framework supporting, urgent need building first, breakthrough at key points " as the overall construction principle to carry out the construction work . It can be specifically divided into:

1. Top-level design

According to the overall needs and development goals of informatization, use a systematic approach to do the top-level design to meet the integration and automation demands of shipping informatization, and realize unified planning, unified architecture, unified standards and integrated management.

2. Construct overall framework

The overall framework is the specific implementation of collaboration and data integrated application in top-level design. For the basin which information construction carried out earlier, the initial construction is lack of top-level design and supporting frame, which results in difficulties in the latter integration between systems. Lancang River waterway information construction should take this as a lesson. It is recommended to take the general framework as support, and realize system bus, unified portal based on single sign-on, security, data exchange, business management and integration of public service.

3. Improve infrastructure

Communication, network, computing and data storage infrastructure are the foundation of information construction. Based on making full use of the province's transportation network construction, we should extend the core network and strengthen the wireless network, and improve network and data security system to provide a safe, stable operating environment for the application system.

4. Achieve breakthroughs in key business systems

Individual business system is the basis of the Lancang digital waterway. Each individual application system can be developed in parallel and debugged simultaneous under the guidance of top-level and the requirements of the overall framework , which can be specifically constructed by the following aspects: inland electronic navigational chart(IENC) production (IENC is the basis for achieving digital waterway, should be constructed first), IENC analysis system, waterway maintenance management system, ship dynamic management systems, navigation mark remote sensing and control system, water level remote sensing and report system, waterway integrated management and information service platform.

5. Use small strides in building mode

It is recommended to take better information supporting regions as pilot area when constructing individual business system. The construction should always keep pace with the frame construction with small steps, establish milestones, build and integrate synchronously. The process quality management should be guaranteed to ensure congruence of goals and integrated approaches in the process of development at the same time.

4.2 System application mode

Lancang River waterway management can use three modes: decentralized management, centralized management, combination of decentralized management and centralized management.

1. Decentralized management

Management departments work independently using their existing office system.

2. Centralized management

When an emergency occurs, waterway management department draw staff from the corresponding departments according to the management needs, and carry out emergency work.

3. Combination of decentralized management and centralized management

These two modes have their own advantages. Decentralized management can play advantage in the daily supervision and management. It reflects staff efficiency better compared to centralized management. Centralized management can reflect the collaboration of different departments in an emergency event. It can eliminate the intermediate links, and greatly improve the rescue efficiency.

After the waterway information system construction is completed, it can achieve the function of online collaborative management and work using a variety of information and communication tools based on network platform construction and SOA architecture. It can achieve a unity of centralized management and decentralized management, and reflect data sharing and data integration, in order to get a "peacetime" and improve the efficiency of emergency rescue without affecting the daily management efficiency.

5 Conclusion

Based on the Lancang River waterway for modernization and development of information technology needs, this paper summarizes the results of the current study, integrates a number of representative application technologies such as digital waterway technology, geographic information technology and so on, and carries out with a strong targeted information technology management methods and application mode of research.

This is the first systematic research on the overall structure and construction mode of Lancang River waterway construction. It reveals the specific characteristics and construction ideas for Lancang River waterway management information, having important significance for “Twelfth Five-year” and even “Thirteen Five-year” Lancang River waterway management modernization and information.

GIS, GPS, and BIM-Based Risk Control of Subway Station Construction

Hualin Du[1]; Jianhua Du[2]; and Shougang Huang[3]

[1]China Railway Tunnel Group Co. Ltd., P.O. Box 100022, Guangqumenwai St. 3, Beijing, PRC. E-mail: 83058404@qq.com
[2]Shijiazhuang Institute of Railway Technology, P.O. Box 050041, Sishuichanglu Rd. No. 18, Shijiazhuang, PRC. E-mail: 11070932@qq.com
[3]Shijiazhuang Tiedao University, P.O. Box 050043, 17 Northeast, Second Inner Ring, Shijiazhuang, Hebei, PRC. E-mail: 370547248@qq.com

Abstract: In the process of subway station construction, many large construction equipments are placed in a narrow area where the operations are highly dense and the equipments have to carry heavy load and move or rotate in a broader space. In addition, there are tall equipments carrying out aerial operation. Some construction equipments are placed in limited underground space. These special conditions bring extremely high risks to subway station construction. This paper probes into (1) the application of BIM in summarizing and dynamically managing all the information and data in the process of construction; and (2) the installation of GPS receiver OEM board on large, high-risk construction equipments, the utilization of GIS and GPS data in dynamic management of three-dimensional geographic spatial location information of machineries and the visualized management of all data and information. In addition, this paper analyzes the risks related to large construction equipments and neighboring buildings and controlling methods. In this paper, the author suggests to integrate GIS, GPS and BIM to develop construction early warning and risk management systems so as to dynamically monitor the conflict risks among cranes, drilling machines, excavators, loaders and dumpers, the risks of collision between equipments and neighboring buildings and the risks of deformation and structure damage of foundation pits and retaining walls. Lastly, this paper analyzes the functional needs of the early warning and management system, which provides a theoretical reference for the development and implementation of this system.

Keywords: GIS; GPS; BIM; Subway station; Construction risk.

1 Research Background

The subway stations are always located at places where there are numerous high-rise buildings and complicated underground utilities. Various equipments are placed in one limited space and a number of workers carry out construction operations both on the ground and underground. On the construction site, it is likely that the large equipments collide with other equipments, or the equipments collide with the neighboring buildings or temporary facilities or the ground bearing pressure is insufficient. All these are potential risks.

At present, the method of artificial control of video monitoring are generally used to monitor the construction risk in the world. From the literature review of the situation, the intelligent control is not a security risk.

Given the characteristics of construction and surrounding conditions, delicacy construction, informatization management and visual dynamic monitoring will be out of question if we can develop the early warning and risk management system using GPS, BIM and WebGIS. This will put the risk under control and speed up the construction.

2 Program of GPS Setting on Construction Equipments

The GPS receiver and OEM board, installed on the tall equipments and fixed on the ground, can identify the real-time accurate spatial location of construction equipments. In order to simplify the motion model building of construction equipments, the OEM board can adopt the following programs: (1) For the self-propelled equipments like excavators and cranes with rotation mechanism, the OEM board can be installed at the middle of the swivel joint, so as to pick up real-time information of the equipments; (2) for the large parallel-movement equipments like gantry crane, the OEM board can be installed in the driving room to collect real-time information; (3) for the equipments with rotating mechanism like tower crane, the OEM board can be mounted on the end of the suspension arm; and (4) the OEM board can be mounted in a fixed location, so it can be used to collect data of pseudo-range difference.

The GPS signal on the moving station is transmitted to the base station via wireless network. After that, the signal goes through universal serial server and the multiport serial card of host computer and then it is connected via serial cable and the serial port of base server. At last, a multi-channel GPS signal acquisition system is set up, just as shown in Figure 1.

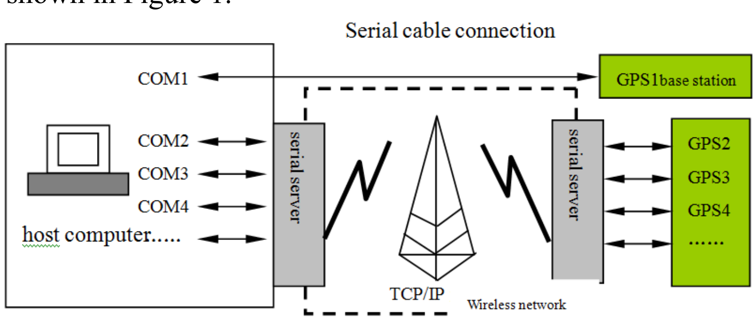

Figure 1. multi-channel GPS signal acquisition system

3 Building of Risk Data Model

3.1 Building-related Information Model

Building-related information model should involve information of (1) line grid and elevation positioning; (2) the spatial position and size of the foundation pit, space enclosing structure, steel shotcrete, pile body and top beam; (3) the main part of the station: floor, column, roof, walls, soil mass and the separated layer; (4) the spatial location and dimensions of adjacent existing architectural complex, structures, civil pipeline facilities; (5) work yard model includes traffic facilities, traffic signs and markings and urban greening. The construction structural element involves attribute parameter of layered soil mass and steel shotcrete, concrete strength, steel strength and the location and load of the steel. These will help to calculate the structural safety and research the load-carrying capability at different stages.

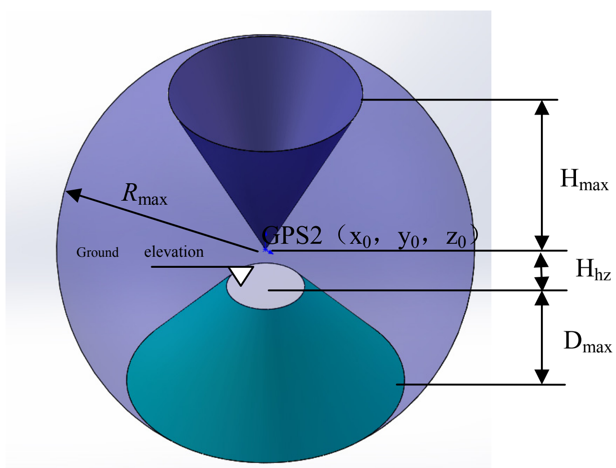

Figure 2. Simplified

3.2 Spatial Data Model of Construction Equipments

The authors of this paper take excavator and truck crane as example and introduce the modeling method of construction equipments (suppose we install the GPS receiver and OEM board at the center of the central swivel joint). (1) We build a simplified spatial model of excavator: namely simplify the activity space of the excavator, just as the spherical body shown in Figure 2. Above the ground, the activity space is a hemispherical space, the center of which is the three-dimensional position of GPS (x0, y0, z0). The three-dimensional position of GPS may change as the excavator moves; the radius of this hemisphere space is maximum radius of the excavator's digging area (one of excavator's parameter). The activity space of the excavator excludes a cone whose height is H_{max} and a circular truncated cone whose height is D_{max}. In the figure 2, R_{max} is the maximum radius of the excavator's digging area, D_{max} is the excavator's maximum digging depth, and H_{max} is the excavator's maximum digging height.

In the process of operation, the excavator may shake. In addition, there is time lag when the OEM board receives data. Therefore, for the sake of safety, the radius of the spherical space should be increased. There is no other equipment under the excavator. Thus, the spatial model can be expressed by parameter equation (1):

$$\begin{cases} x = x_0 + (R_{\max} + C_{\mathrm{V}}) \sin\varphi \cos\theta \\ y = y_0 + (R_{\max} + C_{\mathrm{V}}) \sin\varphi \sin\theta \\ z = z_0 + (R_{\max} + C_{\mathrm{V}}) \cos\varphi \end{cases} \quad (1)$$

In this formula:

x, y, z ——the coordinates of X, Y and Z representing the most farthest points the excavator can reach.

x_0, y_0, z_0 ——the coordinates of X, Y and Z of center of gyration.

R_{max} ——the maximum radius of the excavator's digging area.

C_V ——modification value of radius of the excavator's digging area.

D_{max} ——the excavator's maximum digging depth.

H_{max} ——the excavator's maximum digging height.

H_{hz} ——the height of the center of gyration (in this paper, it represents the height of the GPS).

φ ——elevation (angle of depression) of the excavator's main arm, $\arcsin((-H_{hz} - D_{max})/R_{max}) \le \varphi \le \arcsin((H_{max} - H_{hz})/R_{max})$;

θ ——rotation angle of the excavator, $0 \le \theta \le 2\pi$.

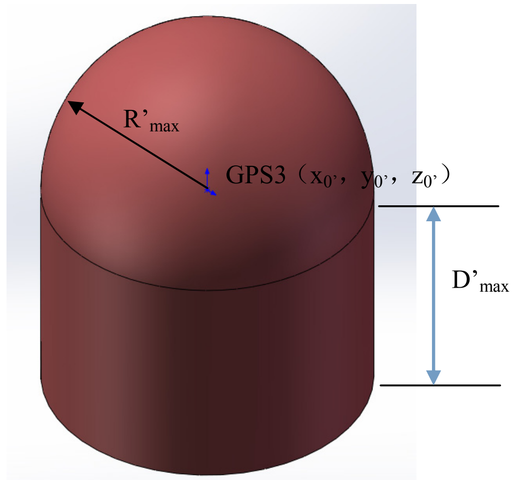

Figure 3. Simplified

(2) The simplified spatial model of truck crane is as shown in Figure 3. The activity space above the swing mechanism is simplified to a hemispherical space, the center of which is the three-dimensional position of GPS (x0 ', y0', z0 '). The radius of this hemispherical space equals to maximum working radius (one of the truck crane's parameters) plus the long side of the hanging object (the centre distance between the object and the steel wire rope); the activity space under the truck crane is a cylinder.

When the object is higher than the center of gyration, the spatial model can be expressed b parameter equation (2):

$$\begin{cases} x = x_0' + (R'_{\max} + C_V')\sin\varphi\cos\theta \\ y = y_0' + (R'_{\max} + C_V')\sin\varphi\sin\theta \\ z = z_0' + (R'_{\max} + C_V')\cos\varphi \end{cases} \qquad (2)$$

In this formula :

x, y, z	---the coordinate of x, y and z of the point that the truck crane (and the object) can reach.
x_0', y_0', z_0'	---the coordinates of x, y and z of the center of gyration.
R'_{max}	---the crane' maximum working radius and the long side of the lifted object.
C_V	---correct value of the crane's radius (the safety stock added due to the shake of crane and lifted object is taken into consideration.)
φ	---the elevation of main arm, $0 \le \varphi \le \pi$.

θ ---the rotation angle of the main arm, $0 \le \theta \le 2\pi$.

When the lifted object is lower than the center of the swing mechanism, the spatial model can be expressed by parameter equation (3):

$$\begin{cases} x = x_0' + (R'_{\max} + C_V')\cos\theta \\ y = y_0' + (R'_{\max} + C_V')\sin\theta \\ z = z_0' - D'_{\max} \end{cases} \quad (3)$$

In this formula :

D'_{max}---the vertical distance between the lifted object's undersurface and the top surface of the swing mechanism.

Meanings of the rest symbols are the same as that of the symbols in parameter equation (2).

4 Analysis and Control of Conflict Risk

4.1 Analysis of Conflict Risk

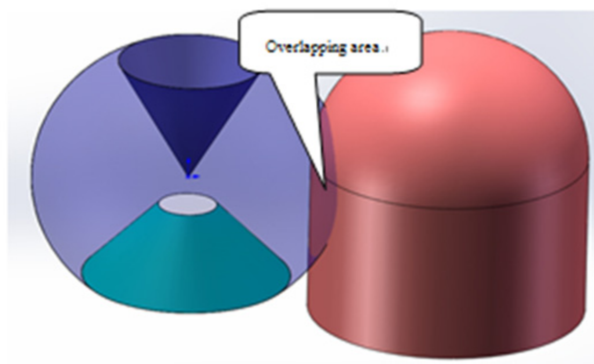

Figure 4.Dynamic space overlapping area

The conflicts in the process of construction may cause decline of productivity and property damage or personal injury. BIM technique can be used to analyze the hazardous area, conflicts between large equipments, collision between equipments and neighboring buildings (temporary facilities), topple of tall equipments, the conflicts between equipments and the pedestrians and the conflicts between equipments and passing-by vehicles.

We also analyze the spatial overlap of some factors that lead to conflicts and the obtained public areas should be the collision risk space. We take excavator and truck crane as an example and overlay the activity spaces of excavator and truck crane.

Just as shown in Figure 4, the overlapped public area is the space where collision may occur.

4.2 Control of Conflict Risk

Controlling methods of conflict risks:

(1) All large equipments are armed with GPS receiver and OEM board, so the system server can identify the location information of each large construction equipment, integrate each equipment' attribute information (various mechanical parameters). In this way, the dynamic real-time analysis of whether there can be a collision area is carried out. In case of any collision, the system automatically and immediately notified the drivers to pay attention to the collision area.

(2) Large equipments may enter the area where the bearing capacity is weaker (for example, the top edge of the pit), which is a collision in the broad sense. Once the mass of a large construction equipment (including loaded or lifted objects) is greater than the carrying capacity (considering the safety factor) of the neighboring building (temporary facilities) (safety factor), the system automatically and immediately notified the drivers to pay attention to the possible collision.

(3) Before the construction starts every day, the security personnel will print the pre-analyzed risk lists and send them to the large equipment drivers, reminding them of the risks of potential collision risk and insufficient bearing capacity.

5 Risk Early Warning of Subway Station Construction and Functional Requirement Analysis of Management System

The field investigation shows that the system should have the following functions: (1) 4D simulation preview and dynamic management of the construction process, equipment installation, existing neighboring buildings, civil pipe network, security facilities (fender post, support and bounding wall); (2) 4D simulation and dynamic management of materials processing, stacking and transportation; (3) real-time tracking simulation and dynamic management of the equipments' 3 D location; (4) 4D simulation rehearsal and analysis of safety conflicts between two construction equipments, staff and construction equipments, construction equipments and engineering structures, and construction equipments and the ground traffic; (5) monitoring information management and feedback; (6) risk analysis and forecasting, risk identification management and accident early warning; (7) emergency plan simulation and visualization selection; and (8) simulation preview of emergency evacuation and emergency rescue visualization.

From the current research and application of early warning system has been similar to the situation, the development of Risk Early Warning and Management System of Subway Station Construction is feasible, and it is very urgent.

6 Conclusions

This paper presents a program to use GPS, BIM and GIS to dynamically monitor the risks in the process of subway station construction, probes into the construction equipment modeling and discusses conflict risk analysis and controlling method. The author's limited ability and shallow knowledge have limited the study, so the author expect more colleagues to spare no efforts to the system development.

Abstract: Constructing underground roads has been important to alleviating traffic pressure. Site selecting of entrances and exits scientifically is significant to controlling the construction scale of underground roads and making it develop rapidly. First, the primary index system was established based on analyzing the factors that affect entrances and exits site of underground roads. The important factors, which include the distribution capacity of entrances and exits, travel costs of the area, construction costs and operation-maintenance costs, were determined after analyzing the primary index system by using ISM and Matlab. Second, the bi-level programming model to optimize the site of entrances and exits was set up. The objective function of the upper level was to minimize the land cost, construction cost, operation cost, maintenance cost of underground roads, the reconstruction cost of the ground transport network, and the travel cost in the area. The objective function of the lower level was to assign the traffic flow equilibrately in the transport network. Then, the iterative optimization algorithm (IOA) was used to solve the bi-level programming model. Finally, an example was employed to prove the feasibility of the model. The results show that the land use scale and the construction costs can be controlled by optimizing the entrances and exits site of the underground roads.
Keywords: Underground roads; Site selection of entrance and exit; ISM system; Matlab; Bi-level programming model.

1 Introduction

With the acceleration of urbanization and the rapid growth of the traffic demand, the contradiction between high motorization and the capacity of roads has become increasingly serious because of the limitation of the land resources and environmental protection (HAN J W, 2010). As a result, the city has experienced from the surface roads to the large-scale development of the elevated roads, which still can't solve the contradiction. The cities both at home and abroad put more effort to the underground road's building to alleviate the traffic pressure, and a few theories and practice achievements have been made (CHEN Z L, ZHANG P, 2009). In foreign countries, the studies about underground roads have been concentrated on the traffic capacity, the traffic management during the construction and operation (Hirata T, Tetsuo Y A I, Mahara T, 2006), and the environmental impact assessment (Thalheimer, Erich S, 2004). In China, researchers focus on how to alleviate the heavy traffic pressure of fast lanes and main roads by building underground roads or underwater tunnels (HU Y C, SIMA B Q, JIN W Z, 2009). These researches are mainly conducted by qualitative analysis, and lack of achievements which can guide the network planning of underground roads. In practice, however, site selection of network nodes, especially entrances and exits is critical which will directly affect the ability of underground roads that attract traffic, guide the needs and connect with other traffic facilities.

In this paper, site selection of entrances and exits of underground roads was taken as the center point, an ISM system was established and the factors affecting the site selection were analyzed. Eventually, a bi-level programming model was set up to optimize the site of entrances and exits.

2 Analyses on ISM System about Site Optimization for Entrances and Exits of Underground Roads

Through analysis, 12 factors that directly affect entrances and exits site of underground roads were divided into four categories, namely:

1) technical standards, including : distribution ability of entrances and exits $A1$, support capabilities of the underground road network $A2$, and connecting effectiveness with the ground road network $A3$, linear indicators $A4$;

2) natural conditions, including : geological conditions $A5$, topographic conditions $A6$, land use conditions $A7$;

3) environmental factors, including: environmental coordination $A8$, transportation environmental impact factors $A9$;

4) economic factors, including: regional travel costs $A10$, construction costs $A11$, operation and maintenance costs $A12$. The factors set is indicated by A, $A=\{A1, A2, A3\cdots, A12\}$, as shown in Table 1.

Above factors include both qualitative and quantitative factors, and they are not important equally. So it’s necessary to select the most important factors and find the optimum proposal by using quantitative methods. The ISM and Matlab will be used to determine the most important factors. Specific steps are as follows:

1) Establish the adjacency matrix. 12 factors in the system relate and influence each other, the relationship among these factors are direct or indirect. Adjacency matrix is used to show the direct relationship. If Ai has direct influence on Aj, then $aij=1$, otherwise $aij=0$.The adjacency matrix is shown in table 2.

2) Obtain reachability matrix by using Matlab. Adjacency matrix in Table 2 reflects the direct relationship between factors, but there are significant indirect

relationships among them. If Ai have direct influence on Aj and Aj have direct influence on Ak at the same time, Ai would have indirect influence on Ak . This influence may be shown through one or more in-between factors. Reachability matrix R will be used to represent these direct or indirect relationships. When Ai has direct or indirect influence on Aj , $aij=1$, otherwise $aij=0$,as shown in Figure 1 .

Table 1. System factors

Element Number	Name of the Elements	Meaning of the Elements
$A1$	distribution ability of entrances and exits	the efficiency of vehicle traveling in and out
$A2$	support capabilities of underground road network	coordination with underground road itself
$A3$	connecting effectiveness with the ground road network	the ability that coordinate with road network
$A4$	linear indicators	the radius of longitudinal slope and curvature
$A5$	geological conditions	engineering geologic conditions, hydro geological conditions
$A6$	topographic conditions	buildings and structures
$A7$	land use conditions	vegetation conditions, land use area
$A8$	environmental coordination	coordination between entrances & exits and their surrounding environment
$A9$	transportation environmental impact factors	traffic impact factors such as noise and exhaust gas
$A10$	regional travel costs	vehicle travel cost in a region
$A11$	construction costs	construction costs
$A12$	operation and maintenance costs	operation and maintenance costs

Fig.2 Caculated results

3) Obtain the antecedent set, outcome set and the intersection of system factors, as well as the layer classification by using the reachability matrix;

According the reachability matrix, we can find all factors affected by Ai to form the set $R(Ai)$ and all factors affected Ai to form the antecedent set $\mathrm{A}(Ai)$. Then we can obtain all factors that not only affect Ai but also are affected by Ai, which form the intersection $\mathrm{S}(Ai)$. As shown in table 3.

The layer classification is a process to determine every factor's level. The basic approach is to identify the factors that have no relation with any other factors, they are senior factors, remove them, and seeking more senior ones from remaining factors, and so on, until determine the lowest level of the collection. The senior factors are defined as following: $L1=\{Ai|Ai\in A, R0(\mathrm{Ai})\cap \mathrm{A}\,0(\mathrm{Ai})=R0(\mathrm{Ai}), \mathrm{i}=1,2,\cdots,\mathrm{n}\}$.

4) Calculated Result by Matlab, as shown in Figure 2.

We can get the conclusions from the result: the first layer factors are $A1$, $A10$, $A11$ and $A12$; the second layer factors are $A8$ and $A9$; the third layer factor is $A7$; the fourth layer factors are $A2$ and $A3$; the fifth layer factors are $A4$ and $A6$; the sixth layer factor is $A5$.

The interpretative structural model is established, as shown in Figure 3.

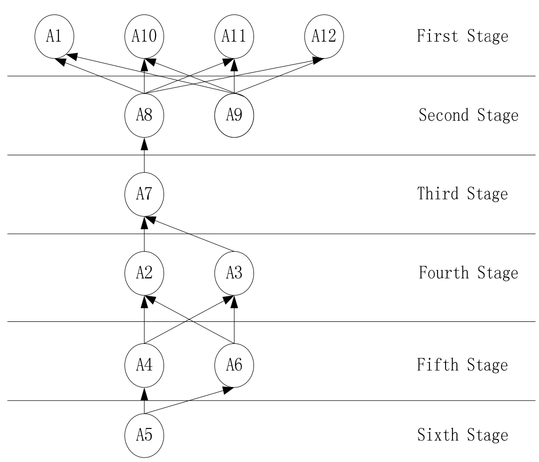

Fig.3 The interpretative structural model

3 Site selection model and algorithm

3.1 Problem description

The site–selecting problem of the underground road entrance-exits can be described as: M entrance-exits of the underground roads are selected within the regional traffic network, the selected ones should have enough traffic capacity and the function of distributing the traffic flow; the land cost, construction cost, traffic network improving cost, and the vehicle operation cost are minimum; the operation and maintenance cost is minimum and the traffic flow of underground roads should be correspond to the capacity of entrance-exits; the traffic flow assigned to the ground road network should be appropriate to the capacity of existing sections. The adverse effect of building the underground road network should be taken into account, in other words, the newly-built underground road entrance-exits will attract a lot of traffic, which may lead to the traffic congestion near the entrance-exits, thus the ground roads in the influence area should be widen or built, the construction cost will rise and the traffic flow of the network will also be redistributed. Based on the traffic equilibrium, the paper set up the bi-level programming model of site selection for entrances and exits of underground roads.

3.2 Mathematic model

The notations used in the model are defined as follows:

L is the nodes number of the traffic network; D is the number of traffic zones; K is the number of traffic zone being suitable for the underground entrance-exits; M is the number of underground road entrance-exits needed to be selected; A is the set of ground road sections in the traffic network; H is the set of underground road sections in the traffic network; A_1 is the number of ground road sections which are planned to be widened or built ; λ is the conversion Coefficient between travel cost and currency; r,s are the start and stop nodes of each section in the traffic network; d is the traffic zone; k is the traffic zone being suitable for underground road entrance-exits; m,m' are the entrances and exits of the underground road; a is the ground road section; h is the underground road sections.

The studied traffic network is divided into D zones, and M underground road entrance-exits will be selected. For convenience, the traffic zone is expressed with its geometric center, and then each traffic zone is a node in the traffic network. In addition, assume only one entrance or exit can be placed in each traffic zone. Actually, some traffic zones are not suitable for placing transport hub due to the geographical position and other reasons, so assume that only K zones are suitable to place entrance/exits of the underground roads, then the inclusion relation can be concluded: $M \in K \in D \in L$.

Set $Z=[z_{md}]_{M\times D}$, where z_{md} is variable of 0-1, $z_{md}=1$ represents placing entrance-exit m in the zone d, otherwise $z_{md}=0$. Matrix Z represents site- selection project of entrance-exit m; Set $P=[c_{md}]_{M\times D}$, where c_{md} is the cost of the land use and construction that placing entrance-exit m in the zone d; Set $G=[c_{mm'}]_{MM'}$, where $c_{mm'}$ is the cost of constructing, operating and maintaining the underground road between entrance-exit m and entrance-exit m' ; $Q=[q_{rs}]_{D\times D}$ represents vehicle-travel-distribution matrix of initial D zones (before underground roads are built); Set $E=[e_{md}]_{M\times D}$, where e_{md} is the vehicle volume from entrance-exit m to zone d and $b_{mm'}$ is the vehicle volume between entrance-exit m and entrance-exit m' in the underground road system.

3.2.1 Upper programming model

According to the above definition of variables, the total of land use and construction cost of M underground road entrance-exits can be expressed as $F_2(Z)=\sum_{m=1}^{M}\sum_{m'=1}^{M}\sum_{d=1}^{D}c_{mm'}z_{md}z_{m'd}$; the total of the construction, operation and maintenance cost of the underground roads can be described as $F_2(Z)=\sum_{m=1}^{M}\sum_{m'=1}^{M}\sum_{d=1}^{D}c_{mm'}z_{md}z_{m'd}$. Considering built entrance-exits, the vehicle-travel-distribution matrix will be expressed with $Q'=[q'_{rs}]_{D\times D}$, where $q'_{rs}=q_{rs}+\sum_{m=1}^{M}z_{md}\,e_{md}+\sum_{m=1}^{M}\sum_{m'=1}^{M}z_{md}z_{m'd}\,b_{mm'}$.

The whole travel cost of the region is expressed by $F_2=\sum_{a\in A}x_at_a+\sum_{h\in H}x_ht_h$, actually, the newly-built underground road entrance-exits will attract a lot of traffic, which may lead to the traffic congestion near the entrance-exits, thus the ground roads in the influence area should be widen or built, the construction cost will rise and the traffic flow of the network will also be redistributed. Then the travel cost and the reconstructive cost would be

$F_3(Z)=\lambda\sum_{a\in A}x_at_a(x_a,y_a)+\lambda\sum_{h\in H}x_ht_h+\sum_{a}^{A_1}G_a(y_a)$, $s.t.$ $y_a\geq 0,(1\leq a\leq A_1)$, of which, y_a is the extension variable of ground section a, Y is the extension vector, $G_a(y_a)$ represents reconstruction cost of section a.

The objective function of the upper model was to minimize the land use cost, construction cost, operation cost, maintenance cost of underground roads, and the reconstruction cost of the ground transport network, as well as the travel cost in the area.

$$\min F(Y,Z)=\sum_{m=1}^{M}\sum_{d=1}^{D}c_{md}z_{md}+\sum_{m=1}^{M}\sum_{m'=1}^{M}\sum_{d=1}^{D}c_{mm'}z_{md}z_{m'd}+\lambda\sum_{a\in A}x_a t_a(x_a,y_a)$$
$$+\lambda\sum_{h\in H}x_h t_h+\sum_{a}^{A_1}G_a(y_a)$$

$s.t.$

$$q'_{rs}=q_{rs}+\sum_{m=1}^{M}z_{md}\,\mathrm{e}_{md}+\sum_{m=1}^{M}\sum_{m'=1}^{M}z_{md}z_{m'd}\,\mathrm{b}_{mm'} \quad (1)$$

$$\mathrm{y}_a\geq 0,(1\leq \mathrm{a}\leq \mathrm{A}_1) \quad (2)$$

In the objective function, the first algebraic term represents the land use and construction cost of building M underground road entrance-exits in the D zones; the second represents the sum of construction, operation, and maintenance cost of underground roads; the third and forth is the total cost of the vehicle trip; the fifth is the charge of the sections extension. The first constraint condition shows when the underground entrance-exits are planned to be constructed, the traffic distribution of the region will be considered, the last one shows that the expanding capacity vectors are negative.

3.2.2 The lower programming model

In the lower level, the section flow vector $X=(\cdots \mathrm{x}_a\cdots \mathrm{x}_h\cdots)$ and the vehicle flow vector $Q'=(\cdots \mathrm{q}'_{rs}\cdots)$ are obtained by using the theory of user equilibrium with elastic demand assignment.

$$\min W(\mathrm{X},\mathrm{Q}')=\sum_{a\in A}\int_0^{x_a}t_a(\omega,y_a)d_\omega+\sum_{h\in H}\int_0^{x_h}t_h(\omega)d_\omega-\sum_{rs}\int_0^{q_{rs}}D_{rs}^{-1}(\omega)d_\omega$$

s.t.

$$\sum_k f_k^{rs}=q'_{rs},\forall r,s \quad (3)$$

$$x_a=\sum_{r,s}\sum_k f_k^{rs}\delta_{a,k}^{rs},\forall a \quad (4)$$

$$x_h=\sum_{r,s}\sum_k f_k^{rs}\delta_{\mathrm{h},k}^{rs},\forall \mathrm{h} \quad (5)$$

$$f_k^{rs}\geq 0,\forall r,s,k \quad (6)$$

$$q'_{rs}\geq 0 \quad (7)$$

Where x_h is the inverse function of demand function correspond to $r-s$ of $O-D$,

t_a is the traffic impedance function of ground road sections, which is related to the extension variable y_a of section a and defined as $t_a(x_a, y_a) = t_0[1+\alpha_a(\frac{x_a}{c_a+y_a})^{\beta_a}]$, α_a, β_a represent the parameters of section a, t_h is the traffic impedance function of underground road section h, which is defined as $t_h(x_h) = t_0[1+x_h\gamma_h]$, γ_h represents the parameters of section h; t_0 represents the travel time while the flow of sections is 0; c_a is the traffic capacity of section a; x_k represents the flow of route k from r to s in $O-D$; $\delta^{rs}_{a,k}$ and $\delta^{rs}_{h,k}$ are 0-1 variables; when route k of $O-D$ from r to s pass section a (or h), $\delta^{rs}_{a,k}=1$ (or $\delta^{rs}_{h,k}=1$) ,otherwise $\delta^{rs}_{a,k}=0$ (or $\delta^{rs}_{h,k}=0$). The five constraint conditions of equation (3), (4), (5), (6), (7) represent the flow within the regional network is conserved.

3.2.3 Algorithm

Using iterative optimization algorithm to solve the bi-level programming model, the basic steps are as follows:

Step1: Set the initial solution $Y^0=(0,\cdots,0), k=0$, Y^0 is the improved variable, the initial network is the present one.

Step2: Plug Y^k into the upper objective function, the third item of it will be a constant term, and then the model will become a simple problem of entrance-exit site selection, which can be solved by the general algorithm, the solution of the objective function is Z^{k+1}.

Step3: Plug Z^{k+1} into the upper objective function, the first item of it will be a constant term and the model will turn into a traffic network equilibrium assignment problem, the related algorithms in the literature (GAO Z Y, ZHANG H Z, SUN H J, 2004) can be used to solve the model, we can obtain the solution of the objective function is Y^{k+1}.

Step4: Conduct significant difference tests on Y^k and Y^{k+1}, if there is a significant difference, then set $k=k+1$, and return to the step 2, if not, Y^{k+1} and Z^{k+1} are the solution.

4 The example

The underground road network is described as figure 4. Assumed: there are 10 nodes, 4 zones: 1, 3, 8, 10; 3 underground entrance-exits:1, 4, 10. L=10，D=4，M=3.

O-D Matrix $[q_{rs}]_{D\times D}$, $[e_{md}]_{M\times D}$, $[b_{mm'}]_{M\times M}$ Can be predicted by the data in table 4.The traffic capacity of each section is $c_a = 2000$, the extension charge of the section is $G_a(y_a) = 0.0002\gamma_a y_a$,parameter $\lambda = 0.00002$.

Table 4. O-D Flow of zones

OD	1	3	4	8	10
1	-	500	600	600	1200
3	300	-	600	540	600
4	330	600	-	540	700
8	400	200	540	-	650
10	1000	600	450	250	-

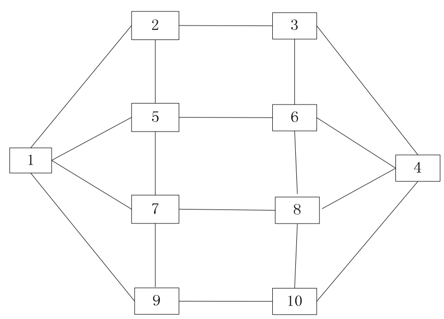

Fig.4 Underground Road Network

Table 5. Optimal Location of Entrance/Exit

Z(m,d)	1	3	8	10
1	1	0	0	0
4	0	1	0	0
10	0	0	0	1

According to the table 5, place entrance-exit 1 into section 1, entrance-exit 4 into section 3, and entrance-exit 10 into section10. The minimum objective function value has been obtained after iterations, which is the optimal scheme.

5 Summary

Entrances-exit site selection of underground roads was studied in this paper. Four important quantitative factors were confirmed by ISM, according to which, a bi-level programming model was established. The objective function of the upper level is to minimize the land use cost, construction and reconstruction cost of the ground transport network, etc. The objective function of the lower level is to assign the traffic flow equilibrately in the transport network. The iterative optimization algorithm (IOA) was used to solve the bi-level programming model. And an example was employed to prove the feasibility of the model. The results show that it is effective in controlling land use and construction cost to optimize the entrance-exit location.

Abstract: Because of the urban road space is relatively limited and the growth of traffic demand is approximately infinite, the phenomenon of traffic congestion is becoming even more serious. According to the attribute mathematical theory, the evaluation index system of traffic congestion was put forward, and the urban traffic congestion evaluation model was set up. The evaluation indexes of urban traffic conditions weights are determined by variation coefficient method. The state of traffic congestion can be recognized by the method of confidence criterion. The final evaluation results can be obtained by calculating the investigation results. Finally, the model can be used to sort the result of traffic congestion evaluation for each road and each intersection. The results show that the method is feasible to solve such problem.
Keywords: Traffic congestion; Attribute mathematical; Coefficient method; Confidence criterion.

1 Introduction

The problem of urban city traffic congestion is becoming even more serious because the continuous expansion of city size and the sustained growth of vehicle possession. At present, there is still no unique definition for the classification criterion of city traffic congestion How to identify the congestion state effectively has aroused a lot of attention from scholars in the field of traffic engineering The independent research of intersections and roads can't reflect the real status of regional traffic network because the urban road expressed in the form of network performance. Aiming at these problems, in recent years, many scholars did a lot of research and achieved some results. Fahmy M. F. and Ranasinghe D. N. (Thajchayapong, S., Pattara-Atikom, W., Chadil, N., & Mitrpant, C., 2006) use the queuing model to discriminate the congestion state. The reference (YANG, Z. Y, 2008)proposed a novel traffic interval programming method based on SFLA and FCM. The reference(Li-chunying, 2010) considered the influence of traffic flow parameters and some related environmental factors of the city traffic condition. However, above methods usually based on the way of single index evaluation or rely on subjective judgment matrix. In order to identify the urban traffic congestion state scientifically and effectively, an investment method based on the model of attribute mathematical has been proposed.

2 The evaluation index system of traffic congestion state

The reference (Qiliang R, 2008) has been cited in order to reflect the traffic congestion state objectively and accurately. The levels of traffic congestion can be divided into four tiers. The four states are unblocked (the first level), relatively smooth(the second level), low-congestion(the third level),congestion(the forth level), Block(the fifth level), the definition of different levels of traffic state, as in table 1 below.

Table 1. The classification of traffic congestion

The level of traffic congestion	Remarks
Unblocked	Free form flow ; No interfering by external environment; No time loss
Relatively smooth	Blocking is weak; Little interference by external environment; Less time loss
Low-congestion	Slightly blocked; Serious interference by external environment; Much time loss
Congestion	Congested traffic flow; Close to saturation; Vehicles hardly leave the intersection for once
Blocked	Blocking; Saturated or overload; Vehicles can not leave the intersection for once

Urban road traffic is composed of roads and intersections from microcosmic angle. Therefore, the state of regional traffic congestion is determined by the congestion status of each intersection and each road. The principle of selecting indicators abide by independence, comparability and representative. Evaluation index refer to the HCM(the level classification of road service), HCM85(the level classification of signal intersection service), the level classification of signal intersection service proposed by Beijing Municipal Engineering Design Institute and other relevant literature. The evaluation index system and grading standards, as shown in Table 2.

Table 2. Evaluation index system and grading standards

The total index	The first indicators	The secondary indicators	Grading standards				
			C_1	C_2	C_3	C_4	C_5
The state of traffic congestion I	Road I_1	Velocity/km•h^{-1} (u_1)	≥40	[35,40)	[28,35)	[20,28)	<20
		Density/pcu•km^{-1}•ln^{-1}(u_2)	<12	[12,25)	[25,45)	[45,70)	≥70
		Saturation(u_3)	<0.35	[0.35,0.65)	[0.65,0.85)	[0.85,1.0)	≥1.0
		Flow rate/pcu•h^{-1}•ln^{-1}(u_4)	<500	[500,950)	[950,1150)	[1150,1950)	≥1950
	Intersection I_2	Delay/s(u_5)	<15	[15,25)	[25,40)	[40,60)	≥60
		Saturation(u_6)	<0.6	[0.6,0.7)	[0.7,0.8)	[0.8,0.9)	≥0.9
		Length of the queue/m(u_7)	<30	[30,40)	[40,50)	[50,60)	≥60
		Parking twice(u_8)	0	0	[0,0.2)	[0.2,0.5)	≥0.5

3 Attribute Mathematical recognition model of the congestion

3.1 The establishment of classification matrix

Urban traffic congestion state needs to measure both the state of roads congestion(I_1) and the state of intersections congestion(I_2). Subjects $X=\{$The state of traffic congestion$\}$, several states of traffic congestion can be taken out from X(x_1 , x_2 , x_3 , $\cdots x_n$).The state of traffic congestion is based on the actual situation and the value of n can not affect the final result of congestion evaluation. Take F as the attribute space, the grading standards are $C=\{c_1, c_2, c_3, c_4, c_5\}$ ={Unblocked, Relatively smooth, Low-congestion, Congestion, Blocked}.Classification standard matrix ,shown as follows.

$$A=\begin{matrix} & c_1 & c_2 & \cdots & c_5 \\ I_1 & [a_{11},b_{11}] & [a_{12},b_{12}] & \cdots & [a_{15},b_{15}] \\ I_2 & [a_{21},b_{21}] & [a_{22},b_{22}] & \cdots & [a_{25},b_{25}] \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ I_4 & [a_{81},b_{81}] & [a_{82},b_{82}] & \cdots & [a_{85},b_{85}] \end{matrix} \tag{1}$$

The benefit index: u_1 (larger means better); The cost index: u_2, u_3, u_4, u_5, u_6, u_7, u_8 (smaller means better).

(1) $a_{j1}>a_{j2}>a_{j3}>a_{j4}>a_{j5}$, $b_{j1}>b_{j2}>b_{j3}>b_{j4}>b_{j5}$, $j=1$.

(2) $a_{j1}<a_{j2}<a_{j3}<a_{j4}<a_{j5}$, $b_{j1}<b_{j2}<b_{j3}<b_{j4}<b_{j5}$, $j=2,3,4,5,6,7,8$.

3.2 Attribute measure space

Attribute measure space means that a method of quantitative analysis to describe the actual survey data which belong to a section in different degrees. The evaluation index system of traffic congestion state has some(j) evaluation index. The actual survey data of I_j (t_1 , t_2 , t_3 , $\cdots$, t_8). The attribute measure spaces of each evaluation index(c_1, c_2, c_3, c_4, c_5) are [u_{jg}]

$$[u_{jg}]=[\underline{u}_{jg},\overline{u}_{jg}] \tag{2}$$

If $a_{j1}<a_{j2}<a_{j3}<a_{j4}<a_{j5}, b_{j1}<b_{j2}<b_{j3}<b_{j4}<b_{j5}$,

When $t_j<a_{j1}$, $\underline{u}_{j1}=1$, $\overline{u}_{j2}=\overline{u}_{j3}=\cdots,\overline{u}_{j5}=0$.

When $t_j<b_{j1}$, $\overline{u}_{j1}=1$, $\underline{u}_{j2}=\underline{u}_{j3}=\cdots,\underline{u}_{j5}=0$.

When $t_j\geq a_{j5}$, $\underline{u}_{j5}=1$, $\overline{u}_{j1}=\overline{u}_{j2}=\cdots,\overline{u}_{j4}=0$.

When $t_j\geq b_{j5}$, $\overline{u}_{j5}=1$, $\underline{u}_{j1}=\underline{u}_{j2}=\cdots,\underline{u}_{j4}=0$.

When $a_{jl}\leq t_j\leq a_{j(l+1)}$, then

$$\begin{cases} \underline{u}_{jl} = \dfrac{|t_j - a_{j(l+1)}|}{|a_{jl} - a_{j(l+1)}|} \\ \underline{u}_{jk} = 0 \quad (k < l \; or \; k > l+1) \\ \underline{u}_{j(l+1)} = \dfrac{|t_j - a_{jl}|}{|a_{jl} - a_{j(l+1)}|} \end{cases} \text{ and } \begin{cases} \overline{u}_{jl} = \dfrac{|t_j - b_{j(l+1)}|}{|b_{jl} - b_{j(l+1)}|} \\ \overline{u}_{jk} = 0 \quad (k < l \; or \; k > l+1) \\ \overline{u}_{j(l+1)} = \dfrac{|t_j - b_{jl}|}{|b_{jl} - b_{j(l+1)}|} \end{cases}$$

3.3 Index weight

The evaluation indexes of urban traffic conditions weights are determined by variation coefficient method in order to avoid the subjective qualitative evaluation. The calculation method of coefficient method shown as follows.

$$C.V_j = \sqrt{1/5 \cdot \sum_{g=1}^{5} (d_{jg} - \overline{d}_j)} \Big/ \overline{d}_j \tag{3}$$

$$\overline{d}_{jg} = 1/2 \cdot (\underline{u}_{jg} + \overline{u}_{jg}) \tag{4}$$

$$\overline{d}_j = 1/5 \cdot \sum_{g=1}^{5} d_{jg} \tag{5}$$

For equations in the text, $C.V_j$ means the coefficient of the evaluation index j.

The coefficient of evaluation index were processed by using the normalization method. The calculation method of the index weight shown as follows.

$$w_j = C.V_j \Big/ \sum_{j=1}^{8} C.V_j \tag{6}$$

For equations in the text, w_j means the weight of the secondary indicators.

3.4 Comprehensive evaluation

The state of traffic congestion can be recognized by the method of confidence criterion.

$$[u_g] = [\underline{u}_g, \overline{u}_g], (1 \leqslant g \leqslant 5)$$

$$\underline{u}_g = \sum_{j=1}^{8} w_j \cdot \underline{u}_{jg}, \; \overline{u}_g = \sum_{j=1}^{8} w_j \cdot \overline{u}_{jg} \tag{7}$$

$$[u_g'] = 1/2 \cdot (\underline{u}_g + \overline{u}_g) \tag{8}$$

$$k = \min\left\{ g : \sum_{i=1}^{g} u(c_i) \geq \lambda, 1 \leq g \leq 5 \right\} \tag{9}$$

For equations in the text, k means the grade of traffic congestion state.

$$q_{xi} = \sum_{i=1}^{n} n_i u_{xi}(c_i) \tag{10}$$

For equations in the text, q_{xi} reflect the situations of different regional traffic network congestion.

4 Empirical study

This paper selected the roads of a city as the research object. The traffic network which selected mainly consists of 6 sections and 5 intersections(see figure 1). The heavy lines represent the roads and the circles represent the intersections. The fine lines represent side-roads.

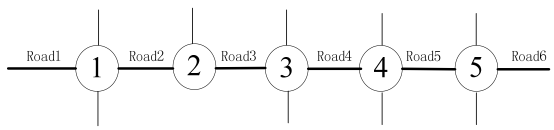

Fig.1 The diagram of the roads and the intersections

Through the actual traffic survey, the data shows as follows.

Table 3. The index value of each road

The label of the road	Velocity	Density	Saturation	Flow rate
r_1	37	32	0.64	873
r_2	35	33	0.65	894
r_3	34	36	0.71	973
r_4	32	39	0.82	1122
r_5	28	43	0.85	1161
r_6	26	51	0.87	1199

Table 4. The index value of each intersection

The label of the intersection	Delay	Saturation	Length of the queue	Parking twice
cr_1	37.7	0.73	49	0.11
cr_2	39.7	0.68	49	0.09
cr_3	43.9	0.76	56	0.13
cr_4	48.8	0.8	57	0.17
cr_5	51.4	0.81	59	0.2
cr_6	37.7	0.73	49	0.11

Refer to equations in the text by (1) and (2), the classification standard matrix and the attribute measure space can be acquired. According to Eq. (3) , (4) and (5), the index weights of each section and each intersection shown as follows.

$W_{r1}=\{0.2272,02311,0.2853,0.2563\}$, $W_{r2}=\{0.2718,0.2105,0.2717,0.2459\}$, $W_{r3}=\{0.2543,0.2300,0.2420,0.2735\}$, $W_{r4}=\{0.2075,0.2469,0.2717,0.2738\}$, $W_{r5}=\{0.2709,0.2318,0.2508,0.2469\}$, $W_{r6}=\{0.2501,0.2349,0.2488,0.2661\}$.

$W_{cr1}=\{0.2380,0.2581,0.2351,0.2688\}$, $W_{cr2}=\{0.2281,0.2748,0.2393,0.2576\}$, $W_{cr3}=\{0.2347,0.2411,0.2227,0.3015\}$, $W_{cr4}=\{0.2101,0.2272,0.2573,0.3054\}$, $W_{cr5}=\{0.1928,0.2388,0.2122,0.3561\}$.

According to Eq. (7) , (8) and (9), the attribute measure spaces of each section and each intersection shown as follows.

$u_{r1}'=\{0.7212,0.4596,0.4279,0.0404\}$, $u_{r2}'=\{0.0153,0.4578,0.4847,0.0421\}$, $u_{r3'}=\{0,0.3665,0.5,0.1335,0\}$, $u_{r4}'=\{0,0.1358,0.5,0.3641,0\}$, $u_{r5}'=\{0,0.0116,0.4983,0.4884,0.0017\}$, $u_{r6}'=\{0,0,0.4158,0.5,0.0842\}$, $uc_{r1}'=\{0,0.1262,0.4415,0.3631,0.1399\}$, $uc_{r2}'=\{0,0.1140,0.4393,0.3780,0.1655\}$, $u_{cr3}'=\{0,0.0768,0.3434,0.4117,0.2370\}$, $u_{cr4}'=\{0,0.0456,0.2872,0.4449,0.3092\}$, $u_{cr5'}=\{0,0.0239,0.2631,0.4699,0.3665\}$.

With reference to score criterion, ranking the state of traffic congestion.

Section(6)>section(5)>section(4)>section(3)>section(2)>section(1),intersection(5)>intersection(4)>intersection(3)>intersection(1)>intersection(2).

5 Conclusions

The method of attribute mathematical was used to recognize the state of urban traffic congestion on the basis of the influence factor index system. On the one hand, the result shows that this method can solve such problems effectively. On the other hand, the model can be used to sort the result of traffic congestion evaluation for each road and each intersection.

At a macroeconomic level the model can be used for the urban traffic management in order to compare different parts of the traffic states. On the micro level, the model can analysis the states of each section and each intersection independently.

Abstract: It is an important premise to identify and predict traffic flow instantly and accurately in ITS. Therefore, it is of great significance to realize the control and induction of ITS. Aiming at the intersection short-term traffic volume forecasting problem, we proposed the combined model prediction algorithm based on the analysis of traffic flow sequence partition and neural network model. This algorithm divides the traffic volume into different patterns along the time and volume dimension by clustering analysis, and then describes and predicts traffic flow value according to different patterns. The experiment results on real data set demonstrate that our algorithm based on the combination model is more accurate.

Keywords: Intelligent transportation system; Traffic flow prediction; Clustering analysis; Neural network.

1 Introduction

So far, researchers have proposed many short-term traffic flow prediction models. In 1981, Stephanedes put forward History Average Model to predict short-term traffic flow; In 1991, Davis utilized K neighbor weight function nonparametric regression model based on Euclidean distance to predict short-term traffic flow value; In 1993, Kim put forward highway traffic flow forecasting method based on ARIMA model; In 1999, Williams applied ARIMA model to predict sections of single point traffic flow; In 2002, Smith compared parameters regression and nonparametric regression model, pointing out that with the data' amount increasing, better nearest neighbor value can be obtained, different state classification definition and distance function had a promoting effect on prediction effect. Yin proposed a fuzzy neural network model to predict urban traffic network flow. Fuzzy clustering was used to analysis on the input data. Building relationships between the clustering and prediction value by using neural network, so as to achieve the result and reduce the complexity of prediction (LU, 2009).

For short-term traffic flow prediction problem in intersection, this paper proposed traffic volume prediction algorithm based on traffic flow sequence partition and neural network. The algorithm firstly uses the clustering method to divide traffic flow mode in time and space dimensions, then adopts the neural network method to model and forecast each traffic flow mode.

2 Traffic Flow Sequence Partition

Traffic flow data are time series, and are segmented according to the characteristics of time series data change. The most commonly used time series partition method is piecewise linear description (LI, 2002). Choosing K - means clustering algorithm as the basis of sequence partition algorithm (YU, 2012), the basic idea of K-means clustering algorithm is as follows:

(1) All the traffic flow data is sorted according to the size of flow rate value. Choose K - means clustering algorithm as the basis of clustering partition algorithm, using Euclidean distance as the clustering distance unit.

(2) Generate three clusters: C_1、C_2、C_3 according to previous step. C_1 is clustered into 2 clusters, C_2 into 3 clusters, C_3 into 2 clusters according to the size of $C_1 > C_2 > C_3$, but the size of each cluster is ordered based on time, so poly C_1 and C_2 into 5 clusters.

(3) After two steps' clustering, poly a day's flow values into 7 clusters. Although there are overlaps between clusters, distinguish their order from time series.

(4) Calculate mass's center and each cluster's quality. The abscissa of mass's center is for time, ordinate of mass's center is for the average of flow. The quality of cluster is the number of objects in each cluster according to the abscissa of mass's center , donated by t_1、t_2、t_3、t_4、t_5、t_6、t_7, the corresponding qualities are m_1、m_2、m_3、m_4、m_5、m_6、m_7.

(5) Calculate according to the formula (1).

$$t_1^* = t_1 + \left|\frac{m_1}{m_2 - m_1}\right| \times (t_2 - t_1) \qquad (1)$$

3 The BP Neural Network Prediction Model

BP neural network in traffic prediction research has made some achievements. Its prediction accuracy is superior to traditional ARIMA model, but inferior to the nonparametric regression method (HAN, 2004). Therefore the BP neural network is chosen as the intersection of short-term traffic flow prediction model. The BP algorithm is one of the most commonly used feed-forward neural network learning algorithm. In the practical application of artificial neural network, there are a lot of artificial neural networks adopting BP network or its changed form, figure 1 is the framework of the BP neural network diagram and the single neuron model.

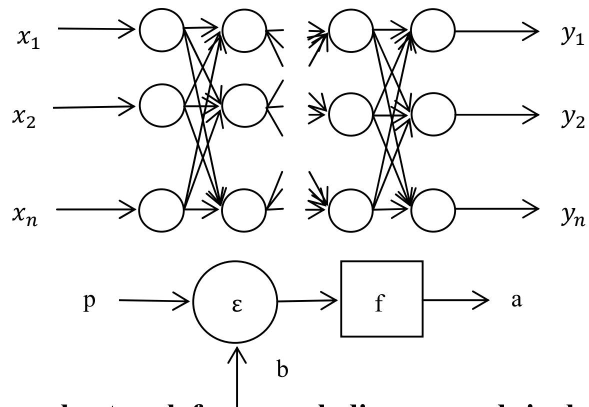

Figure1. BP neural network framework diagram and single neuron model

The characteristics of BP neural network model are: neurons in each layer only have connections with adjacent layer neurons; neurons in the same layer have no connections with each other; neurons in each layer have no feedback connections. BP neural network can be divided into three layers: input layer, hidden layer and output layer. Original weight value and threshold value are given arbitrarily. The two values need to be adjusted to make network's actual output and desired output consistent gradually.

The BP neural network learning is based on samples, including input part and output part. The input layer plays a role of buffer and storage. Data source can be put into neural network directly or after process, and neural network input node depends on the dimensions of input data. Therefore, node number of input layer mainly revolves around the actual demand; neurons number in output layer depends on the result of model dealing.

The basic idea of BP algorithm is through continuous processing of training sample set, calculate the result of output layer and the expected results error. For each training sample, change the weight so as to make the square error between network output and actual category with minimum mean constantly. Reverse is transmitted to the input layer node. In turn, reference error is calculated for each link node, connection weights are adjusted accordingly. Namely, the network learning process can be divided into two propagations: the forward propagation and the error back propagation (SONG, 2009).

The forward propagation: calculate each unit's input and output value in hidden layer and output layer;

The error back propagation: reflect network prediction error and back propagation error by updating weights and bias.

Specific steps are as follows:

① Initialize weights: the adjustable parameters are initialized to smaller random numbers.

② Make following calculation for each input sample:

a. Forward propagation input：calculate net output and net input of each unit in hidden layer and output layer. Net input of each unit in hidden layer and output layer is calculated by linear combination of its input, as shown in figure 2.

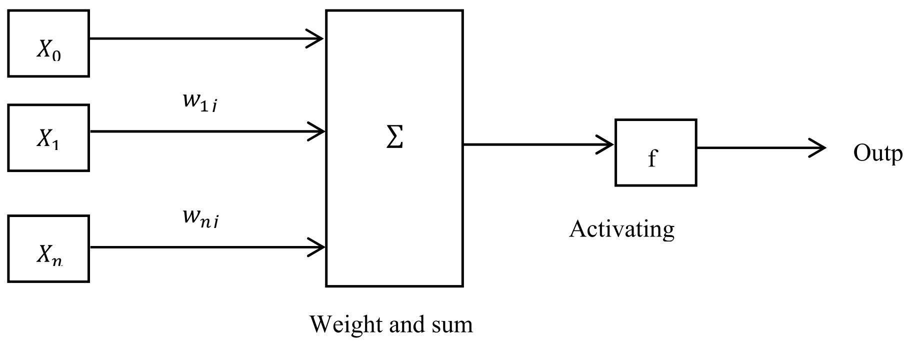

Figure 2. Linear combination process

For a given unit j in hidden layer or output layer, the net input I_j to unit j equals each output connected with this unit multiplies its corresponding wrights, then sum:

$$I_j = \sum_i w_{ij} O_i + \theta_j \tag{2}$$

where w_{ij} the connecting weight from unit *i* in last layer to unit j; O_i is the output of unit i in last layer; θ_j is the deviation value of unit j.

b. Calculate transmission error: reflect network prediction deviation by updating weight and bias, propagate errors backward.

c. Weight correction: the purpose is to reflect error in propagation. The correction formula is as follows:

$$\Delta w_{ij} = (l) Err_j O_i \tag{3}$$

$$w_{ij} = w_{ij} + \Delta w_{ij} \tag{4}$$

where Δw_{ij} is changing value of w_{ij}; l is learning rate, ranging from 0 to 1.

③Judge whether the error converges to required precision. If so, it's over; or input the next round of samples and turn to step ②.

4 Traffic Flow Prediction Portfolio Model

The current limitations of neural network reflect on the following several aspects. First of all, because the neural network model is almost made up by multiple sets of section function, the input and output data between prior knowledge are difficult to integrate into the model and have a certain influence on identification accuracy; Second, a lot of original cleaning data is needed in the process of training, making it difficult to establish the model. Therefore, the BP neural network method has some deficiencies from practical engineering application. In short-term traffic flow prediction, when the road network condition and traffic condition are changed, the trained network is properly updated so as to forecast better. At the same time, the current network type selection and determination of the network structure still lack of guidance in theory, so we need to match experience with theory. In addition, the neural network framework is complex. Precision and approximation ability are relatively high, so the calculation and training time is quite long. There is difficulty in real-time prediction, but the network framework is simple. It is also difficult to guarantee accuracy requirement and solve the problem that the each model has its applicability. Because the complexity of the road is different from other road traffic and particularity, the BP neural network forecasting accuracy of short-term traffic flow has to be improved.

Traffic flow portfolio model is the combination of traffic flow sequence partition and BP neural network model. The specific idea is: on the basis of using traffic flow sequence partition algorithm, use the BP neural network as prediction algorithm for modeling and predict with session data.

5 The Experiment and Analysis

Use a week's traffic flow data of intersection between People's South Road and one ring road in Chengdu City as training samples of BP neural network. Establish BP neural network for each split range. In the prediction of traffic direction, regard the first five time unit value as the input of BP neural network, the next unit of time value as output. Namely, input variables are five, and output variable is one. The BP neural network chooses a three-layer neural network framework, including input layer, hidden layer and output layer. Unit number in hidden layer is seven. Traffic flow prediction result is shown in figure 3:

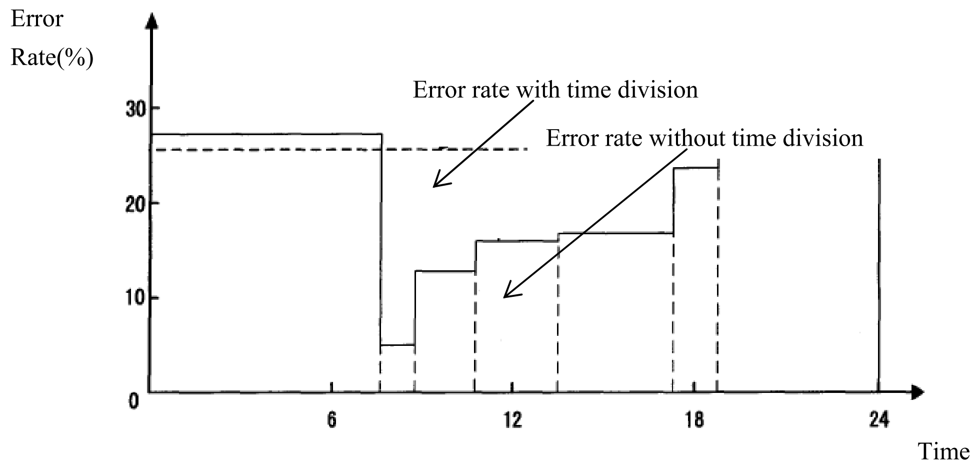

Figure 3. Traffic flow prediction based on traffic flow sequence partition

Prediction error rate above the dotted line in figure 3 is 25.78% without using quadratic clustering algorithm. Seven phase functions in solid line show the forecasting accuracy after a separate modeling with time division. Table 1 shows the detailed instructions.

Table 1. Traffic prediction accuracy based on traffic flow sequence partition

Period of time	0：00-7:30	7:30-8:50	8:50-10:50	10:50-14:00
Error rate（%）	28.22	4.45	13.15	18.08
Period of time	14:00-17:30	17:30-18:50	18:50-24:00	
Error rate（%）	18.95	25.57	28.22	

Through the combination of sequence partition algorithm and BP neural network model to predict traffic flow, we find that two dimensional clustering algorithm of traffic flow model depends on the traffic flow distribution according to flow rate and time. It is easy to draw traffic bimodal shaped by observing: one is early peak, another is late peak. Traffic flow value size clustering can be divided into several classes, so as to distinguish peak flow, largest flow of traffic information, especially for the city's main road. General speaking, traffic signal timing plans are not set fixedly, it can be adjusted in all directions automatically. This state change can be reflected by the size of the traffic flow change indirectly. Secondly, the clustering partition on the time dimension can clearly be divided by the data of early peak and late peak.

6 Conclusions

The experimental result shows there is little difference between two kinds of forecasting methods in low flow period. In other times, traffic flow prediction method's error rate based on combination model is greatly reduced, especially in the early peak, so that the traffic flow prediction accuracy in rush hour can reach to 85%. Therefore, traffic volume prediction algorithm based on traffic flow sequence partition and neural network can meet the needs of the traffic management and forecasting effectively.

Dynamic Response of the Track Irregularity State in a Subway Turnout Zone

Bin Zhang[1,2] and Yanyun Luo[1]

[1]Institute of Railway and Urban Mass Transit, Tongji University, Shanghai 201804, China. E-mail: alva0910@163.com
[2]Engineering Research Center of Railway Environment Vibration and Noise, Ministry of Education, East China Jiaotong University, Nanchang 330013, China. E-mail: zhangbin010@126.com

Abstract: Aiming at the environmental vibration problems of turnout zone, the vibration equations for vehicle and turnout system are developed respectively by means of finite element method and Lagrange equation. According to irregularities characteristics of turnout structure, the wheel/rail contact geometry is introduced to the vehicle-turnout coupling system. Then the computational software is coded with Matlab. Dynamic responses of the irregularities state are analyzed. The calculation results show that large impact of vehicle-turnout system is produced when vehicle passing through the switch area and frog area. The vertical geometric irregularity of turnout has significant influence on wheel/rail interaction force, where turnout wear aggravates this dynamic action. To improve the turnout working state and reduce the maintenance cost, the occurrence and development of wear in frog area should be controlled strictly.
Keywords: Turnout; Irregularity state; Dynamic response; Wheel/rail interaction force.

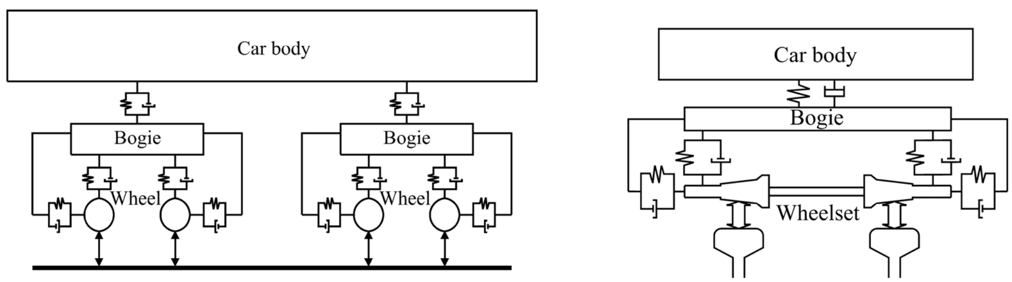
1 Introduction

Turnouts are an important part of the subway track system. Due to the use of high frequency and complex structure, turnout life is shortened greatly, which has a major influence on the maintenance costs of the tracks. Additionally, there are often only small time intervals available for service of turnouts in the track during the night. In turnout zone, a vertical impact of the wheel on the switch area and frog area occurs. The subway company's goal is to optimize the impacts to minimize the dynamic effects. The objectives of operations management have been paid widely attention to by researchers at home and abroad. More recently, the dynamic interaction between train and turnout was simulated by comparison of simulations performed using multi-body software GENSYS and FEM software DIFF3D (Kassa, 2006). The behavior of a vehicle passing a turnout to determine the influence of gauge-widen design on wheel/rail contact relationship was studied (Cao, 2011).

However, for a complex system such as Hadfield steel frog it is a daunting task to develop realistic numerical model. Dynamic vehicle-track interaction in turnout is far more complex than on ordinary tangent or curved track. To further understand the impact damage, a simulation model of the China No.12 turnout is developed to predict magnitude of impact force in this paper. Finally, several advices are advanced for maintenance in subway turnout zone.

2 Vehicle Model

Vehicle system is assumed to be a multi-body dynamic model with primary and secondary suspensions, where mainly references B-type metro vehicle in the process of establishing the model. It contains three components: car body, bogies and wheel sets. The car body and two bogies are both modeled with consideration of swinging, floating-sinking, side rolling, nodding and yawing. The wheel sets are modeled with consideration except nodding. That is, 6-degrees of freedom of the car body, bogie frame and 5-degrees of freedom of the wheel set are included in the model, for a total of 31. The dynamic analysis model of vehicle is shown in Figure 1.



(a) Elevation view (b) Side view

Figure 1. Vehicle model

3 Turnout Model

When dealing with vehicle-turnout interaction, rail profile variation along the track has to be considered. The wheel sets generate vertical movement while passing through the turnout, due to the transition from stock rail to blade rail and from wing rail to nose rail. That way, the rail profile sudden variation leads to high wheel/rail contact force, where wear of turnout tends to exacerbate the effect.

Rail profiles of No.12 turnout are measured by Calipri device. With this device, at some 100 positions on the left and right rails in the main route have been measured, including both new profiles and worn profiles. Track gauge is also measured at these positions. The sampling positions are shown in Figure 2. Figure 3 shows the measured rail profiles on the right rail (facing move) in the switch and frog area of the main route. Then, the rail profiles are represented by cubic parametric B-splines. Besides that, in order to obtain arbitrary section profiles along the track, an interpolation method is used, where its strategy is to interpolate the rail profile between two measured cross-sections. The rail profiles of switch area are plotted in Figure 4.

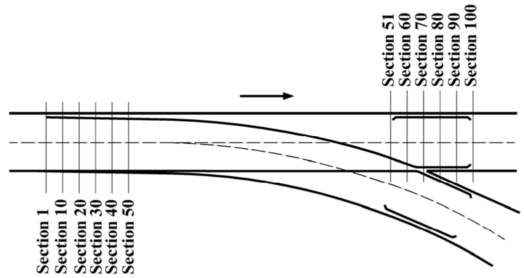


Figure 2. Sampling positions along the track

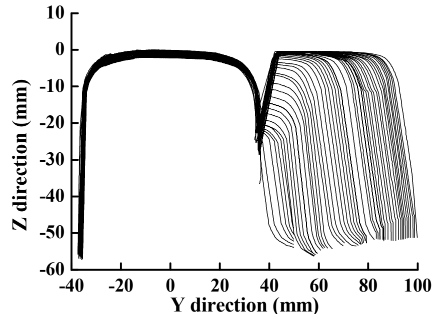

Figure 3. Measured rail profiles

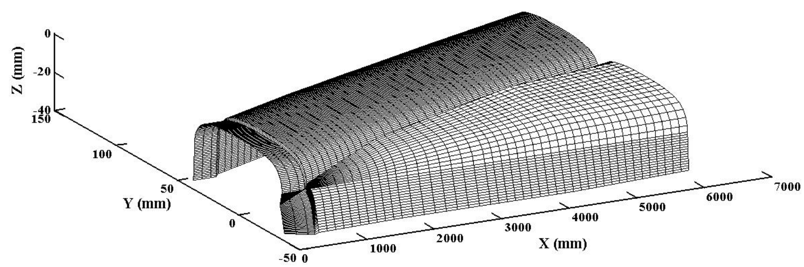

Figure 4. Rail profiles of switch area

Rail structures of the turnout, including stock rail, blade rail, nose and wing rails, and check rails, are discretized by neighbor fasteners on sleepers. Then, they are modeled by Euler beam elements, where one element has 4-DOFs, vertical displacement and slope, lateral displacement and slope. Turnout sleeper is viewed as rigid mass block in horizontal direction with 1-DOF of lateral displacement, and divided into finite beam elements in vertical direction with 2-DOFs of vertical displacement and slope.

4 Numerical Solution of Equations

As previously discussed, the dynamic interaction of vehicle-turnout coupling system is highly influenced by the rail profile variation, where it has significant implications on wheel/rail contact geometry. The contact parameters between wheel and turnout rails can be obtained by the wheel/rail contact point trace method (Ren, 2010), where the contact points are determined by a spatial curve.

According to the principle of Hamilton, finite element equation for vehicle system can be obtained,

$$\boldsymbol{M}_V \ddot{\boldsymbol{a}}_V + \boldsymbol{C}_V \dot{\boldsymbol{a}}_V + \boldsymbol{K}_V \boldsymbol{a}_V = \boldsymbol{Q}_V + \boldsymbol{F}_{VT} \tag{1}$$

Where, $\boldsymbol{M}_V$, $\boldsymbol{C}_V$ and $\boldsymbol{K}_V$ is the corresponding mass matrix, damping matrix and stiffness matrix for vehicle model; $\ddot{\boldsymbol{a}}_V$, $\dot{\boldsymbol{a}}_V$ and $\boldsymbol{a}_V$ is the acceleration vector, speed vector and displacement vector; $\boldsymbol{Q}_V$ is the gravity vector for vehicle model; $\boldsymbol{F}_{VT}$ is the interaction force between vehicle and track.

The finite element dynamic equation for the turnout system can be written as

$$\boldsymbol{M}_T\ddot{\boldsymbol{a}}_T + \boldsymbol{C}_T\dot{\boldsymbol{a}}_T + \boldsymbol{K}_T\boldsymbol{a}_T = \boldsymbol{F}_{TV} \tag{2}$$

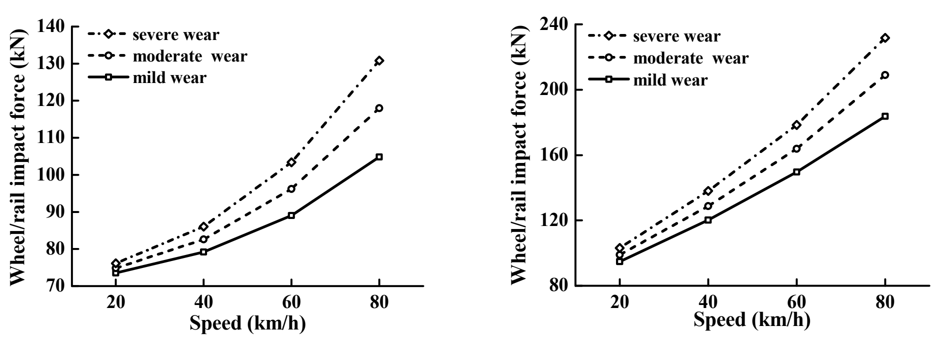
Where, $\boldsymbol{M}_T$, $\boldsymbol{C}_T$, $\boldsymbol{K}_T$ and $\boldsymbol{F}_{TV}$ is the global mass, damping, stiffness, load matrices of turnout subsystem, which is assembled by each element matrices of mass, damping, stiffness and load.

The model of vehicle-turnout coupling system is defined in time domain. The equations of motion for these two subsystems are written separately, where it can solve them independently with an iterative scheme. The vertical wheel/rail contact is coupled by non-linear Hertz contact force, and the lateral is coupled by tread creep force. A rapid method for solving the coupling system vibration response with the improvement of Newmark-β integration can be adopted (Yang, 1996).

5 Examples of Simulation Results

As an application example of the results provided by the modeling method proposed in the paper, vertical impact is considered for No.12 turnout from a subway line negotiated by a B-type vehicle. To comprehensively understand dynamic responses of the vehicle and track coupling system in turnout zone, the following influence factors will be studied: 1) average driving speed, V=20, 40, 60, 80 km/h; 2) the level of wear, mild wear, moderate wear and severe wear, in switch area and frog area respectively; 3) passenger weigh criteria, considering AW2 condition (full load, the vehicle axle load is 14.15 ton) and AW3 condition (crush load, the vehicle axle load is 15.98 ton). The different calculation conditions depicted above will be considered in the analysis of the simulation results presented below.

Results of the computation for the influence of wear under different average driving speed on the wheel/rail impact force in switch area and frog area are shown in Figure 5.

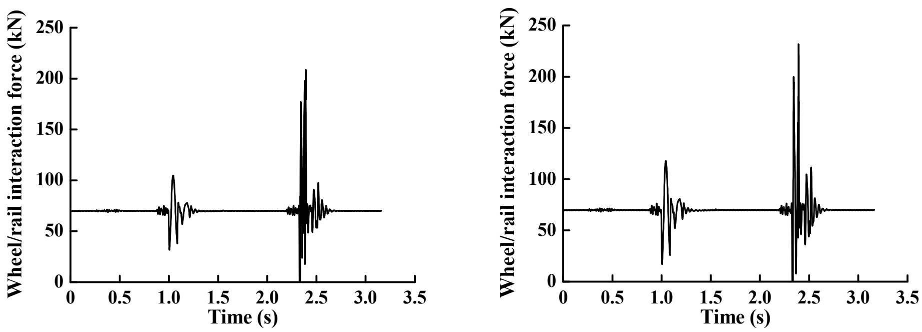


(a) Wheel/rail impact force in switch area (b) Wheel/rail impact force in frog area

Figure 5. Influences of wear and speed on the wheel/rail impact force

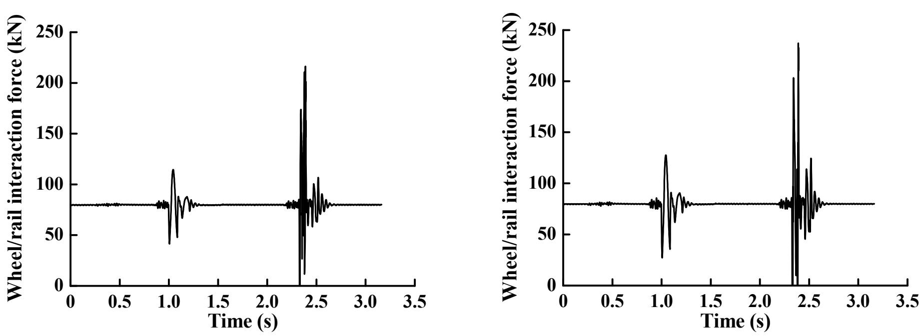
Figure 5 shows that the abrupt change of the rail profiles in two areas has significant influences on the wheel/rail impact force. Severe impact occurs during the vehicle passing over the turnout, which may produce damage of the contact surfaces. Rail profile variation is relatively shorter length of the frog area than the switch area, which will lead to sudden transfer of the contact points and cause higher wheel/rail impact force. Additionally, the level of wear tends to exacerbate the effect, but the influences increase dramatically as the average driving speed increases.

Based on long-term observations in the field, two calculation conditions are discussed with the different passenger weigh criteria. Case 1 is mild wear in both switch area and frog area; Case 2 is moderate wear in switch area and severe wear in frog area. The constant speed of the vehicle V=80 km/h is specified for these simulations. The results computed by varying passenger weigh criteria on the dynamic response of the wheel/rail interaction force have been plotted in Figure 6 and Figure 7.



(a) Calculation condition of Case 1 (b) Calculation condition of Case 2

Figure 6. Influence of AW2 condition on wheel/rail interaction force



(a) Calculation condition of Case 1 (b) Calculation condition of Case 2

Figure 7. Influence of AW3 condition on wheel/rail interaction force

As shown in Figures 6 and 7, two peak values can be observed in the positions of the abrupt change of the rail profiles and hence impact will be induced there. A large impact occurs between the vehicle and the frog, even in presence of an ideal geometry, producing high dynamic loading of the wheel and track in the vertical direction. Increasing the vehicle axle load will significantly strengthen external shocks, where the wheel/rail interaction force will reach 0kN in transient time duration. Meanwhile the level of wear has a certain influence on the magnitude of wheel/rail interaction force. The vehicle axle load, by contrast, is the main factor of further damage. From reducing impact and improving traffic operation's point of view, it should be paid attention to the relationship between the vehicle axle load and the evolution of rail wear.

6 Conclusions

With the aim of increasing the understanding of the complex interaction between vehicle and turnout, two models for dynamic analysis of vehicle-turnout coupling system are developed. As application examples, vertical impact of No.12 turnout from a subway line is investigated. The numerical results demonstrate that the rail profiles variation has significant influence on impact force between vehicle and turnout. In the meantime, operational system parameters, such as average driving speed, wear level, passenger weigh criteria, may accelerate the process of turnout damage. Further, it is expected that the vehicle-turnout coupling model can be applied to guide maintenance in turnout zone, and that the maintenance cost will then reduce.

Data Model of 3D Geological Modeling and Realization

Xikui Lv; Peipei Sun; and Xiaoping Zhou

School of Traffic and Transportation, Shijiazhuang Tiedao University, 17 Northeast, Second Inner Ring, Shijiazhuang, Hebei 050043, P.R. China. E-mail: Lvxikui@163.com

Abstract: The displaying of three-dimensional geological body can describe the complex subsurface geological structure visually, improve the engineer's space imagination effectively, understand the geological spatial relationship more intuitive and design more reasonable. The paper analyzed the three-dimensional geological data model usually used, established a Generalized Triangular Prism (GTP) element model and considered the impact of faults, Set up a three-dimensional geological modeling method based on GTP. Achieved a three-dimensional geological drilling, borehole cross-section and other information visualization inquiry and geological cutting, excavation, hierarchical display and other visualization techniques based on three-dimensional spatial analysis techniques and graphics.

Keywords: Geological; Three-dimensional modeling; Visualization; Generalized triangular prism; Spatial analysis.

1 Introduction

Design and construction of railway engineering generally face complex geological condition, traditional analysis and interpretation of engineering geological data is generally restricted to two-dimensional and static expression, the visibility of description of spatial geological structure fluctuation is poor, usually cannot fully reveal the law of spatial changes, and it is difficult to understand the geological environment directly, completely and accurately. So it cannot meet the demand of engineering design personnel for spatial analysis (LI Mingchao, 2007). Building of three-dimensional geological model can directly describe the complex underground geological tectonic situation. enhance maximize the visibility and the accuracy of geological analysis allows the designer to make engineering design and construction scheme in line with the actual geological phenomena in the distribution and the change rule, reduce the project risk.

2 Engineering geological 3D data model

Due to the complexity of geological body itself and multiplicity of description, thus formed a variety of spatial modeling methods and a variety of data model. At present, the 3D geological data model is mainly including three kinds: based on face expression (Surface-based), based on the body (Voxel-based) expression and mixed structure data model(XIONG Zuqiang, 2007).

2.1 The overview of 3D data model

The 3D data model is directly related to the functionality of three-dimensional geological modeling and the possibility spatial analysis, and provides the basic support for visual expression and analysis of 3D geological modeling and 3D geological data. A good 3D geological data model, must meet the following conditions(XIONG Zuqiang, 2007): ① can correctly, accurately express the geological body, including geological semantics (Geological semantics); ② ensure operational efficiency and robustness ; ③ can express the geometry and topology of 3D geological model construction.

2.2 The data model based on surface representation

Data model based on surface representation that is based on boundary of object to define and describe the spatial entities, mainly through the approach of simulation of geological interface, and then combined into a body, focusing on the three-dimensional surface representation. As grid structure, facets model (such as TIN), boundary representation model, wire frame model, a multi-layer DEM model (Lemon A M, 2003; WANG Chunxiang, 2003; LI Shaojun, 2008). The data model based on surface representation is able to display and data update, and the advantages can be realized conveniently strata visualization and model updating, but also has the defect of being not able to describe the 3D topological relation, it is difficult to analyze spatial (A.A.G. Requicha, 1983). Figure 1 and figure 2 are the 3D geological modeling results using the wire frame model and the multilayer DEM model.

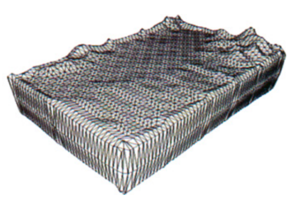

Figure 1. geological body Wire frame model

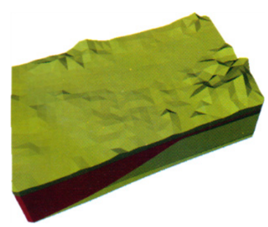

Figure 2. geological body of multilayer DEM model

2.3 The data model based on body representation

The data model based on body representation use the body information instead of surface information to describe the object inside, described the object inside through the body information, focused on the representation of body 3D space. The body element is the most basic unit of composition. According to difference of the body element, it can set up different data model. Mainly includes the 3D grid model, octree model, Constructive Solid Geometry, Tetrahedron Network(Victor J D ,1993; Lemon A M, 2003; CHENG Penggen, GONG Jianya, 2004). Body model with a simple data structure, advantages for space operations and analysis, but the storage space was large; the computing speed is also slow. Figure 3 was mainly several body data structure model of the schematic diagram.

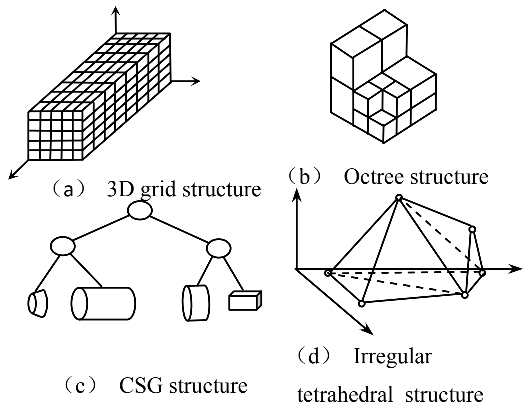

Figure 3. Several body data structure model

2.4 Data model based on the hybrid structure

The Hybrid structure data model comprehensive two or more data models to form an integrated structure data model, such as TIN-CSG,TIN-Octree, TEN-OCtree and Wireframe-Block mixed models and so on (LI Changling，2013). When representing different spatial entity used different data models, advantage of Hybrid model based on the data structure can be effectively complete description of the phenomenon of three-dimensional space. However, due to the complexity and unpredictability of geological spatial objects in practice, it is difficult to make the right choice about the extent of binding of surface and voxel representation. Moreover no good solution in computer, and the excessive stress of complete expression in theoretical dose not conducive to achieving the modeling. Figure 4 is schematic of a hybrid data structure of Octree-TEN.

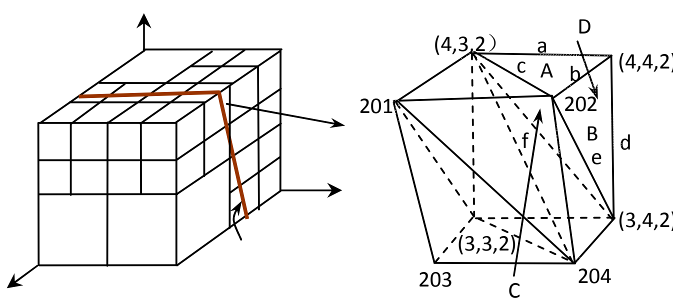

Figure 4. schematic of a hybrid data structure of Octree-TEN

2.5 Analysis of data model

It is obvious that each data model has its own advantages and disadvantages, andifferent applicable scope. Thus the construction of three-dimensional geological model, considering its own characteristics and modeling purposes, should choose a reasonable 3D Spatial Data Model. For example, basing on the long ribbon model of railway lines, the data and methods to build the model should meet the need of space ribbon model characteristics. Therefore, it is particular important to learn how to design three-dimensional data model and structure, which is more easy to implement and suitable for the expression and analysis of circuit.

Because it is geared to the needs of geological modeling, the model can deal with complex geological structure by using the surface, but it is difficult to solve internal properties showing , such as cutting and mining. As well as the surface and body hybrid model just stop at the theoretical level, So the modeling method based on voxel has been more and more adopted. Especially in order to adapt to complex geological model, the improved model based on triangular prism has became the main model of 3D geological modeling. Through exchanged the standard three prism (TP) to meet the needs of the various circumstances of modeling, it named the generalized Tri-Prism.

3 The modeling based on generalized triangular prism model

3.1 GTP model

When used GTP conducted geological modeling, it used the different stratification of borehole data to simulate stratum's hierarchical entity and express stratum form, guaranteed 3D geological modeling accuracy maximize. The GTP model adopt GTP as basic voxel, included six Vertices, edges, TIN triangle, side quadrilateral and triangular prism. The triangle set of GTP bottom surface can express different geological interface, The GTP Side can describe geological spatial adjacencies, morphology and characteristic attributes between ground level. As shown in Figure 5a. Meanwhile for the geological pinch, dislocation and other complex geological modeling, GTP voxels can be deformed, shown in Figure 5 (b) and Figure 5 (c).

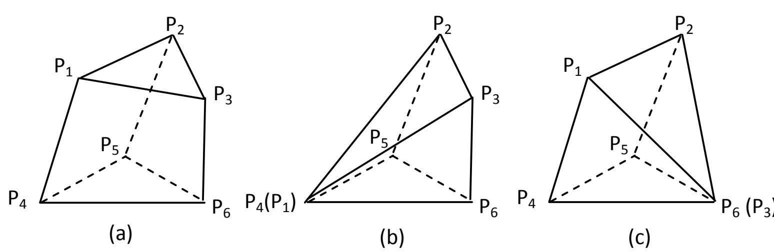

Figure 5. GTP model

Figure 6 shows the GTP-Voxel drawn renderings.

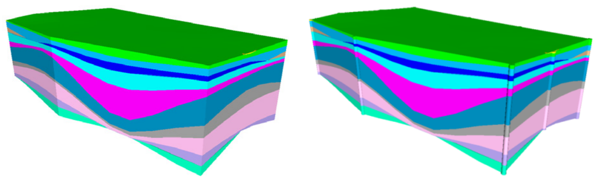

Figure 6. GTP-Voxel drawn renderings

3.2 Three-dimensional geological modeling based GTP

GTP obtained by TIN processing extensions .TIN as constraints controlled the generation process of GTP, expressed the topological relations between voxels and can express the internal structure and properties of three-dimensional geological body . GTP model based on the original borehole data Modeling directly, Make the model more meet with actual geological conditions and ensured modeling accuracy. The three-dimensional geological modeling process based on GTP as shown in Figure 7.

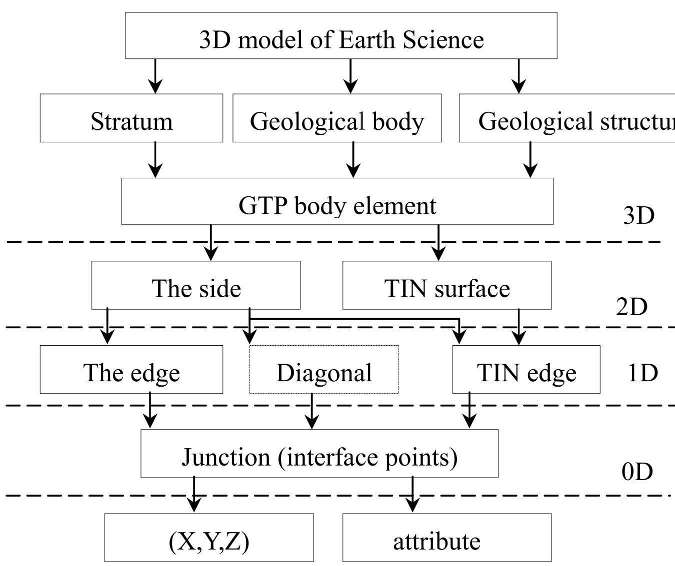

Figure 7. The 3D geological modeling process based on GTP

The thesis adopt GTP-voxel model, achieved the drilling and drilling profile queries shown in Figure 8 and Figure 9, polygon cutting and splitting visualization of model shown in Figure 10 and figure 11 and excavation effect of three-dimensional geological model shown in Figure 12.

Figure 8. 3D drilling map search

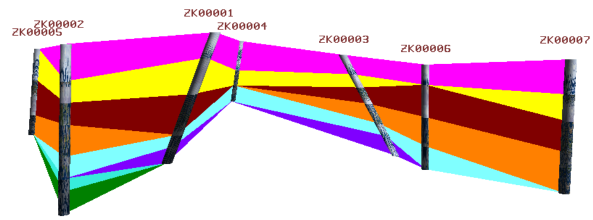

Figure 9. Drilling profile inquiry

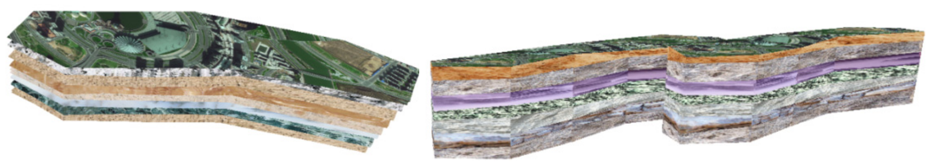

Figure 10. Polygon cutting renderings

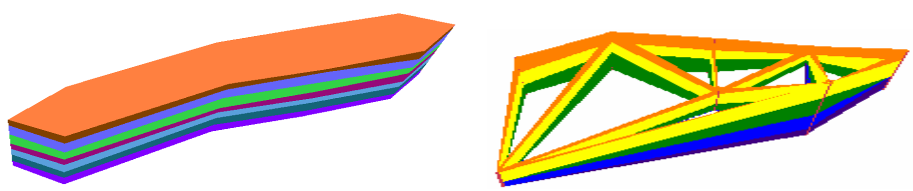

Figure 11. Polygon splitting renderings

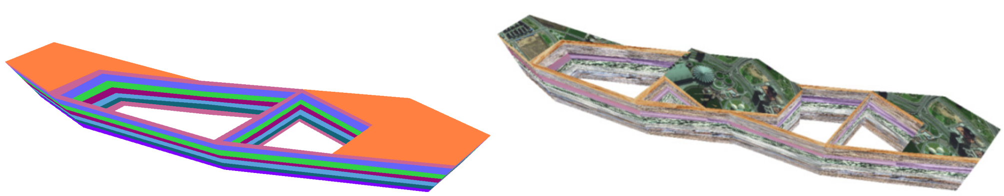

Figure 12. Excavation effect of 3D geological model

4 Conclusions

The theses analyzed the three-dimensional geological modeling features, adopt drilling data as the main data source and achieved a three-dimensional geological modeling method based on GTP. It established the three-dimensional banding geological model which meet the design requirements of railway line, achieved a variety of three-dimensional visualization of the model. The research result opened up an effective way for rapid and real-time reproduction of 3D geology information and visualization comprehensive analysis.

Simulation of Pedestrian Evacuation Flow Based on Crowd Space

Shiwei Li[1] and Huimin Niu[2]

[1]School of Traffic and Transportation, Lanzhou Jiaotong University, P.O. Box 405, Lanzhou 730070. E-mail: lst9647@126.com
[2]School of Traffic and Transportation, Lanzhou Jiaotong University, Lanzhou 730070. E-mail: hmniu@mail.lzjtu.cn

Abstract: Simulation of pedestrian evacuation flow is based on cellular automata model, which defines personal space and information processing space within the field of pedestrian's movement. It uses the pedestrian density to descript evacuation characteristics in the condition of the different environments, in order to determine pedestrian's behavior choice. Furthermore, it analyses system scale, exit's width, pedestrian density and selection strategies on the effect of evacuation time, and observes the self-organization phenomena in the process of simulation. It is shown that the evacuation time is not only influenced by the scale of the system, but also directly with the exit width and selection strategy.
Keywords: Personal space; Information processing space; Cellular automata; Evacuation time; Selection strategy.

1 Introduction

In recent years, there has been a steady growth of interest in concern about pedestrian flow in order to aid the design of pedestrian's evacuation strategy and to optimize the allocation of resources. Helbing (1998, 2000) revealed that a pedestrian could be influenced by three kinds of social forces in the process of movement: (a) repulsive interaction forces between pedestrians, (b) self-driving forces for pedestrians, and (c) attractive forces from collective herding instinct. Based on Helbing's work, Nishihara (2006) took these three kinds of social forces synthesized to two kinds of interaction force field in the process of pedestrian's movement: personal space and information processing space. Yet there have been few studies how to define personal space and information processing space. Consequently, how to present this difference is a subject of much concern.

In studies of pedestrian flow simulation, the model of cellular automata (CA) has widely been used in different kinds of fields, such as pedestrian walkways, traffic intersections, transportation facilities, and other public buildings pedestrian flow. Burstedde (2001) and Schadschneider (2002) proposed a floor field model to describe pedestrian's behavior and self-organization phenomena. Based on their work, Kirchner (2002) modified the transition probability and found a non-monotonic dependence of the evacuation times on the coupling constants. Huang (2008) proposed a floor field model based on the discrete choice model. Peng (2011) presented a multi-floor field to simulate pedestrian flow through a "T" intersection. The essence of these CA models is to study the probability of pedestrians moving to the next target, namely the transition probability.

Based on the basic CA model, this paper aims to define the personal space and information processing space to describe pedestrian's movement in crowd space, and expresses the difference of pedestrian's behavior in the condition of the different environments.

2 Model

The model is described in the $N \times N$ two-dimensional discrete cellular grids system Ω^2, where N is the system scale, Ω^2 is the two-dimensional system. Based on empirical statistics, the size of a cellular grid corresponds to approximately 0.4m×0.4m (Fang, 2003), the average speed of a pedestrian is about 1.00m/s in normal circumstances (Yang, 2008). Therefore, one time-step is approximately 0.4s in this model. In the process of simulation, every pedestrian can wait or move to 8 directions around his neighbors in each time-step of the model's evolution. Therefore, the field of pedestrian's movement is displayed in Figure 1.

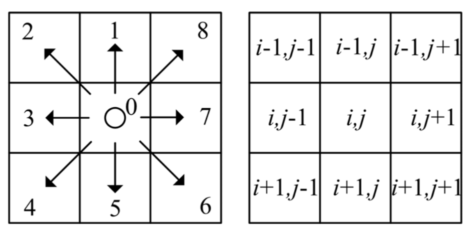

Figure 1. The field of pedestrian's movement

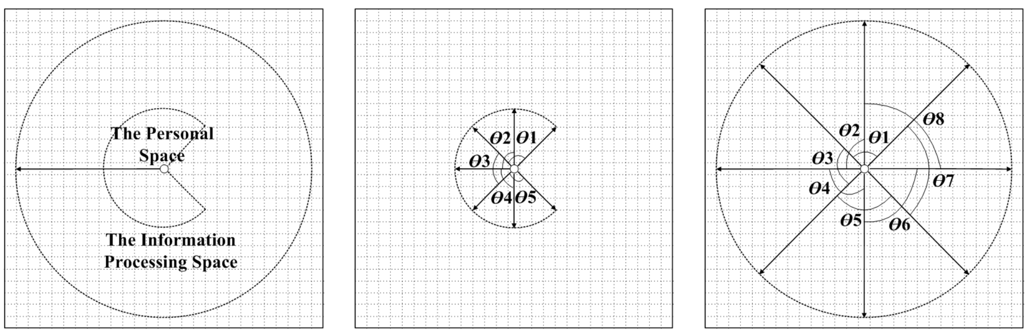
2.1 Crowd Space

Pedestrian's movement is a complex dynamic process. A pedestrian will not only appear to be imitating others moving, but also trying to keep a certain distance with others in the process of movement. This means that there are two forces in the process of pedestrian's movement: (a) a repulsive force field defined as personal space, (b) an attractive force field named as information processing space. In order to define personal space and information processing space in CA, we assume that personal space and information processing space are composed of cellular grids. Supposing the system has enough cellular grids, a pedestrian's personal space is composed of the cellular grids oriented by the shortest distance of exit, which distance is within 2m from his position (Nishihara, 2006). And the cellular grids, which distance from his position is between 0m and 5m, constitute his information processing space (Nishihara, 2006). If a pedestrian is near the wall, we assume that there is a non-existent cellular grid occupied by a virtual pedestrian. In personal space, we assume that there are non-existent cellular grids occupied by pedestrians, this hypothesis demonstrates that walls have repulsive force to pedestrians, and pedestrians do not like to crowd near the wall. In information processing space, we assume that there are non-existent cellular grids occupied by pedestrians, this assumption shows that walls have attractive force to pedestrians, and pedestrians think they will effectively reach an exit along walls. Therefore, there also has two kinds of interaction force fields to influence on pedestrian's movement. In empirical statistics, the maximum angle of vision range on each direction is roughly 90 degrees. Therefore, the crowd space are shown in Figure 2 when the shortest distance of exit is in the left side.



(a) (b) (c)

Figure2. The crowd space in CA. (a) the personal space and the information processing space; (b) the personal space; (c) the information processing space

In personal space, we define the void density of every 8 direction's corresponding cellular grids in personal space to describe this repulsive force. If P is $\forall$ a pedestrian, these densities are expressed as $\dot{\rho}_d^P$, $d\,(d=0,1,\cdots,8)$ is a optional direction as shown in Figure 1. Thereinto, $\dot{\rho}_0^P$ is set zero. When the shortest distance of exit is in the left side, $\dot{\rho}_6^P=\dot{\rho}_7^P=\dot{\rho}_8^P=0$. When the shortest distance of exit is in the right side, $\dot{\rho}_2^P=\dot{\rho}_3^P=\dot{\rho}_4^P=0$. When the shortest distance of exit is in the upper side, $\dot{\rho}_4^P=\dot{\rho}_5^P=\dot{\rho}_6^P=0$. When the shortest distance of exit is in the lower side, $\dot{\rho}_1^P=\dot{\rho}_2^P=\dot{\rho}_8^P=0$. Because these direction's corresponding cellular grids are not in the pedestrian's vision range.

In information processing space, we define the same direction's pedestrian density of every 8 direction's corresponding cellular grids in information processing space to demonstrate this attractive force. If P is $\forall$ a pedestrian, these densities are expressed as $\ddot{\rho}_d^P$. And $\ddot{\rho}_0^P$ is set zero.

2.2 Direction Force Parameter

In order to synthesize a repulsive force of personal space and an attractive force of information processing space, we assume that P is $\forall$ a pedestrian in Ω^2, (i,j)

is his current position's coordinate, his 9 optional position's coordinate is $(x, y) \in \{i-1, i, i+1\} \times \{j-1, j, j+1\}$. Then we have

$$F_d^P = \begin{cases} 0, & d = 0 \\ \omega\xi\dot{\rho}_d^P + (1-\omega)\eta\ddot{\rho}_d^P, & d = 1, \cdots, 8 \end{cases} \quad (1)$$

It is called the direction force parameter of P on direction d. Thereinto, $\{i-1, i, i+1\} \times \{j-1, j, j+1\}$ is shown the set of Cartesian product between $\{i-1, i, i+1\}$ and $\{j-1, j, j+1\}$, ω $(0 \le \omega \le 1)$ is the inertia weight, ξ and η are the random numbers extracted evenly in the range of [0, 1].

2.3 Distance Parameter

This paper calculates the Euclidean distances from every cellular to the exits in the calculation of distance parameter. This calculation process is shown in Eq. (2), where (x, y) is $\forall$ a cellule's coordinate in the system, D_{xy} is the shortest distance from a cellular (x, y) to the exits, (x_w^e, y_w^e) is coordinate of the cellular w in the exit e.

$$D_{xy} = \min_e(\min_w(\sqrt{(x - x_w^e)^2 + (y - y_w^e)^2})) \quad (2)$$

If P is $\forall$ a pedestrian, (i, j) is the current position's coordinate, his 9 optional position's coordinate is $(x, y) \in \{i-1, i, i+1\} \times \{j-1, j, j+1\}$. The shortest distances of P moving to 9 optional positions are shown in Eq. (3), where S_d^P is the shortest distance from the cellular (i, j) to a cellular (x, y) in the process of P moving to 9 optional positions.

$$S_d^P = \begin{cases} 0, & d = 0 \\ \dfrac{\left|D_{ij} - D_{x,y}\right|}{1}, & d = 1,3,5,7 \\ \dfrac{\left|D_{ij} - D_{x,y}\right|}{\sqrt{2}}, & d = 2,4,6,8 \end{cases} \quad (3)$$

2.4 Moving Profit

The model calculates direction force parameter F_d^P and distance parameter S_d^P of 9 optional positions in every pedestrian's neighbors. Furthermore, it obtains moving profit E_d^P of every cellular grid as shown in Eq. (4).

$$E_d^P = F_d^P + S_d^P \quad (4)$$

2.5 Selection Strategy

When multiple pedestrians simultaneous choose a void cellular grid to access, there is conflict among these pedestrians. In the real world, there are mainly two kinds of selection strategy.

(1) The competitive strategy: it will randomly select a pedestrian based on the same probability to access this void cellular grid, while not having selected

pedestrians will hold their positions in the next time-step.

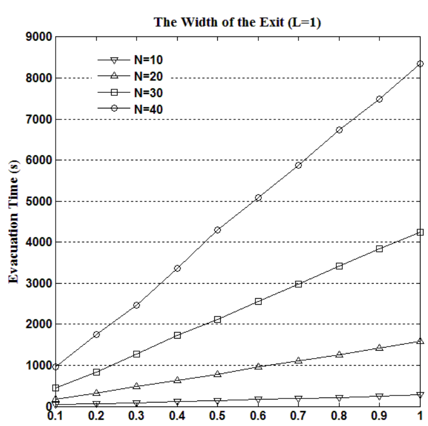
(2) The concessional strategy: it will select a pedestrian, who has the maximum direction force parameter, to access this void cellular grid.

3 Simulation and Analysis

In the process of simulation, the model assumes that there are not have obstacles in the system and every pedestrian sight is not affected. Pedestrian density K is defined as the value of the total number of pedestrians divided by the total number of cellular grids $N \times N$. Pedestrian evacuation time T is described as the required time of all pedestrians leaving the system. L is expressed as the width of the exit. In process of the simulation, we take the average value of operated 20 results as statistical index in order to reduce the effect of initial condition on the statistical indexes.

3.1 Experiment 1

When the simulation chooses the competitive strategy, this paper studies the curves of pedestrian evacuation time T changing with pedestrian density K as demonstrated in Figure 3, based on $N = 10,20,30,40$, only one exit from the system, and $L = 1,10$. In the case of fixed the exit's width from the system, there is an increasing trend in the process of pedestrian evacuation time changing with pedestrian density. This increasing trend approximately obeys the linear function. The pedestrian's evacuation time has significant difference in the condition of different system scale. It is shown that the system scale is a key factor on pedestrian evacuation time.



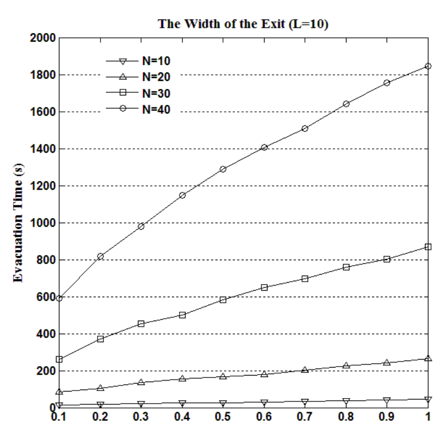


Figure 3. The curves of pedestrian evacuation time changing with pedestrian density based on different system scale

3.2 Experiment 2

When the simulation chooses the competitive strategy, we study the curves of pedestrian evacuation time T changing with the width of the exit L as demonstrated in Figure 4, based on $N = 10,20,30,40$, only one exit, and $K = 0.4,0.6$. In the case of fixed the pedestrian density, pedestrian evacuation time is approximately negative exponential decreasing trend changing with the width of exit. The pedestrian evacuation time has significant difference in the condition of different system scale. It expressed that expanding the width of the exit is the effective way to control pedestrian evacuation time in the case of big gatherings.

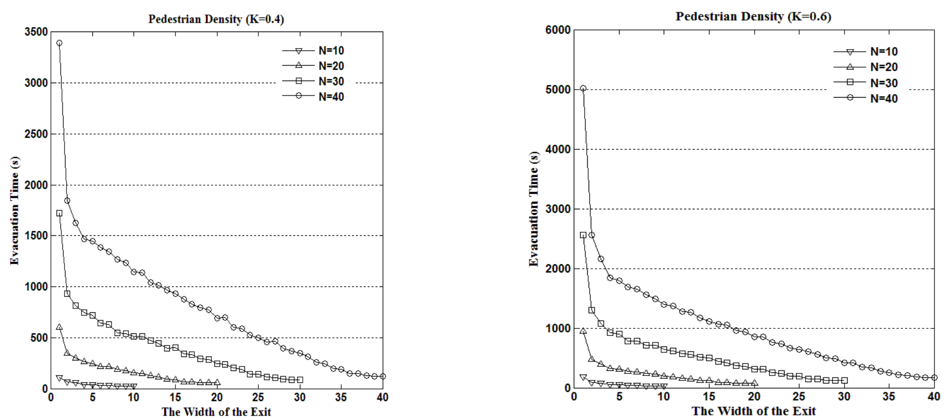

Figure 4. The curves of pedestrian evacuation time changing with the width of the exit based on different system scale.

3.3 Experiment 3

In the case of only one exit from the system, this paper studies the curves of pedestrian evacuation time T changing with the width of the exit L as demonstrated in Figure 5, based on $N = 20$, $K = 0.4,0.6$, and different selection strategies. Selection strategy has critical effects on pedestrian evacuation time. When the exit is narrow, the concessional strategy is better than the competitive strategy in the process of evacuation. With the increase of the width of the exit, the competitive strategy will gradually better than the concessional strategy. When the width of the exit is large enough, there is not a significant difference between the competitive strategy and the concessional strategy.

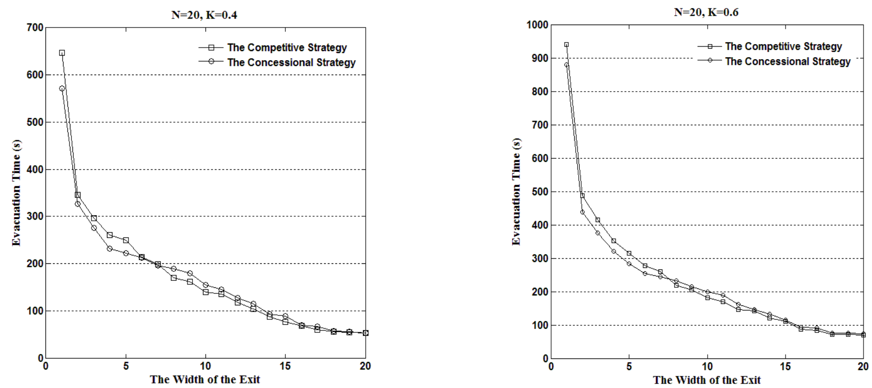

Figure 5. The curves of pedestrian evacuation time changing with the width of the exit in the condition of different selection strategies.

4 Conclusions

Based on the model of CA, this paper defines personal space and information processing space on direction of 9 optional positions to describe pedestrian's behavior in the condition of different environments. Afterwards, it simulates pedestrian's movement in the condition of only one exit from system. The conclusion indicates that evacuation time is approximately a linear increasing trend changing with pedestrian density, the system scale is a key factor on evacuation time, and expanding the width of exit is a effective way to control evacuation time. Selection strategy has critical effects on pedestrian evacuation time. With the increase of the width of the exit, there is a reversal point, which shows the competitive strategy better than the concessional strategy. Some related themes worth further studying are listed as follows: how to determine this reversal point, and how to discover this evolution mechanism.

Abstract: Taking necessary measures to counter the traffic block problem is urgent. First of all, through the investigation and analysis, this article summarizes the congestion causes of Chengdu. And then set the evaluation index such as speed, delay in time, the frequency of parking, parking time and the road load degrees of the sections. Through analysis of the statistics, this paper provided a comprehensive evaluation model and the severity of congestion index concept which used to evaluate the rode congestion degree in the situation. Through the acquisition of data, the results model can be carried out on sections of qualitative and quantitative analysis. By calculating, use the serious traffic congestion index to determine the extent section of the serious congestion. The results in the paper can be used for the Chengdu traffic management departments to provide a scientific and rational evaluation system.
Keywords: Urban traffic; Traffic congestion; Evaluation index; Evaluation model.

1 Introduction

After years of city development, urban area of Chengdu has formed a circular radial road network. Ring and radial road network is the old city center area gradually outward development, reflected by outward radiation with loop and the formation of ring and radial urban road network. At present, the original of road network structure, has been more and more not adapt to the development of the city. The disadvantages of Chengdu city ring radial road network traffic: intersection is not enough rules, does not favor the traffic organization; Easy to form "booth pie" urban layout, in the center of the city land use is too high, the central area of the road network cannot meet the traffic demand. Causing the traffic pressure in the central area increase, bring the urban center traffic congestion problem. The phenomenon of traffic congestion in downtown Chengdu mainly concentrated in commute, holiday peak, and narrow roads. Congestion area mainly is the second ring road peripheral and central urban area within the second ring road.

2 The establishment of traffic congestion evaluation index

2.1 traffic congestion evaluation index

According to the domestic and foreign research results on the problem of traffic congestion and the analysis of current situation of Chengdu traffic congestion causes, based on the basic principles of evaluation for road section, the establishment of evaluation index system of congestion as shown in table 2-1.

Table2- 1. The traffic congestion index system

Index	The meaning of indicators	Formula
The average travel speed	By the time the vehicle total travel length and evaluation section through the sections of consuming ratio	$V = (L\times N) \Big/ \left(\sum_{i=1}^{N} t_i\right)$
Unit mileage average stops	Sections on the comment on every vehicle in the unit operation process occurs within the parking number length	$C = \left(\sum_{i=1}^{N} C_i\right) \Big/ (L\times N)$
Unit mileage average parking time	In the evaluation section ,comment on every vehicle in the unit during operation mileage in parking time	$T = \left(\sum_{i=1}^{N}\sum_{j=1}^{k_j} t_{ij}\right) \Big/ (L\times N)$
Unit mileage average travel delay time	In the evaluation of road vehicle in running process, because of the loss by the driver cannot control the situation of the time	$T = L/V - L/V$
Road load degree	The ratio of link traffic volume and road traffic capacity	$M = N/N'$

Congestion evaluation at home and abroad at present, most research is road congestion index of single factor evaluations, two evaluation indexes were taken into account in the minority. In this paper, the congestion index considering comprehensive, involves the speed, time, service level, traffic flow, road load degree, and can be used to judge the intensity of congestion, the range of congestion, traffic time.

2.2Traffic congestion index reference standard

To evaluate whether sections need to congestion and congestion degree to estimate the range of each evaluation index, so as to carry out the single factor evaluation on different parameters. The road congestion can be divided into 5 levels, respectively is very smooth, smooth, mild congestion, congestion and severe congestion. Through the time of Chengdu City statistics obtained 2013 survey data to carry on the research analysis, can determine the maximum, minimum value range is five kinds of assessment indexes for different level of congestion belongs, determine the evaluation criterion.

2.2.1Average travel speed evaluation standard

This paper mainly uses the installed detector and 2000 vehicles to install GPS positioning system through the road taxi to directly measure the road in different periods of traffic speed, and by using the method of artificial investigation to obtain the road time. Screening of the calculation based on the data from investigation, and based on the survey of related theory and traffic flow speed of the relations among the parameters, given the average travel speed of the expressway section of the reference standard table, as shown in table 2-2.

Table 2-2. Expressway review travel speed evaluation index reference table (unit: km / h)

The average travel speed	The average speed of evaluation grade	The road traffic conditions
[0,20]	severe congestion	The average traffic speed is low, the road traffic movement condition is very poor
(20,35]	congestion	The average speed of road traffic is low, poor traffic conditions
(35,50]	mild congestion	The average speed of traffic, road traffic status in general
(50,65]	smooth	The average traffic speed is higher, the road traffic running state is better
(65,∞)	very smooth	The average traffic speed is high, the road traffic movement condition good

2.2.2 Unit mileage average stops evaluation standard

Unit mileage parking number divided by the velocity in the index definition level is defined as the basis, the use of artificial research data will review the speed and the number of stops for regression analysis fitting, which according to the partition speed range, determine the congestion level corresponding to different parking times per unit mileage, as shown in table 2-3.

Table 2-3. unit mileage average stops evaluation standard reference table [unit: time/(km · a)]

Road service level	very smooth	smooth	mild congestion	congestion	severe congestion
expressway	0	（0,0.5]	(0.5,1.1]	(1.1,2.0]	(2.0,∞)

2.2.3Unit mileage average parking time evaluation standard

Average parking time by using the data of actual unit mileage and average travel speed are fitted, so as to determine the evaluation unit mileage average parking time reference standard. As shown in table 2-4.

Table 2-4.Unit mileage average parking time evaluation standard reference table[(unit: second/(km · a)]

Road service level	very smooth	smooth	mild congestion	congestion	severe congestion
expressway	0	（0,9]	(9,20]	(20,35]	(35,∞)

2.2.4 Unit mileage average trip delay time evaluation standard

According to statistical data of the taxi driver and car drivers, the expressway delay time and the running speed of the size of the corresponding comparative analysis, draw the dividing standard of the time delay as shown in table 2-5.

Table 2-5. Unit mileage average delay time evaluation standard reference table [(unit: second/(km · a)]

Road service level	very smooth	smooth	mild congestion	congestion	severe congestion
expressway	0	（0,17]	(17,48]	(48,125]	(125,∞)

2.2.5 Road load degree evaluation standard

Road load degree has close relationship with traffic running state. Table 2-6 for the road load evaluation grade standard of reference table.

Table 2-6. Road load degree evaluation standard reference table

Road load degree evaluation level	very smooth	smooth	mild congestion	congestion	severe congestion
M	[0,0.4]	（0.4,0.6]	(0.6,0.7]	(0.7,0.8]	(0.8,∞)

3 Road traffic congestion evaluation model

3.1Fuzzy mathematical evaluation model steps

Fuzzy comprehensive evaluation is the application of the theory of fuzzy mathematics object comprehensive variety of features, which will sort these objects, according to one way or select the optimal object from the domain theory. The establishment of fuzzy mathematical evaluation model mainly includes the following steps.

(1) Factors that determine the evaluation object set $U=\{x_1,x_2\ldots\ldots x_n\}$;

(2)Given the object evaluation set $V=\{y_1,y_2,\ldots\ldots y_m\}$;

(3)Determine the single factor discriminant matrix R = $(r_{ij})_{m\times m}$

where

$r_{ij}=(r_{i1},r_{i2},\ldots\ldots,r_{im}\}$,corresponding determination is made when U_i considerations;

(4)Given the factors set weight distribution, where w_i is the weight factor of the *i-th* degree;

(5)Evaluation results by Y=W∘R=（y_1,y_2,……y_m）, respectively, where "∘" is defined as a synthetic operation;

(6)Maximum possible judgment: if max{ y_1,y_2,……y_m}=y_p then the judge considers the greatest possible result for y_p

3.2 Road traffic congestion fuzzy mathematical evaluation model

This article will focus on research in Chengdu Second Ring Road Elevated Expressway, take one of three sections: Southwest Jiaotong University to the North Railway Station, North Railway Station to Sanyou Road, Sanyou Road to Jianshe Road to analyze the operation of its various sections, by actual survey data the process to determine the extent of congestion in various sections.

According to the three sections of the survey and collection of data, get the value list second ring road of each factor of peak hour, as shown in Table 3-1. 1 for Southwest Jiaotong University to the North Railway Station, 2 for North Railway Station to Sanyou Road, 3 for Sanyou Road to Jianshe Road.

Table 3-1.sections of each factor peak hour value list

section	V	C	T	t	M
1	34.8	0.2	7.5	46.0	0.6
2	28.7	0.4	9.0	18.0	0.8
3	23.0	3.0	34.5	187.9	0.9

3.2.1 Determine the index weight

Because of the error, we use a large number of samples for analysis and statistics. First, taxi drivers and other vehicle drivers sample survey, then the statistical results with the combination of expert advice, the final calculation of the overall arithmetic mean, the right to determine the weight of each factor, as shown in Table 3-2.

Table 3-2. Evaluation index weights

Weights	The average travel speed w_1	Unit mileage average stops w_2	Unit mileage average parking time w_3	Unit mileage average travel delay time w_4	Road load degree w_5
	0.212	0.203	0.201	0.195	0.189

3.2.2 Determine the development of evaluation index function

(1) The average travel speed V^i and Unit mileage average stops C^i

$$V^i = \begin{cases} 1 & 65 < V_1 \\ \frac{V_2 - 50}{15} & 50 < V_2 \leq 65 \\ \frac{V_3 - 35}{15} & 35 < V_3 \leq 50 \\ \frac{V_4 - 20}{15} & 20 < V_4 \leq 35 \\ 0 & V_5 \leq 20 \end{cases} \qquad C^i = \begin{cases} 1 & C_1 = 0 \\ \frac{0.5 - C_2}{0.5} & 0 < C_2 < 0.5 \\ \frac{1.1 - C_3}{0.6} & 0.5 \leq C_3 < 1.1 \\ \frac{2.0 - C_4}{0.9} & 1.1 \leq C_4 < 2.0 \\ 0 & 2.0 \leq C_5 \end{cases}$$

(2) Unit mileage average parking time T^i and Unit mileage average travel delay time t^i

$$T^i = \begin{cases} 1 & T_1 = 0 \\ \frac{9 - T_2}{9} & 0 < T_2 < 9 \\ \frac{20 - T_3}{11} & 9 \leq T_3 < 20 \\ \frac{35 - T_4}{15} & 20 \leq T_4 < 35 \\ 0 & 35 \leq T_5 \end{cases} \qquad t^i = \begin{cases} 1 & t_1 = 0 \\ \frac{17 - t_2}{17} & 0 < t_2 < 17 \\ \frac{48 - t_3}{31} & 17 \leq t_3 < 48 \\ \frac{125 - t_4}{77} & 48 \leq t_4 < 125 \\ 0 & 125 \leq t_5 \end{cases}$$

(3) Road load degree M^i

$$M^i = \begin{cases} 1 & M_1 \leq 0.4 \\ \frac{0.6 - M_2}{0.2} & 0.4 < M_2 < 0.6 \\ \frac{0.7 - M_3}{0.1} & 0.6 \leq M_3 < 0.7 \\ \frac{0.8 - M_4}{0.1} & 0.7 \leq M_4 < 0.8 \\ 0 & 0.8 \leq M_5 \end{cases}$$

3.2.3 Determine the degree of congestion

In section 1, for example, to calculate the matrix :

$$D = \begin{bmatrix} 0 & 0 & 0 & 0.987 & 0 \\ 0 & 0.600 & 0 & 0 & 0 \\ 0 & 0.167 & 0 & 0 & 0 \\ 0 & 0 & 0.065 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \end{bmatrix}$$

$Y = W \circ R = \{0, 0.155, 0.202, 0.209, 0\}$， $\max\{y_1, y_2, y_3, y_4, y_5\} = y_4 = 0.209$

As a result, Southwest Jiaotong University to North Railway Station during peak hours in the moderate congestion state, so you can get: section 2 is slightly congested state; 3 is moderate road congestion state.

Abstract: In recent years, the Community bus that plays an essential role in public transit system in metropolises has achieved rapid development domestically. It is on the premise that the temporal-spatial distribution characteristics of passenger-flow are confirmed, a proper network planning and operation program is about to make. In this paper, an analytical method for Community bus demand is put forward based on Smart-card data and GPS data of public transit. The index of passenger-flow could be calculated, including passenger-flow volume of line section and station through correlation analysis of data. Through data mining of passengers' records, the difference of passengers demand is analyzed between Community bus and Conventional bus. Also, taking the Community bus data in Chengdu as example, this paper has verified the rationality and applicability of this method.
Keywords: Community bus; Data mining; Smart-card; Travel behavior.

1 Introduction

Currently, the Community bus has been gradually promoted in metropolises, yet the relevant study should be conducted on its planning and operation program since great differences can be seen in such aspects as function orientation, operation mode, arrange location and development goals between Community bus and common public transit. In urban transportation network, the demand of public transit network changes overtime in temporal-spatial dimension. For public transit operators, the matching supply and demand will enable them to lower the operation cost and optimize the online vehicles allocation, yet it is quite hard to realize. In the process, the most difficult part is to accurately measure the demand changes and completely comprehend the rules of dynamic changes.

This paper aims to analyze the temporal-spatial characteristics of passengers travel in Community bus system through analysis of Smart-card data and GPS data of public transit. Comparing with traditional methods, the data mining method to collect and process data features such advantages as comprehensiveness of study subject (most of the passengers in Community bus lines are local citizens with the Smart-card ratio more than 90%), convenience of data acquisition, and the longer data span, etc. Thus, it is feasible to make detailed analysis on the passenger transit index and citizen travel characteristics.

2 Field Data

In this paper, the data base offered by Chengdu Public Transport Group Co., Ltd. derives from Smart-card data and GPS data of Community bus within a week (from November 10th to 16th, 2014) in Chengdu.

Smart-card record includes such information as Smart-card number, expenditure, the remaining number of times to be redeemed, balance, consume date, consumption type, specific travel line, and vehicle number, etc. The information is contained in a table, a complete card record is shown in a row, and the nature of different information in a column. Table 1 contains a part of Smart-card record of Community bus on November 10th, 2014 in Chengdu.

Table 1. Smart-card Data in Chengdu

CARDNO	CONSUME	REMAINTIMES	BALANCE	CONSUMEDATE	CONSUMETYPE	LINENO	BUSNO
112251029	1.8		11.5	2014/11/2 12:00	1	1075	24034
104341926	1.8		7.9	2014/11/2 14:48	1	1075	24034
104497530	0	10		2014/11/2 7:04	15	1075	24034

GPS data record includes such information as recording time, serial number of vehicle-mounted receiver (corresponding to the vehicle number of Smart-card data), GPS speed, number of line, longitude and latitude, and serial number of station, etc. The information is also contained in a table, a GPS record is shown in a row, and the nature of different information in a column. Table 2 contains a part of GPS data of Community bus on November 10th, 2014 in Chengdu.

Table 2. GPS Data of Vehicles in Chengdu

RECDATETIME	PRODUCTID	GPSSPEED	ROUTEID	SUBROUTEID	LONGITUDE	LATITUDE	STATIONNUM	DATATYPE
2014/11/10 13:59	21014010		1077	1077	104.123281	30.60486	31398	55
2014/11/10 17:21	21014137	0	1048	10480415	104.176316	30.69181	41564	3
2014/11/10 16:03	21034710	6.19	1055	10550320	104.065268	30.60489	30976	4

3 Data Analysis

In this paper, the two data sources are inseparable and comprehensively analyzed by the means of data fusion and data mining. Through analysis of Smart-card data and GPS data of Community bus, the two data sources are found fundamentally linked via the consume date and GPS recording time. No matter a vehicle is moving or stopping, its real-time position data will be uploaded via the running vehicle-mounted GPS receiver. Thereby, while the card data of passengers who just gets on the bus is recorded, the spatial position is also recorded via GPS. Based on the relevance of two records' time, it is preliminary ascertained the time, location and travel line of a passenger who gets on a bus.

The two data sources should be processed before putting them into use. The processing procedure is shown as follows.

(1) Data reduction

Among a variety of natures of Smart-card data and GPS data, a considerate part is independent of this study. Therefore, it is necessary to reduce duplicate information and delete negligible fields.

(2) Unified coding form

Since the coding forms of the same kind of data nature in the two data sources varies from each other, the coding forms need to be unified. Otherwise, an error will occur in the process of conducting a data correlated query.

(3) Selecting correlated information, setting up a database

After selecting the correlated information between the two data sources, a database is set up based on the basic data offered by Chengdu Public Transport Group Co., Ltd., and then the corresponding query work is proceeded.

4 Discussion of the Results

The major achievements of data analysis of Smart-card and GPS is passengers' behavior characteristics, which includes passenger-flow of the whole system, passenger-flow of certain line, passenger-flow of stations and variability in temporal –spatial. Once grasp the variability discipline, managers and planners can formulate reasonable bus network and operation scheme that cohere with demand based on the analysis results. Hence, system costs will decline while residents' trips are sufficiently met.

4.1 Temporal distribution

Generally speaking, passenger-flow of urban public transportation will presents regular variability. In weekdays, commuting travel occupies the main segment, while leisure travel takes over on the weekend. The two figures below are passenger-flow's statistical results of Community bus and Conventional bus in one week.

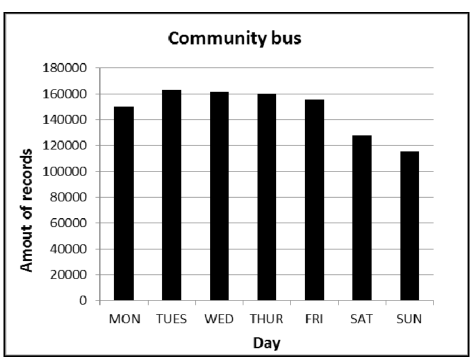

Fig 3. Community bus in one week

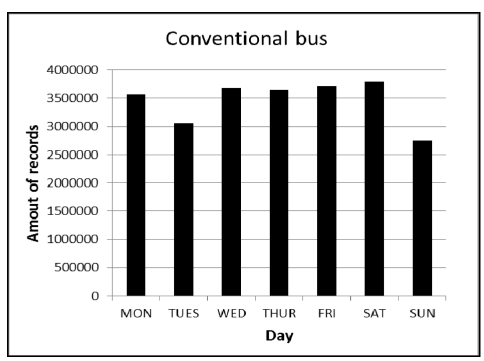

Fig 4. Conventional bus in one week

Two conclusions can received by means of comparison the two figures:

(1)Passenger-flow remain steady

Passenger-flow of the two systems merely show a little bit fluctuate in weekdays. From Saturday Community bus's Passenger-flow begins to slump and reach the minimum on Sunday. In Conventional bus system, Passenger-flow remains equal in Saturday, but decline on Sunday.

(2)Passenger-flow in Community bus system is very low

In Community bus system 1.03 million Smart-card data records are detected compare with 24.21 million records in Conventional bus system. Feeder and collector-distributor service of Community bus system didn't bring into fully play.

The variation of passenger-flow within one day belongs to temporal distribution also. Community bus in Chengdu operates from 6:00 to 21:00, then passenger-flow within every hour is displayed in Fig.5. In weekdays the distribution appears to be double peak phenomenon. The morning and evening peak time are 6:30-7:30 and 16:30-17:30, then passenger-flow will slumps at noon. In weekends, there's no remarkable peak time but a decline also shows at noon.

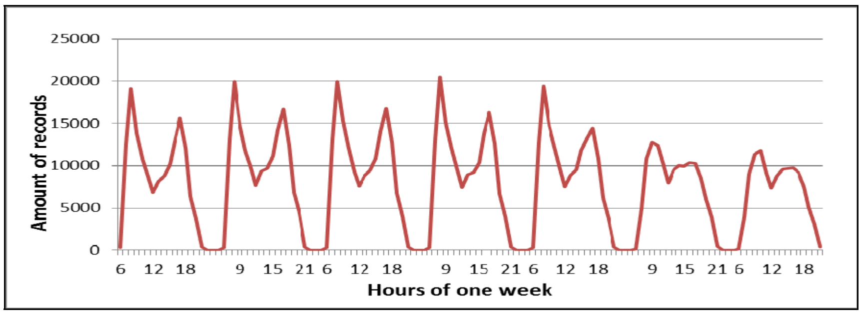

Fig 5. Temporal distribution of Passenger-flow in one week

4.2 Spatial distribution

The Spatial distribution of Passenger-flow can be divide into two aspects: on the one hand, discrepancy among lines; on the other hand, discrepancy among stations that pertain to the same line.

The 82 Community bus lines scatter on different regions of the whole city subdivision. Passenger-flow in different regions may emerge large diversity due to many reasons such as economic land-use population traffic conditions and so on. Passenger-flow of Wed and Sat are showed as Fig.6. We can see that most lines gain 600-2400 boarding transections on weekdays, while 0-2000 at weekends. Moreover, boarding transections within different lines vary considerably.

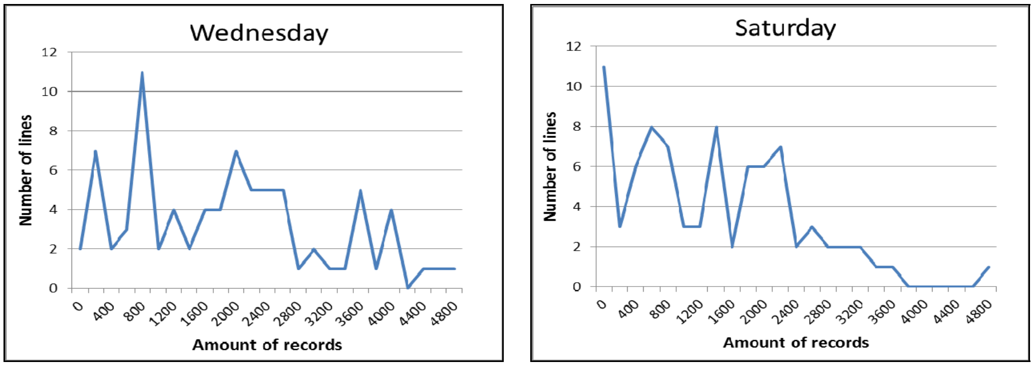

Fig 6. Passenger-flow of Wed and Sat within every line

The discrepancy among stations that pertain to the same line can also demonstrate the spatial distribution of Passenger-flow. We choose route 1030 as example because it received the most Smart-card records. The distribution among stations presents to be triple peak pattern, namely most passengers get on bus at the three main stations. Although the total quantities of two days differ greatly, the variation tendencies are the same in basically.

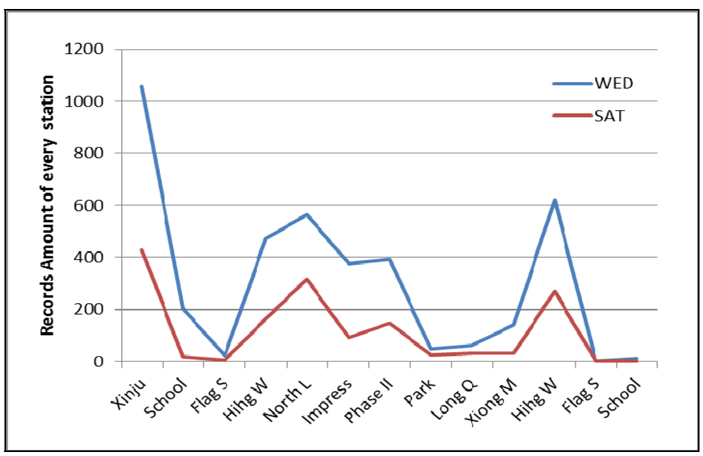

Fig 7. Passenger-flow of Wed and Sat within route 1030

4.3 Dependence degree

Passengers' travel behavior can be formulated by the dependence degree on Community bus service. The degree can be illustrated by two indicators in temporal scale.

(1) Active days in one week

If the system detects a record of one card, then we define the day as active-day. Statistical data of different passengers' active-days will reveal passengers' dependency on Community bus system.

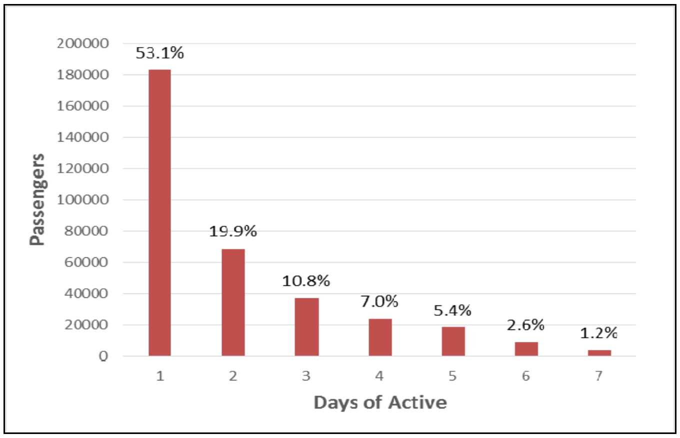

Fig 8. Passengers' active-days in one week

We can deduce from the figure over 70% passengers' active-days are less than three times, and most Smart-card just appears once. This declares that residents hadn't be accustomed to use Community bus, therefore the dependency on the system is extremely low.

(2) Average trips one day

This indicator means the average trips of all active passengers in the system. It can be calculated via dividing records amount by active cards' number. A high level denotes passengers use Community bus for round-tripping issues, nevertheless a low level denotes they use Community bus for chance merely.

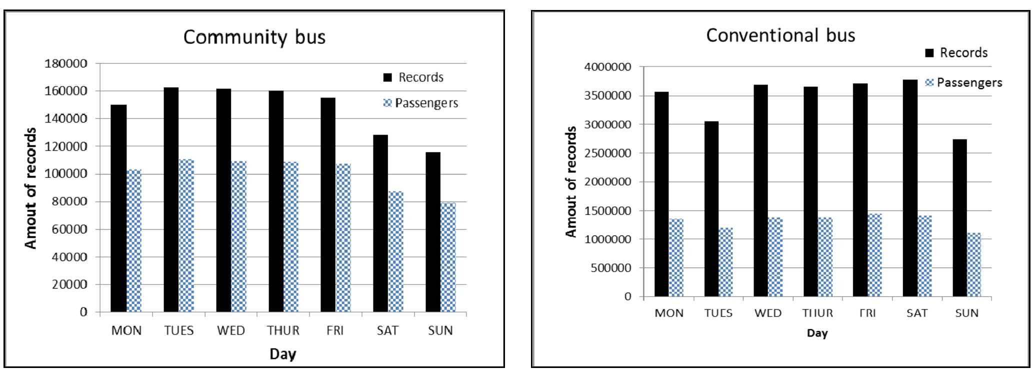

Fig 9. Average trips one day

Table 4. Comparision of average trips in two systems

Systems	MON	YUES	WED	THUR	FRI	SAT	SUN	Average
Community bus	1.461	1.475	1.474	1.469	1.450	1.464	1.465	1.466
Conventional bus	2.630	2.550	2.657	2.645	2.566	2.669	2.464	2.597

We can infer from figure 9 that the gap between records and passengers in

Conventional bus system is quite large, however the one in Community bus system is much small. In another word, the average trips in Community bus is very low.

Table 4 lists average trips in two systems every day in a week. The two average values are 1.466 and 2.597, the big disparity between the two values show that a majority of active passengers use Conventional bus repeatedly, while Community bus is just an alternative set.

5 Conclusions

As the Smart-card system and GPS recording system have been widely used in most of domestic cities, a large amount of historical data has been obtained to powerfully support our study. Comparing with traditional methods, the research methods -- data fusion and data mining in this paper features such advantages as comprehensiveness of study subject, convenience of data acquisition, and the longer data span, etc.

The Smart-card data and GPS data fusion and mining can be used to track the travel of citizens, and analyze the temporal-spatial variation rules, thus finally obtaining the available information about citizens' travel characteristics. This information mainly consists of passenger-flow volume in the whole network, the 24-hour distribution of passenger-flow everyday of a week, differences in passenger-flow and degree of dependence on Community bus of various lines and stations, etc. These data can be used for making public transit decisions, optimizing layout and adjusting operation plans in the entire network.

6 Recommendations for Future Research

The most bus lines of Community bus line in Chengdu is one-way circular, then a majority of trip stages cannot be linked into integrated trips. So this paper merely studies the temporal-spatial distribution and variation rules of passengers' travel behaviors based on boarding transactions without matching the alighting transactions. Some foreign scholars have made related researches on the alighting stations of normal bus transit. The next step for us is to focus on how to infer the alighting stations of Community bus, thus forming a complete OD matrix of citizen travel.

Abstract: The article proposes several key problems about CBTC simulation implementation on the sandbox, researches some problems such as signal equipment detection, train location and wireless communication, and proposes some corresponding solutions. In the process of the research, at first, the article comes up with the reasonable methods by comparing the several techniques; and then designs the circuits to conduct the corresponding experiments. The final solution is applied to the practical simulation sandbox. The solution is verified correctly by combining with the CBTC simulation software which is running for a long period of time on the upper computer. The solution of these key problems can make the CBTC function be simulated and implemented accurately on the sandbox, at the same time; it also provides some service for teaching and training.
Keywords: CBTC; Simulation; Location; Detection.

1 Introduction

ATC is Automatic Train Control, and it consists of three subsystems which are Automatic Train Protection (ATP), Automatic Train Supervision (ATS) and Automatic Train Operation (ATO). At the same time, it is a key system which ensures the operation security and reliability of Urban Rail Transit. Communication Based Train Control (CBTC) system is a continuous, automatic train control system utilizing high-resolution train location, independent of track circuits; high-capacity, continuous, bidirectional train-to-wayside data communications. When the CBTC runs simulation on the sandbox, it can calculate the running direction and speed of the next step according to the feedback location information, but it places a greater demand on the current location information of the train and the real-time of wireless communication. Interlock function can guarantee that the train operate safely. And to ensure the reliable running of the interlock function, the interlock host not only controls the signal equipment on the sandbox, but also reads back the signal equipment states on the sandbox accurately. At present, the domestic railway simulation sandboxes mainly base on the operation simulation which is existing already, and its location accuracy, wireless transmission real-time and data quantity can't meet the need of the simulation of Urban Rail Transit CBTC system. The article refers to many successful experiences of the railway simulation sandbox; but when the CBTC simulation system simulates on the sandbox. the key problems are to solve wireless communication, train location and signal equipment detection.

2 Wireless Communication Problems

At present, the wireless communication technologies which can be used on the sandbox include Bluetooth, zigbee, wifi and RF wireless. The Bluetooth and zigbee transmit fast, but they have shorter communication distance, so they can meet the need of multiple trains communication simultaneously. However, the communication qualities will get bad if there are many obstacles on the sandbox, so the Bluetooth and zigbee are suitable for small-sized sandbox only. The 433MHz RF wireless communication has better penetration and farther transmission distance though, the wireless data take up too much time in the air, and there will take place a phenomenon of the data loss when the multiple points carry out data communications simultaneously, so the RF wireless is suitable for the situation which is long distance and few trains. The wifi possesses some characteristics such as high-speed communication and farther transmission distance, and can support that multiple trains run simultaneously. And its network covers a larger area, so the wifi communication is suitable for medium-sized sandbox. The simulation sandbox of Southwest Jiaotong University-E'mei Campus is 35 meters long, 5 meters wide, and is divided into two layers, so it belongs to large-sized sandbox. The wireless communication modes above are difficult to be adapted to completely. Owing to the convenience of the setting up the wifi network, and it's close to the existed wireless communication mode of Urban Rail Transit, so multiple wireless APs can be used to set up the wireless wifi network. When the simulation train runs on the line, it logs on the corresponding wireless APs according to the detected location.

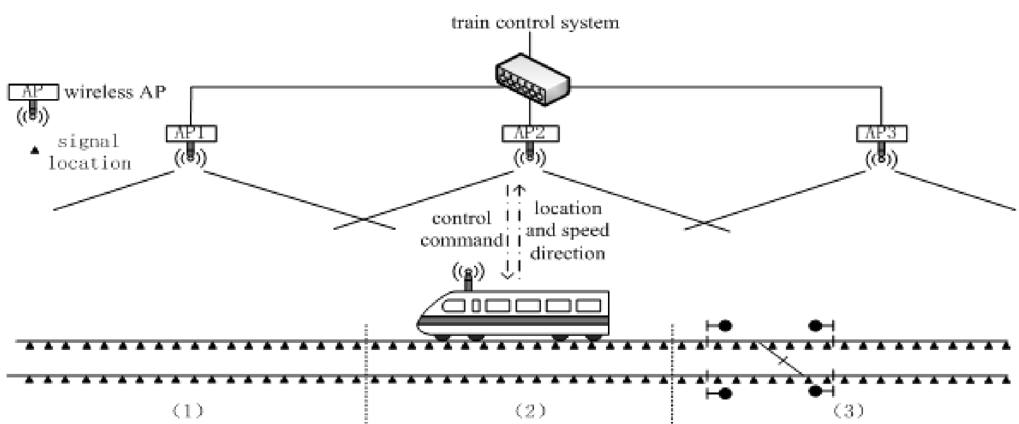

Figure 1. CBTC wireless network schematic diagram

The CBTC wireless network schematic diagram is shown in Figure 1. The line is divided into three regions, and each region uses one AP, in addition, the obducent areas of two adjacent AP wireless have partial overlaps. Because the train will store all the AP ID numbers in advance, the train can log on to the corresponding APs quickly after entering a new region. And all the AP points access to the train control system with the Ethernet.

3 Train Location Problems

At present, the indoor location modes have zigbee network location, ultrasonic location, RFID location, infrared detection and location. The zigbee network location is mainly used to the personnel location of the regions such as mines, prisons, and so on. The location accuracy of mature products could reach about 3 meters, and the accuracy could reach about 25 centimeters after optimizing the location. However, the location accuracy still can't ensure which track the train is running, so it can't be used to the sandbox. The ultrasonic location is influenced by temperature, humidity, and the sandbox's building block, so it's difficult to use on the sandbox. The infrared detection is to lay a lot of infrared emission points on the track, and each emission point will transmit the infrared lights with location code, at the same time, the train has some infrared receivers. When the train read the infrared code data for locating, due to the high location accuracy and a number of signal locations on the sandbox, using infrared detection and location will lead to the increase of the sandbox cables, and decrease the reliability of the sandbox running. The RFID location is to lay a lot of the IC card of 13.156MHz on the track, and some card readers are installed on the trains. The energies are transferred to IC cards by the inductance coupling mode, and then the card readers will carry out data transmissions with IC cards, and the speed is more faster. Because the IC card is passive and without additional wiring. Each fixed address of IC card will write the information such as track location number, track grade, line state, and so on previously. When passing, the train reads the data and adjusts the speed, at the same time, the data will be sent back to the train control system. Each IC card is 8 centimeters long, and lays continuously under the sandbox track. First of all, the trains read the IC data, and then the data will be sent back to the train control center. According to practice, one operation will spend around 40 millisecond, and 25 signal marker points can be read per second. So it can be calculated that the train's maximum operation speed is 2m/s, and the requirements of the CBTC simulation could be satisfied.

When the train card readers aims at the connective places of the two IC cards, so the train could be located accurately by reading back an error number. In the actual measurement, the error of the parking the train is in the range of 2 centimeters when we use this method.

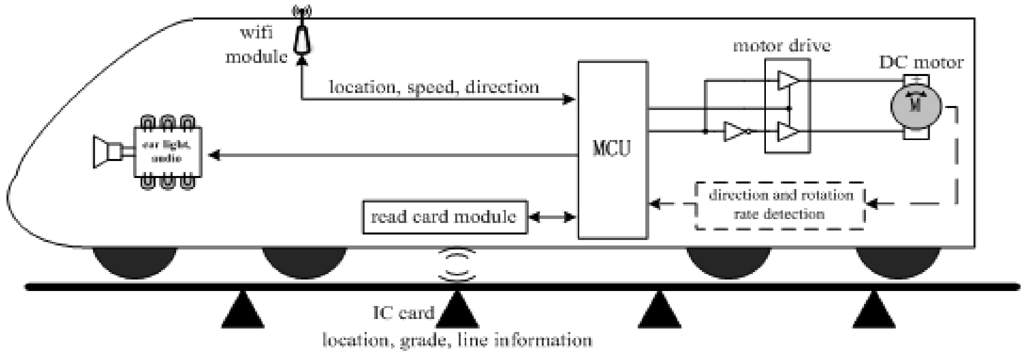

Figure 2. Train location method

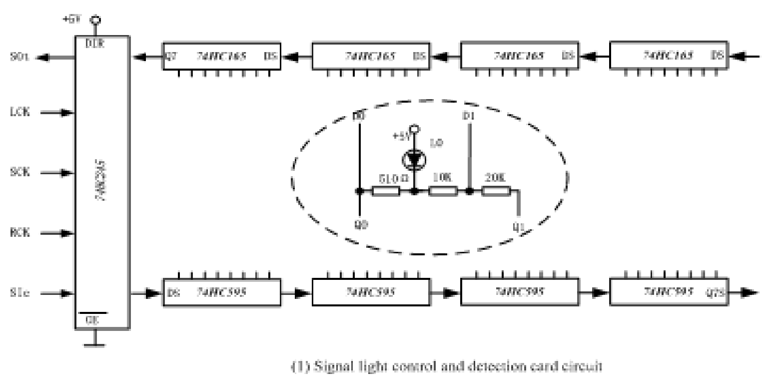
4 Signal Equipment Detection

The main signal equipment of the sandbox is signal light and switch machine, and the detection of departure indicator and emergency stop button is same as the detection of signal light. On the sandbox, there are many signal lights, and there is 1.8V~3.3V voltage drop when the signal light is on. For COMS gate circuit, the reverse input level threshold is always being half of the total power, and according to the feature of the power fluctuation, the judgment of the signal light voltage drop can convert to the judgment of logic value, as shown in Figure 3(1). The control data are sent out by serial-in, parallel-out shift register 74HC595, and the detection data are sent back by parallel-in, serial-out shift register 74HC165. The shift register uses the CMOS craft manufacture, and one signal light is managed by every two bits.



state	input		output		[illegible]
	Q0	Q1	D0	D1

Figure 3. Signal light control and detection circuit

When we want to control signal light L0, the control data need be sent to Q0 port of the 74HC595, and the high or low level signal of output port Q0 can turn off or turn on the signal light L0. When detecting the signal light L0, the port Q0 and port Q1 input separately four logical values which are 00B, 01B, 10B and 11B, and then read back logical values of output port D0, D1. The four logical values of port D0, D1 combine into one byte from low bit to high bit, and form the state values of the equipment. As shown in Figure 3(2), the state values of signal light are different in each state, so the fault states of signal light could be judged. The control method of the other signal lights is similar to the method above, the signal light which is numbered x is managed by *Q2x, Q2x+1, D2x, D2x+1.*

The switch machine uses the push-pull solenoid, and the turnout drive data will be outputted by the parallel port of the 74HC595, and the collected data and the fault data are sent to the parallel port of the 74HC165. Figure 4 is the control and detection circuits of a group of turnout, and the detection of the turnout adopts non-contact photoelectric switch, and the positive or negative location both install one separately. When the turnout is moved, it will drive the turnout linkage mechanism. And when the turnout linkage mechanism reach one side of location (anti-location) detector reliably, the detector will output location (anti-location) pulse signal. At first, the location (anti-location) detection circuit uses the inverter 40106, resistors and capacitors to constitute TTL inverter and RC oscillator, and the output square-wave signal drives the infrared light-emitting diodes. To generate different frequency pulses, the resistors of the location (anti-location) detection circuit set different values, therefore, the input pulse of location and anti-location can be distinguished by the frequency. After the infrared receiver diodes receive the signals, the signals are modulated and outputted to the MCU to identify, and then the identified turnout states are sent back to the main control card by the port D0 of the 74HC165.

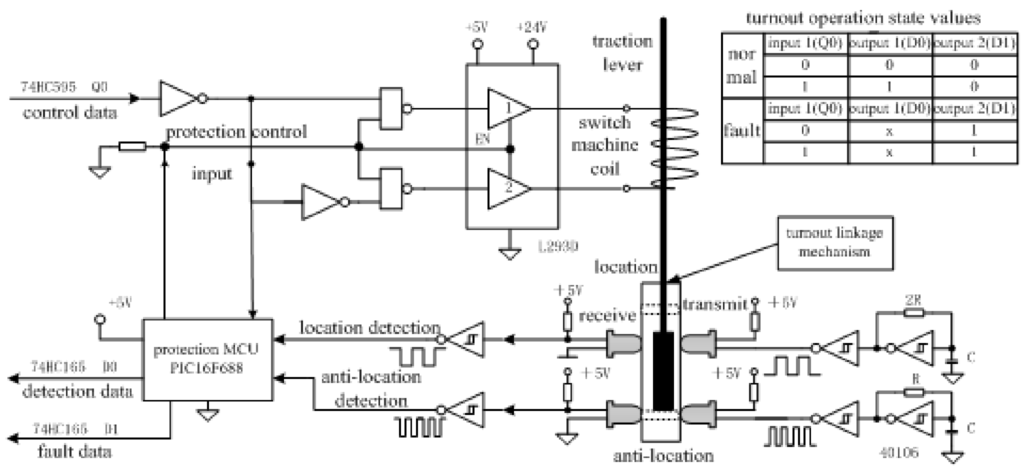

Figure 4. Turnout control and detection circuit

5 Running Test

The control system design of the CBTC simulation sandbox has a set of control system which includes multiple control boxes, and they are connected to the interlock host by RS-485 bus. One control box includes main control card, signal machine driving and detecting card, turnout driving and detecting card, so it can manage one or more intermediate stations. Each control system includes main control card, signal machine driving and detecting card, turnout driving and detecting card, and they are cascaded by SPI bus. The main control card is responsible for communication, outputting the control signals and reading back the detected data. The signal machine driving and detecting card manages the signal machine, departure indicator and emergency stop button. The turnout driving and detecting card are responsible for managing the turnout. The physical diagram of control system is shown in Figure 5.

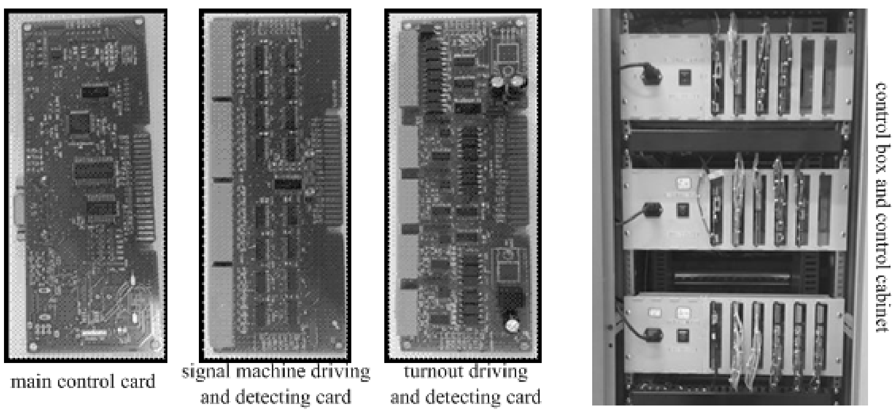

Figure 5. Physical diagram of control system

The wireless wifi is used for the train to communicate with the control center. The data will be sent back quickly to the control center after collecting new location information. The control center combines the distance of the front train to calculate the current train's speed, and then it informs the train of new commands such as direction and speed. When several trains run on the line simultaneously, the control center controls the sandbox's signal equipment with the interlock host, and detects whether the control action is accurate.

The Urban Rail Transit simulation sandbox of Southwest Jiaotong University-E'mei Campus belongs to large-sized sandbox, and it uses 10 wireless APs and 20 control boxes. According to several tests, the sandbox can meet the need of the CBTC simulation adequately. The simulation results of CBTC system is shown in Figure 6.

Figure 6. Simulation results of CBTC system

6 Conclusions

The CBTC simulation laboratory could provide specific practices for all major students. For the students of signal profession, it could train the students' abilities such as interlock logic relationship, system signal control, communication, and so on. For the students of operation management profession, it could provide vertical and horizontal linkage training based on various normal and abnormal situations in the positions such as operation coordination, emergency command center, control center, station, train, and so on. With reference to many relevant experiences how to manufacture the sandboxes, to improve it gradually and make it meet the need of the CBTC simulation, the Urban Rail Transit control sandbox of the Southwest Jiaotong University-E'mei Campus explores and researches step by step. Finally, it provides important references for the same laboratory.

Abstract: Operation of vehicles in urban arterial highway directly affects traffic of entire city. With large traffic volume and too many conflicts in urban arterial highway intersections, congestion problem is particularly prominent. Therefore, rational management of urban arterial highway intersections can effectively alleviate traffic congestion. Choosing the Renmin Street and Jiefang Avenue intersection of Changchun city as the research object, it aims to explore a full-induction control method for urban arterial highway intersection. The full-induction control method is explored with VISVAP to compile VAP (Vehicle Actuated Programming) and the calculation model of detector installation position is modeled. Comparing values of delay and queue length of current signal control with those of full-induction control method, the full-induction control method effectively alleviates congestion.
Keywords: Intersection management; Induction control; VAP; VISSIM.

1 Introduction

With the rapid development of Chinese economy and level of urban, vehicle population is significantly increasing and becomes populated in inner cities, which makes urban traffic congestion persistently deteriorate, especially in intersection. The experience of traffic management in intersection is that the most effective method of traffic management is signal control. Signal control can be divided into timing control, induction control and adaptive control.

Operation of induction control is based on installing detectors under the ground of intersection entrance lane. The most general detector is inductive-loop detector which is used to detect vehicles across or stop at it. Induction control can be divided into half-induction control, which only installs detectors at some entrance lanes, and full-induction, which installs detectors at every entrance lane. This kind of signal is controlled by intelligent controller that can timely detect the information of vehicle flow.

If it cannot achieve desired objectives, economic and social costs will waste. Module VAP of microscopic traffic simulation software VISSIM can realize simulation of traffic situation that around the position of detector. Using VISVAP to draw logic flow chart of VAP, transferring method of signal control to VAP, and simulating with VISSIM, delay and queue length are compared to ensure that whether the method is feasible. Many Chinese experts researched signal control method with VAP. Shao Jinjin(2011)provided a multi-phase induction control method of dynamic phase sequence; Xiu Weijie(2014)proposed an improved induction control method of bicyclic phase by research of characteristic of phase structure in standard of USA NEMA TS2; Wang Yupeng(2009)presented a new induction control method, and improved method of one intersection; He Bisheng(2011)provided a pre-signal induction control method of bus priority, and obtained optimal ahead of light time of pre-signal green and red light; Jing Tai(2014)proposed an induction control method based on probabilistic model; Xie Fei(2014)presented an induction control method based on traffic priority.

Induction control is generally applied at intersections that traffic varies considerably with time or the disparity of primary and secondary highway is distinct. It researches installing position model of detectors and aims to explore a full-induction control method to effectively alleviate urban congestion at arterial highway intersection during peak periods and fully satisfy the control of intersection during common periods.

2 Installing position model of detector

Urban arterial highway intersections are generally controlled by four phases. Detectors should be installed to detect whether there are vehicles across or stop at the entrance lane. Location of detectors should be clear to ensure vehicles that lose right-of-way at the maximum speed and minimum deceleration pass stop line or safely stop at it. Because of driving characteristics of through vehicles and left-turning vehicles, distance from detectors to stop lane should be calculated respectively.

$$S_l = \frac{-v_{0l}^2}{2a_{il}} \tag{1}$$

$$S_t = \frac{-v_{0t}^2}{2a_{it}} \tag{2}$$

S_l---Distance from detectors to left-turning stop lane;
S_t---Distance from detectors to through stop lane;
v_0---Maximum speed when vehicles pass the detector;
a_i---Minimum acceleration when vehicles pass the detector.

Right-of-way of all arterial highway intersection directions is coordinate. As urban highway intersections are close, queue length cannot affect normal pass of abutting intersections, otherwise, congestion would be worse. Therefore, other group of detectors should be installed at exit lane of abutting intersections. Distance from detectors to intersection is shown in Figure 1. When vehicles leave point C2 and drive to intersection A from B, it considers that the queue length does not affect abutting intersection B when vehicle drives from point C2 to C1 at the speed of point C2. S_2 is the distance from other group of detectors to the abutting intersection.

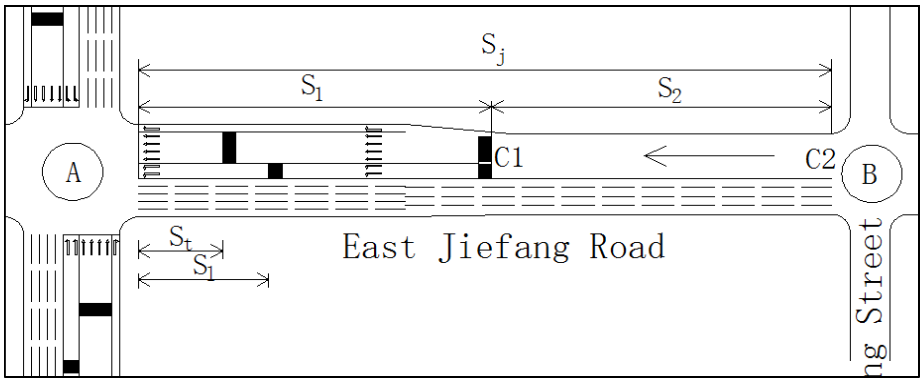

Figure 1. Distance from detectors to intersection

$$\begin{cases} S_1+S_2=S_j \\ S_1=(n-1).d_s+d \\ S_2= v_0.t \\ t=d_t .n \end{cases} \quad (3)$$

S_j---The shortest length from intersection to abutting intersections;
n---Quantity of queuing vehicles;
d_s---Space headway;
d---Average length from vehicles;
v_0---Average speed at exit lane of abutting intersections;
t---Firing time difference between the first vehicle at stop lane and the vehicle at C1, which is also the time vehicles travel from point C2 to C1;
d_t---Average firing time.

Finishing the formula, the distance model of detectors to abutting intersection can be obtained.

$$S_2= v_0 \cdot d_t \cdot \frac{S_j-d+d_s}{d_s+v_0 \cdot d_t} \quad (4)$$

3 Exploration of full-induction control method

Renmin Street and Jiefang Avenue intersection of Changchun city is selected as research object. As these highways are designed with side highway, highway and intersection have been standardized to simplify the exploration in VISSIM. Besides, influence of pedestrians is ignored.

3.1 Determination of detector installing position

With the tool of DETECTORS in VISSIM, the data have been measured in sections as follows: v_{0l} =60.7km/h=16.86m/s, a_{il} =-2.9m/s^2, v_{0t} =59.4km/h=16.5m/s, a_{it} =-4.3 m/s^2, obtained by calculation, S_l =49.01m,S_t =31.66m.The distance from detectors to left-turning stop lane is 49.01m and the detectors to through stop lane is 31.66m.

Direction of the shortest length from intersection to other abutting intersections is the east one, S_j=260m, v_0=20km/h=5.6m/s, d_t=1.1s, d=4.43m, d_s=6m, obtained by calculation, S_2=132.51m. So, detectors should be laid at 132.51m to the abutting intersection, which is shown in Figure 2.

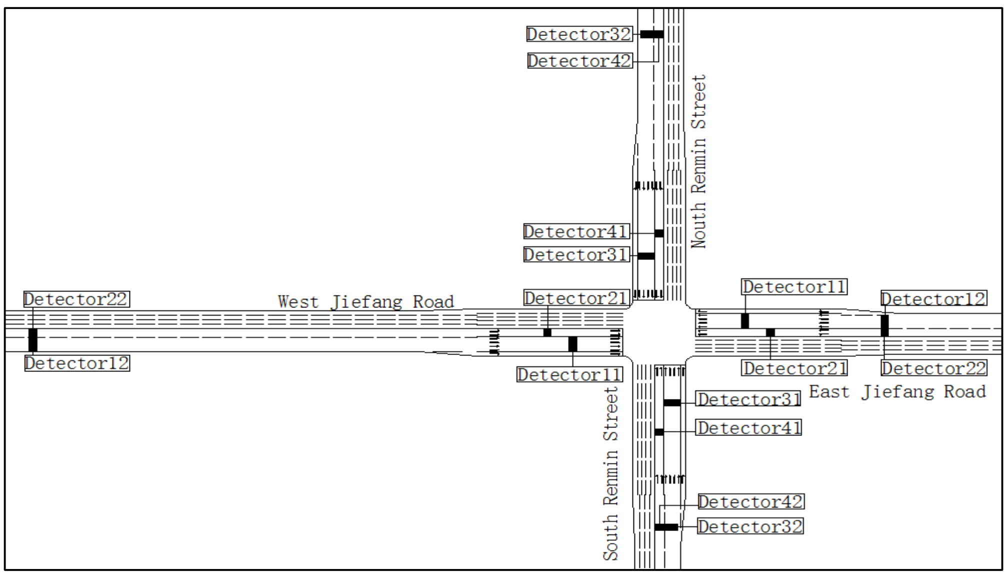

Figure 2. Position of detectors

3.2 Flowchart of VAP

It mainly uses vehicle data acquisition functions with “Occupancy” and “Headway”. Expression definition of VAP is shown in Table 1, and flowchart of VAP is in Figure 3.

Table 1. Expression definition of VAP

EXPRESSIONS	Contents
Queue	(Occupancy(12)>5)OR(Occupancy(22)>5)OR(Occupancy(32)>5)OR(Occupancy(42)>5)
Extend_Stg1	Headway(11)<=MAX_GAP

Extend_Stg2	Headway(21)<=MAX_GAP
Extend_Stg3	Headway(31)<=MAX_GAP
Extend_Stg4	Headway(41)<=MAX_GAP

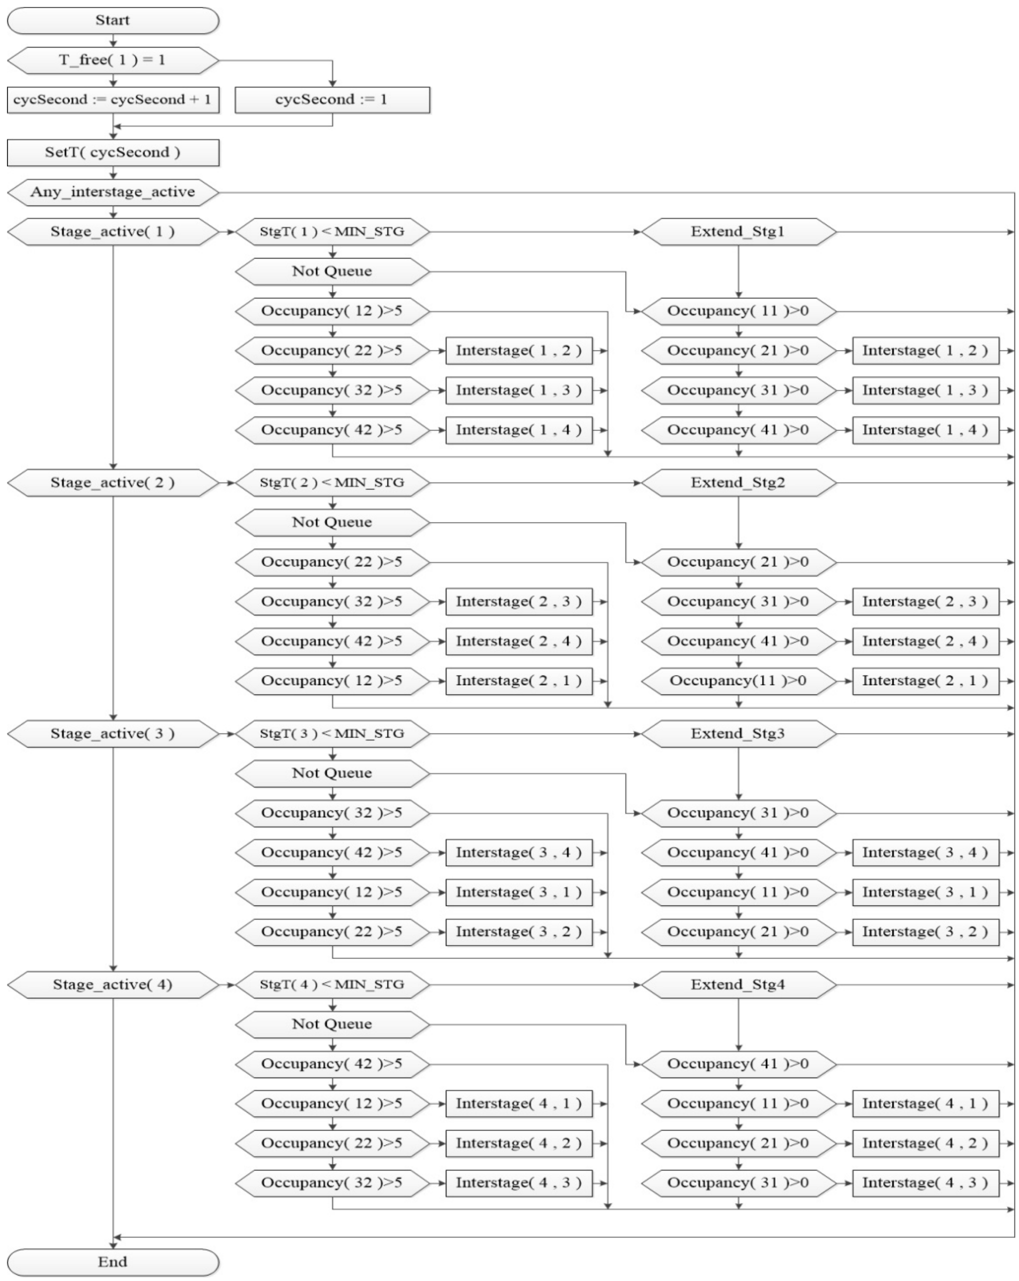

Figure 3. Flowchart of VAP

When current phase is stage 1, east-west through light is green, judging whether it reaches minimum green time. When it reaches, VAP will judge whether queues exist, otherwise, VAP will judge whether it reaches maximum time interval. If queues exist, VAP will check which direction is queuing and give right-of-way to it. If there is no queue, VAP will check detectors near to stop line whether there are vehicles crossing or stopping at detectors. If there are some vehicles crossing or stopping at detectors, VAP will give the right-of-way to it. If headway is greater than the maximum interval time, detectors near to stop line will check whether there are vehicles arriving at it. If headway is less than maximum interval time, this direction will maintain the right-of-way. VAP involves two variables, MAX_GAP is set at 3s, but the MIN_STG is needed to set according to concrete intersection.

Infinite traffic and different green time have been set to determine minimum green time of crowded intersection in VISSIM. Delay comparison of different green times is shown in Figure 4.（etw---east-west through, stn---south-north through）

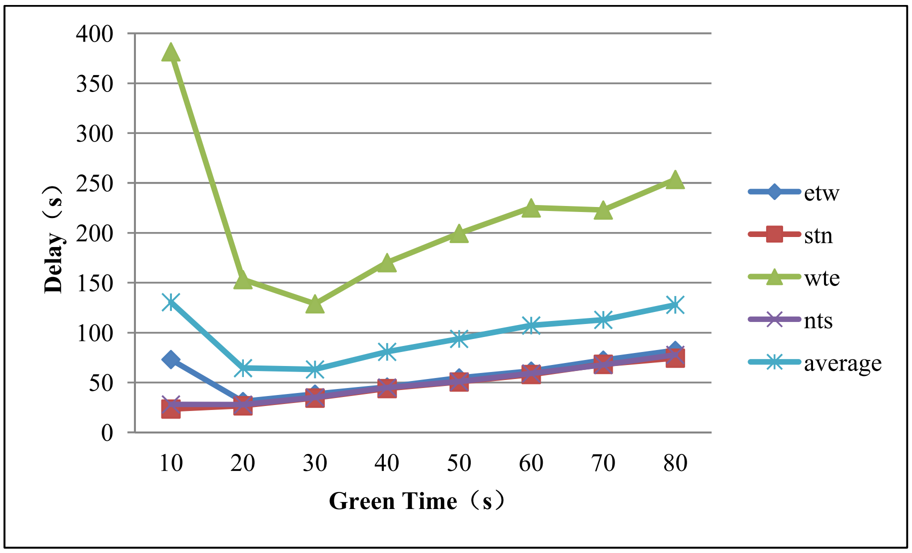

Figure 4. Delay comparison of different green time

When green time of crowded intersection is set at 10s, the numerical value of delay is relatively large; when 20s later, the delay fluctuation is relatively small. So, the MIN_STG is identified as 20s.

4 Comparison of simulation results

The current peak period signal timing of this intersection is that green time of through direction is 105s and left-turning is 45s, peak hour traffic of all directions is shown in Table 2.

Table 2. Peak hour traffic of all directions (veh/h)

	East	South	West	North
Left-turning	360	460	572	496

Straight	1832	1784	2344	1912
Right-turning	276	368	168	288
Total	2468	2612	3084	2696

The simulation effect of current signal control method is shown in Figure 4. There is no vehicle in south-north left-turning, but it does not arrive at the fixed 45s green time, part of time has been wasted. What's worse, other entrance lanes are seriously congesting.

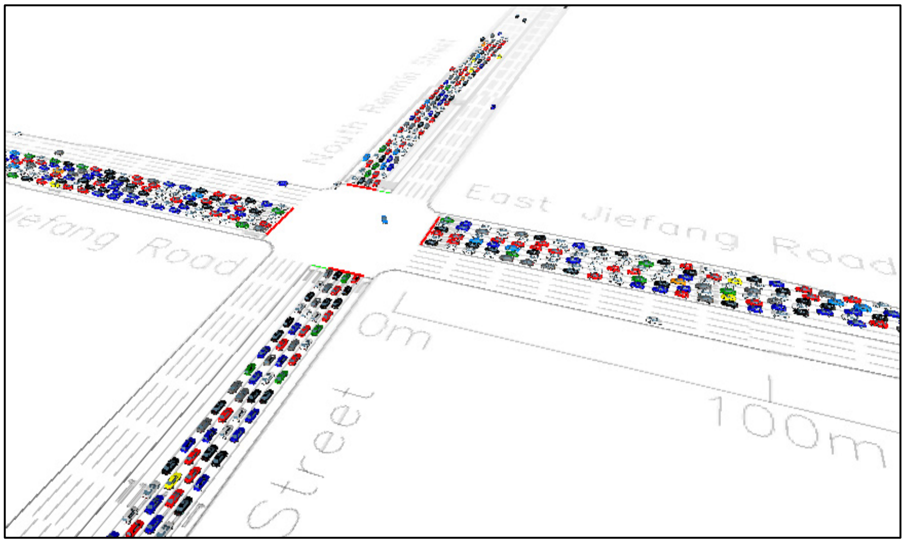

Figure 5. Simulation effect of current signal control method

Transferring control method to VAP, editing the "*.pua" file that contains signal phase, signal groups, starting stage and stage length. Simulation effect of VAP control method is shown in Figure 6. There is no congestion with the control of VAP in an hour. It concludes that the full-induction control method effectively alleviates congestion.

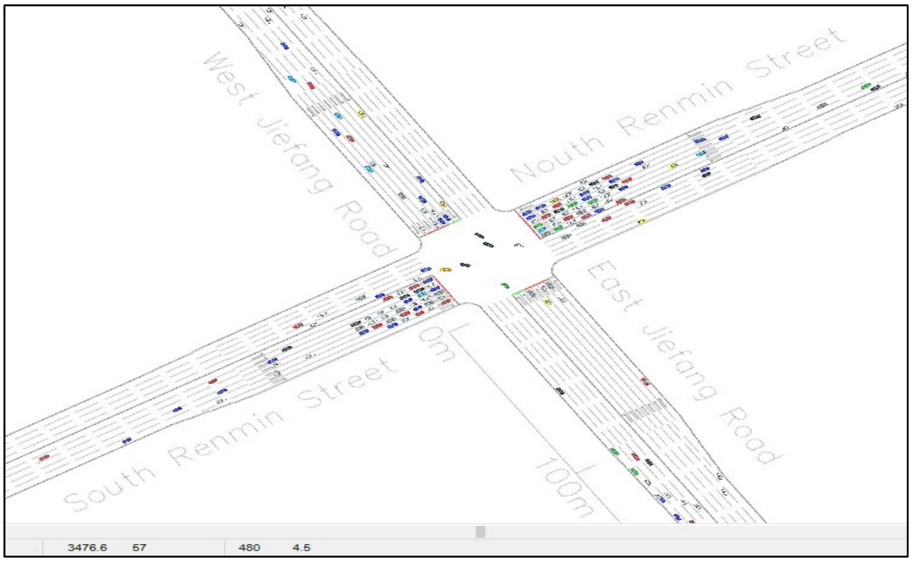

Figure 6. Simulation effect of VAP control method

Contrast diagram of delay is shown in Figure 7, and queue length is in Figure 8. 63.83% and 67.09% are the average reduction of delay and queue length respectively.

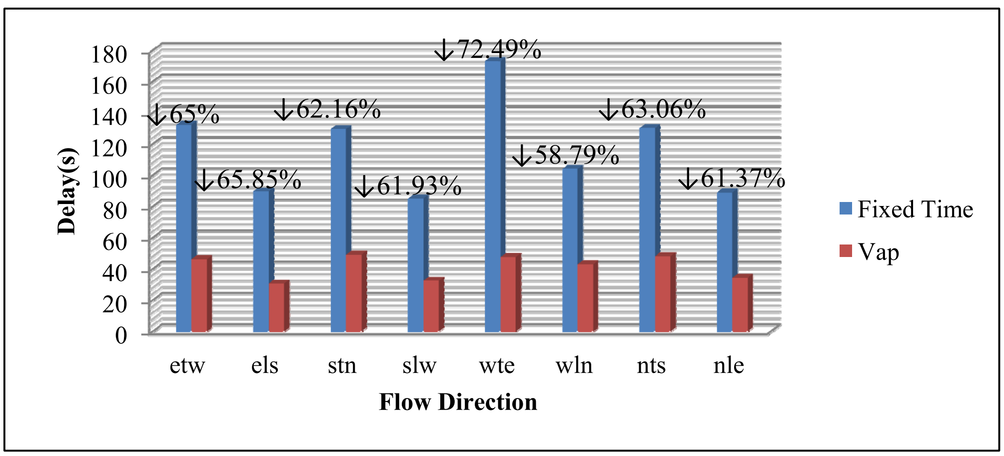

Figure 7. Contrast diagram of delay

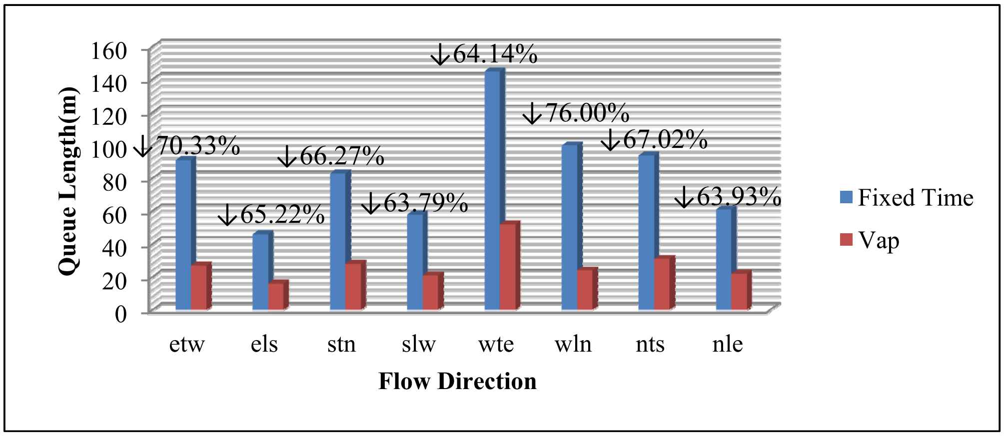

Figure 8. Contrast diagram of queue length

5 Conclusion

It researches calculation model of detectors installing position according to the driving features and explores a full-induction control method of urban arterial highway intersection. In addition, the method has been proved that it effectively alleviates congestion by VAP control in VISSIM.

Potential Conflict Number Prediction of an Intersection's Mixed Traffic Flow

Shuhang Ren; Jingshuai Yang; and Zhizheng Ma

School of Automobile, Chang'an University, P.O. Box 710064, Xi'an, Shanxi. E-mail: spfeikaoyan@163.com

Abstract: In order to reduce the observation time of the intersection traffic conflict and decrease the difficulty of observation, meanwhile achieve the effect of actual measurement, so based on the relevant information, the objective can be realized through the method of predicted the number of potential conflicts. The paper mainly demonstrated the conflict point of mixed traffic flow and predicted the probability of potential conflict about the non-signal intersection in the view of the method of probability statistics, random process, regression analysis and two-dimension table, the theory of traffic flow and traffic conflict. The paper observed the typical intersection in Xi'an so as to test the reliability of the prediction model. The number of prediction conflicts contrasted with the representative predicted value in china, the number of actual conflicts and simulation result. The result shows that the predicted value is a little more than actual value, but contrast with other prediction model, the predicted result is more closer the actual value, so the prediction model can be used to evaluated the traffic safety of intersection instead of the number of actual conflicts.
Keywords: Intersection; Mixed traffic; Traffic conflict; Statistical test; Safety evaluation.

1 Induction

The number of traffic conflict is an important parameter for the analysis of traffic safety of intersection, and also a major evidence for the control of intersection. At the time of observation for traffic conflict, it needs too much time to assure the number of conflicts at the place of intersection (LIU Xiaoming, 1997). And when the traffic volume becomes larger and the traffic order becomes chaotic, some of conflicts are difficult to observe. However, through the method of direct observation, it is difficult to acquire the number of traffic conflicts. So it is necessary to seek other effective methods which can save the observation time of traffic conflict and reduce the difficulty of observation, and also can reach the practical effect. In order to realize this objective, it can based on sectional information predicted the number of potential conflicts that the estimated value of the number of actual conflict.

2 Non-signal intersection motor-motor conflict

2.1 The analysis of non-signal intersection motor-motor conflict

At the situation of non-signal control, as shown in the table 2-1, in the case of three or four roads intersection, the distribution condition of the number of conflict points are different. And figure 2-1and figure2-2 are the distribution condition of the conflict number of the typical T-model crossing and intersection respectively.

Table2-1. The distribution of the conflict point numbers

The types of conflict point	The number of crossing roads	
	3	4
Confluence conflict points	3	8
Split conflict points	3	8
Crossing conflict points	3	16
The total number of conflict points	9	32

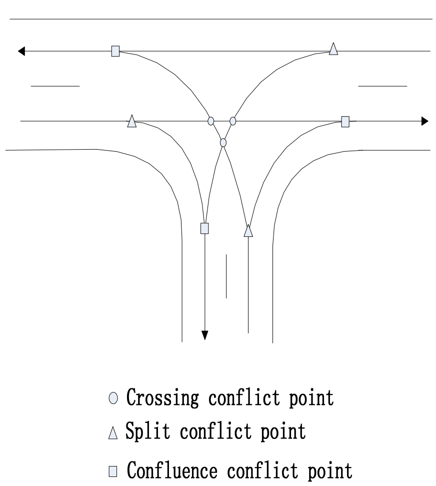

Figure 2-1. non-signal T-model crossing

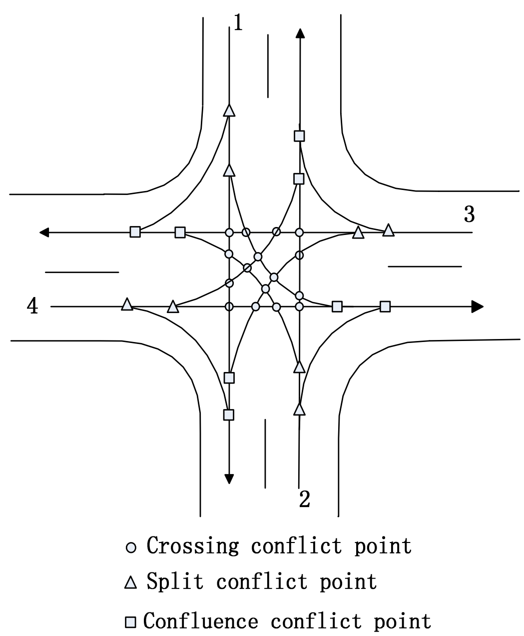

Figure 2-2. non-signal intersection

As shown in the Figures, at the non-signal intersection, the number of crossing, split and confluence conflict points between vehicles will be increased with the increase of the number of crossing roads (ZHANG Su, 1998; Hyden C, 2001).

2.2 Motor-Motor potential conflict model of non-signal intersection

2.2.1 The definition of potential conflict

Conflict is the event that the traveling vehicles slow down or braking when encountered with other vehicles. This two traffic flows are called conflict traffic flow. At intersection, necessary and sufficient condition of conflict shows that two traffic flows are conflict flows and time difference that two traffic flows arrived at conflict point is lesser. Usually, the maximum time difference that happened traffic conflict is called critical interval. It is also the minimum gap that the vehicles of minor road waiting for pass through traffic flow of main road. Call the minimum gap Δt.

According to related research, the value range of Δt is about 6~9s, foreigner experts thought that Δt is about 6~7s(Crowe E C,1989),however, according to actual measurement in china, Δt is about 7~9s(HAN Zhi, 1989).In actual application, it can according to above results to choose appropriated value.

2.2.2The calculation of the potential conflict number

1. The conflict probability of single traffic flow

Assuming all of the vehicles which arrived at the intersection are random, and all kinds of traffic flows which in the area of conflict are independence respectively, meanwhile are follow Poisson distribution. So in the critical gap Δt , the conflicted probability of traffic flow A and B is:

$$p(con)=p_a(k\geq 1)\cdot p_b(k\geq 1) \quad 2\text{-}1$$

p(con): Conflict probability of traffic flow A and B.

$p_a(k\geq 1)$,$p_b(k\geq 1)$: In the times of Δt, the probability of traffic flow A and B arrive at conflict point respectively, and the k is the number of vehicles which arrived at the conflict point.

Because of the traffic volume of the non-signal intersection are not large, so the conflict probability $p(k>1)$ that two or more vehicles arrived at the conflict point simultaneously in the times of Δt is little, so it can ignore $p(k>1)$,and 2-1 can be written as:

$$p(con)=p_a(k=1)\cdot p_b(k=1) \quad 2\text{-}2$$

According to the formula of Poisson distribution:

$$P(\mathrm{x}=\mathrm{k})=\frac{(\lambda t)^k}{k!}e^{-\lambda t},$$

the result is: $p_a(k=1)=\Delta t\cdot\lambda_A e^{-\Delta t\lambda_A}$, $p_b(k=1)=\Delta t\cdot\lambda_B e^{-\Delta t\lambda_B}$,so the 2-2 can be written as :

$$p(\text{con}) = (\Delta t)^2 \cdot \lambda_A e^{-\Delta t \lambda_A} \cdot \lambda_B e^{-\Delta t \lambda_B} \quad 2\text{-}3$$

λ_B: average arrival rate of traffic flow B in unit-time (pcu/s).
λ_A: average arrival rate of traffic flow A in unit-time (pcu/s).

2. The conflict probability of more traffic flows

In the intersection, the traffic flow A not only conflicted with traffic flow B but also conflicted with other traffic flows, at this time, in the times of Δt, the conflict probability of traffic flow A are the sum of the conflict probability that traffic flow from different directions conflicted with traffic flow A respectively. As shown in the figure2-2, meanwhile, i=1,2,3,4 respectively stand for four entrances of intersection, and j=1,2,3 respectively stand for the direction of traffic flows such as left turning, straight and right turning. So:

$$p_{ij} = \sum_k \sum_l q_{ij-kl} \quad 2\text{-}4$$

Combination 2-2 with 2-3, so the 2-4 can be written as:

$$p_{ij} = (\Delta t)^2 \lambda_{ij} e^{-\Delta t \lambda ij} \cdot \sum_k \sum_l \lambda_{kl} e^{-\Delta t \lambda_{kl}} \quad 2\text{-}5$$

p_{ij}:In the times of Δt, the probability of the vehicles of i entrance and j traffic flow conflicted with the vehicles of other traffic flow .

q_{ij-kl}:In the times of Δt, the probability of the vehicles of i entrance and j traffic flow conflicted with the vehicles of k entrance and l traffic flow.

λ_{ij}: average arrival rate of i entrance and j traffic flow vehicle in unit-time(pcu/s).

Assuming $b\,ij = \lambda_{ij} e^{-\Delta t \lambda_{ij}}$,and then 2-5 can be written as:

$$p_{ij} = (\Delta t)^2 \cdot b_{ij} \cdot \sum_k \sum_l b_{kl} \quad 2\text{-}6$$

2.2.3 The calculation of the number of intersection potential conflict per hour

According to formula 2-6, the number of potential conflicts per hour of i entrance and j traffic flow can be calculated. It is shown as below:

$$N_{ij} = \frac{3600}{\Delta t} \cdot (\Delta t)^2 \cdot b_{ij} \cdot \sum_k \sum_l b_{kl} = 3600\Delta t \cdot b_{ij} \cdot \sum_k \sum_l b_{kl} \qquad 2\text{-}7$$

The distributed condition of the conflict point of figure 2-2 can be showed through the two-dimensional table. The table2-2 shows the types of conflict that different traffic flows conflicted with each other. It covered 32 conflict points that included 16 crossing conflict points, 8 confluence conflict points and 8 split conflict points. The detailed condition is shown as below.

Table 2-2. The calculation of different forms of conflict number

	b_{11}	b_{12}	b_{13}	b_{21}	b_{22}	b_{23}	b_{31}	b_{32}	b_{33}	b_{41}	b_{42}	b_{43}
b_{11}		D		A	C			A		A	A	
b_{12}			D	A	A	C	A			C	A	
b_{13}											C	
b_{21}											A	
b_{22}						D	A	A	C	A		
b_{23}												
b_{31}								D		A	C	
b_{32}									D	A	A	C
b_{33}												
b_{41}											D	
b_{42}												D
b_{43}												

A-crossing conflict point, C-confluence conflict point, D-split conflict point.

$$N_A=3600\Delta t[b_{11}(b_{21}+b_{32}+b_{41}+b_{42})+...+b_{32}(b_{41}+b_{42})] \qquad 2\text{-}8$$

$$N_C=3600\Delta t(b_{11}b_{22}+\cdots+b_{32}b_{43}) \qquad 2\text{-}9$$

$$N_D=3600\Delta t(b_{11}b_{12}+\cdots+b_{42}b_{43}) \qquad 2\text{-}10$$

N_A: The number of crossing conflicts per hour.
N_C: The number of confluence conflicts per hour.
N_D: The number of split conflicts per hour.

3 Model validation and results analysis

It takes a typical non-signal intersection of Xi’an to verify the reliability of the prediction model. It spends two hours to observe the entrances of straight and left turning. Regard six minutes as an interval to record the traffic volume and the number of traffic conflicts. And the range of date in this paper basically meet the assumption condition, it means that the arriving rules of vehicles of two entrances basically follow Poisson distribution(the detailed dates are shown as figure 3-1, 3-3 and 3-4) .When the average speed is about 20km/h, according to some suggested values of studies to assure Δ t of straight-left turning conflict is about 7.6s (HAN Zhi 1989,Zegeer J D 1986).So as to calculate the number of the potential conflicts which come from straight-left turning, meanwhile, acquired 20 groups expected value. As shown as figure 3-1, Compared the result of prediction with the representative value in china, the value of SAMM simulation and the result of actual measurement. From figure 3-1 we can see that the prediction value is more closer to the actual value. In the actual, because of the factor of traffic condition, the reaction of drivers and the psychological condition of drivers, most of the drivers will slow down ahead to avoid the traffic conflict, so, It will lead to the observed number are less than the predicted number. From figure 3-2 we can see that the number of traffic conflicts will be increased with the traffic volume. But, in actual observation, when the traffic volume increased to a definite value, the number of traffic conflicts will be decreased. Because of the increased traffic volume will make the speed of vehicles slower, so, the number of traffic conflicts will be decreased. Furthermore, the predicted model based on Poisson distribution just applied to the condition of the arriving characteristics of vehicles follow Poisson distribution. When the traffic volume is larger, the arriving characteristics of vehicles are not follow Poisson distribution, it will needs other model to predict the traffic conflict.

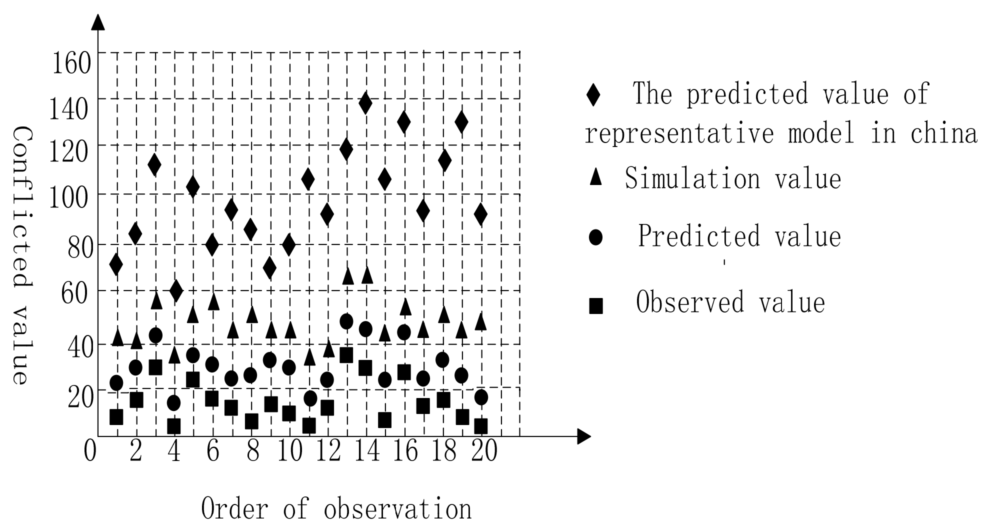

Figure 3-1. Comparison of predicted results

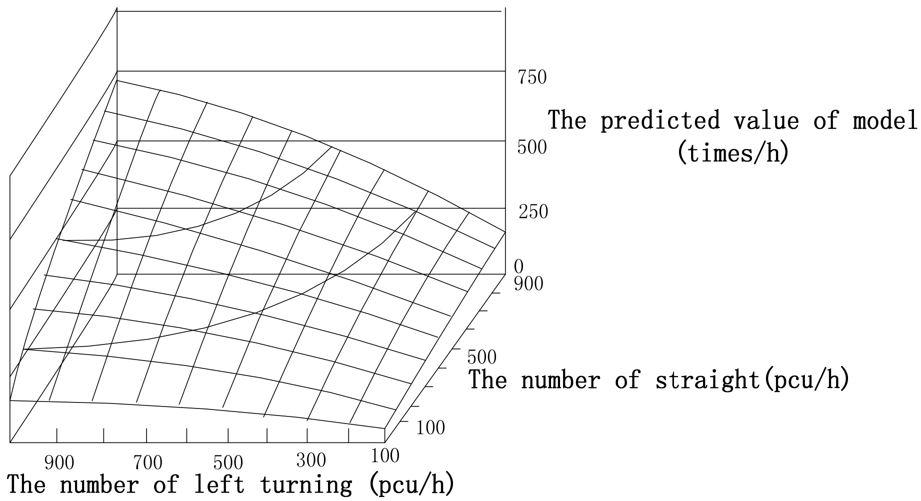

Figure 3-2. Relation of the number of conflicts and traffic flow

It is important to noted that the assumption of the arriving and depart rules of vehicles follow Poisson distribution is basically meet the parameter range of this paper. （The specific parameters are shown as figure 3-3 and figure 3-4） Abroad is generally believed that 600 pcu/h is the critical flow of Poisson distribution. And domestic study shows that when the single lane flow less than 350pcu/h, the arriving rules of vehicles follow Poisson distribution, and when the traffic flow between 350 pcu/h and 400pcu/h, the arriving rules of vehicles basically follow Poisson distribution, but sometimes follow binomial distribution (because of the affect of upstream intersection), when the traffic flow between 400pcu/h and 500pch/h(the maximum value of observation), with the larger counting interval, the arriving rules of vehicles also follow Poisson distribution.(WANG Haixing,2004)

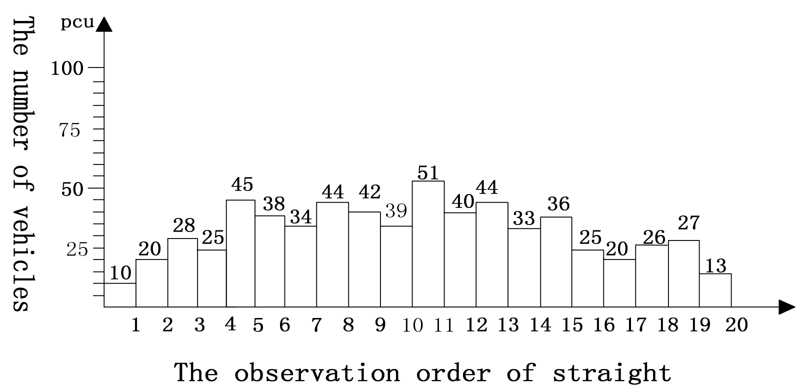

Figure 3-3. The number of vehicles from straight direction

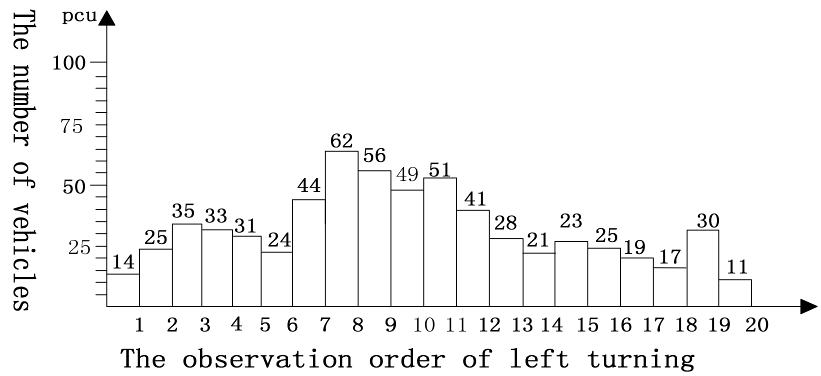

Figure 3-4. The number of vehicles from left turning direction

4 Conclusions

The paper based on the analysis of traffic volume discussed the calculated method of traffic conflict number of non-signal intersection. The results of calculation show that with the increased of traffic volume, the average number of traffic conflict and the severity of traffic conflict will be increased, furthermore, the growth speed will be more and more faster.

In the actual road condition, it is easy to see the multiple lanes of main road (two-lane or more), when the traffic volume of main road is not large, the number of lanes has a little effect on traffic conflict. But, when the traffic volume are more than a certain quantity(350pcu/h), With the increased of the lanes, it will be increase the difficulty of the minor road vehicles pass through the main road vehicles and also increase the average number of traffic conflict. Because of limited by conditions, the paper mainly discussed the calculation of traffic conflict of simply single lane, and the condition of multi-lane and the factors of vehicle speed, the range visibility and coefficient of road adhesion will also have an important effect on traffic conflict, and it will need next step study.

Abstract: The semi-rigid barriers were generally used in tunnel entrance. When impact occurred, some deformation of facilities could cause vehicles' rolling or impacting on tunnel wall, effective protection would not be provided. New transition structures combining connection sections with strengthen lap beams between standard barriers and tunnel were set to solve the above problems. According to new standards, crash simulation tests were analyzed, which small passenger car, medium truck and bus with impact angle (20°) and impact velocity on transition structures. By analyzing vehicle tracks, the buffering and redirective performances, maximum dynamic lateral deflection (D) , the maximum dynamic widening distance of lateral deflection (W), and maximum dynamic vehicle incline-out distance (VI), the results showed that the improved barriers with transition structures met the anti-collision requirements.
Keywords: Expressway; Tunnel entrance transition; Protection facilities; Simulation.

1 Introduction

From the statistics (H • Mashimo, 2012; FHAmundsen, G.Ranes, 2000), accident rates in highway tunnels, especially relatively long tunnels, were significantly less than the open sections. However, for different drivers' quality, operations management and traffic composition, driving safety of highway tunnel in China was significantly different with abroad.

Domestic highway tunnel accident investigations (Li Xinwei, 2014) indicated that the accidents mainly concentrated in the front section out of the tunnel entrance, were far higher than their proportions in highways, while the rear-end collision tunnel walls, rollover accidents accounted about 96.49% of the total accidents; the proportion of accidents caused by fire or other causes were lower; and the large trucks, passenger cars accounted about 89.85% of vehicle accidents.

In China, lacking of relevant norms of tunnel safety aspects of facility design, tunnel safety designs in expressways primarily focused on active protection measures to tunnel alignment, pavement, lighting, etc. When the accident occurred, effective passive protection facilities to vehicles were few. Generally, no protection facilities were set in tunnels, the ordinary crash barrier facilities were set outside of tunnels, and therefore serious security vulnerability leading to frequent accidents were existed at the transition section of tunnel entrances (Meng Guangcheng, Tai Yonggang, 2011).

For no protective measures, approach of fundamental shape of the concrete barrier fence or bridge extends to the tunnel and energy absorbing crash cushions were currently used, but there still had different security risks.

To improve operation safety and reduce the severity of accidents in highway tunnel entrance transition, the protection facilities with double transitions in stiffness and height need be set between the general sections and tunnels. Based on the requirements (Ministry of Transport of the People's Republic of China, 2013), existing protection facilities were improved, and collision simulations on passenger car, medium bus and truck were analyzed. By the analysis on passenger car, the buffering and redirective performances, maximum dynamic lateral deflection (D) and the maximum dynamic widening distance of lateral deflection (W) of highway barriers were tested. By the analyses of medium bus and truck, containment and redirective performances, maximum dynamic lateral deflection (D), the maximum dynamic widening distance of lateral deflection (W), and maximum dynamic vehicle incline-out distance (VI) were detected.

2 Structure design of protection facilities in highway tunnel entrance transition

According to the analysis of the accident cause in tunnel entrance transition, double transitions in stiffness and height on protection facilities and guardrail landscape change effects on traffic generation should be considered. The structure should be optimized as Figure 1.

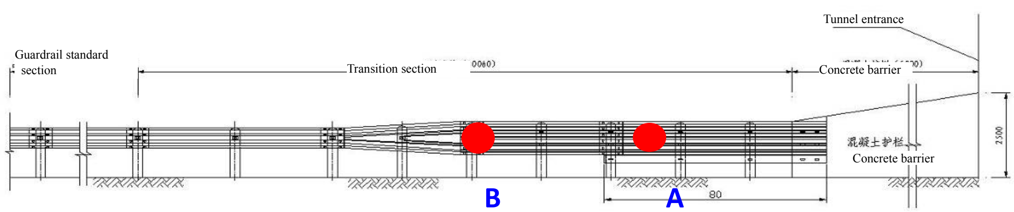

Fig 1. Design of protection facility in tunnel entrance transition

Between the normal and tunnel, the transition section was set, which was composed with stiffness and height transition. For the stiffness transition, enhanced double wave beam guardrail with column spacing 2m, three wave beam guardrail with column spacing 1m, and the strengthen lap beam were set. The length of above stiffness transition section was 10m. In order to realize the height transition, reinforced concrete guardrail was set to connect with the tunnel wall, that the length was 5m and the maximum height was 2.5 m.

The above structure scheme with 3 anti-collision level, local reinforcement could be improved to other anti-collision level when the normal section guardrail with higher protection grade.

3 Collision condition and evaluation standard

According the requirements (Ministry of Transport of the People's Republic of China, 2013), the collision condition and evaluation standard on protection facility in highway tunnel entrance transition should meet the requirements of table 1 and table 2.

Tab 1. Collision condition for transition sections of barriers

Impact Vehicle	Vehicle quality(t)	Impact velocity(km/h)	Impact angle（°）
passenger car	1.5	100	20
medium bus	10	60	20
medium truck	10	60	20

Table 2. Evaluation standard for transition sections of barriers

Evaluation Contents			**Standard**
containment performance	Whether the test cushion or divorced parts enter vehicle crew capsule		No.
	Whether the scattered location of divorced parts(≥2kg) from test cushion met the requirement		No.
redirective performance	whether the vehicle overturned after collision		No.
	Whether the wheel track met required redirective ranges after collision		Yes.
buffering performance	Occupant Impact velocity(OIV)（m/s）	longitudinal	≤12
		horizontal	≤12
	Occupant Ridedown Acceleration(ORA)（m/s^2）	longitudinal	≤200
		horizontal	≤200

4 Simulation of improved protection facility in tunnel entrance transition

According to the collision conditions, establishing full-size finite element models (XIE Suchao, 2008), impact simulations were analyzed, and results were evaluated whether meet the requirements of evaluation standards. According the requirements on collision point of transition section (Ministry of Transport of the People's Republic of China, 2013), the collision point of passenger car was point A, and that of medium bus or truck was point B in figure 2.

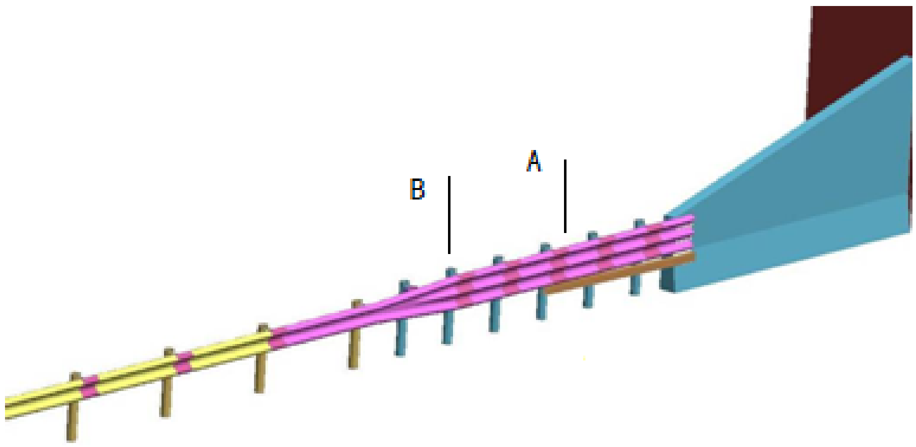

Fig 2. model of improved protection facility for tunnel entrance transition

4.1 Simulation of passenger car

Impact processing of small car and improved protection facility was showed in figure 3, the acceleration time curves of vehicle's gravity center were showed in figure 4, and the impact velocity curves of occupant after collision were showed in figure 5.

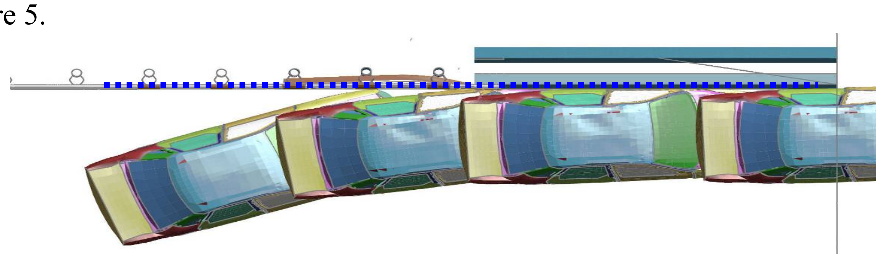

Fig 3. Impact processing of small car and improved protection facility

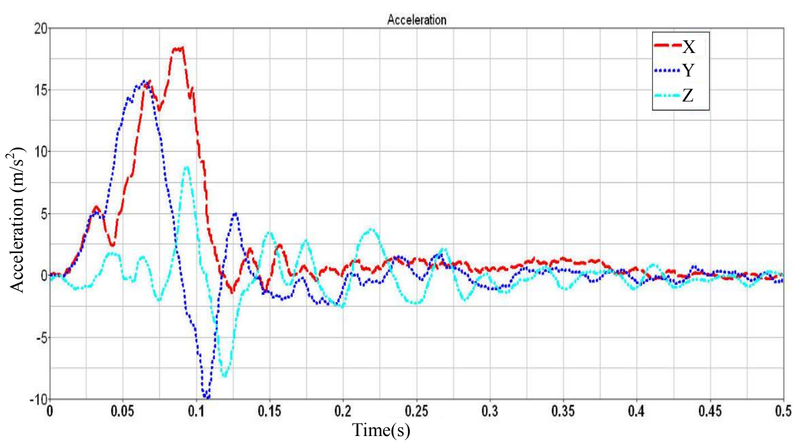

Fig 4. The acceleration time curves of vehicle's gravity center

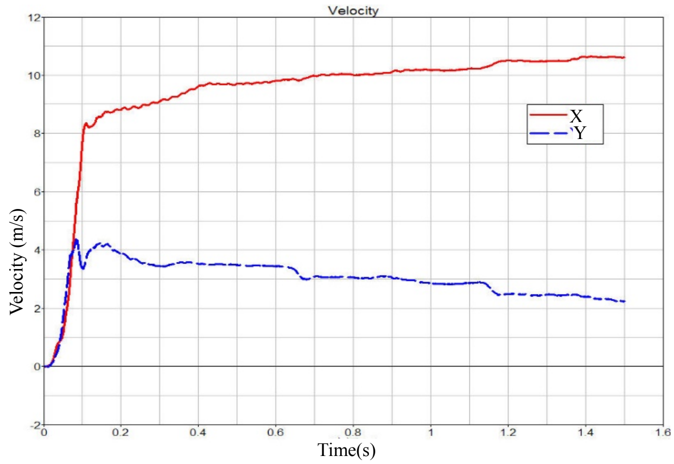

Fig 5. the curves of occupant impact velocity (OIV)

After passenger car impacted on improved protection facility, the vehicle's attitude was normal. Vehicle's Roll-over, Lateral turn and U-turn did not take place, and the Running track was still in redirective exit box. The longitudinal and lateral accelerations of maximum passenger car center were 186m/s^2 and 157 m/s^2, the longitudinal and lateral occupant impact velocity (OIV) were 9.6m/s and 4.4m/s, which meet the requirements of evaluation standards.

4.2 Simulation of medium bus

Impact processing of medium bus and improved protection facility was showed in figure 6.

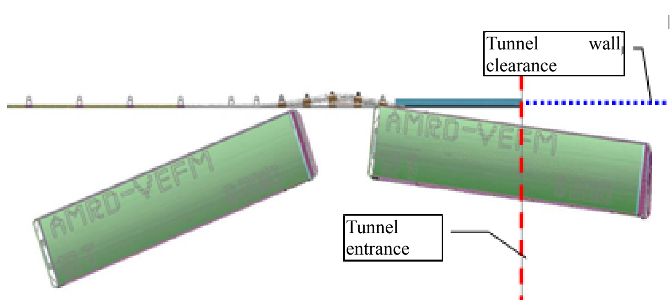

Fig 6. Impact processing of medium bus and improved protection facility

According to the simulation results, during the impact processing, the Driving state of medium bus was normal. Vehicle's Roll-over, Lateral turn and U-turn did not take place, and the Running track was still in redirective exit box. The maximum dynamic lateral deflection of transition sections of highway barriers was 408mm.

4.3 Simulation of medium truck

Impact processing of medium truck and improved protection facility was showed in figure 7.

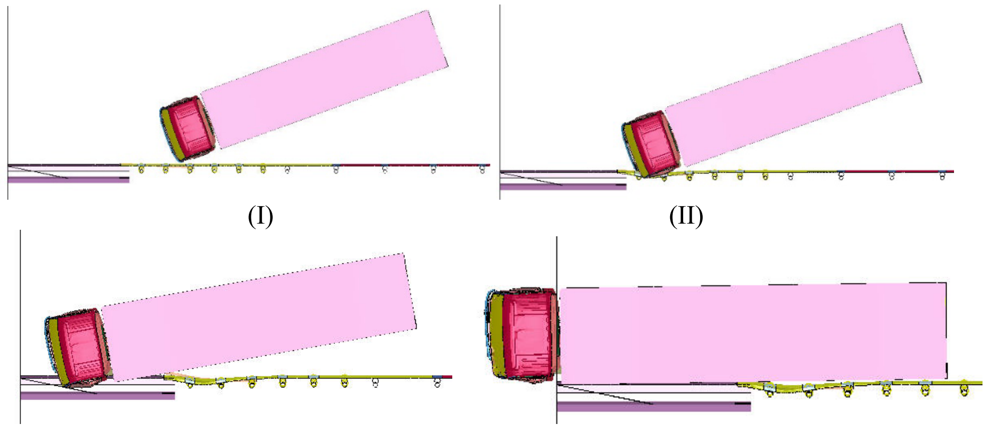

Fig 7. Impact processing of medium truck and improved protection facility

According to the simulation results, during the impact processing, the Driving state of medium truck was normal. Vehicle's Roll-over, Lateral turn and U-turn did not take place, and the Running track was still in redirective exit box. The maximum dynamic lateral deflection of transition sections of highway barriers was 343mm.

4.4 The evaluation of simulation results

The simulation results showed that the indicators of safety performance of barriers in transition sections of tunnels in expressways meet the requirements of the evaluation criteria under different impact conditions, and the improved transition section of barriers could provide protection degree of A-level.

Table 3. the evaluation of simulation results

	Evaluation criteria		Simulation results			Whether the results meet the criteria(Yes/No)
			Passenger car	Medium bus	Medium truck	
1	Whether the vehicle crossing, over ,or straddle the test barriers		No	No	No	Yes
2	Whether the test cushion or divorced parts enter vehicle crew capsule		No	No	No	Yes
3	Whether the vehicle rollover after impact		No	No	No	Yes
4	Whether the vehicle Running track beyond redirective exit box		No	No	No	Yes
5	OIV（m/s）	Longitudinal(≤12)	9.6	/	/	Yes
		Horizontal(≤12)	4.4	/	/	Yes
6	ORA（m/s2）	Longitudinal(≤200)	186	/	/	Yes
		Horizontal(≤200)	157	/	/	Yes

5 CONCLUSIONS

(1) By numerical simulation, an improved transition sections of barriers for tunnel entrance and standard section in expressway was analyzed. With the help of the barriers, the protection level can be greatly improved, and the impact risk could

be greatly reduced. According the landscape of tunnel entrances, the transition sections of barriers can be adjusted to maintain visual continuity.

(2) In application, the construction quality inspection of improved transition sections of barriers for tunnel entrance must be conducted to prevent bolt looseness.

Abstract: The current guidelines in China are mainly based on four-lane freeway, which do not fit eight-lane freeway well. Therefore, this paper researched traffic stream characteristics of the on-ramp region of Zhengyi interchange. As a result, the acceleration lane is divided into three regions—the region marked with entrance markings, the region where lane 1 connected with the inside lane of the ramp and the region where lane 1 connected with the outside lane, among which, the minimum length of merging length is calculated as a non-linear integer programming (NLIP) based on the gap acceptance theory and traffic volume. The trial results of the models above show that the present recommended value of acceleration lane length and cannot meet the vehicles' merging demand under secondary serve level when the freeway is eight-lane with two-lane ramp.

Keywords: Eight-lane freeway; Two-lane ramp; Gap acceptance theory; NLIP.

1 Introduction

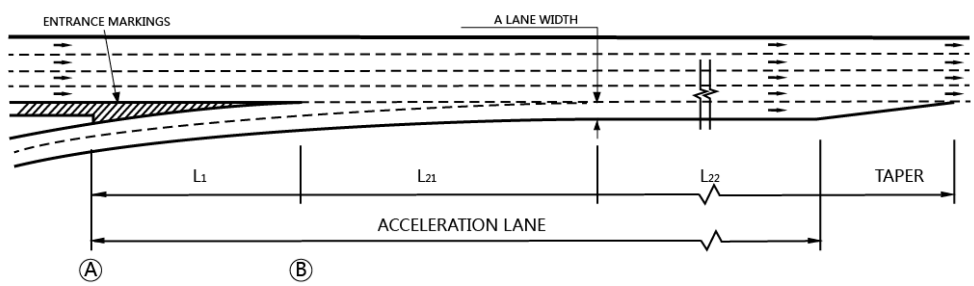
Current national standards and design specifications primarily are based on four-lane freeway. With growing number of eight-lane freeway, its design standard and management cannot meet the requirement of multi-lane freeway to some extent. This paper focuses on acceleration lane length of eight-lane freeway with two-lane ramp.

There are many studies about accelerate length calculation model. In Xu's research (Xu et al. 2007), the recommended acceleration lane length in Chinese design specification have not considered the traffic volume, and is shorter than the length needed as well. According to the traffic volume and the minimal acceptable headway in the mainline and acceleration lane, a new optimal design method of the acceleration lane length was presented in Zhi's study (Zhi et al. 2009). However, the merging model is on the assumption that vehicles search for a gap with uniform acceleration at the same time which doesn't fit the actual driving behaviors well. LI Shuo's study (Li et al. 2000) presents a new design philosophy on acceleration lane that the traffic volumes on mainline of freeway and on-ramp are considered in the computation of the acceleration lane length, which is significant to the engineering practice in the design of on-ramp especially when the mainline is in congestion.

Lane management to separate passenger car and truck is quite common in China, which may cause changes about speed and traffic flow distribution on each lane. Meanwhile, the drivers' behavior on two-lane ramp merging area have changed as well. Considering all the above, an acceleration length calculation model of eight-lane freeway with two-lane ramp is developed in this paper, with attention to the influence of drivers' behavior, eight-lane freeway traffic volume, and two-lane ramp as well.

2 Field Data Analysis of Influencing Factors

The acceleration lane is set to provide vehicles on ramp a considerable distance to accelerate to freeway speed and merge opportunities on the mainline. It is classified as either a taper or parallel type, according to the configuration of the ramp terminals and as either single or multilane, according to the number of the lanes on the ramp. In China, the most widely used type of the two-lane entrance ramp is the taper type, thus this paper focuses on the length of the two-lane entrance ramp in the taper type (Figure 1).



NOTES:
1. SPEED AT POINT A IS THE INITIAL SPEED OF THE ACCELERATION LANE
2. THE TOTAL LENGTH OF L21 AND L22 IS REQUIRED GAP ACCEPTANCE LENGTH.

Figure 1. Tapered design for entrance ramp

Constraints and decisions of the acceleration lane length diverse. Many factors should be considered, such as speeds, traffic volumes, percentage of trucks, capacity, lane management and so on. In order to provide scientific basis for modeling, headway distribution of the on-ramp merging region, speed at the ramp nose, driving characteristics were analyzed emphatically.

(1) Headway distribution of the on-ramp merging region

Based on investigation of a number of on-ramp merging region on the freeways in China, Li Wen-quan from Southeast University (Li et al. 2000) found that Erlang distribution can fit the headway data on lane 1 of on-ramp merging region through adopting suitable K values. The probability density function of Erlang distribution is written as:

$$f(t) = (\lambda K)^K t^{K-1} e^{(-\lambda K t)/(K-1)!} \quad (1)$$

Where K and λ are parameters of the probability density function and K is a positive integer which is decided by traffic volume.

In this paper, the Zhengyi Entrance of Freeway G42 is investigated, and the headway data on lane 1 at point B has been recorded. Chi-square test was applied at 5% level for 2° of freedom to see how closely the frequencies of the observed sample values agree with the expected Erlang distribution frequencies. As a result, the Chi-square test result suggested that there is no significant difference between the observed and negative exponentially distribution at 5% significance level.

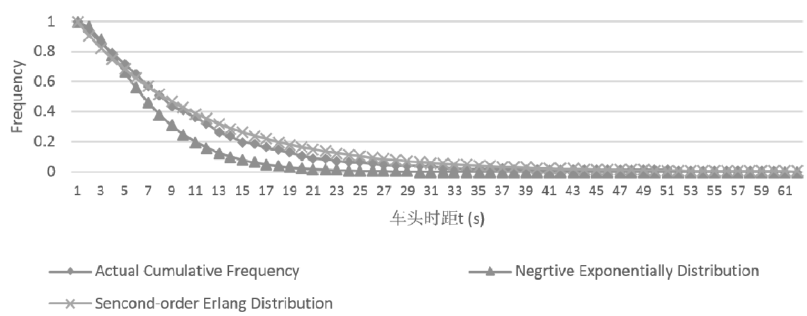


Figure 2. The Headway Frequency of lane 1 at Point B

(2) Initial Speed

In normal conditions, the noes is set as starting point of the acceleration lane, so we take the speed at the nose as initial speed. In the investigation, the actual measurement data of vehicles' speed (such as average speed, operating speed) is higher than the ramp design speed 60km/h, while the trucks' speed data is located around 60 km/h. Therefore, the design speed of ramp could be used as the initial speed of acceleration lane.

(3) Driving Behavior

Acceleration lane is divided into--accelerating, gap acceptance and triangle transition, three regions in most surveys in China. The research surveyed the on-ramp region of Zhengyi interchange (eight-lane freeway with two-lane ramp) to find which region the drivers would choose to merge. Investigation results show that the driving behavior is also affected by the entrance markings. Only 2.46% of drivers merge into the mainline crossing the entrance markings,compared with 81.57% for

L_{21} and 15.97% for L_{22}, which means that the drivers do not start to merge into the mainline traffic flow until the acceleration process is finished, but choose the proper gap to merge and adjust their speed at the same time when the entrance markings ends.

As a result, the on-ramp region is divided into three regions—the region marked with entrance markings (in length of L_1), the region where lane 1 connected with the inside lane of the ramp (in length of L_{21}) and the region where lane 1 connected with the outside lane (in length of L_{22}).

Furthermore, through the statistical analysis of the headway, the following conclusions have been drawn: (1) Drivers tend to merge after the painted nose. (2) When there is no acceptable gap to merge in L_{21}, drivers will go further to search. (3) More than 99% drivers will choose the headway more than 2.5 seconds (Figure 3). "Drivers(L21)" are the drivers whose merge point is on L_{21}, and Drivers(L22) are the drivers whose merge point is on L_{22} in figure 3.

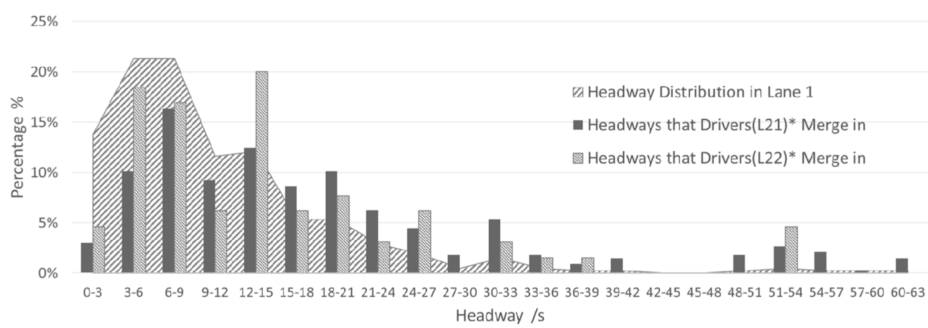

Figure 3.Frequency of headways that drivers merge in

3. Acceleration lane length calculation model

The analysis divided the acceleration lane into two parts:

- Entrance marking segment (Most of the drivers speed up only)
- Merging segment (Drivers may vary their acceleration behavior, slowing down to wait for a gap or speeding up to catch a gap)

3.1 Entrance marking segment

The minimum length of entrance marking segment is based on a combination of the following assumption:

- The drivers will enter the merging region at the ramp design speed.
- Drivers will accelerate with a constant comfortable rate.
- Because of the limitation of ramp grade, the minimum entrance marking length doesn't consider the longitudinal slope effect on acceleration.

Based on the assumptions described above, the following equation to determine the minimum length of entrance marking segment is put forward.

$$L_1 = \frac{V_1^2 - V_0^2}{2a} \tag{2}$$

Where, L_1——Entrance marking segment length, m

V_1 ——Merge speed, m/s

V_0——Initial speed on ramp， m/s

a——Acceleration rate， m/s^2

3.2 Minimum length of merging segment

The model to calculate the minimum length of merging segment is based on the gap acceptance theory. According to the results of the above, as well as the conclusion of research both in China and abroad (Torbic et al. 2012), this paper assign the critical headway (t_a) the value of 2.5 seconds, and makes the following assumptions to simplify the problem:

- Drivers will merge into the mainline when there is one or more acceptable gap on lane 1.
- Drivers will merge once there is an acceptable gap forward which means the headway is more than 2.5s.

The headway of vehicles on lane 1 is subjected to Erlang distribution. So that the probability of any gap is more than t_a is as follows.

$$p_c = f(Q_1, K) = P(h \geq t) = e^{-\frac{Q_1}{3600}t} \quad \text{（K=1）}$$

$$p_c = f(Q_1, K) = P(h \geq t) = \left(1 + \frac{Q_1}{900}t\right) e^{-\frac{Q_1}{900}t} \quad \text{（K=2）} \tag{3}$$

This research assumes that slower entry is unavoidable and is generally accepted by the public, so the probability that a vehicle could merge is set to be 0.95. Let e be the percentage of the vehicles which merge in through L_{21} and keep running on lane 1 at L_{22} region.

The probability of there are more than m headways longer than t_a in n headways could be expressed as: $p = \sum_{i=1}^{n} C_n^i p_c{}^i (1-p_c)^{n-i}$. When m=1, $p = 1-(1-p_c)^n$. The formula is the probability vehicles merge in is p. Furthermore, the length of n headways is

$$L = n \cdot h \cdot v_{85} = \frac{1000 v_{85}}{Q} n \tag{4}$$

Therefore, the model of minimum length (total length of the two ramp lanes) of merging segment could be expressed as a non-linear integer programming (NLIP).

$$\begin{aligned}
\min \quad & 2\frac{1000 v_{85}}{Q_1} n_1 + \frac{1000 v_{85}}{Q_2} n_2 \\
s.t. \quad & p_{l1} + (1 - p_{l1}) p_{l2} \geq 0.95; \\
& p_{l1} = \sum_{i=1}^{n_1} C_{n_1}^{i} p_{cl1}{}^{i} (1 - p_{cl1})^{n_1 - i} = 1 - (1 - p_{cl1})^{n_1}; \qquad p_{l2} = \sum_{i=1}^{n_2} C_{n_2}^{i} p_{cl2}{}^{i} (1 - p_{cl2})^{n_2 - i} = 1 - (1 - p_{cl2})^{n_2} \\
& p_{cl1} = f(q1, K); \qquad p_{cl2} = f((q1 + q2 \cdot p_{l1} \cdot e), K)
\end{aligned}$$

Where p_{l1} and p_{l2} mean the probability of vehicles merge through L_{21} and L_{22}, $q1$ and $q2$ mean the traffic volume of lane 1 and ramp.

4 Discussion of Results

The trial results of the models above using several groups of representative data show that the minimum length of acceleration lane is more sensitive to operating speed than traffic volume. At the same time, because of the number of headways in the model is designed to be an integer, the more the traffic volume of main line, the smaller the required minimum length of acceleration lane within certain limits.

Comparing to the current specification, the code values of acceleration lane length cannot meet the vehicles' merging demand under secondary serve level especially when the operating speed is more than 80km/h.

	60km/h			70km/h			80km/h		
	A	B	C	A	B	C	A	B	C
■L1	65	65	65	105	105	105	150	150	150
L21	260	250	240	300	290	280	345	335	320
L22	105	80	90	125	80	110	140	105	125

Composition of The Minimum Acceleration Lane

■L1 L21 L22

Figure 3. The Composition of Acceleration Lane Length

5 Conclusions

(1) The drivers do not start to merge into the mainline traffic flow until the acceleration process is finished, but choose the proper gap to merge and adjust their speed at the same time when the entrance markings ends.

(2) Based on the gap acceptance theory, the minimum length calculation model of merging region is simplified as a non-linear integer programming (NLIP).

(3) The trial results of the models above using several groups of representative data show that the minimum length of acceleration lane is more sensitive to operating speed than traffic volume. And the current specifications' recommended values of acceleration lane length cannot meet the vehicles' merging demand under secondary serve level when the freeway is eight-lane and with two-lane ramp.

6 Recommendations for Future Research

The transportation flow distribution and traffic capacity of eight-lane freeway under different lane management need further investigation, especially the on-ramp lane, which is important to determine the recommended value.

Abstract: Based on the geological environment recognition of Hypermap Model and application technology of location design, and based on orthophoto map environment of remote sensing (RS), this thesis introducing the concept of Hypermap to the railway location system. Establishing Hypermap Model of railway location which based on geographic information, geology, and geological knowledge. Based on Extended-Catalog Structure Model to realize function which to store nonlinearly, organize, manage and browse the relationship between the information. Provide illustrations of geology, geography and geological knowledge environment for railway locating engineer, and to realize integration and application of remote sensing (RS) geological information system in three-dimensional railway location design.

Keywords: Hypermap; Railway location; Geological environment recognition.

1 Introduction

Three-dimensional geographic environment is the carrier to realize the design of railway location in virtual environment. It is an important problem in three-dimensional geographic environment modeling of railway location system that how to automatically or interactively provide railway location engineer with geographic, geological and hydrological information, and make these information more effective express, organization and application. Hypermap is a multimedia hyper-document with function of geographic data acquisition and we can get access to geographic data through geographical coordinates. The introduction of Hypermap's concept provides a more effective method for the understanding of the environment. Therefore, this paper is based on the remote sensing orthophoto map, establish the railway location's Hypermap model of geographic, geological and hydrological information in three-dimensional geographical environment. Based on Hypermap, to realize the storage, organization, management and browse of the nonlinear relationship between these information. Provided illustrations for railway location engineer with environment of geology, geography, and help railway location engineers to improve the efficiency of design in three dimensional environment.

2 The Concept of Hypermap

Laurini and Milleret-Raffort reference Hypertext and hypermedia thought, put forward the concept of Hypermap in 1990.They put map as the reference frame of a multimedia hyper-document's location, and applied to GIS. Hypermap is a combination of map and hypermedia. The connection between the map data and a variety of hypermedia data not only can through function interface or determined area on the map, but also search window. So it allows users to navigate multimedia data by themes or space. Maps and hypermedia express different data. Maps express the geoscience data but hypermedia express the non-geo-data information. Map can be used as a functional interface of hypermedia data. The way we determine the area on the map as hypermedia document information can through geographic coordinates. The retrieval way we can select a target or a regional on a map or define a window.

Hypermap theory through setting the node and hyperlinks to link different targets with way of hypertext; By the definition of nodes, to realize the obtainment of geographic information by hyperlinks and achieve management and organization of geographic information by a directory services. The concept of railway location Hypermap model which established in this paper include the Hypermap work area and Hypermap nodes. The following further is definition of these concepts.

2.1 The Hypermap work area

The Hypermap work area is a collection of the mainland layer in a certain area. As for railway location design in three-dimensional environment, it means that determine a region interactively or automatically, and all the geographical, geological and hydrological information and geological knowledge of this area.

2.2 The Hypermap nodes

As a special object, Hypermap node shows as link relations of a certain area of map or a space object. As for the three-dimensional environment of railway location design, node type is mainly the vector graphics Hypermap nodes of close geographic information relationship. Define hot zone in the image map as spatial scope of node response to of super chain. For the determine of hot zone there are generally 3 kinds of methods: set rectangular area, set the polygon area and set point, line, surface and other space objects. In which, a spatial region-wide of digital geological objects can be used as vector graphics Hypermap node directly.

3 The Hypermap Model of Railway Location in 3D Environment

3.1 The composition of model

From an object-oriented perspective, the Hypermap model of railway location in three-dimensional environment is the collection of spatial object (OS):

$$H = \{O_1^S, O_2^S, ..., O_n^S\}, i = 1,2,...,n \quad (1)$$

The spatial objects include objects of Hypermap work area: the geological object, corresponding geological knowledge, geographical, hydrological information, 3D geologic model and so on.

Every spatial object O^S includes four basic contents: the object identifier (ID^S), hypermedia (H^M), hypergraphics (H^G)and hyperlinks (H^L),expressed as:

$$O^S = \{ID^S, H^M, H^G, H^L\} \quad (2)$$

In the formula, ID^S is the unique identifier for the object; H^M on behalf of the non-geometric properties, the multimedia information such as graphics, images, 3D virtual reality; H^G representative geometric properties, such as spatial attributes and other numerical data. H^M and H^G together form the internal state of O^S; H^L is a collection of O^S method, and define the non sequential connection relation and collection of operation method between the internal object of O^S, between the object, between Hypermap and between the Hypermap inside.

3.2 Hyper-Catalog structure of model

Hypermap theory can through setting the node and the hyperlink, to link up different objects with hypertext links, and to relize the conversion of information. But like as hypertext, since the final result of hyperlink will be a complex and endless network topology. Therefore, in the case of having the information or jump too often, the structural relationship of linked is complex, and it is very inconvenient for information organization, so the efficiency is relatively low. The purpose of establishing Hyper-Catalog structure of Hypermap model is to apply the directory tree structure to the basic organization of information in Hypermap model. And with all kinds of object types as basic unit, set up a comprehensive organization structure and form of object-oriented. Putting all kinds of objects into the same concept frame, unified organization and management by Hyper-Catalog structure, and provide directory index which has function of rapid positioning.

According to the type of each object in the work area of Hypermap, organized the node by the directory tree. Every kind of geological object and its corresponding geological knowledge consists of a class, as shown in figure 1.

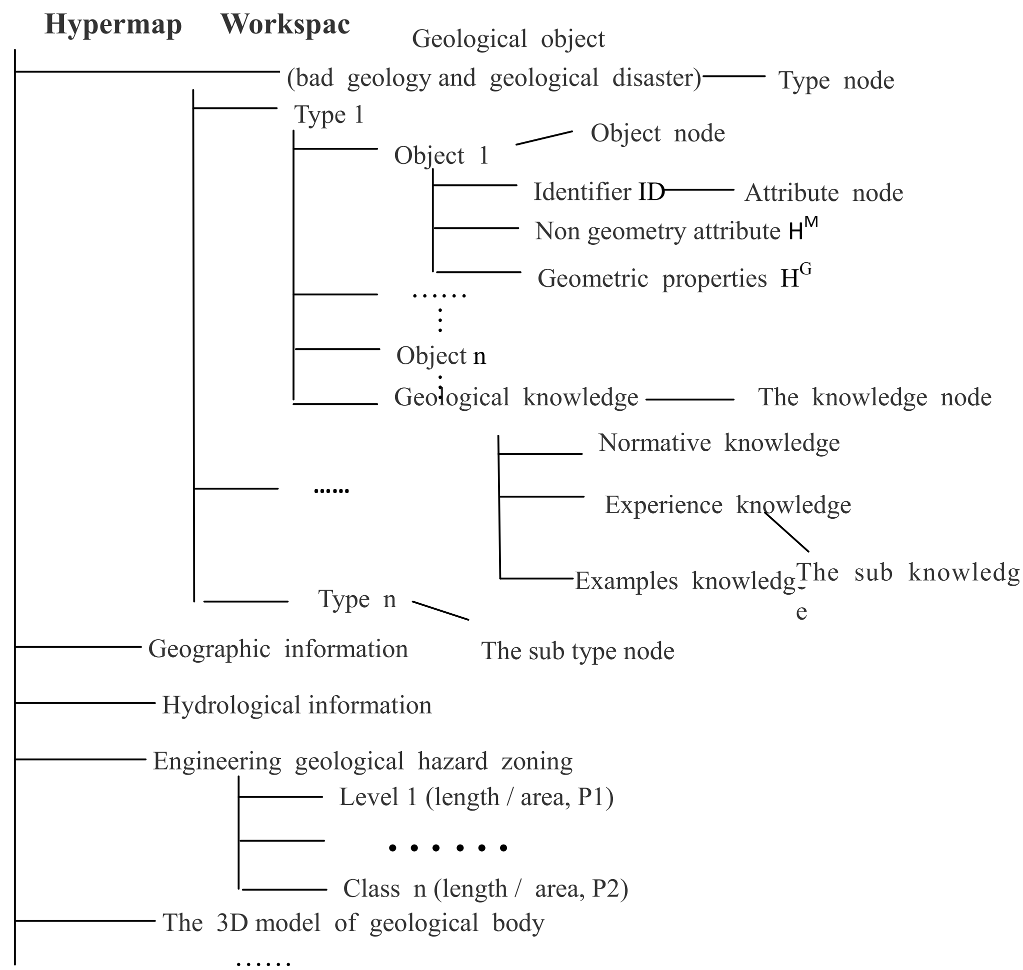

Figure 1. Hyper-Catalog structure of Hypermap model

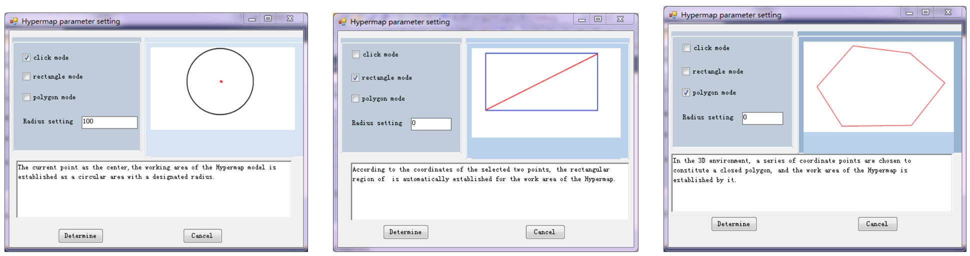
4 Geological Environment Recognition Based on Hypermap Model

The Hypermap model of railway location in 3D environment is built in a Hypermap work area, and using Hyper-Catalog structure to organize and manage all objects (information) in the work area. Therefore, the premise of establishing Hypermap model of railway location is to establish Hypermap work region, and the premise to establish Hyper-Catalog work area is to determine the scope of regional.

4.1 Three ways of establishing Hypermap work area

Railway location engineer uses the mouse to determine interactively a closed region as the range of Hypermap work area in three-dimensional geographical environment. Then retrieval all relevant information which located in the region: the geological objects, corresponding geological knowledge and geographic hydrology and so on, and to establish Hypermap model. Classifing information, and establishing Hyper-Catalog structure, and use the Hyper-Catalog to organize and manage these objects (information). Railway location engineers can analyze and evaluate the regional geology, geography ,hydrology and other information. Determine interactively the regional range of Hypermap work area mainly in three ways: click, rectangle and polygon mode. In Fig2, (a), (b) and(c), diagram is presented.



(a) (b) (c)

Figure 2. Determine interactively the Hypermap work area – click mode, rectangle mode and polygon mode

4.2 The geological environment recognition based on Hypermap model

Recognition of geological environment based on Hypermap model also namely spatial geological objects recognition, and the problems is how to judge geological objects and other related information of railway location in the scope of working area. The way to judge by point selection mode are simple, and can be converted to the problem that judging the distance between point; The way to judge by mode of set rectangular and polygonal interactive involves to straight line, polygon and polygon spatial relation judge problem. The above two types illustrate respectively as follow.

(1) Relationship's judgment between points

Judging the distance (D) between the geological objects boundary coordinates of space and the center of a circle. If it is less than or equal to the radius(R), then can conclude the object is located in the work area. The process can be used the following pseudo code representation:

```
for(long i=1;i<=M;i++)
{for(long j=1;j<=Conpts(i);j++)
  {dij=GetDistence(Pti, j,Pcenter)       // solving for the distance between the j-th point of the
                                          // i-th geological objects border and the center
      if(dij<=R) // If less than or equal to R
      {
            SaveToArray(); // Save the geological object information
```

```
                    break;                  // to exit the current judgment of i-the geological object
                }
            }
        }
```

(2) Relation's judgment between line, polygon and polygon

Through the algorithm in this paper the problem that a straight line, polygon and polygon relation judgment can be converted to the point and polygon spatial relation judgment problem. As long as one point of the geological objects boundary in working area or on the boundary of polygon range, it can be considered that geological objects are in the work area. The process can be used the following pseudo code representation:

```
for(long i=1;i<=M;i++)
{
   for(long j=1;j<=Conpts(i);j++)
   {
      // solving if the j-the boundary point of i-the geological objects is located within the
      //workspace or on the boundary of the polygon
      BOOL m_bIn=PtInRegion (Pt_{i, j},*Pts)
      if(m_bIn==TRUE)        // If located inside or on the boundary
      {
            SaveToArray();     // Save the geological object information
            break;             // To exit the current  judgment of i-th geological object
       }
   }
}
```

5 The Application Based on Hypermap Model of Railway Location

Through the geological environment recognition technology of Hypermap model, railway location engineers will be able to identify the geological environment interactively. And the geological information will be provides to the railway location engineer with Hypermap mode. Figure 3, Figure 4 and Figure 5 shows an application example click, rectangles and polygons way, Figure 6 shows the application examples of Hypermap model.

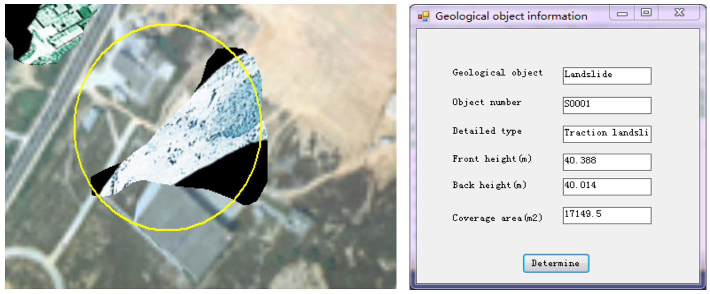


Figure 3. Hypermap model – the application of point selection mode

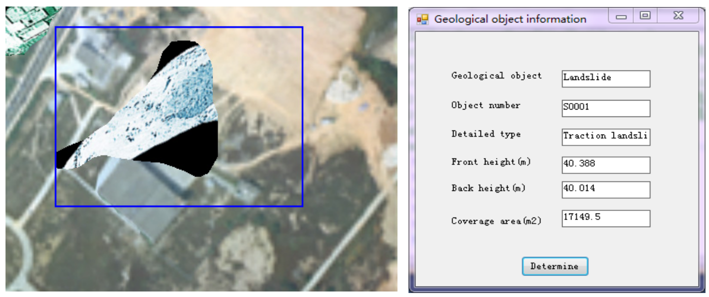

Figure 4. Hypermap model – the application of rectangles mode

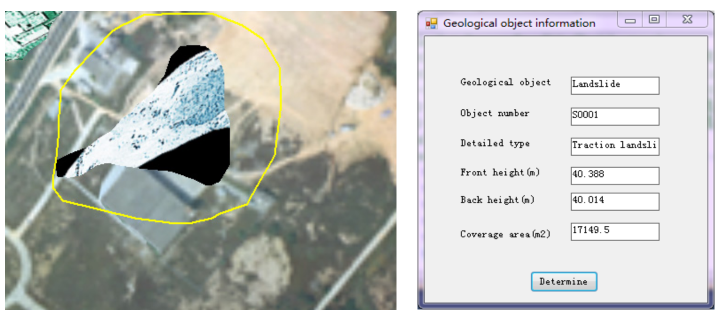

Figure 5. Hypermap model – the application of polygon mode

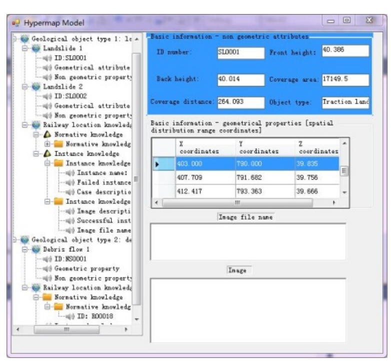

Figure 6. Application example of Hypermap model

6 Conclusions

This paper based on remote sensing images orthophoto map environment, introducing the concept of Hypermap to the railway location system. The Hypermap model of railway location is established based on geographic information, geology, and geological knowledge. To realize the relationships' non-linear storage, organization, management and browsing between the information based on Hyper-Catalog structure model. Provide engineers with illustration of geological, geographical and geological knowledge environment. To realize the integration and application of remote sensing geology information system in 3D railway location.

Abstract: Bus rapid transit is one of the best ways to improve urban transit. However, how to integrate the traditional bus and BRT is a problem that limits the efficiency of BRT system. Elastic route BRT system is a new BRT mode, which allows the BRT buses turn into or turn out of the bus lane at intersections. This paper puts forward a BRT approach capacity calculation method at intersection in Elastic route BRT system based on the data of Guangzhou BRT. And a case of Guangzhou BRT is studied to verify the validity developed method.
Keywords: BRT lane capacity; Elastic route BRT system; Saturation flow rate.

1 Introduction

Elastic route BRT system is an open system that allows BRT turn into or out of the BRT lane at intersections. The elastic mode ensures the connection of BRT and normal buses, and also makes the bus route more flexible. Meanwhile, there are some places that buses and cars share one lane, which makes the capacity influence factors of BRT approach become more complex. According to the current study, the researches of BRT capacity mainly concentrate on bus lane, including main factors of bus lane capacity (*Transit Capacity and Quality of Service Manual-3rd Edition*), large vehicle correction factor which influences the capacity of intersection approach (*Zhao Jing, 2008*), approach capacity model (*Code for design of municipal road* and *HCM*). The approach capacity is the maximum number of vehicles in one approach passing through the intersection in unit time. As an important part of BRT capacity, the intersection is the bottleneck. The actual BRT approach capacity at intersection is significant for completion of the intersection capacity model, bus line arrangement and reference to capacity design.

2 Analyses of Influence Factors

Four factors influence the capacity: road condition, traffic condition, management and control condition and environment condition. This paper supposes that the road condition of intersection approach basically conforms to the construction specification and the environment condition is good, so it mainly focuses on traffic condition and management and control condition. This paper places emphasis on these factors: the lost time and dwell time that influence the effective green time, and traffic composition and turning proportion that influence the saturation headway.

2.1 Lost Time of Bus Signal

(1) Front Lost Time

Figure1 shows the headway counting from the second queuing bus in each cycle.

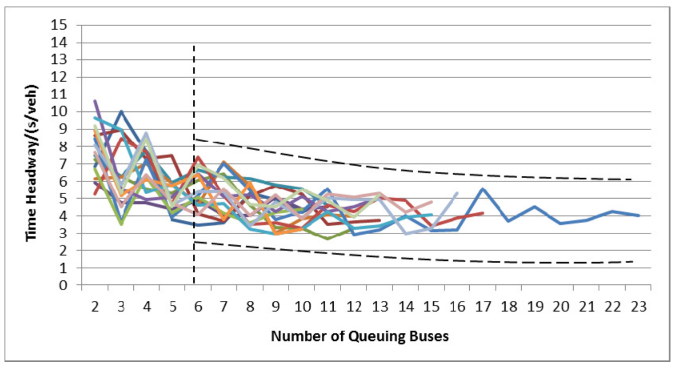

Figure1. Headway series of signal cycles

The cartogram shows that the headway of the first four buses is longer and scattered, caused by the differences in driver's response time and starting time. It becomes shorter and gradually tends to steady value starting from the fifth bus. It can be inferred that the average headway calculated from the fifth bus is more approximate to the saturation headway. Therefore, the green time subtracts the sum of first four buses headway, the time left can be regarded as the effective time of saturation flow rate.

This paper aims at building the actual capacity model, so the front lost time is divided into two parts: starting lost time of the first bus and lost time of the first four buses running at non-saturation headway. The first vehicle in a fleet composed of BRT and other social vehicles is random. It could be a BRT bus or social car, and the probability depends on the ratio of bus or car. Statistics shows that the average starting lost time of BRT is $t_{FLB} = 2.43s$ while the car's is $t_{FLC} = 1.1s$. Then, a linear equation about bus ratio and front lost time can be obtained.

$$t_{\mathrm{FL}} = 2.4\rho_{\mathrm{B}} + 1.1\rho_{\mathrm{C}} = 1.3\rho_{\mathrm{B}} + 1.1 \tag{1}$$

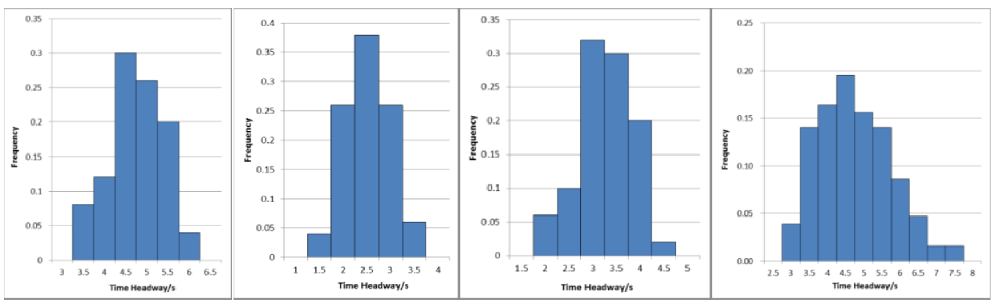
(2) Back Lost Time

The back lost time can be defined as the time that the last vehicle takes subtracts saturation headway. $t_{BL} = t_L - h_t$. Statistics tells the fact that when vehicles pass the intersection in queue, the average time is 3s from the last vehicle passing the stop line to the red light turning on. Comparison with the average headway obtained by field data shows that this 3s is less than average headway and the back lost time does not exist.

2.2 Traffic Composition

Traffic composition has great influence on saturation headway. This paper divides the queuing vehicles into two parts: the operating initial stage is the process of first four vehicles passing the stop line, and the steady stage is for the rest vehicles. The average headway of these two stages should be calculated separately.

There are four vehicle following patterns in a fleet composed of BRT and social vehicles. According to the field investigation, the headway of these four patterns is different.



(a) (b) (c) (d)

Figure2. Cartograms of four following patterns

(a) The headway of car following bus. (b) The headway of car following car.

(c) The headway of car following bus. (d) The headway of car following car.

The distribution of these four vehicle following patterns are all basically similar to normal distributionX~N(μ, σ^2). The average headway of each following pattern is obtained.

Table1. Average Headway of Four Following Patterns on Steady Stage

Vehicle following pattern	Car following bus	Car following car	Bus following bus	Bus follo- -wing bus
Average headway（s）	4.01	1.98	2.86	4.49

(1) Headway of operating initial stage

Figure3 shows the sum of first four buses' headway in BRT-only fleet in fifty signal cycles. The average of the sum is $t_{H4} = 22.91s$, so the average headway of buses on the operating initial stage is $h_t = 5.73s$.

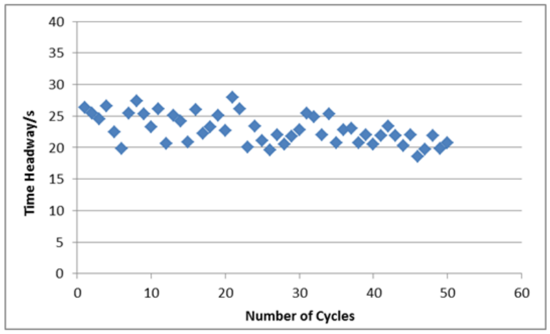


Figure3. The sum of first four buses' headway scatter diagram

According to the rules of permutation, there are 32 combinations of different probabilities for the first five vehicles. The fifth vehicle which determines the last following pattern is taken into consideration. The probability of type of vehicles arriving at the intersection can be regarded as the ratio of such type in queue, which means the probability of following vehicle's type won't change with the type of vehicles ahead. The product of sum of the first four vehicles' headway and its probability is the headway of each combination. Thus the average sum of headway of each traffic proportion can be obtained by the headway of all 32 combinations.

$$t_{H4}{}' = \sum_{i=1}^{32} P_i \times (t_{H4})_i \qquad P_i = {\rho_B}^n \times (1-\rho_B)^{5-n} \qquad (2)$$

(n is the number of bus in the first five vehicles)

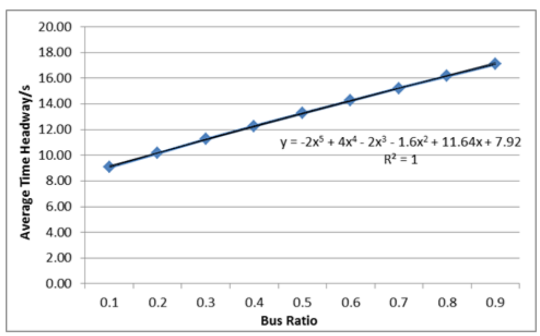

Figure4. Function of bus ratio and the sum of the first four vehicles' headway

Although the coefficient of determination is less than the quantic polynomial, linear fitting method can be used to simplify the computation.

$$t_{H4}{}' = 10\rho_B + 8.2 \qquad (3)$$

The conclusions above derive from the data of steady stage which is not suitable for operating initial stage. It is difficult to collect the first five vehicles' headway of different combinations, and the sample size is too small to support a fitting function. When there are all buses in line, which means$\rho_B = 1$, the headway of operating initial stage is 1.28 times more than that of the steady stage. This conclusion can be used here to simply deduce the headway equation on operating initial stage.

$$t_{H4} = 1.28 \times t_{H4}{}' = 12.8\rho_B + 10.5 \qquad (4)$$

(2) Headway of steady stage

Headway of the second stage – steady stage depends on the ratio of different vehicle type too. But because of the large amount of queuing vehicles and possible combinations, only the probabilistic method can be used to estimate.

The probability of bus following bus: $P_{B+B} = \rho_B^2$;
The probability of car following bus: $P_{B+C} = \rho_B \times \rho_C$;
The probability of bus following car: $P_{C+B} = \rho_C \times \rho_B$;
The probability of car following car: $P_{C+C} = \rho_C^2$.

The average headway of steady stage can be calculated by the equation below:

$$h_t = \rho_B^2 \times t_{B+B} + \rho_B \times \rho_C \times t_{B+C} + \rho_C \times \rho_B \times t_{C+B} + \rho_C^2 \times t_{C+C}$$
$$= -0.4{\rho_B}^2 + 2.91\rho_B + 1.98$$

The equation can be linear fitted for the purpose of simplification.

$$h_t = 2.51\rho_B + 2.05 \tag{5}$$

2.3 Dwell Time

The distance between the bus stop and intersection influences the effective green time. When the distance is short, queuing vehicles probably extend to bus stop and result in the dwell delay of following buses. These buses can't move into the stop until queuing vehicles dissipate out in green phase, which affects the full use of green time.

Assume D as the distance between the bus station platform and stop line of intersection approach, t_s as the lost green time(Wang Qian, 2003), t_R as the length of red phase. t_T represents the time bus stopping and starting in the stop and t_a represents the bus arriving time in one cycle. The arrival curve of buses is defined as a(t), and the leaving curve is l(t). The maximum queue length forms in the final stage of red phase, $L_{max} = a(t_R) - l(t_R)$.

Table2. Relationship of Distance and Lost Green Time

Distance	Situation No.	Time Arriving at Stop	Time Leaving Stop	Lost Time (t_s)
D>L_{max}	-	-	-	0
D>L_{max}	a	During Red Phase	During Red Phase	0
	b	During Red Phase	During Green Phase	$t_T - (t_R - t_a)$
	c	During Green Phase	During Green Phase	t_T

The probability of each situation changes with the distance. As the distance is not the main part of data collection, this paper does not emphasize the evaluation research on it but provides a thought here. Assuming the probability of each situation is 1-b%-c%, b% and c%, the average lost green time can be obtained by following equation.

$$t_s = [t_T - (t_R - t_a)] \times b\% + t_T \times c\% \tag{6}$$

2.4 Turning Proportion

When straight going and left-turn traffic share one lane, turning proportion has great influence on the value of headway since the headway of left-turn traffic is longer than that of straight going traffic. Based on the analysis of a large amount of straight going and left-turn traffic data, it can be concluded that the headway of left-turn traffic is 1.15 times longer than that of the straight going traffic. The headway of bus turning left is $h_{tl} = 4.49 * 1.15 = 5.16$, according to data above. Assume the turning proportion is ρ_l and straight going proportion is ρ_s, the average headway can be express as:

$$h_t = 5.16\rho_l + 4.49\rho_s = 0.67\rho_l + 4.49 \tag{7}$$

3 Capacity computation model

3.1 Computation of Saturation Flow Rate

Saturation flow rate is the per unit time flow that traffic continuously flows at the saturation headway under the condition without signal control. Saturation flow rate is equivalent to the steady value of Webster saturation flow rate curve.

$$\mathrm{S} = \frac{3600}{h_t} \tag{8}$$

The influence factors of headway mentioned in the last chapter include traffic composition and turning proportion. Assume the correction factor of traffic composition is f_C. It can be obtained by the way the linear function divide the average headway of straight going bus -- $h_t = 4.49$s. ρ_B represents the bus ratio in arriving traffic.

$$f_C = \frac{h_t}{h_t{'}} = \frac{4.49}{2.51\rho_B + 2.05} = \frac{1}{0.56\rho_B + 0.46} \tag{9}$$

And there is also a linear relation between saturation headway and turning proportion. The defined correction factor of turning proportion --f_{LT} can be obtained by division too. ρ_l is the proportion of left-turn traffic.

$$f_{\mathrm{LT}} = \frac{h_t}{h_t{''}} = \frac{4.49}{0.67\rho_l + 4.49} = \frac{1}{1 + 0.15\rho_l} \tag{10}$$

The corrected equation of saturation flow rate is as follows.

$$\mathrm{S} = f_C \times f_{\mathrm{LT}} \times \frac{3600}{h_t} \qquad (f_C = \frac{1}{0.56\rho_B + 0.46};\ f_{\mathrm{LT}} = \frac{1}{1 + 0.15\rho_l}) \tag{11}$$

3.2 Computation of Capacity

The capacity model is also corrected by another way – refining effective green time. So the BRT approach capacity model at intersection is corrected as the equation below.

$$\mathrm{C} = \mathrm{S} \times \frac{t_{EG}}{T} = \mathrm{S} \times \frac{t_g - t_{FL} - \Delta t_{H4} - t_S}{T} \tag{12}$$

t_g is the time of green phase. t_{FL} refers to the starting time of the first vehicle. t_s is the symbol of dwell time. Δt_{H4} represents the lost time of the first four vehicles. The actual time from the first vehicle passing the stop line to the fifth is different from the total time of these first four vehicles running at saturation headway. And the difference is the lost time.

$$\Delta t_{H4} = t_{H4} - 4 \times h_t$$
$$= 12.8\rho_B + 10.5 - 4 \times (2.51\rho_B + 2.05) = 2.76\rho_B + 2.3 \quad (13)$$

This paper counts by headway, and the last vehicle may not be included in when its passing time is shorter than the average headway. So the decimal acquired by the equation carries into integer to make up for this problem. The capacity model is shown below.

$$\mathrm{C} = \mathrm{S} \times \frac{t_{EG}}{T} = \mathrm{S} \times \frac{t_g - t_{FL} - \Delta t_{H4} - t_s}{T} = \mathrm{S} \times \frac{t_g - 4.06\rho_B - 3.4 - t_s}{T} \quad (14)$$

The complete capacity model is:

$$\mathrm{C} = \mathrm{S} \times \frac{t_{EG}}{T} = f_C \times f_{\mathrm{LT}} \times \frac{3600}{h_t} \times \frac{t_g - 4.06\rho_B - 3.4 - t_s}{T}$$
$$\left(f_C = \frac{1}{0.56\rho_B + 0.46};\ f_{\mathrm{LT}} = \frac{1}{1 + 0.15\rho_l}\right) \quad (15)$$

Assume there is an intersection, the BRT approach capacity at intersection with each bus ratio and turning proportion under the assumption above. ($t_s = 0$,T = 225s,$t_g = 60$s,$h_t = 4.49$s)

Table3. BRT Approach Capacity at Intersection with Each Proportion

7:3	222	228	215	212	209	206	203	201	198
8:2	206	214	200	198	195	192	189	187	184
9:1	193	202	187	185	182	180	177	175	172

4 Case Study

Gangwan Road and Zhongshan Avenue intersection is located in the eastern section of Guangzhou BRT corridor. There is a straight going BRT lane and a left-turn mixed-traffic lane in one approach of this intersection. The BRT and social vehicles are under the same signal control. The time of amber light at this intersection is 3 seconds, and cycle time is 153s. The signal phase and phase sequence is shown below.

Table4. the Signal Phase and Phase Sequence

Phase	Phase 1	Phase 2	Phase 3
Phase Diagram			Time	49s	50s	45s

Apply 3 different models including the model acquired in this paper to the capacity computation of this case, and compare the result to actual capacity data of field measurement.

(1) Measured Actual Capacity

The volume of vehicles in the mixed-traffic lane passing through the intersection in one cycle is 16 on average.

$$C_0 = \frac{3600}{T} * 16 = 376.5veh/h \cong 377veh/h$$

(2) Capacity Computed by the Model Acquired in This Paper

Substituting $t_s = 0$, $h_t = 4.3$, $T = 153$, $t_g = 45$ and $\rho_B = 0.1$ into the new model, the capacity is obtained as follows.

$$C_1 = 379.6veh/h \cong 380veh/h$$

(3) Capacity Computed by the Model in Code For Design Of Municipal Road

The *Code for design of municipal road* provides a capacity model of intersection approach lane shared by straight going and left-turn traffic. Because there is no straight going vehicle in this lane mentioned here, β_l' is equal to 1. According to the value recommendations in the standard manual, $t_0 = 2.3$ and $t_i = 2.55$. Substituting $\mathrm{T} = 153$ and $t_g = 45$ into the equation above, the design capacity of this left-turn mixed-traffic lane is shown below.

$$C_2 = \frac{3600}{T}\left(\frac{t_g - t_0}{t_i} + 1\right)\varphi * \left(1 - \frac{\beta_l'}{2}\right) = 187.89veh/h \cong 188veh/h$$

(4) Capacity Computed by the HCM Model

The *Highway Capacity Manual* provides the following equation.

$$S = S_0 \times N \times f_w \times f_{HV} \times f_g \times f_p \times f_{bb} \times f_a \times f_{RT} \times f_{LT}, (S_0 = 1800\mathrm{ve}h/h)$$

In this case, $f_w = 1 + (\mathrm{W} - 3.6)/9 = 0.99$, $\mathrm{f_{HV}} = \frac{100}{100+\%HV*(E_r-1)} = 0.91$, $N = 1$ and other coefficients are all equal to 1.

$$C_3 = 476.9\mathrm{ve}h/h \cong 477\mathrm{ve}h/h$$

After comparing the 3 models above, it is obvious that the result of model obtained in this paper is closer to the actual capacity, so this model is more appropriate to compute the BRT approach capacity at intersection.

5 Conclusions

This paper uses samples collected from Guangzhou elastic route BRT system to analyze the influence factors of entrance lane capacity, and build a BRT approach capacity model at intersection based on these factors. The model makes it possible to compute the lost time and makes the Webster saturation flow rate curve equivalent to step function.

Abstract: With the development of intelligent transportation system, more and more traffic events need to be tested through modeling and simulation. In this paper, C++ as the main programming language, builds simulation platform through integrating MATALB and VISSIM. It solves the problem that it's difficult to do the secondary development of VISSIM directly and program for solving model of complex problems. The method combines the VISSIM software simulation's good effect, MATLAB's powerful calculation ability and the relevant advantages of C++ programming. On the one hand, the VISSIM and C++ editor can exchange data through VISSIM COM. On the other hand C++ can call MATLAB dynamic link library to implement the hybrid programming. The simulation platform which is used to establish by this method provides a new way for building and solving traffic management and control modes. Finally, according to the platform, this paper studies a case related to theories and applications of transport information granular computing.

Keywords: ITS; Simulation platform; VISSIM COM; VC++; MATLAB dynamic link library.

1 Introduction

In recent years, with continuous development of traffic theory of artificial intelligence, especially the big data applications, offers a new approach to study traffic management and control. Fuzzy control, neural network, genetic algorithm and ant colony algorithm and other various theories are increasingly upsurge, in the field of traffic control. But the key technical difficulties attendant is how to achieve control model, and, how to verify the model. The summary from the theory, in order to achieve and verify the control model there are three kinds of methods. The first, the model applied in practice, verified it by the field observation data, this is the most direct and most effective verification method, but it's the high cost, high risk. The second method, calculated using the mathematical theory, this method is rapid and convenient, but it simplifies the complexity of the traffic flow, reduce the credibility of the control effect. The third method is the simulation method, it's based on the programming or computer software, simulate the real scene, get the evaluation report, data analysis. But the program or software could accurately simulate the operation law of the actual traffic flow, reflect the traffic characteristics. With the advent of the mature traffic simulation software, TSIS, VISSIM, TransCad and so on, moreover, scholars continue to explore these simulation technology, the software already can effectively simulate the traffic flow. Using traffic simulation technology to verify the effect of control, has become the most effective method of peer recognition.

Chen Dewang, Cai Bogen, Wu Jianping have studied integrated construction technology of TSIS, VC, MATLAB interface traffic control simulation platform. Chen Qian, Jean Jiang Yu, Wang Wei integrated the external program VC prepared with TSIS using the interface principle of traffic dissipation, large activities conducted by simulation, to simulate of large activities traffic dissipation. Li Wenyong, Chen Xuewu integrated the TSIS and VC by using the interface principle, simulation of the traffic guidance.

The research object of this paper is the microscopic traffic simulation software, VISSIM. VISSIM has become the main traffic flow simulation software, appeared in the China traffic field since 2001. VISSIM is the most widely used in the field of traffic simulation, but VISSIM software modification based on the model parameters and VISSIM secondary development research is less. In 2010, Zhang Yu, Yu Lei studied the function of SPSA algorithm in the parameter calibration in VISSIM. In 2010, Xie Zhengquan made a study on the application of real-time data traffic simulation technology based on VISSIM. In 2012, Zhang Qinghua, Ja Limin, made a study on calibrating VISSIM microscopic traffic simulation model. In 2012, Lu Shoufeng, Wei Qin made a study of integration VISSIM, Excel VBA and MATLAB simulation platform using VISSIM secondary development technology, but it isn't fully exert the MATLAB calculation ability, at the same time, the VBA language cannot be widely used, in object-oriented programming.

In this paper, based on VISSIM COM interface technology, the master program is VC++, mixed with the MATLAB programming and interacted with the data of VISSIM, so as to establish a simulation platform, integrated VISSIM, VC++ and MATLAB, It aims to expand the VISSIM simulation function, at the same time play a MATLAB powerful numerical computation ability and the advantage of C++, make traffic control model are easier to implement.

2 Introduction of VISSIM

VISSIM is developed by PTV Corporation in Germany, a micro simulation modeling tool, based on the time interval and driving behavior, modeling for city and highway traffic. It is suitable for various modes of transportation such as personal transport, railway, walk, bike and Metro etc... It can simulate traffic conditions in all kinds of microscopic traffic conditions (lane, traffic composition, traffic signal, bus stops, etc…), VISSIM are divided into two modules: traffic simulation module and signal control module. In the traffic simulation module mainly include car following model and lane change model. Signal control module mainly extract traffic information from the detector, with 0.1 second time interval, used to identify and change the current and the next state of the signal lamp.

The use of VISSIM is divided into 3 grades according to the technical difficulty. The first is the primary use, modeling and evaluation is completed by using the basic toolbox of VISSIM. The second level is the intermediate use, complete the inductive control, using VAP module of VISSIM itself. The third level is the advanced development, realize the real-time traffic data interaction, intelligent traffic control and dynamic traffic assignment, using the COM interface provided by VISSIM and programming.

3 VISSIM and VC++ interface technology

In order to realize the external model algorithm, feature attribute, solve the user personalized control, PTV company developed the COM interface technology of VISSIM, it supports Microsoft Automation, the user can apply Rapid Application Development, scripting languages can be docked (Visual Basic or Java), programming environment can be docked(Visual C++). COM interface provides many objects list(Links， Nodes， Vehicles ,simulation…) Each object has a corresponding control method and data extraction function. For example, ‘links’ represents a collection of all the road simulation, it provides a "Get link By Number" taken out of each section of the link object, the further you can call the density （Speed, volume, simulation time , simulation lane…） of road evaluation.

COM module with the function of a library, can obtain and change almost all the impact factors of VISSIM simulation. The COM interface supports many programming languages, such as Java and Python. In this paper, the language used is C++, the main idea is to use C++ to do the external driver, create your own car type, using the external driver to achieve the related traffic management and control model.

Through the Visual C++ compiler, users can use the #import command to make the Visual C++ compiler to obtain VISSIM objects. A user may use no_namespace of this command options, if the user does not want to use a namespace to VISSIM COM server. Or the user can input VISSIM_COM Server.tlb, to achieve the same effect. Operating on the COM object, use this command to direct call Microsoft specific smart Pointers. When using other compilers, instead of using the Microsoft Visual C++, must adopta more standard way to invoke the COM component. The VISSIM_COMServer.h file and VISSIM_COMServer_i.c file contain the description of VISSIM server interface standard for C++ coding. The effects of preprocessing directives include these files or VC++ #import are similar. The language commands are #include "VISSIM_COMServer.h", #include "VISSIM_COMServer_i.c".

Now using the VISUAL STUDIO editor C++ language is the most widely, if using VISUAL STUDIO in VISSIM secondary development, it can be divided into four steps.

(1) Open a new project in Visual Studio. Choose Console Application.

(2) A COM program example to load VISSIM network and start the simulation (copy the code below into the vissim_c.cpp file)

(3) Build project: Build/Build Solution

(4) Start simulation is Debug mode from Visual Studio or by the created exe file (…\debug\ProjectName.exe).

4 VC++ and MATLAB mixed programming

MATLAB has strong ability of numerical computation and analysis, and high-level programming language of C++ is the most popular, the hybrid programming combined with both of them is very vital significance in scientific research and engineering practice. In the engineering practice, the methods C++ calling MATLAB mainly include calling MATLAB engine, C++ files with m file conversion, and DLL files generated when call m.

(1) The MATLAB engine library provides some interface functions for user, using these interface functions, the user can call MATLAB file as calculating engine in their own program. The method uses MATLAB engine to connect MATLAB and C++, adopting the client/server mode. In practical applications, the C++ as a client, MATLAB as a local server. C++ program transmit commands and data information to the MATLAB calculating engine, and receive the data information from the MATLAB calculating engine. MATLAB offers the following C++ engine functions for users: engOpen, engClose, engGetVariable, engPutVariable, engEvalString, engOutputBuffer，engOpenSingleUse, engGetVisible, engSetVisible. The user can call these interface function in the foreground program, to control of the MATLAB Engine. Using this method can almost use all function of MATLAB, but need to install MATLAB software in the machine, and the execution efficiency is low. Therefore, this method is not used in practice, it is suitable for personal use or demonstration.

(2) MATLAB Compiler is the role of the m file transform into the C++ (known as the MCC command), this source code needed to use C++ compiler to transform into a standalone application, then m files transform into independent C++ files. In principle, it is can be invoked by other C++ code. The compiler can compile M files into a series of documents, such as dynamic link library files, C++ files, executables and, by setting the MCC command. But so far, it has a lot of restrictions that the m program of MATLAB compiler is converted into C++ code.

(3) The DLL is the abbreviation of dynamic link library, and is a binary executable file. It can put a lot of general function in the DLL for multiple application calls, instead of every application in connection to add a copy of the object code in the library. Through MATLAB own Compiler, we can compile m

function file into a dynamic link library (DLL file) by MATLAB. Another method is using VC++ the wizard automatically generated m dynamic link library file through the component functionality provided by MATLAB. The following, calling encapsulated function in C++ programs can realize the use of numerical algorithm. This method makes program running out of MATLAB, reduce the uneven distribution of external storage space of file, and code sharing could be achieved, which has made great user code design. The main steps are:

a) Set MATLAB compiler, using external VC compiler.
b) Compile m file into a DLL file
c) Set up the VC the Include path and lib link library paths
d) Write C++ calling DLL

These three methods is superior to domestication, we can take different approaches to combine with different conditions. This article takes the example of the third method that is using MATLAB to produce dynamic link libraries, due to it can make data visualization by using dynamic link library and the CPU occupancy rate is lower.

5 Integrated simulation platform of VISSIM, VC ++ and MATLAB

Combined part 3 and part 4 discusses technology, advanced traffic control simulation platform is built by using VISSIM microscopic traffic flow simulation ability, efficient data communication ability of C++ editor, and ability of complex algorithm and graphic visualization in MATLAB. The main idea of the paper is using the VISSIM simulation program to get traffic index, and input it into the new traffic control model. First, make C++ as master program, through the COM interface directly call VISSIM object, and through dynamic link library directly calling MATLAB object. Second, finish the implementation of complex intelligent traffic control model in C++ editor and MATLAB. As shown in figure 2, VISSIM, C++ and MATLAB all have their own advantages, so it is necessary to integrate the advantages to build advanced traffic control simulation platform, which method is simple and versatility, and is of great significance to the study of intelligent traffic control model.

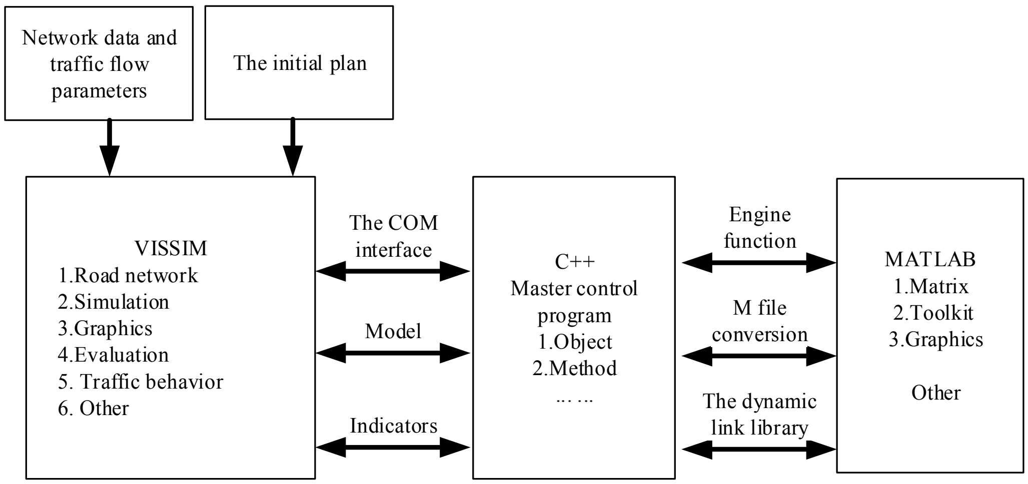

Figure 1. Integrated simulation platform of VISSIM, VC++ and MATLAB

6 Case

In this paper, an instance can be simply described as a four phase intersection in the VISSIM, which uses C++ for secondary development to realize the adaptive control, and uses MATLAB dynamic link library output one of the imports section density change trend in the form of graphics. Figure 2 shows the interface of the simulation platform, which is the interface of three kinds of software interactive operation at the same time. In the Figure 2, the lower picture is VS2010 master program interface, used to invoke the VISSIM and MATLAB, and store the data. Middle pictures of VISSIM simulation interface. The upper picture shows MATLAB graphical editor, which make a time interval of data visualization.

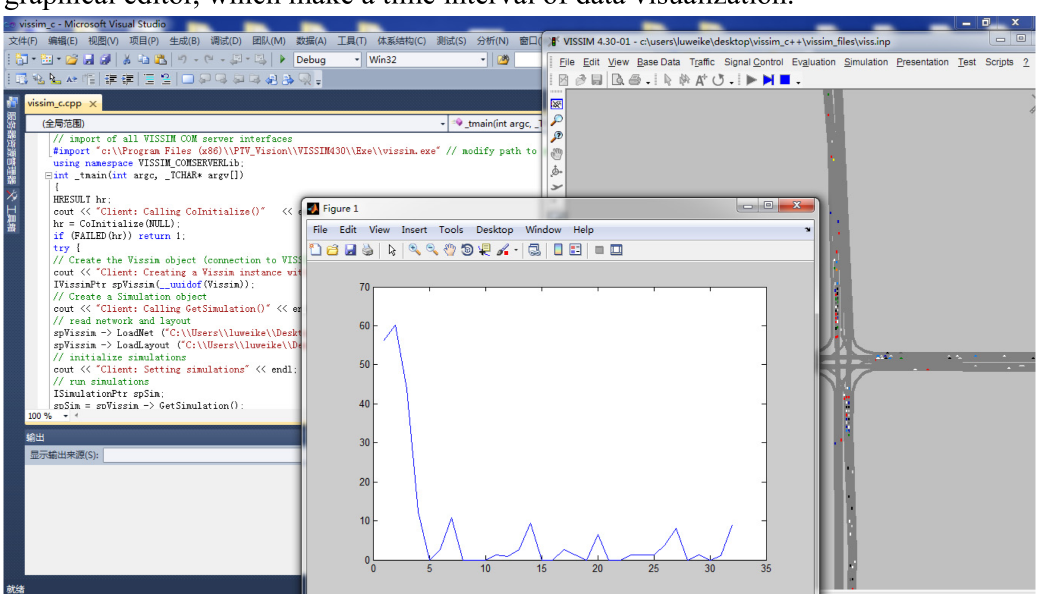

Figure 2. The interface of the simulation platform

7 Conclusions

This paper comes up with a new method that the COM interface and C++ are used to integrate VISSIM and MATLAB, which integrates the advantages of the three software to build advanced traffic control simulation platform. In the final, the paper gives detailed methods and steps to implement traffic control simulation platform, and provides examples based on the simulation platform. Compared to use single VB or VA to finish the secondary development of VISSIM, this simulation platform combines several advantages of MATLAB. But MATLAB simulation module and other mathematical functions haven't through this platform for testing and inspection in this paper, this also is the next step research main work. In order to make the simulation effect as much as possible close to the actual traffic simulation platform, it is important to make a detailed calibration parameters, such as flow, speed, acceleration, right-of-way rules, driving behavior parameters and so on, which is basis to construct almost consistent with the real operation situation of traffic flow of traffic simulation experimental environment and implement more accurate evaluation of the effect of traffic control model.

Abstract: Aiming to solving the problem of tram delays be caused by disturbing of social vehicles, on the basis of ensuring operational efficiency of tram, an approach of intersection signal strategy of priority coordinated control contrary to unidirectional trams delay sand bidirectional tram intersection in this paper, tram load, traffic safety interval and tram delays are taken into account in this paper. Modeling by indicative function, an example is described; delays are reduced obviously as a result which can ensure trams run ordered according to diagram.
Keywords: Tram; Delay; Intersection signal priority.

1 Introduction

While operating along an incomplete separated right-of-way, it refers to trams are separated from social vehicles in road sections, but share the intersections with vehicles and pedestrians, which means tram operation is influenced by a lot of random factors (HCM, 2000). Traffic efficiency at intersections becomes the main factor which determines the stability and reliability of tram system (MA, 2010). So the study on the intersection signal priority mode of tram has great practical significance.

At present, tram control strategy at intersections can be classified into two general categories. (1) Without signal priority strategy. Trams comply with social traffic signals, and enjoy no priority right in this case. Due to the delays which incur at intersections are increased, not only affect the tram transportation efficiency (MA, 2010), but also increase the conflict points between trams and social vehicles which go against Traffic Safety (SUI, 2001). (2) Isolated signal priority strategy. This strategy requires the ability to detect trams at the signalized intersections, and provides trams priority by either extending the current phase or activating a phase early (LI, 2005). While improving trams traffic efficiency, but the delays of social vehicles are increased significantly. This strategy is not conducive to the stability of the entire traffic system (MA, 2010 and WEI, 2008).

To avoid above shortages, this paper proposed a signal priority mode of tram on the condition of delays, which be constrained by traffic flow, traffic condition and

ITS equipment condition. This mode can improve the operation efficiency of trams by the premise of traffic efficiency of social vehicles.

2 Measurement Factors of Tram Intersection Signal Priority

In this paper, tram intersection signal priority strategy is based on optimizing passenger delays, which involve the passenger counts not only in trams but also in social vehicles. In other words, the trams are given a weight that depends on the number of passengers, and whether the bus is behind schedule. The measurement factors of tram intersection signal priority determined by tram occupancy rate, social vehicle queue length, time interval of pre and post trams and tram delay.

(1) Tram occupancy rate (C)

Tram Occupancy Rate is defined as the radio of the practical passenger number and the largest passenger number of tram. It can reflect operation efficiency and service level of current tram, and can be calculated as

$$C = {c_1}/{c_2} \tag{1}$$

where c_1 is the number of passengers counts in the tram; c_2 is the largest passenger number of tram.

(2) Social vehicle queue length (L)

The intersection signal control is simplified to be dual-phase in this paper. The maximum length of social vehicles in the vertical direction of intersection can be considered as the factor of traffic flow, which can be calculated as

$$L = \max\left\{l_1, l_2\right\} \tag{2}$$

where l_1 and l_2 respectively expresse the queue lengths of social vehicle on both vertical sides direction of intersection.

(3) Time interval of pre and post trams (ΔT)

To ensure the operation safety and maintain the departing interval, time interval of pre and post trams is proposed, that is defined as the time deviation between pre and post trams by traveling through the same station. It is calculated as

$$\Delta T = \left(T_1 + t_1 + t_2\right) - T_2 \tag{3}$$

where T_1 is the arrival instant of current tram at the intersection; t_1 is the waiting time of current tram in red phase; t_2 is the travel time of current tram from current intersection to the next station by maximum speed; T_2 is the arrival instant of following tram at the same station by planned schedule.

(4) Tram delay

To ensure the practical operation is according to the planned schedule, the tram delays at every stations and intersections should be calculated, which can be expressed as the time difference between practical arrival time and planned arrival time. In other words, the departure degree of operation status from practical to plan can be responsed by this factor.

3 Tram Signal Priority Strategies

3.1 Indicative Function Model

This paper is modeled by indicative function. The indicative function of Event A can be expressed as

$$\phi_{\{A\}} = \begin{cases} 1 & \text{Event A occurs} \\ 0 & \text{Event A dosen't occurr} \end{cases} \tag{4}$$

Event A, Event B and Event C can be described as

$A \bigcup B$: Event A and Event B at least one occur;

$A \bigcap B$: Event A and Event B occur simultaneously;

$A \bigcup B \bigcup C$: Event A, Event B and Event C at least one occur;

$B \big| A$: Event B occurs unless Event A occurs.

3.2 Endowing Conditions of Tram signal priority

The endowing conditions of tram intersection signal priority, which can be described by indicative function, are including occupancy, delay and time interval of pre and post trams.

(1) Endowing condition based on tram occupancy

In order to maintain the service level of intersections, tram intersection signal priority can be endowed only when practical occupancy exceeds a certain threshold, which means the most of passengers can enjoy the priority. This endowing condition can be expressed as

$$\phi_{\{A\}} = \begin{cases} 1 & C > C_{\max} \\ 0 & C \le C_{\max} \end{cases} \tag{5}$$

where $C_{\max}$ is the threshold of tram occupancy.

(2) Endowing condition based on compensation for tram delay

If tram has been delayed at current intersection, the endowing condition of signal priority at current intersection is determined by the operation status at the following intersection. If the delay can be compensated at the *k*-th station by travelling at the speed which is lower than the maximum speed limits, then the intersection signal priority doesn't be endowed. Otherwise, because of no compensation, delays will be accumulated gradually and become uncontrollable finally. So the signal priority should be endowed in this case. This endowing condition can be expressed as

$$\phi_{\{B\}} = \begin{cases} 1 & T_1 + \Delta t + t_1 + \sum_{i=1}^{k} t_2^i > T_k \\ 0 & T_1 + \Delta t + t_1 + \sum_{i=1}^{k} t_2^i \le T_k \end{cases} \tag{6}$$

where T_k is the planned instant when current tram arrival at the *k*-th station.

(3) Endowing condition based on time interval of pre and post trams

If the time interval of pre and post trams is shorter than safety interval, which is caused by the delays of pre tram, then the signal priority must be endowed, otherwise the operation safety may be affected. This endowing condition can be expressed as

$$\phi_{\{C\}} = \begin{cases} 1 & \left|(T_1 + \Delta t + t_1 + t_2) - T_2\right| < \Delta t_1 \\ 0 & \left|(T_1 + \Delta t + t_1 + t_2) - T_2\right| \ge \Delta t_1 \end{cases} \tag{7}$$

where Δt_1 is the safety time interval of pre and post trams.

3.3 Tram Intersection Signal Control Strategies

According to the different status of arriving at intersections, three kinds of intersection signal priority strategies are proposed in this paper.

(1) Endowing strategy of priority in one direction

When endowing conditions in 3.2 at least one accrues, then tram enjoys the signal priority, otherwise implement the original traffic signal timing. The indicative function of this strategy can be described as follow.

$$\phi = \begin{cases} 1 & \phi(A) \cup \phi(B) \cup \phi(C) = 1 \\ 0 & \phi(A) \cup \phi(B) \cup \phi(C) = 0 \end{cases} \tag{8}$$

(2) Endowing strategy of priority in two direction

In order to improve the efficiency of intersections, once the first tram enjoys signal priority in one direction, then the after tram in opposite direction should be better passes the intersection as in the same green phase as possible.

1) The after tram in opposite direction passes the intersection in original priority green phase

On the condition of the first tram has enjoyed the priority in one direction, if the after tram in opposite direction doesn't satisfy the endowing conditions and can't pass the intersection in the same priority phase by accelerate, then it is operated by planned schedule; if the after tram in opposite direction satisfys the endowing conditions, then it can pass the intersection in the same priority phase by accelerate. The indicative function of this strategy can be described as

$$G^2 = \begin{cases} 0 \ (\phi^2(A) \cup \phi^2(B) \cup \phi^2(C) = 0) \cap \phi(T^2 + t^2 \notin (T_s^1, T_e^1)) = 0 \\ 1 \ (\phi^2(A) \cup \phi^2(B) \cup \phi^2(C) = 1) \cap \phi(T^2 + t^2 \in (T_s^1, T_e^1)) = 1 \end{cases} \tag{9}$$

where T_s^1 is the beginning instant of priority phase, T_e^1 is the ending instant of priority phase, T^2 is the instant of the after tram in opposite direction arriving at the station which is the neatest one to the intersection, t^2 is the time to travel from the neatest station to the intersection of the after tram by the maximum limited speed.

2) The after tram in opposite direction passes the intersection in extend priority green phase

On the condition of that the first tram has enjoyed the priority in one direction, if the after tram in opposite direction satisfys the endowing conditions but can't pass the intersection in the same priority phase by accelerate, then a time threshold (Δtf) of the arriving interval between the first and the after trams is set. When the actual interval is lower than the threshold, the green phase is extended and the both trams pass the intersection in the same priority phase. The indicative function of this strategy can be described as

$$D^2 = \begin{cases} 0 \ (\phi^2(A) \cup \phi^2(B) \cup \phi^2(C) = 0) \cap \phi(T^2 + t^2 \notin (T_s^1, T_e^1)) = 0 \\ 1 \ (\phi^2(A) \cup \phi^2(B) \cup \phi^2(C) = 1) \cap \phi(T_l^2 - T_l^1 \le \Delta tf_{\min}) = 1 \\ 0 \ (\phi^2(A) \cup \phi^2(B) \cup \phi^2(C) = 1) \cap \phi(T_l^2 - T_l^1 > \Delta tf_{\min}) = 1 \end{cases} \tag{10}$$

where T_l^1 is the time to leave the intersection of the first tram, T_l^2 is the time to leave the intersection of the after tram, $\Delta tf_{\min}$ is the minimum time interval to leave the intersection between the first and the after trams.

4 Examples

A two-phase signal intersection scene is supposed in this paper. In order to explain conveniently, the yellow phase is not considered. The signal period is supposed to be 60s, which red phase and green phase is 30s respectively. The distance from intersection to the first stations A and the after station B is 900m as the same. The normal operating speed of tram is 36 km/h. The maximum limited speed is 60 km/h. The threshold of tram occupancy is 120%.

(1) Priority strategy in one direction

This direction is defined to be the down-direction. The first tram is planned to arriving at Station A at 6:30:00 and leaving at 6:31:00. Due to the increased number of boarding and alighting passengers, the tram is delayed and leaving at 6:32:00 actually. The tram arrives at the intersection at 6:33:30 by normal operating speed.

The tram occupancy is 130% at this time, which is higher than the threshold. If signal priority is not considered, then the waiting time of this tram at the intersection is $t_1 = 30s$. The traveling time to the Station B by the maximum limited speed is $t_2 = 54s$. So the actual instant to arrive at Station B is

$$T_B^- = T_I^- + t_1 + t_2 = 6:34:54 > T_k = 6:34:30$$

where T_k is the planned instant to arrive at Station B, and $k = 1$.

According to above calculation, the tram must be delayed when it arrive at Station B without signal priority. So the purpose of signal priority is to minimize the delay. The working diagram of this strategy can be described as Fig. 1 (a).

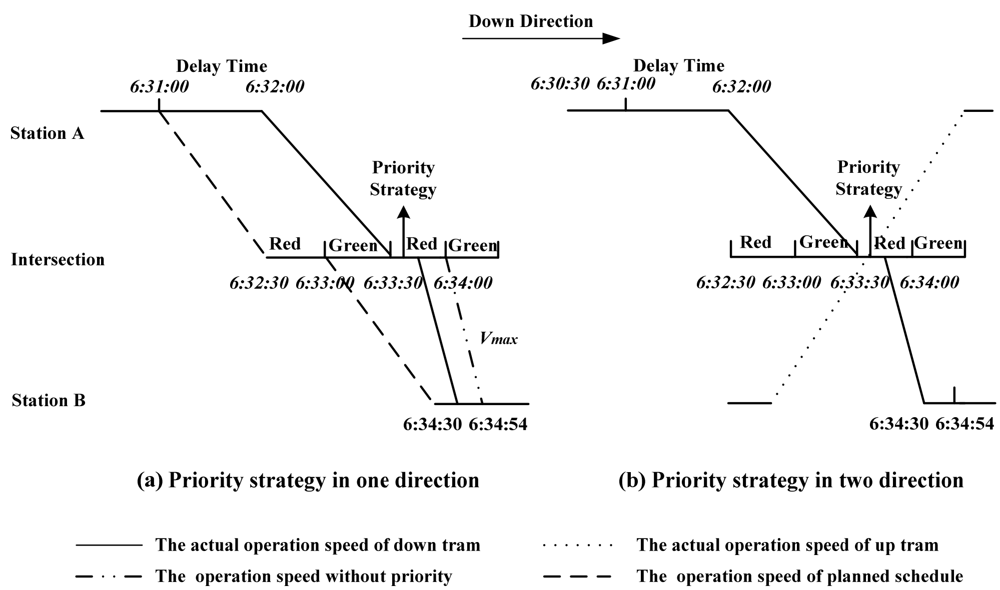

Fig.1 The operation diagram of priority strategies of tram

(2) Priority strategy in two directions

Based on the priority strategy in the down-direction, the occupancy of the up tram is assumed to be $C_A^+(1) = 80\%$, which is lower than the threshold, and the instant of the up tram to arrive at the intersection is $T_I^{'}$=6:33:33. A green priority signal phase of 5s is endowed to the down tram, which time to leave the intersection is 6:33:35. In order to ensure the up tram can pass the intersection as in the same priority phase as down tram dose, a extend strategy of green priority phase is proposed to up tram, which is additional green phase of 3s. The operation diagram of up and down tram can be described as Fig. 1 (b).

5 Conclusions

Based on the delay of tram operation, three kinds of intersection signal priority strategies are proposed in this paper. According to occupancy, delay compensation and operation interval, the indicative function model of tram operation in one direction is proposed to describe the priority control of single direction. Based on the priority control of single direction, the tram in opposite direction can pass the intersection as the same priority phase as possible by a extend priority phase.

The priority strategies proposed in this paper depend on the application of gathering, transmission and processing of tram information, which are based on the improvement of the intelligent of tram system. The organic integration of signal system of tram and urban transportation is the key point of the efficient signal management. The order of the priority measurement factors is decided based on the conditions of practical projects. The focus of the following research is the simulation design of the priority strategies.

Performance of Left-Turning Motor Vehicles from a Minor Road Approach at Non-Signalized At-Grade Intersections

Guoqiang Zhang[1,2]

[1]Jiangsu Key Laboratory of Urban ITS, Southeast University, Nanjing 210096, China. E-mail: guoqiang.zhang@163.com
[2]Jiangsu Province Collaborative Innovation Center of Modern Urban Traffic Technologies, Nanjing 210096, China.

Abstract: The paper has analyzed the performance characteristics of motor vehicles which turn left from minor road approach systematically, and has studied characteristics of speed variation and various impacting factors for left-turning vehicles from minor road approach, using statistical methods. Theory analysis of the performance of left-turning vehicles has been carried out and has been verified by using data collected in the field. Forecast models for acceleration of left-turning motor vehicles from minor road approach have been constructed and impacts upon traffic safety have also been discussed. Results of the paper can be used to analyze traffic performance of motor vehicles making left-turn movements from minor road approach at non-signalized at-grade intersections. They are also helpful for the analysis of traffic safety at those locations.
Keywords: Non-signalized at-grade intersection; Minor road approach; Motor vehicles; Deceleration; Acceleration.

1 Introduction

Because traffic volumes at non-signalized intersections are rather low, traffic accidents at those places are usually fewer than those at signalized intersections. However, severity of traffic accidents at non-signalized at-grade intersections is higher due to the high speeds of vehicles on intersection approaches.

Traffic accident data are used to study traffic safety and it has been used for many years. Numerous researches of traffic safety have been carried out by this kind of approach (Cirillo, 1970; Chen, 2011). Besides, traffic conflict analysis, traffic simulation and psychology survey have also been used to study traffic safety (Allen, 1978; Zhang, 2010; Zhang, 2013). Because speed variations were proved to be closely linked with traffic accidents, some researchers started to use speed variations for the study of traffic safety (Tsui, 2013).

At non-signalized intersections, drivers tend to change speeds more frequently in order to avoid potential conflicts. The aim of the paper is to explore speed variations of left-turning motor vehicles from minor road approach so as to understand their performance while turning left, which is the underlying mechanism for traffic safety of non-signalized intersections.

2 Data Collection and Methods

2.1 Data collection

A typical non-signalized at-grade intersection was chosen as the object of research. The major road has two lanes on each side. The minor road approach has two lanes; the outside lane is for right turn movement and the inside lane is for left turn movement. Traffic markings and signs at the intersection are maintained in good condition. Traffic volumes of the major road are moderate and traffic volumes of the minor road are rather low. To facilitate data collection, video recorders were used to record the movements of vehicles.

According to the characteristics of motor vehicles recorded by researchers, vehicles from the minor road approach has been classified into four types: small sized passenger car, medium sized passenger car and small sized freight car, large sized passenger car and medium sized freight car and large sized freight car. The types discussed above are represented by 1, 2, 3 and 4 respectively.

2.2 Statistical methods

Linear regression is one of the most widely studied and applied statistical techniques. The simple linear regression model with only one independent variable is given by the follows:

$$Y_i = \alpha_0 + \alpha_1 X_i + \varepsilon_i \qquad (i = 1,2,3,\cdots,n) \tag{1}$$

Where Y_i=value of dependent variable for observation i; X_i =value of independent variable for observation i; ε_i=value of disturbance term for observation i; α_1=coefficient of independent variable; and α_0=intercept (constant) term.

Nonlinear relationships can be accommodated within the linear regression framework by variable transformations. In the paper, using methods discussed above, predict models were then set up to estimate speed changes of motor vehicles making left turns from minor road approach.

3 Deceleration Performance Near Stop Line

When drivers are prepared to make left turns form minor road approach, they usually make deceleration performance in order to avoid potential conflicts with major road vehicles. Several factors were found to impact deceleration of motor vehicles near stop line during the process of left-turning movements. These factors were analyzed and discussed as follows.

3.1 Types of left-turning motor vehicles

Data analysis indicated that decelerations of most left-turning motor vehicles lie in the range of 0 and 2.5 m/s^2 and different type of vehicles had various decelerations. Among the four types of motor vehicles from minor road approach, small sized passenger cars, which are represented by 1, had the highest decelerations and the degree of dispersion of their decelerations was also the highest. Decelerations of type 2 motor vehicles (medium sized passenger car and small sized freight car) go after those of type 1 motor vehicles in both average value and degree of dispersion.

The phenomenon concerning performance of type 1 motor vehicles can be explained by the following reasons: First of all, compared with other types of motor vehicles, small sized passenger cars had better power performance and braking ability. Therefore drivers of small sized passenger cars tend to brake more harshly, resulting in higher decelerations. Besides, the driving skills of drivers of small passenger cars vary a lot, which partly explained the extremely high degree of dispersion of decelerations.

3.2 Initial speed of left-turning motor vehicles

When motor vehicles on minor road are arriving at the approach and are preparing to make left turns, their initial speed has great impact upon their subsequent deceleration performance. Based upon a psychological analysis of drivers' behavior, a higher initial speed of left-turning motor vehicles will force drivers to brake more harshly so as to obtain a low speed near stop line to ensure the safe movement of left-turning vehicles. In order to confirm the assumption discussed above, data were analyzed to study the relationship between initial speed and deceleration for left-turning motor vehicles and by using liner regression, a model was set up to predict the impact of initial speed of left-turning motor vehicles quantitatively. The model is as follows:

$$Y=-0.7555+0.0617X \tag{2}$$

Where Y=deceleration of left-turning motor vehicle near stop line on minor road approach (m/s^2); and X= initial speed of left-turning motor vehicle before braking near stop line on minor road approach (km/h).

In the model, the coefficient for independent variable is positive. This indicates that when initial speeds of left-turning motor vehicles increase, their subsequent decelerations will increase, which is in agreement with the assumption discussed above.

3.3 Average time headway of vehicles on major road

According to traffic safety law, drivers of motor vehicles from minor road approach should choose a gap in the traffic on major road, which is large enough for left-turn movements. Large time headways of vehicles on major road provide vehicles from minor road such gaps to get across the road safely. When average time headway of vehicles on major road decreases, the capacity and level of service for vehicles on minor road will be lowered and average delay will be increased. It will become more difficult for drivers to choose a gap large enough for left-turn movements. Under such circumstance, drivers from minor road approach will be more likely to brake in order to wait for a suitable gap in the traffic on major road. This means that a smaller average time headway of vehicles on major road may lead to harsher deceleration performance.

To confirm the assumption discussed above, data were analyzed to study the relationship between average time headway of vehicles on major road and deceleration of left-turning motor vehicles from minor road. By using liner regression, a model was set up to predict the impact of average time headway of vehicles on major road. The model is as follows:

$$Y=2.6174-0.39X \quad (3)$$

Where Y=deceleration of left-turning motor vehicle near stop line on minor road approach (m/s^2); and X= average time headway of vehicles on major road (km/h).

In the model, the coefficient for independent variable is negative, which indicates that when average time headways of vehicles on major road decrease, decelerations of motor vehicles making left-turns from minor road will increase, which means that drivers will brake more harshly. This is in agreement with the assumption discussed above.

4 Acceleration Performance While Merging

After crossing half of the major road, motor vehicles performing left-turns from minor road will try to merge with vehicles on the other side of the major road. This will require drivers to accelerate in order to gain speeds. Several factors were found to impact acceleration of motor vehicles during the process of merging with major road vehicles. These factors were analyzed and discussed as follows.

4.1 Types of left-turning motor vehicles

The study indicated that accelerations of left-turning vehicles are in the range of 0 and 3 m/s^2 Among the different types of motor vehicles merging with vehicles on major road, small sized passenger cars which are represented by 1, had the highest accelerations and for them the degree of dispersion of accelerations was also the highest. The phenomenon about the performance characteristics of small sized passenger cars can be explained by the following reasons: First of all, compared with other types of motor vehicles, small sized passenger cars had better power performance and braking ability. Therefore drivers of small sized passenger cars had more choice during the process of merging. Besides, most of the drivers of small passenger cars were not full-time drivers and their driving skills might not be as good as those of full-time drivers, which could cause unsteady and diverse driving behaviors, which partly explained the extremely high degree of dispersion of accelerations. The performance characteristics of small sized vehicles may bring some risks to them when they are merging with major road vehicles after crossing half of the major road.

4.2 Speeds of anterior vehicles of the merging gap

When drivers of motor vehicles from the minor road are entering the other side of the major road, they need to choose an adequate gap in the traffic stream of the other side of the major road, with which they are going to merge. During the merging process, their driving behaviors are affected and constrained by anterior vehicle of the gap greatly. If the speed of the anterior vehicle is lower, the driver of the left-turning vehicle from the minor road will be constrained and cannot choose to reach a fast running speed by quick acceleration. However, when the speed of the anterior vehicle is higher, under the influence of the front vehicle, the driver of the left-turning vehicle will tend to accelerate more quickly while merging so that the driver can follow the anterior vehicle in front of him more closely.

In order to study the assumption discussed above, data concerning accelerations of left-turning motor vehicles while merging and speeds of anterior vehicles of the gaps were analyzed. A non-linear statistical model was set up based on the data and the model is as follows:

$$Y = 0.0059X^2 - 0.2014X + 2.1484 \quad (4)$$

Where Y= acceleration of left-turning motor vehicle from the minor road while merging (m/s^2); and X= speed of anterior vehicle of the merging gap (km/h).

It was found out that when the independent variable is larger than 17 km/h, first order derivative of the dependent variable is positive and will increase with the increasing of the independent variable. Therefore, when the speed of anterior vehicle of the gap is larger than 17 km/h, acceleration of left-turning motor vehicle from the minor road will increase with the increasing of the speed of anterior vehicle, which indicates that the model is in agreement with the assumption discussed above.

4.3 Speeds of posterior vehicles of the merging gap

Similarly, when motor vehicles from minor road approach are merging with vehicles on the other side the major road, drivers' behaviors are also constrained and influenced by posterior vehicles of the gap into which they are trying to merge. If the speeds of posterior vehicles are very high, vehicles from minor road will be threatened substantially and are forced to accelerate urgently. However, if the speeds of posterior vehicles are low, drivers of vehicles from minor road will feel less pressed and therefore tend to perform acceleration more gently.

In order to confirm the assumption, data concerning accelerations of left-turning motor vehicles from the minor road and speeds of posterior vehicles of the merging gap were analyzed. A non-linear statistical model was set up based on the data and the model is as follows:

$$Y = 0.046e^{0.117x} \quad (5)$$

Where Y= acceleration of left-turning motor vehicle from the minor road approach (m/s^2); and X= speed of posterior vehicle of the merging gap (km/h).

Equation 5 shows that the dependent variable increases with the increase of the independent variable of the exponential function. Therefore, acceleration of left-turning motor vehicle from the minor road will increase with the increasing of the speed of posterior vehicle of the gap, which indicates that the model is in agreement with the assumption discussed above.

5 Conclusions

At non-signalized at-grade intersections, left-turning motor vehicles from the minor road approach have substantial impact upon the performance of traffic streams of the major road. Results of the paper can be used to analyze traffic performance of motor vehicles making left-turn movements from minor road approach at non-signalized at-grade intersections. They are also helpful for the analysis of traffic safety at those locations. In the future, similar researches should be carried out to further explore the complicated operation of motor vehicles at non-signalized at-grade highway intersections.

Abstract: Cyclists' running red lights is very common in China and has been one of the major reasons for traffic accidents in urban areas. This paper has discussed psychological factors behind bicyclists' behavior of running red lights at signalized intersections such as anxiety, group psychology, deliberate action, convenience psychology, recklessness and ignorance and subconsciousness. Next, a psychological questionnaire survey has been analyzed and studied. The survey includes three subjects: reasons for running red lights, maximum waiting time and measures for prevention of running red lights. Meaningful conclusions have been drawn as to what are the main reasons that underlie cyclists' running red lights and how to prevent cyclists from running red lights effectively.
Keywords: Signalized intersections; Cyclists; Running red lights; Psychology; Questionnaire survey.

1 Introduction

Many researches were carried out both in China and abroad to study the behaviors of cyclists (Johnson, 2013; Pai, 2014; Yang, 2015; Yang, 2012; Zhang, 2013). Some meaningful conclusions were drawn to help to understand their impact upon traffic safety. However, further studies should be carried out to explore the psychological mechanism underlying cyclists' dangerous behaviors at signalized intersections.

According to the present situation in China, the research was carried out to explore reasons underlying behaviors of cyclists' running red lights by analysis of a psychological questionnaire survey. Based upon analysis of psychological factors, the survey centered around three aspects: reasons for running red lights; maximum waiting time; measures for prevention of running red lights. More than three hundred questionnaires were handed out and in all, 130 effective questionnaires were received. Among participants who had given effective questionnaires, 96 were male and 34 were female. Most of the participants were young people and 84 participants were below 30 years old, accounting for 64.6%.

2 Psychological factors for Bicyclists' Running Red Lights

2.1 Anxiety

Anxiety is such a kind of psychology with little patience in dealing with daily business. When people are anxious, they tend to lack enough patience in doing routine matters. For cyclists with anxiety psychology, they usually make haste on the road in order to get to their destination on time and they will run a red light at signalized intersections whenever it is possible.

2.2 Group psychology

Group psychology means that people who are in a group usually behave alike. The behaviors of some members of a group impacts behaviors of other members and finally everyone behaves the same way. At signalized intersections, the behaviors of red light running cyclists will have great influence upon other cyclists and will prompt other people to do the same thing as they have just done.

2.3 Deliberate action

Still, there are a few cyclists who run red lights on purpose. They have little regard for other people and do not like to obey laws. Though they know that running red lights will interfere with people or vehicles coming from other directions, they chose to do it deliberately and routinely, without respect for other traveler's lawful right. However, when policemen are present, they usually don't dare to run red lights for fear of being caught.

2.4 Convenience psychology

Convenience psychology refers to such personality, with which a person is usually a self-centered egomaniac and emphasizes efficiency, paying little attention to processes and plots. When confronted with red lights at signalized intersections, some cyclists might find it difficult to wait for a long time, especially when the traffic volumes in operation are not heavy. For convenience's sake, they will be tempted to run red lights as soon as there is a chance for them to do so.

2.5 Recklessness

The so called recklessness means that a person's mind is apart from his or her behavior so that his behavior does not correspond with his psyche completely. We usually regard this kind of psychological phenomenon as recklessness or carelessness. Those cyclists who are very concerned with their own business often get across the street while thinking about their own business without giving much attention to ambient information. At signalized intersection, without noticing the traffic signal, they might run red lights.

2.6 Ignorance and subconsciousness

Ignorance is a kind of psychological activity for people with low levels of knowledge and civilization. Lacking enough education, a few cyclists are ignorant of the modern laws and rules. They know little about traffic rules and traffic safety and chose to do whatever they want. When confronted with red lights, they usually tend to violate the laws. Once they have formed the habit of running red lights, they will do it without even being conscious of it and that is a kind of subconsciousness.

3 Psychological Questionnaire Survey

3.1 Reasons for running red lights

Eight choices were listed in the questionnaire survey concerning reasons for cyclists'running red lights. These choices are as follows: having urgent matters, waiting for the green light too long, influenced by other people's running red lights, lacking strict law enforcement, bad weather and subconsciousness. To facilitate data processing, the choices are represented by 1, 2, 3, 4, 5 and 6 respectively. People who attended the survey were asked to choose at least one item from them. Data from the questionnaire survey were carefully analyzed. The results are shown in Figure 1.

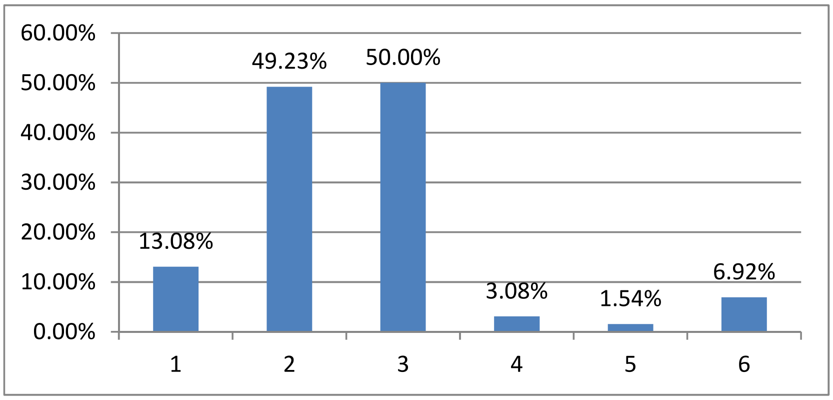

Figure 1. Reasons for running red lights

The third item, influenced by other people's running red lights, is the most frequently chosen reason for interviewees' red light running. 50 percent people have chosen it. Phycology theories indicate that people are easily influenced by others when making choices. Besides, when running red lights together, violators are more likely to be yielded by rightful motorists because the illegal crossing movements of many violators can form a traffic stream thick enough to block any other conflicting traffic no matter whether they are legal or illegal. At last, people tend to do simple tasks unconsciously and influenced by other violators. Some cyclists may run red lights out of Subconsciousness.

49.23 percent interviewees chose the second item, waiting for the green light too long. Researches have shown that patience of human beings is very limited. When confronted with long periods of waiting, most people will become anxious and are ready to behave illegally or dangerously, which can be used to explain why so many cyclists have chosen the second item as a reason for running red lights.

Item 1, having urgent matters, was chosen by 13.08 percent interviewees for reason of running red lights. In urgent situations, people tend to behave unreasonably and hastily. Therefore, during rush hours, when people are urgent to go to work on time, they have the motivation to run red lights.

6.92 percent interviewees chose Item 6, subconsciousness, for reason of running red lights while bicycling. It should be pointed out that subconsciousness alone seldom leads to cyclists' behavior of running red lights. It is combination of subconsciousness and other factors such as long waiting time and lack of strict law enforcement that leads to cyclists' running red lights. Only 3.08 percent interviewees chose Item 4, lacking strict law enforcement, for reason of running red lights. At last, 1.54 percent interviewees chose Item 5, bad weather, for reason of running red lights.

3.2 Maximum waiting time

Interviewees were asked to estimate their maximum waiting time as a cyclist at signalized intersections. There were six choices and they were as follows: less than 15 seconds, 15-30 seconds, 30-45 seconds, 45-60 seconds, 60-75 seconds and more than 75 seconds. The frequency for each of those that was chosen was calculated and their corresponding percentages were then obtained. The results are shown in Figure 2, which is a histogram for the different choices. Most people chose 30-45 seconds, 45-60 seconds or 60-75 seconds as their maximum waiting time, which accounted for 73.85 percent questionnaire survey participants.

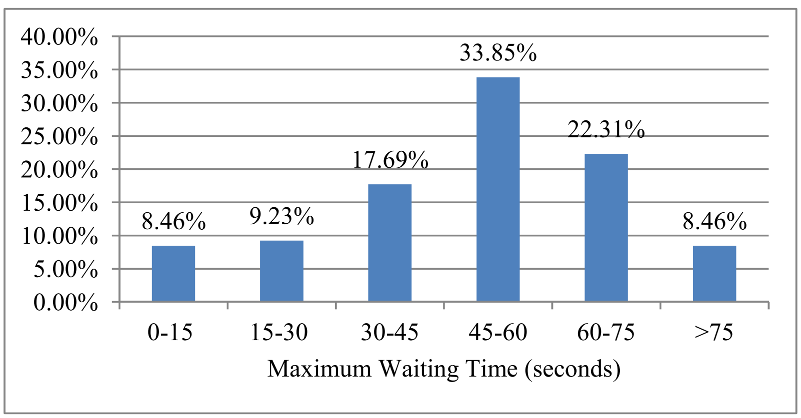

Figure 2. Relative frequency for maximum waiting time

The relative frequency for each choice has been added up to get the cumulative relative frequency, which is shown in Figure 3. It can be estimated that the proportion of interviewees whose maximum waiting time was no more than 45 seconds is approximately 35.38%, the proportion no more than 60 seconds is 69.23% and the proportion no more than 75 seconds is 91.54%.

If the pattern in Figure 3 represent the real situation, it is safe to say that at signalized intersections, the red lights for cyclists which is no more than 45 seconds is very agreeable, because most people can accept such a waiting time. And if such a time cannot be guaranteed, the red lights had to be no more than 60 seconds. On the other side, when red lights are more than 75 seconds, most cyclists cannot endure it and might possibly fail to refrain from running red lights.

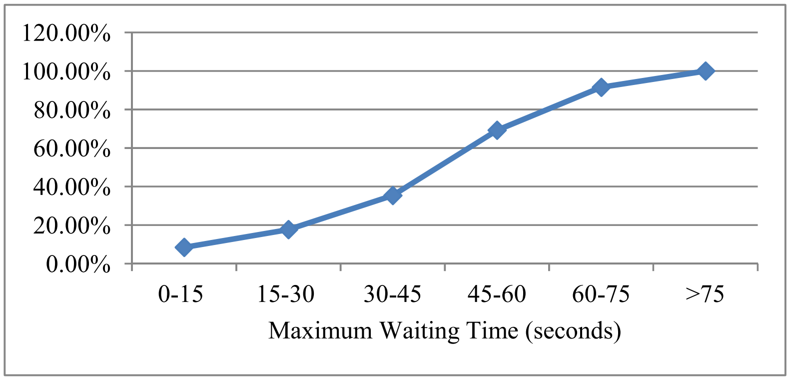

Figure 3. Cumulative relative frequency for maximum waiting time

3.3 Measures for prevention of running red lights

As for phenomenon of running red lights, the questionnaire survey has put forward three measures to prevent it and they are as follows: safety education, law enforcement and traffic engineering. The interviewees were asked to choose one from the three items as the best measure to prevent the behavior of running red lights.

Relative frequencies for selection of those measures were calculated and they are shown in Figure 4. It is obvious that most of the interviewees favor the measure of traffic engineering, which can reduce red time of traffic signals by optimizing signal timing and installing actuated signal control devices. 51.8 percent participants chose this measure. Therefore, although safety education and law enforcement are important for the prevention of red light running, improvement of service level of pedestrians and cyclists at intersections is more appealing.

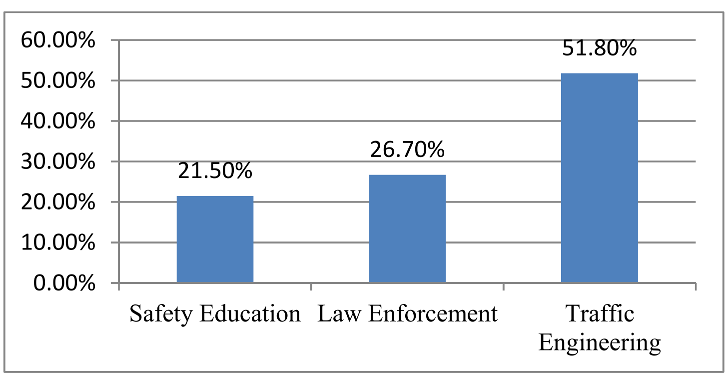

Figure 4. Relative frequency for measures to prevent red light running

4 Conclusions

The paper has discussed psychological factors underlying the behavior of cyclists' running red lights and analyzed a questionnaire survey. The results of survey shows that dangerous and unlawful behavior of cyclists' running red lights is usually brought about by the influence of other cyclists' behavior, which indicates the great impact of group psychology on people's everyday life. Besides, waiting for the green time too long is also an important factor. Cyclists' patience is rather limited when confronted with red lights and the study shows that red lights should be no more than 60 seconds. Thus, greater efforts should be made to reduce red light and improve service level of cyclists.

Although safety education and law enforcement are important for the prevention of red light running, the study indicates that traffic engineering is more preferred. Improvement of service level at signalized intersections is more acceptable, which can be realized by such traffic engineering technologies as optimizing signal timing and installing new signal control devices such as semi-actuated signal control devices and full-actuated signal control devices.

A Parking Space Detection Algorithm Based on Magnetic Sensors

Xiangjun He; Dongxiu Ou; Yang Yang; and Jingyi Xu

Key Laboratory of Road Traffic Engineering, Ministry of Education, Tongji University, Shanghai 201804. E-mail: henchhxj@163.com

Abstract: Magnetic detector is a new type of vehicle detection equipment. A new roadside parking space detection algorithm is proposed based on AMR sensors in this paper. It uses state machine mechanism and overcomes the limitation of existing threshold-based algorithm. The current status is identified via processing two types of magnetic data. Combined with state-related parameters, it can achieve an accurate detection of the parking space status in different scenarios and parking modes. The experiment results show that the accuracy can reach 95%.

Keywords: Magnetic detector; Wireless sensor network; Roadside parking system; Intelligent transportation system.

1 Introduction

In recent years, with the rapid development of economy and urbanization, the amount of vehicles maintains a fast growth. However, with the limit of city land usage and expenditure, the number of parking lot does not increase correspondingly, so the parking problem is becoming a severe problem in various cities. Intelligent parking guidance system is an effective way to solve such a problem and the accurate detection is the key of the system.

Up to now, some algorithms based on magnetic sensors have been proposed for vehicle detection. Cheung proposed an algorithm using a threshold of z-axis magnetic field. In such a method, it is difficult to select the appropriate threshold to all situations. Furthermore, Knaia proposed a single intermediate state of the vehicle detection method; Jiagen Ding proposed a plurality of intermediate state machine detection, but as they rely on a reference value, the offset of the value will greatly affect their accuracy.

In order to achieve a higher detection success rate and lower computational complexity, based on the analysis of a large amount of experimental data, we propose a new method which using a state machine mechanism, and through multiple state-related parameters, it can achieve accurate real-time detection of parking spaces state in different parking modes and environment.

2 Characteristics of the Signal

The feature analysis and recognition of parking geomagnetic signal is the basis of vehicle detection algorithm in different circumstances. In our experiment, we select Honeywll's HMC1052L, a low-power two-dimensional magneto-resistive sensor, as our magnetic detector. During the experiment, each sensor is placed in the middle of parking space. Figure 1 describes the specific deployment of sensor nodes: X-axis is parallel to the direction of vehicle entering, Z-axis is perpendicular to the ground.

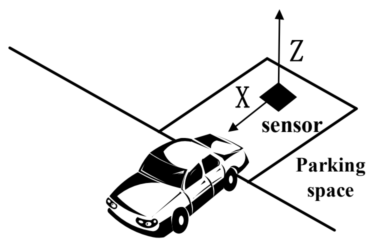

Fig 1. Placement and detection direction magnetic sensor

For considering the energy consumption problem, the magnetic sensor we use has a sleep mode and will wake up once every 100 milliseconds to collect magnetic field data. Under the aforementioned deployment and the detection direction, Figure 2 shows the magnetic signal for a vehicle entering the parking space with its head forwarding, stopping in the parking space for some time then leaving the parking space.

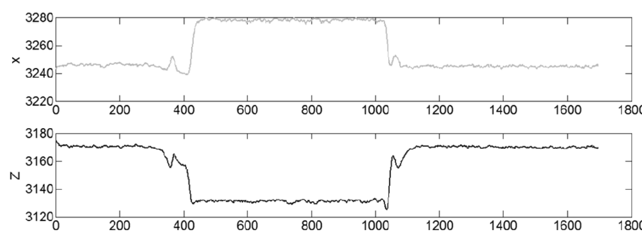

Fig 2. The ideal waveform of normal parking

Figure 2 is a normal parking process and the waveform we obtained is ideal. From the observation, we can see that when the vehicle enters or leaves the parking space, it causes a big fluctuation in both x-axis and z-axis. When the vehicle stops on the parking space, the magnetic signal returns to a stable state. Compare with the situation that no car is on the parking space, there is a distinctive offset in both axes. However, it is not always the case. Given the same situation, sometimes we may get a waveform like the Figure 3 shows. In this case, we find there is no obvious offset in the z-axis. According to several test results, we find that the stationary amplitude offset phenomenon exits at least in one axis, but on which axis it is not certain.

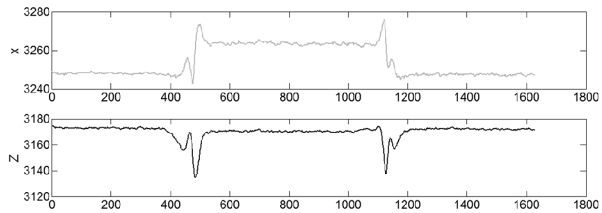

Fig 3. The imperfect waveform of normal parking

3 Vehicle Detection Algorithm

The signal data acquired from magnetic sensors is a time series data. The original data of x-axis and z-axis is denoted as $X[k]$ and $Z[k]$ respectively. As there exits electromagnetic interference, in order to ensure the accuracy of detection, it is necessary to have some filtering process to the original signal. In this paper, we use a simple weighting filtering. The process is defined as Equation (1),where $\hat{X}[k]$ and $\hat{Z}[k]$ respectively represents deal data of x-axis and z-axis.

$$\hat{X}[k] = \frac{7}{8} * X[k-1] + \frac{1}{8} * X[k]$$

$$\hat{Z}[k] = \frac{7}{8} * Z[k-1] + \frac{1}{8} * Z[k] \quad (1)$$

The processing of x-axis data and z-axis data is the same in this algorithm. So in the following description, we elaborate the whole algorithm through the process of the x-axis data. According to the previous analysis of the characteristic of the magnetic waveform, the algorithm we proposed uses state machine. It has 5 different states, presented as State(x)={init, flat, count, up, down}.

The transition between different states is decided by $E(k)$, which represents the magnetic signal's summation value in the same direction. If the sign of the current fluctuation is the same with previous one, then $E(k-1)$ accumulates current fluctuation value. Otherwise, using current fluctuation value to update $E(k-1)$. The process is defined as equation (2).

$$E(k) = \begin{cases} E(k-1) + \widehat{X}[k] - \widehat{X}[k-1] & sign(\widehat{X}[k] - \widehat{X}[k-1]) = sign(\widehat{X}[k-1] - \widehat{X}[k-2]) \\ \widehat{X}[k] - \widehat{X}[k-1] & otherwise \end{cases} \quad (2)$$

Comparing the $E(k)$ with the minimum threshold $\min\_delta$, we can get $u(k)$. The process is defined as equation (3).

$$u(k) = \begin{cases} 1 & E(k) > \text{min\_delta} \\ -1 & E(k) < -\text{min\_delta} \\ 0 & \textit{otherwise} \end{cases} \tag{3}$$

According to the value of u(k), we can get the transition relationship between different states. The transition is described in Figure 4.

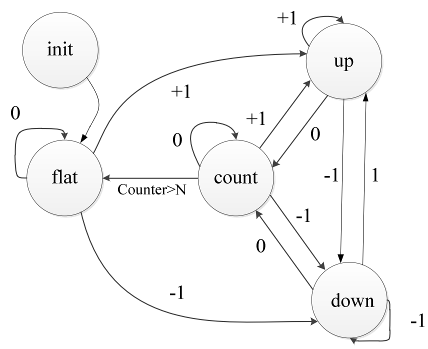

Fig 4. State transition diagram

Flat: After the system's initialization, it jumps into the flat state and stays at this state if u(k)=0.If u(k)=1, the state machine jumps into up state. If u(k)=-1, the state machine jumps into down state.

Up: The state machine stays where it is if u(k)=1.If u(k)=0, it jumps into count state. Then if u(k)=-1, it jumps into down state.

Down: The state machine stays where it is if u(k)=-1.If u(k)=0, it jumps into count state. Then if u(k)=1, it jumps into up state.

Count: The state machine jumps into down state if u(k)=-1.If u(k)=1, it jumps into up state. If u(k)=0 and the Counter value is less than N, it remains in flat state and variable Counter counts up. If u(k)=0 and Counter value is larger than N, then it jumps into flat state.

In addition to these state variables, there are still some parameters defined in the detection algorithm. These parameters include *flat_current, flat_previous, delta_flat_max, E_max.* Their updating process is defined as equation (4)-(6).

$$flat\_\text{previous} = \begin{cases} flat\_current & current\_state\_x \in \{\text{flat}\} \\ unchanged & otherwise \end{cases} \tag{4}$$

$$flat\_\text{current} = \begin{cases} \hat{X}[\text{k}] & current\_state\_x \in \{\text{flat}\} \\ unchanged & otherwise \end{cases} \tag{5}$$

$$E\_max = \begin{cases} E(k) & E(k) > E\_max \\ unchanged & otherwise \end{cases} \quad (6)$$

Based on the current state machine's status and the calculated parameter values, we can identify current parking space's status. The flow chart of the arithmetic is described in Figure 5, wherein U, FLAT_DELAT are pre-set threshold parameters and the values should be determined based on experiment results.

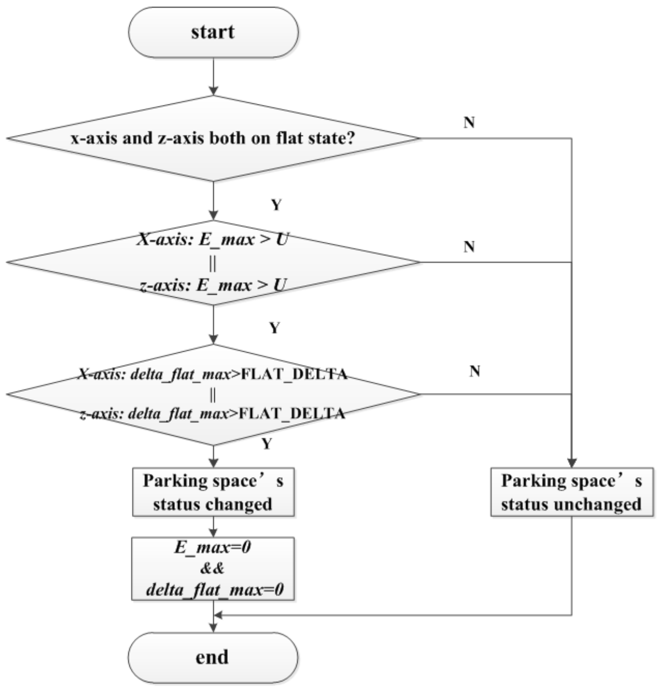

Fig 5. Flow chart of the arithmetic of parking state judgment

4 Experiment

In order to verify the accuracy and feasibility of the proposed detection algorithm, we deploy some magnetic sensors in Tongji university's roadside parking lot and conduct a number of experimental tests. The AMR chip and the actual deployment are in figure 6.

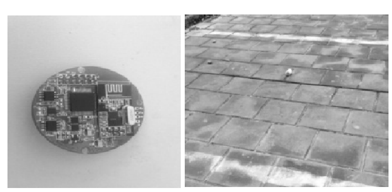

Fig 6. AMR chip and the actual testing deployment

According to the data obtained by several actual tests, we find that the algorithm can have the best performance when the parameters are set as table 1 shows.

Tab.1 Parameter Value

parameter	value	parameter	value
N	200	FLAT_DELTA	12
U	20	min_delta	6

Based on the aforementioned algorithm and the parameters setting, we conduct several testing in different parking scenarios and the results are shown in Table 2 and Table 3.

Tab 2. Results of different parking mode

Parking mode	The number of times of vehicle parking	The number of times of detected vehicle parking	Accuracy
Normal parking	120	118	0.983
Vehicle leaves on the process of parking	120	114	0.950
Vehicle enters the parking space after several times	120	115	0.958

Tab 3. Results of different adjacent condition

Condition of adjacent parking space	The number of times of vehicle parking	The number of times of detected vehicle parking	Accuracy
None	240	235	0.979
A car on the left	240	232	0.967
A car on the right	240	230	0.958
Two cars on left &right	240	228	0.950

5 Conclusion

In this paper, we have studied the magnetic sensor's application in the roadside parking lot. Based on the analysis of enormous experiment data, we have proposed a new vehicle detection algorithm, which uses state machine mechanism and overcomes the limitation of existing threshold-based algorithm. Our experiment result has proven that the algorithm is quite robust and has a high accuracy in different scenarios.

Abstract: There might be wheel slips and slides when a train is moving. The coded odometer can be employed to measure the speed and the location of the train, which turns the linear speed of the wheel to the forward velocity of the train. Slips and slides make the two speeds different and measurement errors happen, which would be bigger and bigger over time. This paper summarizes several algorithms of identifying the wheel slips and slides such as comparing the measured accelerations with their upper bound, calculating the standard deviation of the accelerations, counting the residuals of the Kalman filtering, redundant sensors and so on. The paper also introduces a bunch of methods for compensating the errors, for example, using a fixed acceleration, interpolation and multiple sensors. Moreover, the detecting and compensating methods mentioned are simulated in Matlab with the actual experiment data and their effects of compensation are analyzed and compared at the end of this paper.
Keywords: Coded odometer; Slips and slides; Error detection; Error compensation.

1 Introduction

Wheel slips and slides always happen when a train is moving ahead. Slips are thought of as a wheel rotating fast without corresponding horizontal displacement, which are caused by the excessive pulling force over the adhesive capacity of the wheel and rail. Slides mean that the huge braking force destroys the wheel's adhesive state and makes it from rolling to sliding when the train is decelerating or braking. The slipping and sliding phenomena are shown in Figure 1.

According to the principles of the coded odometer, it approximately replaces the train velocity with the linear speed of the wheel. The two of them are almost same when the adhesive state of the wheel and rail is perfect. But when the wheel slips and slides happen, the linear speed would be greater and less than the train speed respectively. If no actions of detecting and correcting the slips and slides errors taken, the serious errors would be accumulated to an intolerable value. Consequently, it is very significant to detect and compensate for the errors of the train localization and speed measurement which is caused by wheel slips and slides.

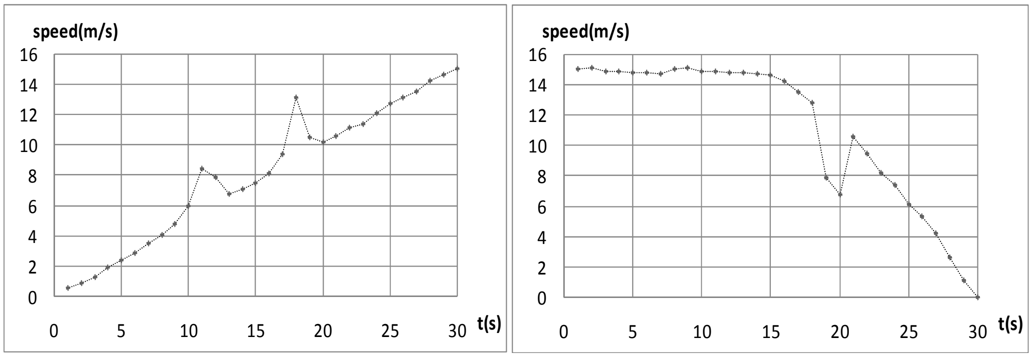

Figure 1. Wheel slips and slides phenomena

2 Detection and compensation of the wheel slips/ slides with one coded odometer

When a single coded odometer is adopted to measure the train velocity independently, the judgment of the slips/ slides should depend on the information underneath the measured data of the odometer.

2.1 Detection of the errors due to slips and slides

(1)Comparing the measured accelerations with the upper bound

The velocities measured by the coded odometer would increase or decrease sharply when the slips and slides happen to the wheel. In other words, great accelerations or decelerations would appear. One can set an upper acceleration bound a_m to sense the slips/slides, which stands for the maximum wheel acceleration or deceleration of normal rotating exclusive of slips and slides with experiences, experiments and theoretical arithmetic. The wheel is thought to have slips and slides as soon as the variation of the odometer measured speeds in unit time is greater than the upper acceleration bound a_m.

(2)Calculating the standard deviation of the measured accelerations

The accelerations also change fast when slips/slides occur to a wheel. Based on that principle, Samer S.Saab et al. designed an algorithm to decide if a train is slipping or sliding by calculating the standard deviation of the measured accelerations. k is the iteration index and T_s is the sampling time. Compute the standard deviation of the acceleration for the k th and previous $N-1$ time samples to make a decision of the slips/slides conditions of the k th sample.

$$\sigma_{\hat{a}}\left(kT_s\right) = std\left(\left[\hat{a}\left[\left(k-N\right)T_s\right], \hat{a}\left[\left(k-N+1\right)T_s\right], \cdots, \hat{a}\left[kT_s\right]\right]\right) \tag{1}$$

On the premise that the train runs perfectly at time $\left(k-1\right)T_s$ and the standard deviation of the sampling accelerations in time kT_s exceeds the tolerance, $\sigma_a\left(kT_s\right) > \varepsilon_{\hat{a}}^M$, the starting time of slips or slides can be positioned between $\left(k-1\right)T_s$ and kT_s. If the wheel slips or slides are considered on-going at time $\left(k-1\right)T_s$, and the standard deviation of the sampling accelerations in time kT_s suddenly below the judgment threshold for the end of the slips and slides, which can be presented as

$\sigma_a(kT_s) < \varepsilon_{\bar{a}}^m$, the slips and slides are thought to be finished.

(3)Counting the residuals of the Kalman filtering

Slips and slides just happen as abrupt phenomena with the train moving ahead, which is an unexpected deviate from the normal expected velocities. Technically, it is possible to judge a slip or slide by the differences between the estimated value and the observed value.

System state estimated value $\widehat{X}_{k-1}$ from the Kalman filtering for time $k-1$ should be proper when the slips and slides have not happened yet. The system state estimator $\widehat{X}_{k|k-1}$ for time k which is not considering of the observed velocity of time k can be reached by system state equations and one-step prediction equations. $\Phi_{k,k-1}$ is the one-step transfer matrix from time $k-1$ to time k.

$$\widehat{X}_{k|k-1} = \Phi_{k,k-1}\widehat{X}_{k-1} \tag{2}$$

According to the system state estimator $\widehat{X}_{k|k-1}$ at time k and the system measurement equations, the predicted measurement values $\widehat{Z}_{k|k-1}$ without considering of the actual measured velocities can be obtained. H_k mentioned here is the corresponding measurement matrix.

$$\widehat{Z}_{k|k-1} = H_k\widehat{X}_{k|k-1} \tag{3}$$

The residuals D_k of the accelerations are defined as the differences between the predicted measurement values $\widehat{Z}_{k|k-1}$ and the real measured values Z_k.

$$D_k = \widehat{Z}_{k|k-1} - Z_k \tag{4}$$

The residuals theory shows that the residuals should be the Gaussian White noises with zero mean value on condition that no slips and slides ever occur. The mean square error of the one-step prediction is $P_{k|k-1}$. The variance matrix of the measurement noises is R_k, and the variance of the residuals S_k can be calculated by:

$$S_k = H_k P_{k|k-1} H_k^T + R_k \tag{5}$$

Suppose a slips/slides detection function λ_k, which follows χ^2 distribution with freedom degree m. Stipulate a threshold value T_D, and the train is thought to run normally when the equation $\lambda_k \le T_D$ is satisfied, otherwise, slips/slides are happening.

$$\lambda_k = D_k^T S_k^{-1} D_k \tag{6}$$

2.2 Compensation of the errors due to slips and slides

After confirming the wheel slips and slides, solutions to compensate the errors caused by the odometer should be adopted immediately to avoid more errors accumulating for the moving distance calculation.

(1)Using a fixed acceleration

Set a slips/slides compensation acceleration on the basis of the train parameters and the performance of the slipping or sliding train. The slips/slides compensation acceleration would take the place of the current accelerations to get the velocities and the position of the train over the slipping or sliding period.

(2)Interpolation method

The interpolation method can be utilized to estimate the train speed during the train slips or slides after the corresponding section is identified smoothly. Although other interpolation techniques can be used as well, linear interpolation is used a lot for simplicity. Assume that the sampling time before the slips or slides is marked as $k_{start}T_s$, and we call the finished time $k_{end}T_s$. It should be noted that the train operated normally on both of the two times. In other words, the velocities measured by the odometer are the actual moving speed of the train on that two times (ignoring the calibration errors and the quantization errors). The compensation values of the train speed from time $k_{start}T_s$ to time $k_{end}T_s$ are given by (7).

$$\left[\tilde{v}\left(k_{start}T_s\right), \tilde{v}\left[\left(k_{start}+1\right)T_s\right], \cdots, \tilde{v}\left(k_{\mathrm{end}}T_s\right)\right] \equiv \mathrm{int}\,erpolate\left\{\hat{v}\left(k_{start}T_s\right), \hat{v}\left(k_{end}T_s\right)\right\} \quad (7)$$

When the linear interpolation method is employed, the corresponding model can be built as $\tilde{v}\left(kT_s\right) = a_k\left(kT_s\right) + b_k$. The parameters a_k and b_k can be determined by $\left(\left(k_{start}T_s\right), \hat{v}\left(k_{start}T_s\right)\right)$ and $\left(\left(k_{end}T_s\right), \hat{v}\left(k_{end}T_s\right)\right)$.

3 Detection and compensation of the wheel slips/ slides relying on other sensors

The methods of detecting and compensating the wheel slips and slides independently by a coded odometer mentioned in chapter 2 always need mathematical modeling or complex operations to improve the success rate of detection. In addition to that part, one can consider of using hardware redundancy to achieve the goal of slips/slides errors identification, which means using more than one coded odometer or using other sensors like an accelerometer or a Doppler radar.

3.1 Detection of the errors due to slips and slides

(1)Detection with redundant coded odometers

It is possible for two or more coded odometers installed on different train wheels to slip or slide asynchronously because of the mismatch of the installation position. So, more coded odometers can be taken into account. If the absolute value of wheel acceleration is greater than a fixed threshold, the wheel is slipping or sliding. If the difference between wheel velocities is greater than a fixed threshold, both the wheels are slipping or sliding.

(2) Detection with other train location and speed detection sensors

Other train location and speed detection sensors like accelerometers and Doppler radars would not be influenced by the slips and slides of the train according to their principles. The accelerometer can get the accelerations of the train directly which is an important evaluation indicator of slips/slides identification. The Doppler radar is derived from Doppler effects, which has nothing to do with wheel rotating. Although other sensors are not as sensitive or reliable as a coded odometer, they do identify the slips and slides efficiently. There are three methods to compare the odometer data with the other sensor's data, acceleration calculation method, velocity calculation method and sliding rate method.

The acceleration calculation method is handled this way: figure out the accelerations of the vehicle by the measured data of the two sensors respectively, and make the difference of the two accelerations. The train is slipping or sliding if the result is higher than one threshold. The velocity calculation method works in the same way but change the accelerations to velocities. The sliding rate method needs to compute the sliding rate λ of the train.

$$\lambda = \frac{v_z - v_j}{v_j} \times 100\% \tag{8}$$

v_z is the cross velocity of the wheel and v_j is the actual velocity of the train. The train is running normally if the sliding rate is between 8%~12%, but if the sliding rate is higher than 35%, the train must have a slip or slide.

3.2 Compensation of the errors due to slips and slides

(1) Compensation with several coded odometers

Install coded odometers on the different two wheels respectively. The identification results of the slips and slides will be represented by p_i. i means the i th wheel and $i = 1, 2$. p_i=0 means that wheel i is certainly not slipping or sliding, and p_i=1 just has the opposite meaning. The algorithm should judge the dynamic state of the train of being speed up or cut and express the results with variable q. The train is decelerating if $q = 0$, otherwise the train is speeding up. The compensated velocity v_k is given by (9).

$$\begin{aligned}
v_k &= \frac{v_{k1} + v_{k2}}{2} && if \quad p_1{=}0 \& p_2{=}0 \\
v_k &= v_{k1} && if \quad p_1{=}0 \& p_2{=}1 \\
v_k &= v_{k2} && if \quad p_1{=}1 \& p_2{=}0 \\
v_k &= v_{k-1} + aT_s && if \quad p_1 = 1 \& p_2 = 1 \& q = 1 \\
v_k &= v_{k-1} - dT_s && if \quad p_1 = 1 \& p_2 = 1 \& q = 0
\end{aligned} \tag{9}$$

Where a is a fixed acceleration value to compensate for the train slipping state, and d is the mean train deceleration which is given by the arithmetic mean between instantaneous wheel accelerations, filtered by a low pass filter and saturated between a higher value and a lower one.

(2)Compensation with other sensors

More and more types of speed sensors are used in modern train control systems.

The measurement accuracy of other speed sensors can be great higher than the coded odometer when slips/slides occur. Therefore, the measured data of coded odometer can be adopted when they are correct and data from other sensors would be utilized to calculate speed and distance of the train when the wheel is slipping or sliding.

Besides, to take full advantage of the data from all sensors, it can be considered to distribute weights for the sensors according to their measurement accuracy, reliability and other indexes. The least square estimation, the minimum variance estimation and other estimation theories can also be used to mix the samples together and get a better estimator. Also note that the wrong measurement values of the odometer due to wheel slips and slides should be removed. But what is astonishing is that not all information restructuring and fusion can improve the accuracy. For example, use two instruments to measure simultaneously, and one is twice as accurate as the other. The results of the least square estimate processing of the two machines are poorer than the higher precision one.

4 Comparison and analysis

This paper introduced the methods of detecting and compensating slips and slides with the own data of the coded odometer or the external data of the other sensors. Besides, we can identify the slip/slide faults by the odometer measurements and correct them with other sensors.

We made the simulation of the detection and compensation of slips and slides with the actual experimental data in matlab. The velocity and acceleration curves before compensation are shown in Figure 2.

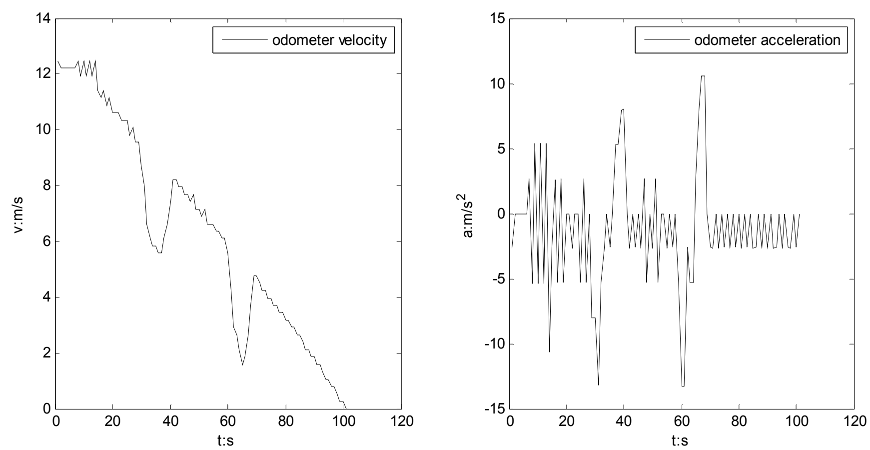

Figure 2. The velocity and acceleration curves before compensation

Figure 3 gives the results of comparing the measured accelerations with the upper bound to detect and using a fixed acceleration to compensate the slips and slides. Identification of slip/slide errors with the internal odometer data always base on the theory that the speeds and accelerations of the train would change sharply when the slips and slides occur. Although these methods do not need to increase the hardware redundancy, it is necessary to sacrifice the complexity of the algorithm to get higher precision. Comparing the measured accelerations with the fixed upper bound can be the simplest way to distinguish the rotating faults and it would not take too much operations. Besides, that method used a lot in the existing systems and it can identify most obvious slips/slides. The downside is that it is not very sensitive with the tiny changes of the velocities and accelerations and it can do nothing if there is a smooth curve in a sharp slip or slide (like the first slide of in Figure 3) . Besides, the choice of the upper boundary affects a lot about the amendment effects. After the diagnosis of wheel slips and slides, except for the absolute location correction of the transponders, other effective ways should be tried to overcome the bad influence for the measurement of train speed and distance caused by slips and slides. Using a fixed acceleration can be very simple, but using one default acceleration set beforehand to compensate in all the possible situations and no matter how serious the slips/slides are may give rise to great errors. The compensation curve is a broken line because the acceleration and deceleration situations use the different default accelerations opposite in sign.

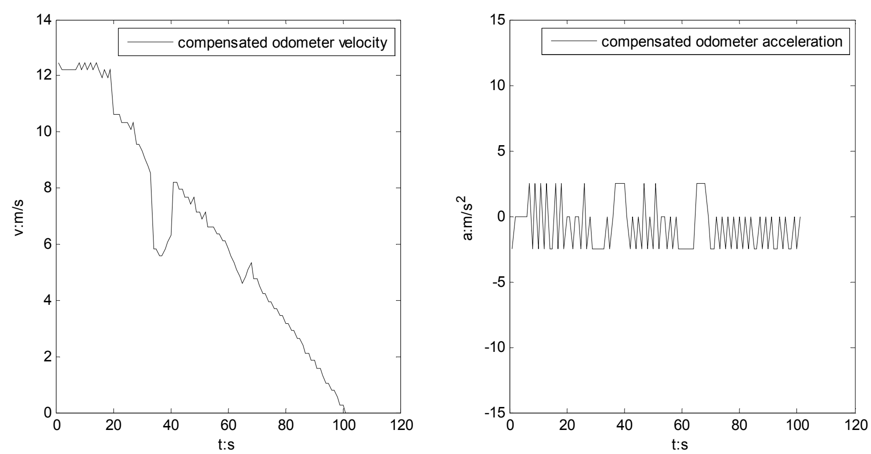

Figure 3. The velocity and acceleration curves after compensation

Figure 4 shows the results of calculating the standard deviation of the measured accelerations to detect and using the interpolation method to compensate the slips and slides. Calculating the standard deviation of the measured accelerations can work better than the acceleration compared method. Although the algorithm still cannot identify the slips and slides corresponding to angular acceleration with magnitude smaller than the maximum achievable train acceleration, the algorithm can compensate at least 86% of the errors due to wheel slips and slides successfully. And the interpolation method can be more intelligent than the fixed one. For example, we can analyze a linear interpolation situation. Although it takes a constant acceleration to calculate the speed and the displacement of the train, the acceleration is determined in real time by the correct samples before and after the abnormal wheel rotating. The improved interpolation algorithms can make the speed-time curve smoother.

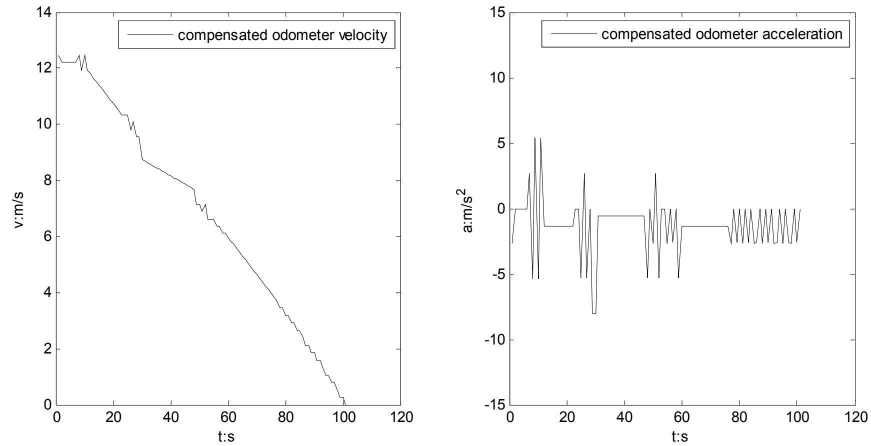

Figure 4. The velocity and acceleration curves after compensation

Figure 5 shows the detection and compensation results of using Doppler radar. Employing other sensors to realize the redundancy and complementary information is a more simple solution. But which measured result should be taken needs a proven selection criteria. Moreover, the weight allocation of the sensors or the selection of the boundary condition parameters should be taken carefully by the theoretical derivation or the experiments. Employ other sensors to compensate the wheel slip and slide errors can be the trend of the development. And it is always an emphasis of the domain.

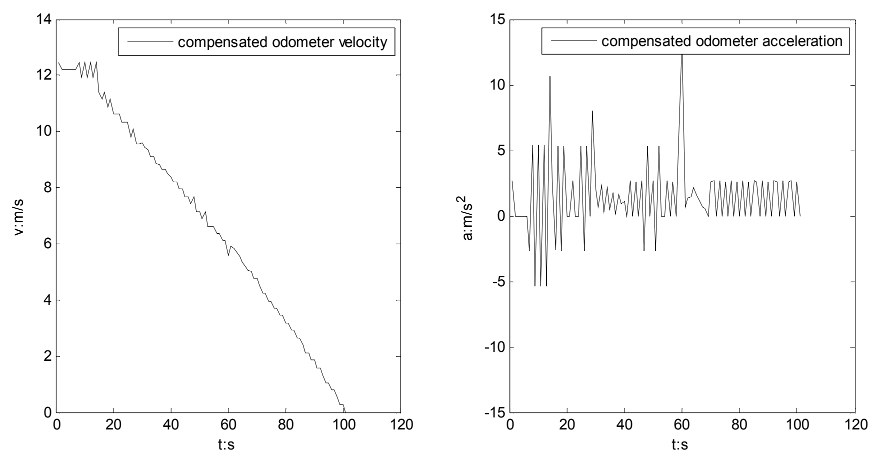

Figure 5. The velocity and acceleration curves after compensation

5 Conclusion

This paper summarizes the typical methods to detect and correct the train slips and slides. The detection of the slips and slides can be dependent on upper bound acceleration method, acceleration standard deviation method, Kalman filtering residuals method, redundant coded odometers method and the method of combined with other sensors. Methods to compensate the wheel slips and slides include fixed acceleration method, interpolation method and multi-sensors method which is more and more popular. The paper focuses on the merits and demerits of the methods. Besides, the simulation, comparison and analysis are given in the end of the paper. The comprehensive application of the methods can get more precise train localization and speed detection information.

Abstract: With the development of China's economy and transportation industries, high-speed railway continues to grow in strength in recent years, as the command center of high-speed trains operation, high-speed railway dispatching system plays an important role in ensuring the safety, high-speed and punctuality of trains. By using structural entropy evaluation theory, this paper analyzes the influence of the information flow within the system of three kinds of high-speed railway dispatching system: the whole way centralized dispatching mode, the region concentrated secondary mode and the trunk line (passage) secondary mode. This paper evaluates the ability of information transfer of the three command system modes from the perspective of time-effect, quality and order degree of information transfer, and puts forward the time-effect and quality analysis model of the information flow within the three command modes, and makes a quantitative evaluation of time-effect, quality and order degree of the system.
Keywords: Dispatching command system; High-speed rail; Structural entropy; Order degree.

1 Introduction

In the high-speed railway dispatching system, there is a longitudinal and transverse information flow of the vertical structure and the horizontal structure. In general, the information flow throughout a system is relatively stable, the time-effect and accuracy of information flows in the system are two conflicting indicators, namely, reducing the total layer of dispatching system structure will increase the speed of information flows, but due to an increasing elements of each level, it will make the bifurcation of information transmission increase, which will greatly increase the probability of error information, thus reducing the accuracy of information transmission. High-speed railway dispatching command must guarantee the traffic safety, and requires high quality of information transmission, therefore, how to configure these two conflicting indicators, the time-effect and accuracy of information transmission, to achieve the optimal system information transmission ability is an urgent problem. This paper introduces the evaluation theory of system structure entropy, through the establishment of three optional organization structure model of dispatching command modes, and then calculate and compare the order degree of the system as a comprehensive measure index of information transmission, carrying on the quantitative analysis of information communication mechanism.

2 Three kinds of high-speed railway dispatching system structure model

2.1 The whole way centralized dispatching mode

The whole way centralized dispatching mode is to set up an integrated dispatching center, and then according to the number of lines, traffic volume and other settings, build up appropriate number of dispatcher stations. And through professional dispatch, each dispatching console releases dispatching orders directly to the basic stations, and commands the fieldwork. Therefore, the system architecture can be divided into two layers: China Railway Corporation dispatching center and dispatching section. According to Rail transport [2011] No. 180 document, which considers train pairs as a main factor of dispatching section division and indicates the dispatching section-dividing principle: if there are 60 or more than 60 pairs of trains within the jurisdiction section, we set a train dispatch console at every 200-300 km; if there are less than 60 pairs of trains within the jurisdiction section, we set up a train dispatch console at every 300-400 km. In the future, China will build a "four vertical and four horizontal" high-speed railway network, China's high-speed railway mileage will reach 13000 kilometers, according to an estimation of setting up a train dispatcher station by an average of 300 kilometers, the whole high-speed network will be divided into 43 dispatching sections, as shown in figure 1.

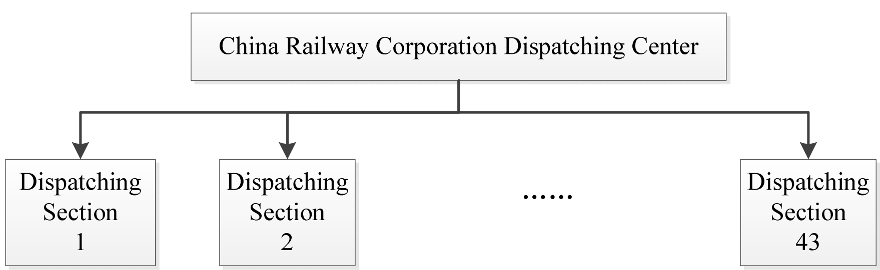

Figure 1. Structure model of the whole way centralized dispatching mode

2.2 The region concentrated secondary mode

This mode divides the entire high-speed railway dispatching system into two layers: the whole high-speed railway network dispatching command center and the regional dispatch center. Regional dispatch center is responsible for dispatching trains' daily work, releasing dispatching orders to the basic stations through each professional dispatching console. In this mode, the dispatching system structure can be divided into three layers: China Railway Corporation dispatch center, the regional dispatch center and the dispatch section. The whole high-speed network can be divided into 16 regional dispatch centers (including Harbin, Shenyang, Beijing, Jinan, Lanzhou, Taiyuan, Xi'an, Shanghai, Zhengzhou, Wuhan, Chengdu, Nanchang, Kunming, Nanning and Guangzhou dispatching center) and 43 dispatching section, as shown in Figure 2.

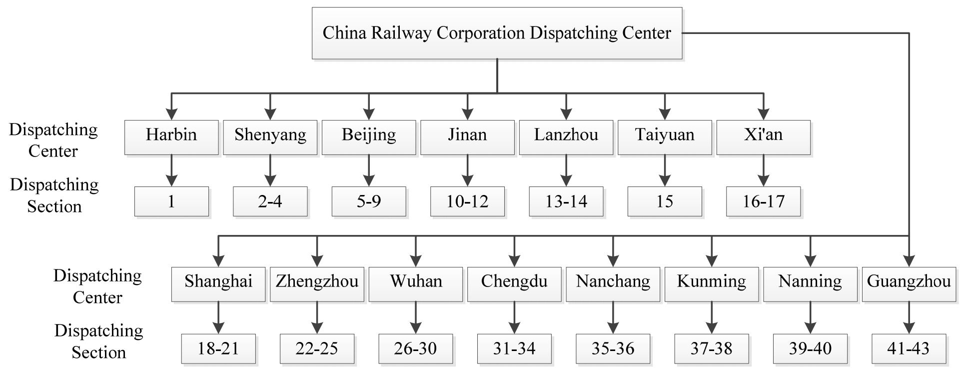

Figure 2. Structure model of the region concentrated secondary mode

2.3 The trunk line (passage) secondary mode

This mode divides also the entire high-speed railway dispatching system into two layers: the whole high-speed railway network dispatching command center and high-speed rail company dispatch center, we set up high-speed rail company dispatch center by trunk line (passage). High-speed rail company dispatch center is responsible for the daily work of train dispatching within the scope of the jurisdiction, releasing directly dispatching orders to the basic stations, and the basic stations organize the Traffic organization work at the scene in accordance with the dispatching order. In this mode, the dispatching system structure can be divided into three layers: China Railway Corporation dispatch center, trunk (channel) dispatch center and dispatch section. The whole high-speed network will be divided into 8 trunk (channel) dispatch centers and 43 dispatch sections, as shown in Figure 3.

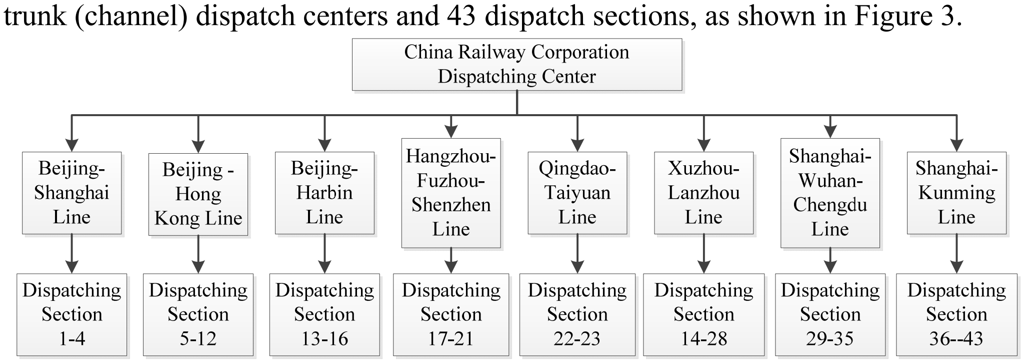

Figure 3. Structure model of the trunk line (passage) secondary mode

3. Evaluation of information transfer mechanism

3.1 The time-effect of information transfer

Time-effect entropy is defined as the measurement of the size of time-effect uncertainty when the information flows in a system. Time-effect reflects the efficiency of the mutual coordination between nodes unit in system. Assuming that there exists communication of information between k units in the m middle management agency whose span is n.

The contact length of the two elements is defined as the shortest path between two elements in the structure; the length directly connected is 1, adding one at a time at each transit.

When the organizational structure is determined, we can determine the shortest contact length L_{ij} between the subordinate elements in the system. Number of the possible routes that system evolves into a certain state is defined as the total number of micro state, the total number of microstates is larger, the system is more likely end up in this state, the total number of microstates of time-effect in a system A_t is:

$$A_t = \sum_i \sum_j L_{ij} \qquad (\mathrm{i} = 1,2 \ldots, \mathrm{m};\ \ \mathrm{j} = 1,2 \ldots, \mathrm{n})$$

Calculate the achieving probability of time-effect microscopic state of each contact:

$$P_t(i,j) = \frac{L_{ij}}{A_t}$$

Time-effect entropy between any two elements of the longitudinal hierarchy and same layer in the system:

$$H_t(i,j) = -P_t(i,j) log_2 P_t(i,j)$$

Calculate the total time-effect entropy of the system:

$$H_t = \sum_{i=1}^{m} \sum_{j=1}^{n} H_t\,(i,j)$$

Calculate the maximum time-effect entropy of the system:

$$H_{t\,max} = log_2 A_t$$

Calculate the time-effect of the system:

$$R_t = 1 - \frac{H_t}{H_{t\,max}}$$

3.2 Quality of information transfer

The quality of the system describes the accuracy of information transfer flows in the system, the quality entropy describes the uncertainty size of information quality, that is, describes the uncertainty of error opportunities in the process of information transfer.

k_i is the contact span of each node, defined as the number of nodes that directly contact with the elements in the structure diagram, total quality systems microscopic state is:

$$A_m = \sum_i k_i$$

Calculate the achieving probability of quality microscopic state of each contact:

$$P_m(i) = \frac{k_i}{A_m}$$

Calculate the quality entropy of each node of the system:

$$H_m(i) = -P_m(i) log_2 P_m(i)$$

Calculate the total quality entropy of the system:

$$H_m = \sum_i H_m(i)$$

Calculate the maximum quality entropy of the system:

$$H_{m\,max} = log_2 A_m$$

Calculate the quality of the system:

$$R_m = 1 - \frac{H_m}{H_{m\,max}}$$

3.3 The order degree of information transfer

Time-effect and quality of information transfer reflect the information transfer capability in a system, a certain level do not represent the strength of information transfer capability of the system. Therefore, in order to fully assess the information transfer capability, introduce the order degree as the comprehensive index of time-effect and quality of information transfer:

$$R = \alpha R_t + (1 - \alpha) R_m,\ \alpha \in [0,1]$$

α is the weight coefficient time-effect and quality of information transfer, $\alpha > 0.5$ means that we pay more attention to time-effect than quality of information transmission, conversely, $\alpha < 0.5$ means that we pay more attention to the quality of information transmission. The bigger R is, the higher the order degree of system is.

4 The result of order degree of three dispatching command modes

4.1 The calculation of order degree of the whole way centralized dispatching mode

According to the high-speed railway dispatching system structure model of the whole way centralized dispatching mode (Figure 1), the time-effect R_t^1 and quality

R_m^1 of this mode are calculated as shown in Table 1 and Table 2.

Table 1. The calculation of the time-effect R_t^1

Link length	$P_t(i,j)$	Sum	Micro state A_t	Time-effect R_t^1
1	1/43	43	43	$H_t^1 = 5.4263$ $H_{t\,max}^1 = 5.4263$ $R_t^1 = 0$
Sum	1.0	43	43	

Table 2. The calculation of the quality R_m^1

Link Span	$P_t(i,j)$	Sum	Micro state A_t	Quality R_m^1
1	1/86	43	43	$H_m^1 = 3.7131$
43	43/86	1	43	$H_{m\,max}^1 = 6.4263$
Sum	1.0	44	86	$R_m^1 = 0.4222$

4.2 The comparison of order degree of three modes

By the same method, we can calculate the time-effect and quality of the other two modes, and the results are shown in Table 3.

Table3. The comparison of order degree of three modes

Mode	Time-effect entropy	Quality entropy	Order degree of time-effect	Order degree of quality
The whole way centralized dispatching mode	5.4263	3.7131	0	0.4222
The region concentrated secondary mode	6.5727	3.6151	0.0833	0.3829
The trunk line (passage) secondary mode	6.4703	2.9951	0.0884	0.4720

According to the definition of order degree and the data above, the results of the order degree of three modes are shown in Figure 4.

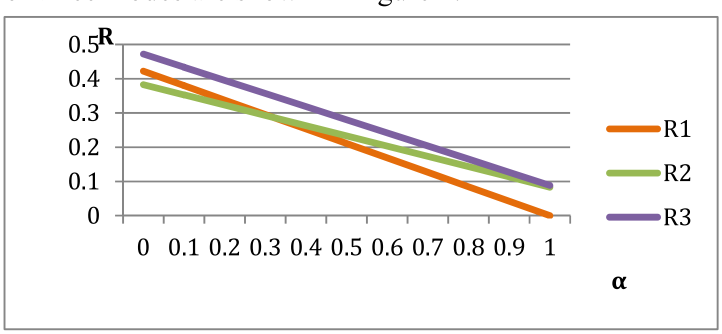

Figure 4 The order degree of three modes

No matter what value α, information transfer ability of the trunk line (channel) secondary mode are higher than the other two modes. From the perspective of the information transfer quality, the accuracy of the information transfer of the whole way centralized dispatching mode is very low, high-speed railway dispatching command must guarantee the traffic safety, and requires high quality of information transmission, therefore, this kind of mode is not recommended. In the early stages of development, China's high-speed railway that has been opened mainly adopts the region concentrated secondary mode. After our high-speed rail into the net, dispatching could be considered using trunk line (channel) centralized secondary mode in the future, although it cannot be asserted merits of these two models, but at least be able to provide a reference from the perspective of information transmission.

5 Conclusions

With the fast development high-speed railway, China's high-speed railway has gradually formed a railway net, which puts forward higher requirements on security and efficiency of dispatching command. Taking order degree of system as a comprehensive measure index of information transfer, this paper has made a quantitative evaluation of information communication mechanism, which provides a reference for the selection of information delivery mechanisms high-speed railway dispatching mode to ensure fast and accurate information transfer in the process of dispatching.

Abstract: As important nodes on urban roads, intersections are prone to cause traffic jams and chaos. Therefore, the traffic organization of intersection is closely related to the overall performance level of the urban road net. It's necessary to improve traffic organization of existed intersections, so that the capacity of at-grade intersections can be enhanced, the traffic congestion of urban roads can be alleviated, to a certain degree. This research includes two major parts. The first part is studying the theories about timing signal control based on the running mechanism of at-grade intersection's traffic flow from the perspective of both time and space, in order to find efficient ways to optimize intersection's traffic organization. The second part is conducting a further optimization and modification on road channelization and signal control combining the above-mentioned theory with current status, eventually establishing a feasible and effective scheme. The following step is applying the micro traffic simulation software VISSIM to evaluate the present traffic of the XiYing Road-XiYan Road intersection in Xi'An based on relevant data.
Keywords: Intersection optimization; Signal control; Road channelization; VISSIM simulation.

1 Introduction

Urban transportation is the main artery for urban economy to run through. Meanwhile, the rapid development of economy does require the traffic to flow smoothly. Thus, organization of at-grade intersection is essential in traffic control. Methods for controlling the traffic of at-grade intersection contains stop control, way-giving control, signal control, etc. The first two of the methods accommodate to the intersections where the flow isn't too heavy. The rest are suitable for the intersections where the flow is heavy, which make great contribution to relieving the congestion of intersections. Compared with interchange, signal control does not overuse the land resource essentially, whereas it can effectively fulfill the departure of conflict flows. Therefore, to improve the capacity of the urban intersections in our country, the most important task of all is to improve the capacity of the intersections where signal controlled systems are applied.

2 Theoretical Consideration

2.1 Normal phase delay

As is shown in Figure 1, vertical axis represents the length of the queue, horizontal axis represents time. N_j is the length of vertical link between link *OC* and *DC* as well as the length of the queue at the entrance lane at that time. The slope of *OC* is the rate of arrival, and the slope of *DC* is the saturated flows of entrance lane. Automobile *A* needs to wait a certain time of delay t_A to pass the stop-line if there are vehicles in the front before its arrival.

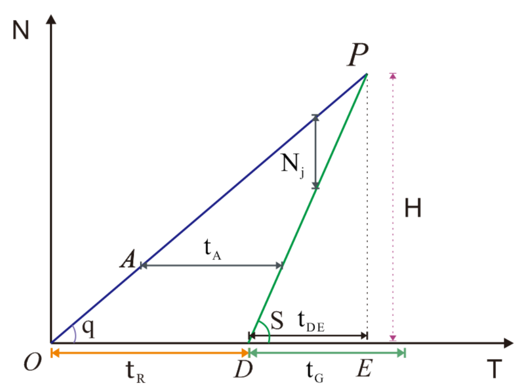

Figure 1.Chart of normal phase delay

If the arrival time is a constant, the total delay time of all vehicles within a signal cycle can be determined by the area of ΔOCD, and thus it reaches

$$\overline{d_I} = \frac{C \cdot (1-\lambda)^2}{2(1-\chi\lambda)} \tag{1}$$

with $\lambda = t_G / C$ and $\chi = q / (s \cdot \lambda)$, since $t_R = C - t_G$

where C is the cycle length of signal, t_R symbolizes time for red light, t_G symbolizes time for green light.

2.2 Random delay

Actually, the arrival rate of vehicles within different signal cycles fluctuates at random, which can result in temporary over saturated phenomenon, namely, the vehicles behind the stop-line cannot be cleared up only to increase the delay at the intersection greatly, such a phenomenon is called random delay, Webster figured out the model of random delay on the assumption that the traffic obeys Poisson Distribution, thus the average delay of vehicles is:

$$\overline{d_2} = \frac{\chi^2}{2q \cdot (1-\chi)} - 0.65\left(\frac{C}{q^2}\right)^{\frac{1}{3}} \cdot \chi^{2+5\lambda} \tag{2}$$

In the equation, the first term is the Poisson Distribution arrival that takes random fluctuation into account, the second term is the correction term figured out by means of simulation (Pu Q.,1999).

2.3 Webster delay

Combining Eq.1 and Eq.2, we can figure out the expressive equation of Webster Delay model as follows:

$$\overline{d} = \frac{C \cdot (1-\lambda)^2}{2(1-\chi\lambda)} + \frac{\chi^2}{2q \cdot (1-\chi)} - 0.65\left(\frac{C}{q^2}\right)^{\frac{1}{3}} \cdot \chi^{2+5\lambda} \tag{3}$$

2.4 Confirmation of the time span of Webster's best signal circulation

According to the theory for stable flow, the average delay time of the main traffic at an intersection can be expressed with the following equation:

$$d = \sum_{i=1}^{n}\left[\left(\frac{C \cdot (1-\lambda_i)^2}{2(1-y_i)} + \frac{\chi_i^{\ 2}}{2q_i \cdot (1-\chi_i)}\right) \cdot q_i\right] \Big/ \sum_{i=1}^{n} q_i \tag{4}$$

where *d* with index *i* is the average delay time of the main flow on the relevant lane, q_i reflects the arrival rate of the main flow on lane *i*.

As we know, "The average delay time of main flow is the least" is equivalent to "The degree of saturation of each main flow is equal". Namely:

$$\frac{y_j}{\lambda_j} = \chi_j = \chi_k = \frac{y_k}{\lambda_k} \Rightarrow \lambda_j = \frac{y_j}{Y} \cdot \frac{C-L}{C} \tag{5}$$

where *L* is the total time lost during the whole signal cycle.

Therefore it's also clear that there is certain relationship between the green ratio and signal circulation. If the circulation formula of average delay time is derivate of circulation *C*, assuming the derivative is zero, through repeated calculations, we can get the simplified formula for the best signal circulation:

$$C_0 = \frac{1.5L + 5}{1 - Y} \tag{6}$$

3 Basic Data

3.1 On-the-spot investigation

The intersection where Xiying Rd. and Xiyan Rd. cross is a typical intersection where two avenues cross. Via investigating the geometric condition, the current traffic signal control and the flow in the peak hour, we worked out the intersection plan, the current phase diagram at the intersection and the figure of the traffic, which are shown in Figures 2 and 3 and Table1.

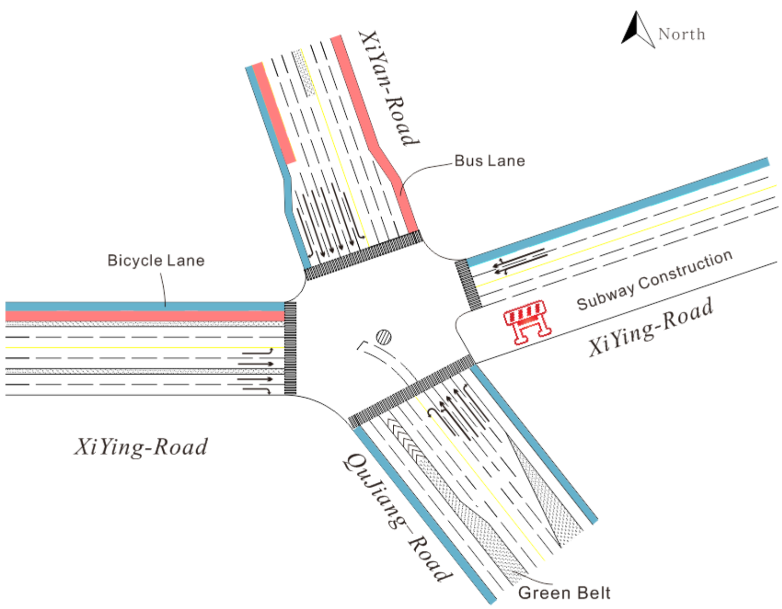

Figure 2.Current intersection plan

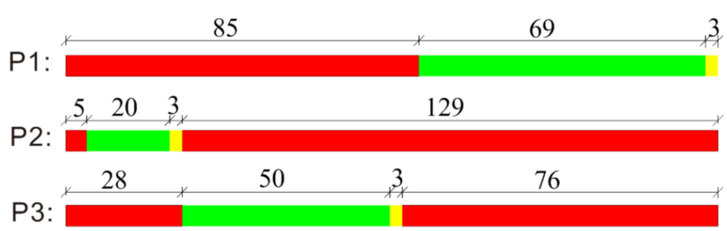

Figure 3.Current phase diagram

Table 1.Traffic distribution of peak hour

Lane / *Type*	East entrance			West entrance			South entrance			North entrance		
	L	S	R	L	S	R	L	S	R	L	S	R
Small	145	488	175	353	398	86	322	1689	218	172	1795	342
Medium	4	78	1	36	62	6	4	43	3	4	18	22
Large	0	1	0	0	1	0	0	3	0	0	0	0

L – left lane, S – straight lane, R – right lane.

3.2 Existing problems

(1) The time spent driving straight through west entrance and standing in the queue to turn right is comparatively long, causing a phenomenon of residual queue.

(2) The straight-running car at north entrance is prone to have conflicts with the pedestrian, which threatens personal safety.

(3) The set time for all-red for the 1st phase and the 2nd phase aren't so reasonable because the intersection there is larger than normal; meanwhile the all-red time can't satisfy the requirement that all the vehicles shall run across the intersection from the stop-line when the green light is coming to its end.

(4) The straight-running flows at east entrance and for the straight-running flow at west entrance as well as the left-turning flow have a more serious conflict with the flow running south or north. That's because the left-turning flow at east entrance and west entrance is heavier which is caused by no left-turning phase.

(5) This intersection isn't a firmly symmetric one, for the straight-running flow at east entrance has some serious conflict with the left-turning flow of west entrance.

(6) Since the metro construction occupied part of the lanes, it keeps an imbalance between the number of the lanes at east entrance and west entrance.

4 Rectification Measures

4.1 Rectify the plan

The rectified intersection is shown in the following figure.

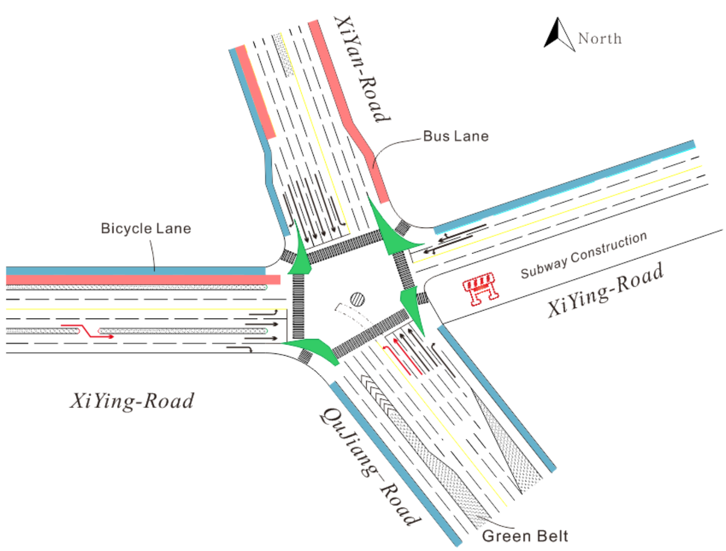

Figure 4.Rectified design for intersection plan

As is shown in Figure 4, the rectification includes the following measures:

(1) Now that the investigation reveals the fact that there is less flow along the straight lanes on the southern side, we should cut off a certain part of the green belt

to build a access which is about 50 meters away from the intersection at west entrance so that some vehicles can be led to the through lane on the southern side, as a result, the length of the queue will get shortened, which contributes to decrease the delay there.

(2) Setting traffic islands which, on one hand, is convenient for right-turning vehicles to pass; on the other shortens the distance between the stop-line and the intersection so that vehicles can pass the intersection more quickly and at the same moment pedestrians to go straightly across the street becomes safer, which can decrease the possibility for pedestrians to have conflicts with vehicles.

(3) Due to a much heavier straight-running traffic at north entrance, adjust the turning-around lane into a left-turning lane, and the straight-to left lane into a straight-running lane.

4.2 Time optimization for signals

Saturated flow is estimated by means of multiplying the common saturated flow by the correction coefficient of each affective factor, namely, the estimated saturated flow on the lanes at the entrance:

$$S_f = S_{bi} \times f(F_i) \tag{7}$$

where: S_f is the estimated saturated flow on the lanes at the entrance, pcu/h, and S_{bi} is the common saturated flow on the lanes of i style. When index i is replaced with T, L or R, it separately stands for the relevant flow of straight-running, left-turning, or right-turning. $f(F_i)$ is the correction coefficient relevant to each style of lanes at the entrance.

Correction coefficient of lane width is necessary to be determined since the width of the lane would generate some influence to the capacity:

$$f_w = \begin{cases} 1 & 3.0 \le W \le 3.5 \\ 0.4(W - 0.5) & 2.7 \le W < 3.0 \\ 0.05(W + 16.5) & W > 3.5 \end{cases} \tag{8}$$

where W is the width of the lanes at each entrance.

Influence coefficient of gradient and large vehicles' ratio should be taken into consideration due to the consumption of different space resources are different in accordance with the type of vehicles, and the road's vertical slope affects vehicle's dynamic performance (Yang X.,2013)

$$f_g = 1 - (G + HV) \tag{9}$$

where G is vertical slope, and HV is ratio of large scale vehicles.

According to Eqs.7-9, Table 2 shows the calculated parameters in signal timing.

Table 2.Signal timing parameters

Ent.	Lane	NOL	q	S_{bi}	f_W	f_g	S_f	y_i
East	T&L	1	451	1800	1	0.882	1588	0.284
	T&R	1	490	1800	1	0.882	1588	0.309
West	R	1	95	1380	1	0.905	1249	0.076
	T	2	493	2520	1	0.807	2034	0.242
	L	1	407	1800	1	0.867	1561	0.261
South	L	1	322	1550	1	0.982	1522	0.212
	T	3	1760	5400	1	0.960	5184	0.340
	R	1	223	1550	1	0.980	1519	0.147
North	L	1	178	1600	1	0.966	1546	0.115
	T	4	1822	6320	1	0.985	6226	0.293
	R	1	375	1530	1	0.912	1395	0.269

NOL – number of lane.

The calculation formula for green light interval time is:

$$I = p/v_a + t_s \tag{10}$$

If the average speed of vehicles running on the lanes v_a is 6m/s; braking time relevant to the vehicles t_s is 2s (Zheng C.J.,2005); P is the distance from the stop-line to the conflict point, here is 25m, on condition that the flow running east and west is easy to have conflicts with the flow running south and north.

According to phase order, we can get $I = 6.17$s, thus we can confirm 6s as the interval time between 3rd phase and 1st phase.

The calculation formula of total lost time L is:

$$L = \sum_{i=1}^{3} (L_c + I_i - A) \tag{11}$$

where L_c is the lost time for vehicles to start, I is the green light interval time (it contains yellow-light time and all-red time), A is the yellow light time.

Through the investigation on the spot, we can calculate the total loss time L is about 12 seconds inside one cycle.

According to Table 2, the aggregate of each phase's max flow ratio Y is 0.861, then using Eq.6, we can get the Webster best signal circulation C_0 is 165 seconds.

Through the calculation result of the above, we can work out the time of green light according to the following formula:

$$g_{ei} = G_e \times \frac{Max(y_{i1}, y_{i2}, \cdots)}{Y} \quad (12)$$

$$g_i = g_{ei} - A_i + L_i \quad (13)$$

Where g_e with the index i is the effective green time of each phase, G_e is the total effective green time, and g_i is the displaying time.

The 1st phase is for running through south and north, the 2nd phase for left-turning of south and north, the 3rd phase for all direction of east and west.

According to Eq.12 and Eq.13, through calculation we can work out the green-light time displaying in each phase are 60s, 38s, 55s in turns. Figure 5 shows the signal phase diagram according to our calculation.

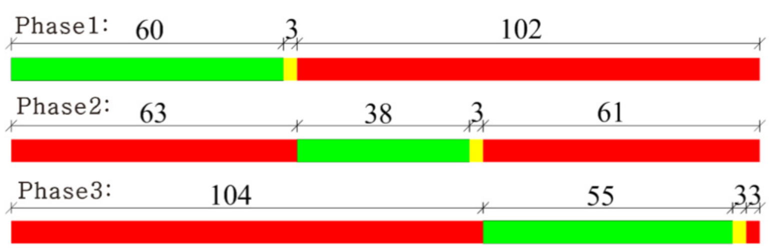

Figure5. Optimized signal phase diagram

5 Simulation and Conclusions

By modeling and calibrating the model of this at-grade intersection in VISSIM (PTV, 2007), as well as setting relative parameters while simulating, we can get a simple comparison between the current intersection and the optimized one, as shown in Table 3.

Table 3. Simulation under different situation

Time interval(sec)		200-700	700-1200	1200-1700	1700-2200	Total
Delay	Current	37.9	42.4	44.3	42	41.6
	Optimized	37	38.5	42.5	34.5	38.2
Stopd	Current	31.7	35.2	36.3	35	34.5
	Optimized	29.8	31	34.4	28.2	30.9
Stops	Current	0.61	0.72	0.83	0.64	0.7
	Optimized	0.53	0.61	0.65	0.61	0.6
#Veh	Current	568	532	530	506	2136
	Optimized	761	705	714	718	2898

Stopd – the average dwell time per vehicle (unit: second);
Stops – the average stop frequency per vehicle;
#Veh – number of vehicles passing the intersection;
Statistics start from at 200 sec, when the flow becomes stable.

As is indicated in the table, we can draw the conclusion that the optimized intersection does have minimized the total delayed cost of system, and the vehicle will stop less. And at the same time, the capacity of optimized intersection shall be improved according to the results of simulation.

The capacity and level of delay of signal controlled intersection are directly influenced by the timing scheme, therefore an optimal timing scheme is the key of improving the efficiency of the intersection. This passage has conducted a typical optimization of a current intersection using classical theory of timing signal control without taking the non-motor vehicles into account, while the signal control of non-motor vehicles under mixed traffic is rather important, which is a study aspect need of endeavor.

Prediction of Market Segmentation Based on Attitudes towards Bus Trips and Risk Preference in an Urban Transit System by Bayesian Network

Yu Bao; Sida Luo; Hanxia Shen; Haoyang Ding; and Yufeng Zhang

School of Transportation, Southeast University, Nanjing 210096, China.

Abstract: Transportation policy can be more efficient in attracting a considerable number of people to choose public transit as their travel mode when decision-makers tend to develop specific policies considering different groups of people. The market segmentation method based on bus commuters' attitude towards bus trip and their own risk preference is a significant approach to characterize various demands from bus commuters. Traditional segmentation approaches, however, rarely attempted to reveal the connection between commuters' socioeconomics attributes and the result of segmentation due to the fact that classic market segmentation is conducted on the basis of commuters' attitude investigation and analysis. Bayesian Network, an advanced method to make fantastic prediction, can directly predict market segmentation based on commuters' socioeconomic attributes and risk preferences. In this way, the segmentation method can still be valid on the lack of original data of attitude and risk preference. It helps market segmentation to be more practical in demand forecasting. This paper applies Bayesian Network based on K2 and TAN structure learning algorithm respectively to predict market segmentation of attitude and risk preference on the basis of socioeconomics attributes. Traditional segmentation approach is used in this work to verify the precision of predicting segmentation results. Moreover, comparison between K2 and TAN Bayesian Network is made. The results show that the total relative error of TAN network is 29.5% while that of K2 network is 32.7%. Besides, TAN Bayesian Network takes more socioeconomic attributes into consideration than that of K2 Bayesian Network, which means the structure of TAN network coincides with common sense better. It comes to the conclusion that using Bayesian Network to predict market segmentation based on attitude towards bus trip and risk preference is capable of making the segmentation method plays a more important role in traffic demand forecasting. TAN Bayesian Network, furthermore, owns much stronger effectiveness. The proposed approach is of great help to establish potent transit systems planning and management strategies.
Keywords: Bayesian network; Urban transit; Market segmentation; Attitude; Risk preference.

1 Introduction

The diversity of people is often ignored when various kinds of strategies are developed to promote public transportation. Market segmentation approach is helpful in dividing commuting market into several submarkets, where people in the same submarket share the same or similar characteristics in choosing trip mode. Hence, specialized strategies can be developed in attracting more people to choose bus as their travel mode.

In this study, the diversity of commuters in urban transit system is observed in two ways: peoples' attitude towards bus and their risk preferences. Various kinds of segmentation method have been adopted in numerous fields. (Badoe et al., 1998) As for traffic and transportation field, market segmentation according to people's attitude and risk preference has already been used in the study of traffic mode choice. (Shiftan et al., 2008) For example, attitude-based market segmentation approach has been successfully applied in the study of bicycle commuting market. (Bergstrom and Magnusson, 2003) Numerous kinds of classification approaches such as k-means Clustering method are successfully used in extracting homogeneous travelers and generating distinct market segmentation. (Li Zhibin et al., 2012)

However, it usually takes extra investigation and evaluation to measure travelers' attitude and risk preference before conducting classification while Bayesian Network is capable of predicting the result of market segmentation directly from people's socioeconomic characteristics. It is important and practical to find the inner connection between people's risk preference and their socioeconomic characteristics since the latter one is convenient to be obtained from census. With the help of Bayesian Network, market segmentation method can still be functional even when the basic information of people's attitude or risk preference towards bus trip is absent. In our work, Bayesian Network is applied in the prediction of the segmentation result of bus commuting market based on attitude and risk preference, respectively.

The remainder of this paper is organized as follows. Section 2 introduces the methodology used in this study. It contains the summary of K2-structure Bayesian Network and TAN-structure Bayesian Network. Section 3 presents the model application of this study. Comparison between those two structure learning algorithms demonstrates that TAN-structure Bayesian Network has privilege in the accuracy of prediction. Section 4 discusses the characteristics of submarkets and policy implications. The paper ends with final conclusion in Section 5.

2 Bayesian Network

This section introduces the specific methods of this study including both K2 and TAN structure Bayesian Networks.

Bayesian Network (BN) is a widely-adopted model consisted with directed acyclic graph (DAG) structure and a set of parameters. It studies probability distribution among conditional independent variables $X=\{x_1,\ldots,x_n\}$ in the following way:

$$P(x_1,\ldots,x_n)=\prod_{i=1}^{n} P(x_i \mid \prod(x_i)) \qquad (1)$$

In this paper, we focus on the structure learning part of establishing a BN. The structure of a BN reflects the underlying relations among nodes. Robinson (1977) demonstrated that the number r(n) of possible structures for a BN with n nodes is:

$$r(n)=\sum_{i=1}^{n}(-1)^{i+1}\frac{n!}{i!(n-i)!}2^{i(n-1)}r(n-i) \quad (2)$$

Function (2) reveals that the number of potential structures for a BN is massive when variables of the case are diverse. The intention of Bayesian structure learning is to find B_S which inosculates database (D) best. In other words, it means to find the BN with the biggest posterior probability ($P(B_s|D)$).

$$P((B_s|D)=\frac{P(B_s,D)}{P(D)} \quad (3)$$

In function (3), P(D) is a constant which makes the intention of Bayesian structure learning to find out the B_s with the biggest $P(B_s, D)$.

$$\max_{B_s}[P(B_s,D)] = P(B_s)\prod_1^n \max_{\pi_i}[\prod_{j=1}^{q_i}\frac{(r_i-1)!}{(N_{ij}+r_i-1)!}\prod_{k=1}^{r_i}N_{ijk}!] \quad (4)$$

As for function (4), n is the number of nodes. r_i represents the possible value assignments of variable x_i. π_i represents a set of parents that each variable x_i in B_s has. q_i represents the unique instantiations of π_i. N_{ijk} represents the number of samples in D in which variable x_i has the k value and π_i is instantiated as w_{ij}. Let $N_{ij} = \sum_{k=1}^{r_i} N_{ijk}$.

K2 and TAN structure learning algorithm are respectively applied in this paper to predict the market segmentation of bus commuters. The flow chart of K2 and TAN algorithm to construct Bayesian Network is presented as follows.

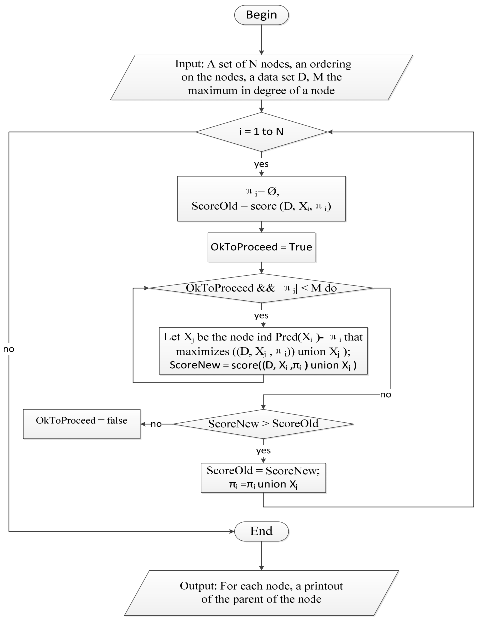

Fig 1. Flow chart of K2 algorithm

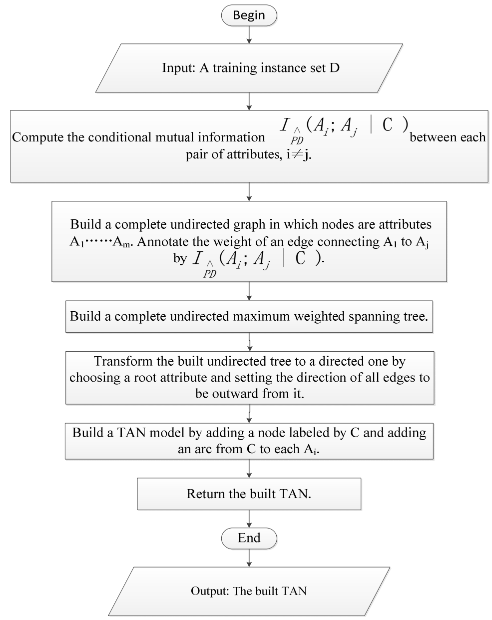

Fig 2. Flow chart of TAN algorithm

3 Results

3.1 Data resources

The survey was conducted in seven bus routes in 2014 in Nanjing, China. Respondents are people who take bus as one of the trip methods. The investigation contains three parts which are respectively socioeconomic characteristics, attitudinal factors and risk preference of respondents concerned with bus trip. Our work is conducted on the basis of 657 valid questionnaires after eliminating invalid information. The effective rate of the survey is 84.5%.

Both K2 and TAN algorithms are implemented with the help of toolbox of Matlab using the socioeconomic characteristic data. Specifically, the socioeconomic variables are gender, age, education, annual income, number of children at home, number of cars in possession and average travel time. 70% of the samples are used to establish a BN, while 30% of the samples are used for the verification of the BN.

3.2 Market segmentation based on attitude

To evaluate the performance of BN, we adopted the market segmentation result of K-means clustering which is conducted on the basis of the attitudinal data from this research. Four attitudinal factors (time, price, comfort, and transfer times) are selected to conduct K-means clustering on account of Structural Equation Model Examples. Bayesian Network is established through learning the result of K-means clustering.

With the help of BNT toolbox, structure learning is conducted by K2 structure learning algorithm in Matlab. K2-structure Bayesian Network is built through learning the discrete data generated from K-means clustering. The structure is generated and presented in Fig 3.

According to K2 Bayesian Network, gender makes no difference in attitudinal market segmentation of bus commuters in this study. The segmentation has two obvious parent nodes: education and time. In addition, characteristics themselves are interplayed at the same time.

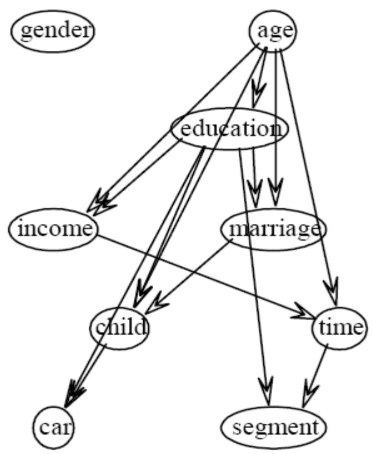

Fig 3. Structure of K2 Bayesian Network based on attitude

Statistics of each submarket are presented in Table 1. Comparison between prediction result of K2-sturcture Bayesian Network and classic segmentation result of K-means clustering are made in Table 1 as well.

Table 1. Comparison of statistics between K2 and original data in attitude

Submarket	Prediction of K2	Original data	Relative error (%)
1	71.55	79	9.4
2	69.58	71	2.0
3	32.92	31	6.2
4	19.57	17	15.1

According to Table 1, the total relative error of K2 structure Bayesian Network is 32.7%.

Similarly, TAN structure learning algorithm in Matlab with the help of BNT toolbox as well. TAN-structure Bayesian Network is built through learning the discrete data generated from K-means clustering. The structure of TAN is presented in Fig 4.

According to TAN Bayesian Network, the segmentation has eight parent nodes: income, education, time and so on. In addition, characteristics themselves are interplayed in a more complicated way than that of K2-structure Bayesian Network.

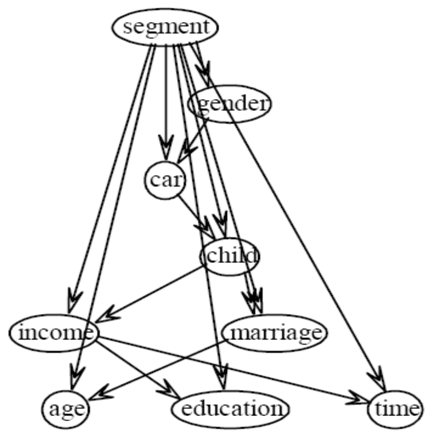

Fig 4. Structure of TAN Bayesian Network based on attitude

Statistics of each submarket are presented in Table 2. Comparison between prediction result of TAN-structure Bayesian Network and classic segmentation result of K-means clustering are made in Table 2.

Table 2. Comparison of statistics between TAN and original data in attitude

Submarket	Prediction of TAN	Original data	Relative error (%)
1	72.44	79	8.3
2	66.53	71	6.3
3	29.63	31	4.4
4	18.79	17	10.5

The total relative error of TAN structure Bayesian Network is 29.5%. It is found that both K2 and TAN Bayesian Networks show approximant with K-means clustering in predicting submarket 1, 2 and 3. Both of them present a relatively high error in predicting submarket 4. However, considering the size of our sample is limited and the number of S4 is small comparing to others, the relative error is considered to be acceptable and the prediction results are advisable.

3.3 Market segmentation based on risk preference

In this paper, bus commuters are divided into four submarkets based on risk preference. The classification is made according to our risk investigation and it has been verified through scenarios. The features of every submarket are presented in Table 3.

Table 3. Characteristic of submarket based on risk preference

	Preference towards certainty	Preference towards avoidance
M1	High	High
M2	Low	High
M3	High	Low
M4	Low	Low

The structure of K2 and TAN Bayesian Networks are respectively presented in Fig 5 and Fig 6.

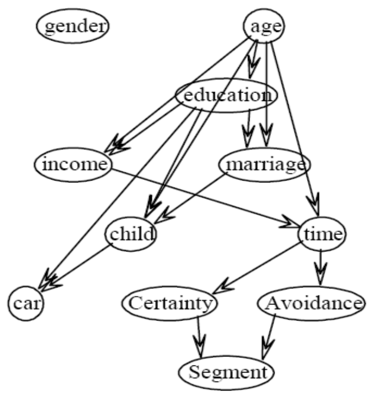

Fig 5. Structure of K2 Bayesian Network based on risk preference

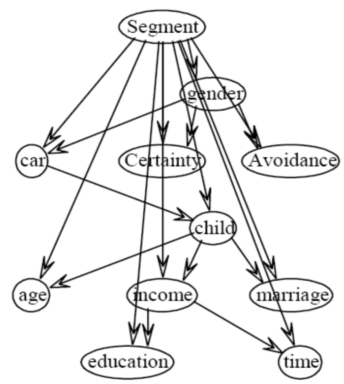

Fig 6. Structure of TAN Bayesian Network based on risk preference

Detailed results of comparison between the prediction precision of K2 and TAN structure Bayesian Network and original segmentation are presented in Table 4 and Table 5.

Table 4. Comparison of statistics between K2 and original data in risk preference

Submarket	Prediction of K2	Original data	Relative error (%)
1	63	51	23.5
2	52	64	18.8
3	34	38	10.5
4	50	45	11.1

Table 5. Comparison of statistics between TAN and original data in risk preference

Submarket	Prediction of TAN	Original data	Relative error (%)
1	66	51	29.4
2	59	64	7.8
3	34	38	10.5
4	40	45	11.1

The result indicates that the total relative error of TAN structure Bayesian Network is 58.8% while that of K2 structure is 63.9%.

Table 6. Comparison between the predictions

Segmentation	Total relative error of K2	Total relative error of TAN
Based on attitude	32.7%	29.5%
Based on risk preference	63.9%	58.8%

Comparison between four predictions is made in Table 6 to present a legible result. In conclusion, TAN Bayesian Network is superior to K2 Bayesian Network in its structure and accuracy when predicting. It reveals the connection between bus commuters' characteristics and their risk preference in a better way in this study.

4 Conclusions

This study increases the feasibility of market segmentation with the support of BN. With the help of BN, market segmentation can be preceded without inquiring bus commuters' attitude or risk preference. Bus commuters are clustered into several submarkets with the data from census. Then, more focused strategies or policies can be made to attract more people to choose bus as their trip mode. Bus commuters' needs are taken into consideration in a more practical way.

As the comparison reveals, the relative error of BN reveals its defect in accuracy. Future studies can focus on improving the accuracy of BN. Furthermore, different kinds of parameter learning methods may result to different result while this study only considers the diversity of structure of BN. The authors recommend that future studies could focus on various kinds of BN based on other algorithms.

Abstract: Priority to the development of public transport is the only way to solve the increasingly serious urban traffic problems, it also become the consensus of the governments at all levels in our country. Bus, subway as one of the most important part of urban public traffic, reasonable transfer to join to play their respective advantages, to achieve convenient passenger travel is of great significance. This article summarized domestic and foreign research status on transit with other public transportation transfer, on the basis of analysis of the bus and subway and other public transportation transfer to research the basic train of thought, finally bring forward the transfer process and the recognition principle of public traffic transfer.
Keywords: Public transport; Transfer process; Recognition principle.

1 Summary

With the acceleration of urbanization, urban economic level and increasing levels of urban vehicles, there has been a series of traffic problems, including urban traffic congestion, accidents and environmental pollution. Faced with such a complex environment and residents' growing travel demand, priority to the development of public transport has become the only way to solve the growing problem of urban traffic problems, which has become the consensus of all levels of government. Bus, subway as the most important part of urban public transportation, it is important to optimize the transfer and play their strengths to achieve convenient passenger travel. In addition, the emergence of public bicycles, bus rapid transit, urban light rail and other public transportation, but also has made important contributions to ease the pressure on urban public transport to meet passenger demand. Based on this, the priority development of public transport, the construction of city bus system, which build a rapid rail transit as the backbone, conventional ground bus as the main, feeder buses to supplement, has become a major urban passenger transport development strategy of our country. The research work on transfer convergence of urban public transport systems, for the convenience of passengers traveling to achieve urban transport efficient, timely, orderly, integrated transport is essential to form.

2 **Literature review**

The transfer of urban public transport is the demand of urban public transport development in recent years, which has become one of the hot issues of public transportation development research. Currently, researches on the transfer of urban public transport system mainly from the following aspects:

(1)The planning and operation of the urban public transport transfer system.

(2)Transfer between bus, BRT, rail, bike and other public transport.

(3)Recognition and application of urban public transport interchange behavior.

In the planning of urban public transport hubs, studies start very early abroad. Lee.Schonfeld (1992),IanS. J.Dickins(1998), Chen,I.J.Steven and Feng-Ming Tsai (2003) have been studied on the existing urban transport system transfer function and type of facilities, transfer stations scale, configuration, location and other issues, and made recommendations for improvement in order to optimize the bus lines, improve transfer efficiency, passengers are encouraged to use public transport.At home, Xie Yujie (2006) discusses the layout on conventional rail and bus lines, the integration and coordination of vote transfers and other issues raised in the integration thinking of transport modes. Xu Kun (2009) mentioned that take the travel time as a major factor in the transfer selection, and made a function on travel time, transfer distance and the transfer ways, determined the value of the three variables.

Bus Rapid Transit is an advanced public transportation developed in recent years, as a supplement to conventional buses, it plays an important role for ease traffic pressure. Studies abroad on BRT mainly in the rapid transit hub and route planning(Steven I.chiental(2003),Pedro Szasz (2007));BRT and rail traffic or slow traffic coordination to facilitate the transfer; real-time scheduling(Lee & Chonfeld(1991),Md.Shoaib Chowdhur(2001), Manuel J.Martinez(2003),).In domestic, studies on BRT mostly based on the actual situation of our country, in broad areas. Rapid transit public transportation network planning and infrastructure utilization (Wang Yang et al. (2009)); coordination and operations of bus and BRT (Huang Wenjuan,Jiang Ping (2008)); the transfer optimization of BRT and bus(Sun Mingzheng et al. (2009)); grid frequency optimization(Bai Zijian et al. (2007)); BRT planning, operations and service evaluation(Wu Jiaqing (2006),Chen Zhangyuan et al.(2008)).

The transfer between a bike and public transport has become one of the main contents of the current city transport studies, the current study focused primarily on how to improve the cycling environment, improving public transport and convergence transfer service levels, improve satisfaction of resident traffic travel, proposed construction of an integrated urban bike and public transport interchange system, and discuss specific issues transfer implementation. (Martens (2007), Ryosuke Ando et al. (2007), Marc Dijk et al. (2011), Cao Ping & Chen Jun (2008), Liu Fang (2012) et al.).

In the recognition and application of urban bus transfer behavior, scholars also made some achievements. Widespread use of public transportation IC card has brought great convenience to the research. Chu and Chapleau (2008) infer full passenger journeys for a bus network, then analyze multiple days of AFC data to estimate general activity types for cardholder's recurrent journeys. Farzin (2008) automates the majority of the destination-inference process on a portion of a large bus network and constructs a zonally aggregated OD matrix. Munizaga et al (2011) automate the inference of origins and destinations for a large multi-modal network and, using a simple interchange-inference algorithm, construct a full-journey origin-destination matrix for AFC cardholders.Gao Yong, Deng Xiaoyong(2008) proposed road bus transfer recognition method based on the IC card data, travel time is about twice time difference when typing on the bus, compared with the threshold and then identify whether the transfer behavior and analyzed factors affecting the method. Zhang Zi, Zou Liang, Zhu Lingxiang (2011) take the bus IC card as the starting point, the time difference of twice card typing data and the bus GPS time points were analyzed, and then identify the passenger car is the transfer behavior or travel behavior. Li Haibo, Chen Xuewu (2013) to start the process from bus travel, bus transfer process will be for some time abstract node. Combined with the characteristics of existing bus system data, through the effective integration of bus IC card and AVL data, calculate the time passengers get off before the transfer time and walk to the transfer site. Judgment based on the "pick away" travel assumptions made by the comparison of the transfer time off, take time on the bus line and transfer vehicle arrival time to conduct transfers.

3 Transfer process and the recognition principle

Transfer (Interchange), refers to the replacement of vehicles traveling on the way. It can refer to switch to a different means of transport properties; can also refer to the replacement of the same nature in different lines of transport. In the urban public transport system, to interchange is the act of transferring between modes or between different services of the same mode. For example of a transfer between bus services, when a passenger alights from Route 119 and then waits for and boards Route 56 in order to continue his or her journey to the ultimate destination, it is considered to be an interchange. However, transfers between trains without exiting the system, the passenger enters through a ticket gate until they exit through a ticket gate, which is hard to recognize the interchange. Besides, if the passenger who is transferring between modes or between different services of the same mode takes time to buy a magazine at the corner, is this still considered an interchange? What if they meet a friend for lunch? Or, they take 15 minutes to pick up their child from school? The point is that there is a spectrum of activities that people may engage in between journey stages and often that activity is actually the purpose of the journey, such as meeting a friend for lunch, rather than some non-travel activity incidental to the interchange, such as buying a magazine. In the case of incidental activities, the passenger would consider the two journey stages to be part of the same complete journey so they should be linked together, however in the case of an activity that was the main purpose of travel we do not want to link the journey stages together into a complete journey even if the activity duration is very short.

However, intelligent traffic data itself has no way to determine whether the activities of the different stages should be linked together. These data can only provide up to passenger travel time and location information for us. Therefore, we can make the necessary assumptions, passengers will not stay too long at the transfer position, and will select the most convenient transportation as much as possible to start the next journey stage. Therefore, transfer time and transfer distance is an important constraint. However, the value of the two constraints may have a great difference in different cities, different traffic conditions, and even in different regions. Therefore, it is determined after an analysis according to the corresponding conditions and data. Temporarily not discussed here.

According to the analysis of the foregoing, reference Seaborn (2009) study, the whole process is determined as follows figure 1:

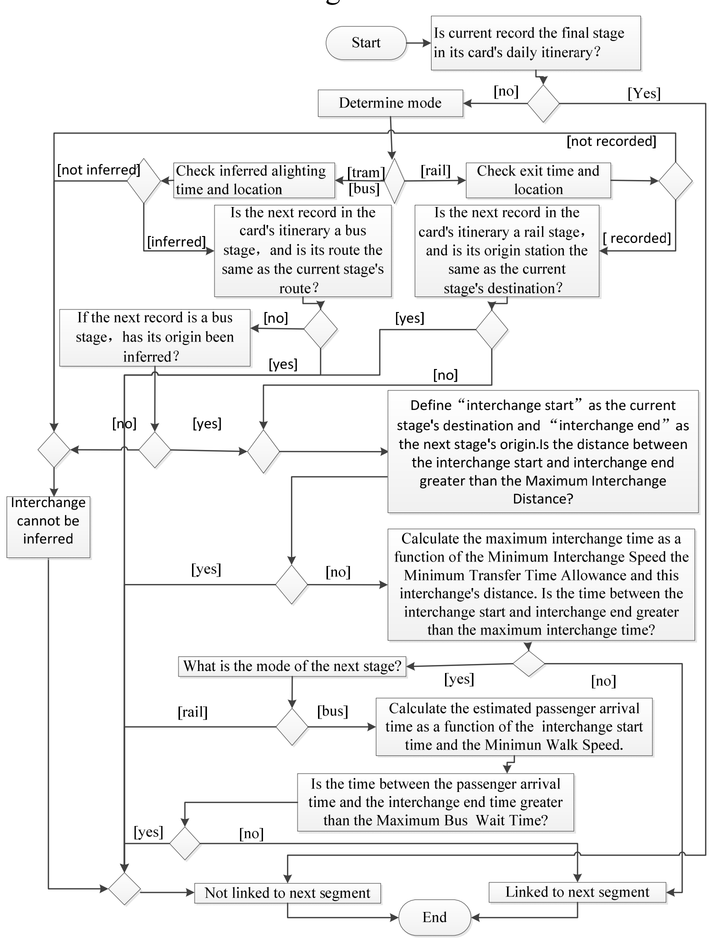

Figure 1. Activity diagram of the interchange-inference process

As showed in Figure 1, we take every single record of IC card as a journey, the diagram presents a method for inferring whether each of a card's journey stages was linked to the next through an interchange (or transfer). Doing so, we should first infer the origin and destination of every single journey stage, and then through the test to finish the transfer recognition. If any one test fails, the transaction record is considered "not linked" to the following transaction: all further tests are skipped for that record and testing resumes with the next transaction record. If a test fails because of missing data, the interchange status is considered to be "non-inferable."

Optimal Path Choice Based on Multi-Modal Public Transport—A Case Study of the Chengdu Qinghua Road Area

Renjie Du; Nian Zhang; Xunfei Gao; Yuxi He; and Tong Zou

School of Transportation and Logistics, Southwest Jiaotong University, Chengdu 610031, China.

Abstract: In recent years, Chengdu has opened the subway and BRT. Among them, Chengdu Qinghua Road area has constituted a multi-modal public transport network which involves regular bus, rapid rail and BRT. Therefore, paper chooses Chengdu Qinghua Road area as the research object chooses generalized minimum cost as optimum principle, builds a multi-mode transit network model and a multi-mode transit optimal path choice model in Chengdu Qinghua Road Area. Quantitative analysis of the value of the generalized impedance, through the psychological characteristics of Chengdu residents' bus travel survey. Utilization breadth-first search obtained options which have the minimum generalized impedance as the recommended travel schemes and selecting the optimal scheme among the recommended schemes by passenger travel conditions .Otherwise, the case analysis of the optimal path from Huiyuan Building to the Sichuan Province Orthopedics Hospital, and the result that different passenger travel conditions affect the optimal path proves the optimal path search algorithm in this thesis has certain reference.
Keywords: Multi-mode bus; Route search; Generalized cost.

1 Introduction

Public transport network plays an important role in urban transport systems; therefore, study on the optimal route of multi-modal Public transport network has positive significance.

In the analysis of the multi-modal transit optimal path, there are several path search algorithms: The first algorithm combines graph theory, including the classic Dijkstra algorithm and Floyd algorithm; second algorithm combining traditional intelligence theories, including depth-first algorithm, breadth-first algorithm; third algorithm combines intelligent simulation technology, such as the ant colony algorithm.

China's rail transportation, BRT and other modes of public transport's development have a late start compared to abroad. Related research domestic, most optimal path selection is on regular bus about. For the combination of multiple modes of public transport travel path of the research is still relatively lacking.

2 Modeling foundation

Scope of this study is the demonstration of a block area of Chengdu, specifically selected by the Second Ring Road, West Fuqin Road, West Dashi Road, Xiaonan Street and other roads, enclosed area as the scope of the demonstration area, shown in Figure 1. Selected part of the road network, regular bus lines, BRT and subway lines to build the road network and multi-modal public transport network as a case study in this paper.

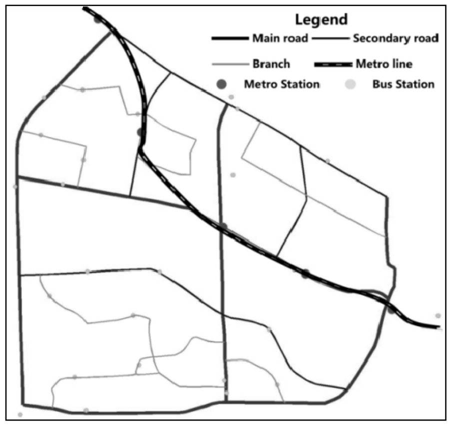

Figure 1. The area of demonstration zone

Summary the Public transport in the region constituted. BRT: K2 Rapid Transit Line Metro: Chengdu Metro Line 2; Bus: Bus No.59, Bus No.43, Bus No.1031, Bus No.82, Bus No.53. Above are summarized in Table 1.

Table 1 .Summarizes the bus information

Transit Type	Transit Line Name	Passing road
Metro	Line 2	——
BRT	K2	Second Ring Road
Bus	No.59	West Fuqin Road, Jinqin Road, East Qingjiang Road, Ring Road
	No.43	West Fuqin Road, Ring Road, Jinhe Road
	No.1031	Second Ring Road, North Caotang Road, East Qingjiang Road, Ring Road, Qinghua Road
	No.82	Second Ring Road, Qinghua Road, Ring Road
	No.53	Xiaonan Street, East Dashi Road

According to the results of Chengdu Public transport survey, take a data processing of the importance of walking time, waiting time, travel time and ticket cost for residents in Chengdu. The conclusions as a generalized cost weighting of each factor, So get the weights: ω_1=0.2， ω_2 =0.19， ω_3=0.48， ω_4 =0.13.

3 Methodologies

In this paper, take a trip which chose building Huiyuan as the starting point and Orthopedic Hospital in Sichuan Province as the final point for a case study. Consider the case of public transport, combining Public transport driving route, re-edit the road network. The transfer point as a node, use public transport travel route connecting the nodes, the public transport network simplified to Figure 3.

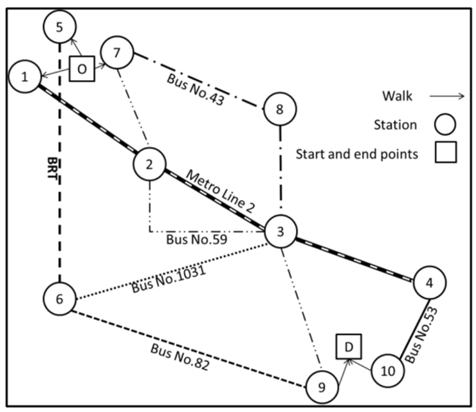

Figure 2. The public transport network diagram

According to the diagram, list the public transport options between the Building Huiyuan and Orthopedic Hospital in Sichuan Province. All transportation travel schemes are summarized in Table 2.

Table 2. Scenario summary

Numbe r	Scheme	Number	Scheme
1	7-BUS59-9	7	1-Rail2-2*-BUS59-9
2	7-BUS43-3*-BUS59-9	8	5-K2-6*-BUS82-9
3	7-BUS59-2*-Rail2-3*-BUS59-9	9	5-K2-6*-BUS1031-3*-BUS59-9
4	7-BUS59-2*-Rail2-4*-BUS53-10	10	1-Rail2-2*-BUS59-9
5	7-BUS59-3*-Rail2-4*-BUS53-10	11	1-Rail2-3*-BUS59-9
6	7-BUS43-3*-Rail2-4*-BUS53-10	12	1-Rail2-4*-BUS53-10

* Indicates a transfer Station

Multi-modal public transport network models are available for established schemes described above. Since the scheme up to as many as 12, there only a brief description of the front three scheme. As shown in Figure 3.

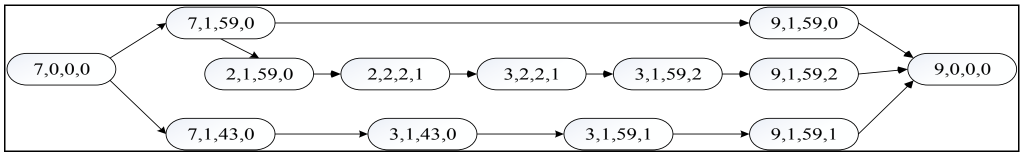

Figure 3. Schematic diagram of front three schemes

The first number indicates the node, and the second number indicates the bus type (0 indicates this point is the start 1 indicates regular bus, 2 indicates subway, 3 indicates BRT), the third number indicates the type of bus number, and the fourth number indicates the number of transfers.

fter all alternative travel program search is completed, take a second layer of search, and calculate generalized impedance of the programs. Select a minimum of five generalized impedance path of travel program as recommended scheme. In Scenario 1 and 4, for example, is described alternatives generalized impedance calculation process.

Scheme 1 includes a walking time for starting point and a walking time for ending point. Where the walking time for starting point $T_{w(O\text{-}7)}$=6.5min, the walking time for ending point $T_{w(9\text{-}D)}$ =2.5min. The total walking time

$$T_w = T_{w(O\text{-}7)} + T_{w(9\text{-}D)} = 9\text{min} \quad (3\text{-}1)$$

Waiting time of Bus No.59 is the total waiting time (f indicate bus service frequency, ∂ indicate the deviation between theory and practice).

$$T_{wa} = \frac{1}{2f} + \partial = 3+1 = 4\text{min} \quad (3\text{-}2)$$

Travel time is the time spending in taking the Bus No.59 from site 7 to site 9.

$$T_{bus(7\text{-}9)} = 3.5+13+4.5 = 21\text{min} \quad (3\text{-}3)$$

Take the bus costs 2 Yuan for ticket, so a generalized impedance scheme 1 is

$$C^1_{O-D} = \omega_1 \cdot T_{wa} + \omega_2 \cdot T_w + \omega_3 \cdot T_{bus} + \omega_4 \cdot Fare \cdot T_F = 13.19 \quad (3\text{-}4)$$

Scheme 4 includes a walking time for starting point, a walking time for transfer point and a walking time for ending point. Where the walking time for starting point $T_{w(O\text{-}7)}$=6.5min, the walking time for transfer point $T_{w(BUS59\text{-}Rail2)}$=1.5min, $T_{w(Rail2\text{-}BUS53)}$ =4.5min, the walking time for ending point $T_{w(10\text{-}D)}$=4.5min. The total walking time

$$T_w = T_{w(O\text{-}7)} + T_{w(BUS59\text{-}Rail2)} + T_{w(Rail2\text{-}BUS53)} + T_{w(10\text{-}D)} = 17\text{min} \quad (3\text{-}5)$$

Total waiting time includes Waiting time of Bus No.59, $T_{wa(BUS59)}$ =4min, Waiting time of Bus No.53, $T_{wa(BUS53)}$ =4min, and Waiting time of metro line 2, $T_{wa(Rail2)}$ =2.5min.

$$T_{wa} = T_{wa(BUS59)} + T_{wa(BUS53)} + T_{wa(Rail2)} = 10.5\text{min} \quad (3\text{-}6)$$

Travel time is the time spending in taking the Bus No.59 from site 7 to site 2, taking the metro line 2 from site 2 to site 4 and taking the Bus No.53 from site 4 to site 10.

$$T_{bus(rail)} = T_{bus(7\text{-}2)} + T_{rail(2\text{-}4)} + T_{bus(4\text{-}10)} = 14.5\text{mi} \quad (3\text{-}7)$$

The tickets cost 6 Yuan, so a generalized impedance scheme 4 is

$$C_{O-D}^{4} = \omega_1 \cdot T_{wa} + \omega_2 \cdot T_w + \omega_3 \cdot T_{bus(rail)} + \omega_4 \cdot Fare \cdot T_F = 15.9 \quad (3\text{-}8)$$

Compare scheme 1 and 4.The generalized impedance of scheme 1 is smaller so the scheme 1 for a better comparing to scheme 4. Intuitively, scheme 1 for a direct, do not spend time walking on transfer and cost less in waiting time and ticket costs. But it is undeniable that longer travel time in Scheme 1, there may be alternatives to a travel scheme generalized impedance is smaller that have shorter travel time and need to transfer. In order to compare the various bus travel scheme generalized impedance better, according to the method above, calculation generalized impedance for each schemes. As shown in Table 3.

Table 3. Generalized impedance of each scheme

Sche-me	Walking time for starting point	Walking time for transfer point	Walking time for ending point	Waiting time for transit	Waitin-g time for transfer	Trav-el time	Tick-ets cost	Gener-alized imped-ance
1	6.5	0	2.5	4	0	21	2	13.79
2	6.5	3	2.5	4	4	10.5	4	11.33
3	6.5	6	2.5	4	6.5	10	6	13.36
4	6.5	6	4.5	4	6.5	14.5	6	15.90
5	6.5	8.5	4.5	4	6.5	25.5	6	21.66
6	6.5	7	4.5	4	6.5	15	6	16.33
7	5	2	2.5	2.5	4	19	4	14.63
8	6.5	3.5	2.5	0.5	4	15.5	4	13.12
9	6.5	2	2.5	0.5	6.5	17.5	6	15.50
10	5	2	2.5	2.5	4	19	4	14.63
11	5	4.5	2.5	2.5	4	8	4	9.83
12	5	4.5	4.5	2.5	4	12.5	4	12.37

Shown in the above table, most of the schemes have a value of distributed between 10 and 15. The largest value of generalized impedance is 21.66, from scheme 5. The least value of generalized impedance is 9.83, from scheme 11. The generalized impedance values are arranged in ascending order of each scheme, Followed by the first five: scheme 11, scheme 2, scheme 12, scheme 8 and scheme 3. Analysis for single factor, minimum walking time is 5min, from scheme 7, scheme10, scheme11 and scheme 12. Minimum number of transfers is 0, from scheme 1, and it has lowest fare, 2 Yuan. The shortest travel time is 8min, from scheme 8.

If the principles of passengers choose bus travel path are not the optimal generalized least, recommended travel scheme may change. When travelers choose minimal transfer times or the least cost or fare, recommended travel scheme is scheme 1. And when travelers choose the shortest travel time, recommended travel scheme is scheme 11.

4 Discussions of Results

In this paper, the actual data have collection to modeling and analysis wishes of passengers choose to travel path in multi-modal public transport network. And through the actual trip simulated recommended travel plan. As can be seen from the subjective, recommended solutions have high acceptability. Description methods and theories used in this modeling analysis is feasible

In the modeling process in this paper, the proportion of generalized impedance of each factor determines by a field survey. The single survey in some areas does not have complete universality. So when the generalized impedance counts with a certain bias between the actual situations that this conclusion may not apply to every resident in Chengdu. This parts of the content needs to be demonstrated b further research.

5 Conclusions

This paper dissertation on the established multi-modal public transport network in Chengdu to investigate, to complete the network attribute parameter calibration, combined with the optimal path search algorithm, Calculate the five travel route plan from the Orthopaedic Hospital of Sichuan Huiyuan Building that haveminimum generalized impedance values. In these five schemes, travel for passengers of different process requirements will affect the choice of the optimal path. Public transport proved optimal path search algorithm used paper has certain significance.

The idea of the algorithm is: First in a multi-modal transit network to search out the options that transfer less than or equal to 2 times from the station between the end starting point and ending point. Then the generalized impedance values calculated for each option. Generalized minimum impedance value of several multi-mode transit trip paths as the recommended travel plan, and finally find the travel path in line with the requirements of the passengers in the recommended plan as the optimal solution.

Short-Time Traffic Flow Forecasting Based on the K-Nearest Neighbor Model

Tong Zou; Yuxi He; Nian Zhang; Renjie Du; and Xunfei Gao

School of Transportation and Logistics, Southwest Jiaotong University, No. 111 of the North Second Ring Rd., Chengdu City, Sichuan 610031.

Abstract: In order to accurately forecast the short-term traffic flow, a K-nearest neighbor model was set up, study the influence of key factors in model on predicted result. Using combination of different state vectors and distance metrics to form four kinds of K-nearest neighbor model, combined with Beijing real road traffic data apply four kinds of models to carry out example verification, pick up relative error and equalization coefficient evaluate forecasting result. The results show that: with time-space parameters of a higher prediction accuracy, which has minimum prediction error, average 7.8%. take index weights into distance metric can be more precise in neighbor selection, which has minimum prediction error, average 7.34%. Visibly, compared to traditional K-nearest neighbor short-term traffic flow forecasting model which only consider the time dimension, K-nearest neighbor model with time-space parameters and index weights more accurately reflect the state of the traffic flow change condition, can be used as effective road traffic flow forecasting means.
Keywords: Flow forecast; K-nearest neighbor model; Time-space parameters; Exponent weight.

1 Introduction

K-nearest neighbor algorithm is a common one in nonparametric regression relatively, need no prior knowledge, just enough historical data[3], the new observational data can be easily added to the model, and the algorithm has good data digging and transplanting performance [4]. there are many researchers has applied it in short- term traffic flow forecasting for now[5]. But all these studies mostly focused on the relationship between the target road traffic real-time conditions and historical conditions, ignoring the spatial dimension, also ignoring several key factors in different settings' affection on the predicted outcome at the same time.

In this paper, proposed the improved k-nearest neighbor model with time-space parameters and exponent weight. Firstly, four kinds of k-nearest neighbor model is formed by setting the state vector and the distance metrics. Then carry simulation experiments based on the same historical database and test data. Finally compare the forecasting result. Verify the impact on forecasting results caused by the time-space parameters and the exponent weight, proved the improved K-nearest neighbor algorithm can more accurately reflect the changes of traffic flow. The method can be used as an effective means of forecasting.

2 Data source

This paper mainly consider the impact on model accuracy caused by spatial dimension, therefor only select traffic as a state factor. This paper selects the Haidian District Willow road as target road. The total length of road sections is 0.58km, 10-lane two-way, north access Zaojun temple road, south access sorghum-bridge road, the spatial location of each section as figure2-1 below.

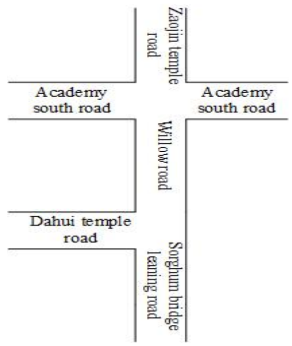

Figure 2-1. The position of research road

Select the morning rush hour (6:30 - 9:30) as research period, collected willow road and adjacent sections (Zaojun temple road and sorghum-bridge road) morning peak flow to build a historical database. In this paper, the traffic data come from the Beijing Traffic Operation Monitoring and control Centre (TOCC). Because that there usually have a small amount of data gaps and abnormal data in original data, need to do the necessary screening, excluding outliers. Select September 8, 2014 to September 21, 2014 morning peak continuous traffic data as samples. Set 5min for the prediction time interval. After dealing with data, we got a continuous traffic flow sample size for 504. Sample data shows periodicity of this road morning peak flow, as shown in Figure 2-2. Abscissa 1~8 respectively represents 8 to 15 September at 6:30 every day.

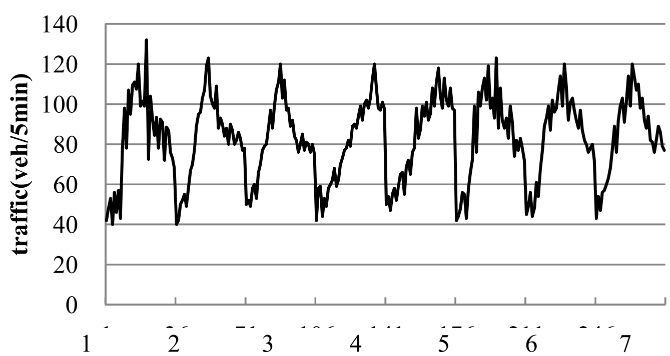

Figure 2-2. traffic volumes

3 Model Construction

3.1 The definition of state vector

Take time dimension and spatial dimension into the state vector will theoretically get higher forecasting accuracy. Because it searches neighbors witch have higher quality. Tow kinds of prediction mechanism as figure3-1.

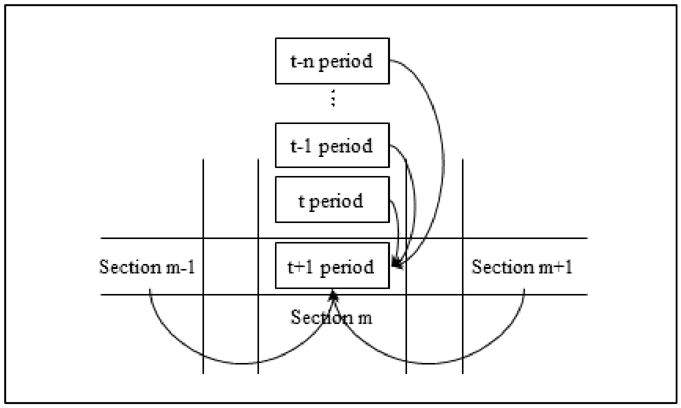

Figure 3-1. prediction mechanism based on time-space parameter

To compare the experimental results, the state vector is divided into the following article groups:

$$X(1)=[v_m(t),v_m(t-1),v_m(t-2),v_m(t-3),v_m^{'}(t),v_m^{'}(t-1)v_m^{'}(t-2),v_m^{'}(t-3)] \quad (1)$$

Wherein, $v(t)$ and v(t-1) respectively represent the current time and the previous time traffic; $v\ '(t)$ and $v'(t\text{-}1)$ represent current time and the previous time traffic in the historical database. Here take four adjacent time intervals to current time, and the four corresponding traffic in the historical database. Herein the interval is 5 minutes.

$$X(1)=[v_m(t),v_m(t-1),v_m(t-2),v_m(t-3),v_{m-1}(t),v_{m+1}(t),v_m^{'}(t),v_m^{'}(t-1)v_m^{'}(t-2),v_m^{'}(t-3), v_{m-1}^{'}(t),v_{m+1}^{'}(t)] \quad (2)$$

Wherein, $v_{m-1}(t)$ and $v_{m+1}(t)$ respectively represent sections m-1 (upstream section) and the sections m+1 (downstream section) traffic; $v'_{m-1}(t)$ and $v'_{m+1}(t)$, respectively represent section m-1 (upstream section) and the sections m+1 (downstream section) traffic in the historical database.

3.2 Distance metrics

Due to road traffic system variability is strong, the same road section traffic conditions in different historical periods vary greatly, importance to predict the future traffic condition is also different. Therefore, this paper add weights to components of the time dimension state vector to get higher accuracy, using two methods: the correlation coefficient weighted method and the index weighted method.

The correlation coefficient weighted method mechanism shown as Figure 3-2, the t+1 period is the target period.

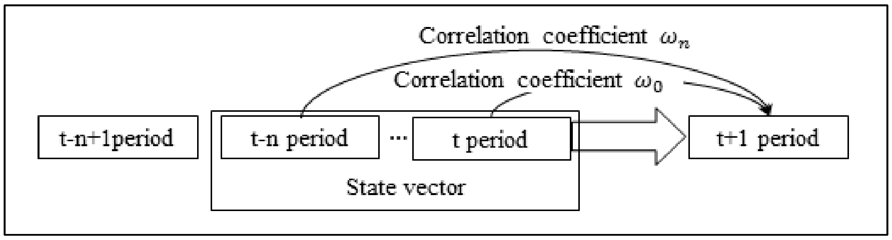

Figure 3-2. The correlation coefficient weighted method

Index weighted method mechanism shown as figure3-3, thought that the closer the distance to the target period t + 1, the greater the impact on the target time by the historical period data.

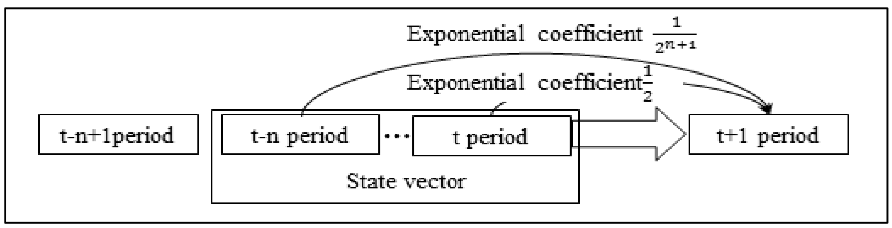

Figure 3-3. The exponential coefficient weighted method

3.3 Selection of the value of k

K value chosen related to historical data largely, there is no determined metrics to guide the selection of k. both too large k and too small k affect the prediction accuracy. In this paper, make k value vary between 2~20 in the experiment, and finally discuss the value of k count on result.

3.4 Prediction Algorithm

$$v_m(t+1) = \sum_{k=1}^{k} \frac{d_k^{-1}}{\sum_{k=1}^{k} d_k^{-1}} v_k^{'}(t+1) \tag{3}$$

Wherein, d_k represent the distance of the current data and the k-nearest neighbor; $v_m(t+1)$represent the traffic of section m; $v_k'(t+1)$ represent the t+1 period the traffic correspond the k-nearest neighbor searched in the historical database.

3.5 Model Set

Consider the combination of two state vectors and three distance metrics, formed 4 kinds of K-nearest neighbor short-term traffic flow forecasting models, for convenience of description, numbered models, as table3-1 shown below, using pre-treated historical database to predict. Evaluate the forecasting result by relative error, properly considered equalization coefficients.

Table 3-1. Models Set Description

Method Number	State Vector	Distance Metric
F1	X(1)	Equal Weight
F2	X(2)	Equal Weight
F3	X(2)	Correlation coefficient weighted method
F4	X(2)	Index weighted method

4 Discussion of Results

Experiments use historical database mentioned above, and the k values 2~20, respectively use four methods forecast morning rush hour traffic flow every 5min of September 22, 2014. Record relative error of forecasting traffic under different k. And summarizes the results of the entire peak periods forecast result.

4.1 Discussion On The Value Of K

As shown as table 4-1, forecasting results of 4 kinds of model all have good effect, the equalization coefficients are greater than 0.9. Seeing from Figure 4-1, 4 kinds of methods error decreases as K increases from 2 to 8, and after it the effect of decreases is less obvious. Particularly among the three methods got the smallest average relative error when K is 13.

Table 4-1. average equalization coefficient under different K

	F1	F2	F3	F4
equalization coefficient	0.961905	0.962095	0.962295	0.962242

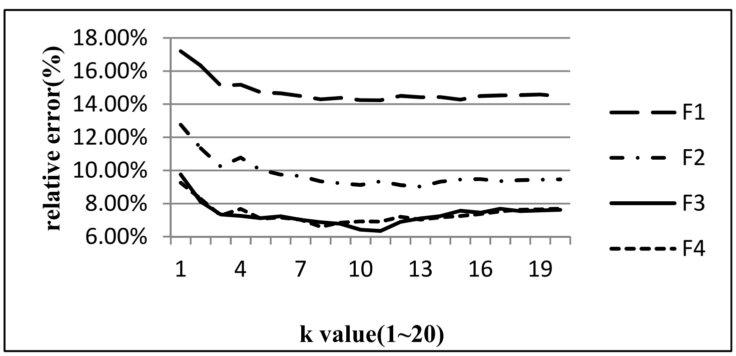

Figure 4-1. relative error graph under different k

4.2 Comparison Of Different Models

Effect of four models forecasting have differences. Comparing F1 and F2 can test effect on results with different state vector. As figure 4-2 shown, the forecasting effect of the first model is worst, relative error is 14.75%, which shows the forecasting effect of the k-nearest neighbor model only consider the time dimension was significantly worse than the model take the time and spatial dimensions into consideration.

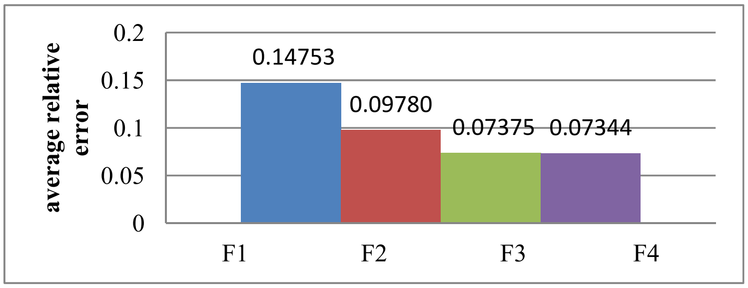

Figure 4-2. relative error

Contrast F2, F3 and F4 can test the proved effect on model with different distance measure metrics. By comparison with the weighted distance metric is significantly better than the distance metric without weights, and different weighed measure effect on improving model have little difference. Compared to the correlation coefficient weighted method, the average relative error of index weighted coefficient is lowest, is 7.34%, indicating that use a weighted distance measure in the model is a reasonable way, can significantly improve the prediction accuracy of k-nearest neighbor model

.

5 Conclusions

This paper pick up the Haidian district Willow sections in Beijing as research object, constructed improved K-nearest neighbor short-tome traffic flow forecasting model based on time-space parameters and weighed distance metrics, use morning rush hour traffic data to verify different parameters' effect on predicted result accuracy. By comparing before and after the improvement of the prediction accuracy of the model, found take time dimension and spatial dimension into account at the same time is obviously better than the model only consider time dimension, and use a weighted distance metric in the model is better than the model without weighted distance metrics. After comparison, found the improved K-nearest neighbor model, the prediction accuracy can reach above 90%, more suited to real-time road traffic flow in real-time forecasting.

Abstract: To improve the traffic capacity in signalized intersections, stretching-segment are applied both in upstream and in downstream in some criteria and guidance. However, the methods to calculating the traffic capacity of signalized intersections usually consider the impact of stretching-segment in upstream. Based on investigations on some intersections in Chengdu, this study analyzes the impacts on traffic capacity caused by downstream stretching-segment, and shows that the length of downstream stretching-segment and the signal of the intersections are the two key factors for its capacity. Then this study investigate the trends and the extent of the impact using a VISSIM simulation model.
Keywords: Downstream stretching-segment; Signalized intersections; Traffic capacity; Simulation and analysis.

1 Introduction

It has been widely applied in many cities about downstream stretching-segment (it is also called short lanes or lane drop in downstream) in intersections. However, there isn't a reasonable criterion about downstream stretching-segment. It also does not have any quantitative procedure with respect to lane drop effects in assessing the capacity of signalized intersections.

The objective of this study was to assess the effects of downstream stretching-segment in signalized intersections and analyze the trends of the impact caused by two key factors--the length of downstream stretching-segment and the signal cycle. The methods of this study were field investigation and VISSIM simulation. In the field research, this study adopted a method of comparative analysis. The intersection with downstream stretching-segment was selected as the experimental group, and intersections without downstream stretching-segment were selected as the control groups. This study measured the saturation headway of three kinds of intersections and then made a contrast. The impacts on capacity would reflected through the difference of saturation headway. Since there were some uncontrollable factors in field study, VISSIM simulation was applied to make further research. In the simulation research, the length of downstream stretching-segment and signal cycle were selected as two key factors to study the impacts on capacity in signalized intersections.

The research scope was restricted to three-lane-to-two-lane drops for the through movements, such as figure1.

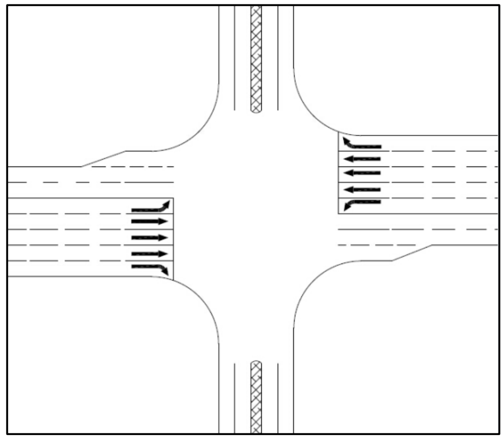

Figure 1. three-lane-to-two-lane drops for the through movement

The structure of the paper is the following. Firstly, in section 2, literature review focuses on some criteria and research, which were related to downstream stretching-segment. Then section 3 is some request for the investigation sites. Section 4 shows the analysis result of the field investigation. The section 5 is the research on VISSIM simulation. The last section is the conclusion of the paper and proposes directions for further research.

2 Literature Review

The study on stretching-segment is usually associated to short lanes in signalized intersection. They assessed the impact of short lanes through the lane utilization.

The Highway Capacity Manual (National Research Council, Washington, D.C., 2000) involved lane utilization in some special lanes when estimating capacity and LOS for signalized intersections. However, current guidance on the selection of lane utilization in the HCM is inadequate and could lead to poor estimation of capacity, delay, and LOS when a lane drops shortly after the signal (Jae-Joon Lee, 2005).

The Canadian Capacity Guide (CCG) for signalized intersections estimates lane flow based on equal flow ratio (that is, the ratio of demand flow to saturation flow). However, the CCG does not put the case of downstream lane drops into account (Teply, 1995).

The Swedish Capacity Guide (Stenberg, 1995) addresses the effects of short lanes on intersection capacity. However, it just considered the upstream short lane effect on capacity without taking the downstream short lane impact into account.

The aaSIDRA model in the Australian Capacity Guide (Akcelik,1984) takes into account the downstream lane-drop effect and regards the length of short lane as a main factor influencing the capacity of signalized intersections. However, this method was not widely used.

The criteria in these countries do not have a reasonable description about the downstream stretching-segment.

Some researchers has made contributions to the impacts of lane drops in downstream on capacity. Tarawneh (Tarawneh, 2001) put forward a view that the utilization of short lane will vary with the degree of crowd of traffic. Lee (Jae-Joon Lee, 2005) researched variety of lane drops in downstream and studied fourteen possible factors influencing the capacity when there is a downstream stretching-segment.

There are also some criterion and research about downstream stretching-segment in China. Table 1and 2 show the criteria.

Table 1. Criteria about downstream stretching-segment in China

	Setting conditions	composition	length	width	Influence by bus stop	Number of lanes
Urban Road Intersections Planning Norms （GB50647-2011）	√	√	√	—	√	—
Urban Road Intersections Design Procedures （CJJ152-2010）	√	√	√	√	√	√
Urban planning Norms Provision in Road Intersections（GB2010）	√	—	—	—	—	√
Urban Road Engineering Design Specifications （CJJ37-2010）	√	—	—	√	—	—

Table 2. Criteria about downstream stretching-segment in some cities

	Setting conditions	composition	length	width	Influence by bus stop	Number of lanes
Shanghai Urban Planning and Design of Intersection Rules	√	√	√	√	√	√
Wuhan Urban Traffic Intersection Planning ,design and management	√	√	√	√	—	√
Intersections of Urban	√	√	√	√	—	√

Road Planning and Design Specifications in Zhejiang						
Tianjin Urban Planning and Management Technical Requirements	—	√	√	√	—	—

However, these criteria were not well consistent, they were also lack of the impact on capacity caused by downstream stretching-segment in signalized intersections. There is few researches of downstream stretching-segment in China. Zhang Hai and Zhao Jing (Zhang Hai, 2007) put forward that three factors made key contributions to the capacity of signalized intersections with short lane in downstream. They were the length of short lane, effective green time, and obstruction wave velocity.

However, criteria and researches on downstream stretching-segment are not complete, especially in China. In addition, some research results were based on data from other countries, which might exhibit different driving behavior.

3 Experimental Sites and Control Sites

There are several requirements for experimental sites, they should be as follow:

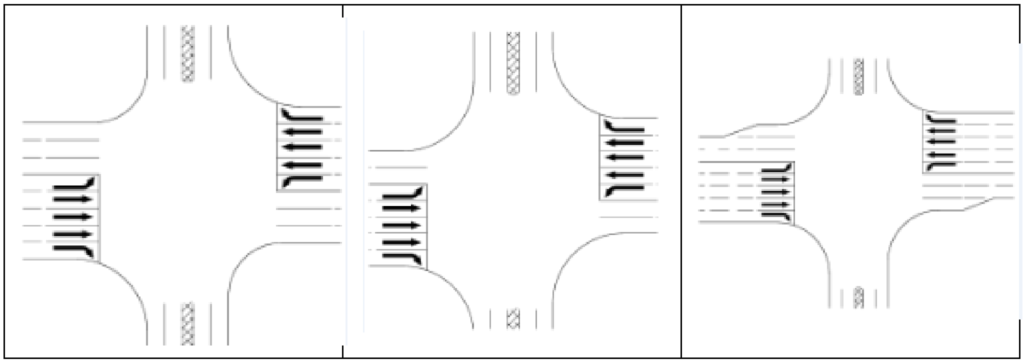
- less heavy vehicles and signalized intersection;
- three through lanes in upstream and three-lanes-to-two-lanes in downstream;
- more than 8 vehicles before the green time in a signal cycle in morning peak or evening peak;

The control sites is similar to the experimental sites, but lane of downstream should be three lanes or two lanes without stretching-segment.

Finally, we selected Yizhou-Jiaozi Intersection (three through lanes to two lanes in downstream) for experimental sites and Hongxing-Shudu intersection (only two lanes in downstream but three through lanes in upstream) and Dongannan-Shudu intersection (there is no stretching-segment) for control sites. They were shown as table 3.

Table 3. experimental sites and control sites

Control sites		Experimental sites
Dongannan-Shudu Intersection	Hongxing-Shudu Intersection	Yizhou-Jiaozi Intersection



4 Data Collection and Reduction

Since capacity of intersections can be reflected by the saturation flow rate, we recorded the selected intersections in the morning peak, and get the saturation headway. The saturation flow rate can be calculated with following equations:

$$S = \frac{3600}{\overline{h}_t} \tag{1}$$

where S=saturation flow rate;

$\overline{h}_t$ =saturation headway.

The results were shown in table 4.

Table 4 Saturation Flow Rate

		Saturation headway （s）	Saturation flow rate （pcu/h）	Total saturation flow rate(pcu/h)
Dongannan-Shudu intersection	inner lane	2.66	1353	1416
	middle lane	2.29	1572	
	outside lane	2.76	1304	
Hongxing-Shudu intersection	inner lane	2.37	1519	1358
	middle lane	2.83	1272	
	outside lane	2.89	1246	
Yizhou-Jiaozi intersection	inner lane	2.74	1314	1425
	middle lane	2.43	1481	
	outside lane	2.43	1481	

From table 4, it can not clearly reflect the impact caused by downstream stretching-segment on saturation flow rate. This is because saturation flow rate is not just influenced by downstream stretching-segment, other factors can also have an effect on saturation flow rate.

To weaken effects caused by other factors, the survey date is subjected to degree of fitting processing. Every saturation headway divided the average saturation headway in every intersection in this study. Then making a comparison between three curves. Results are shown in figure 2.

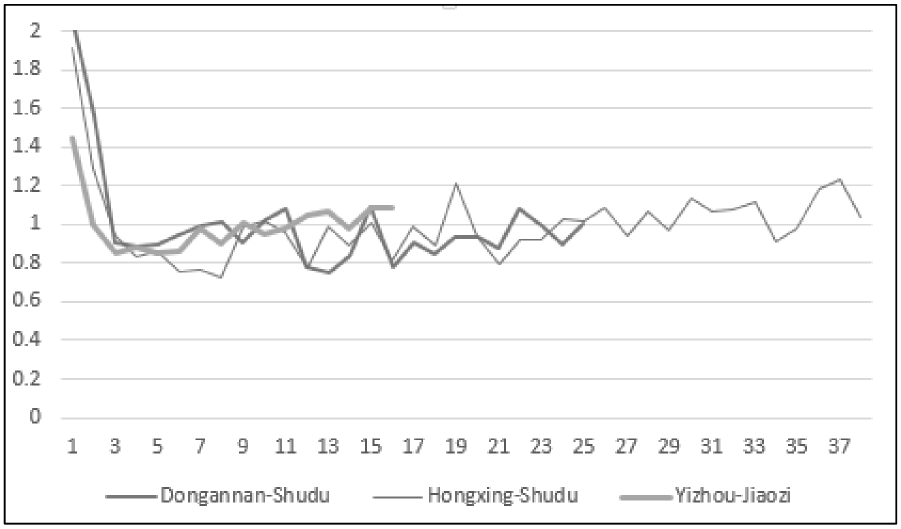


Figure 2. three curves about saturation headway after degree of fitting

We can see from figure 2: the longest curve(Hongxing-Shudu intersection) start to descended behind 1 rapidly, then raise up to 1 , and finally reached 1.2; the second longest curve(Dongannan-Shudu intersection) start to descended behind 1 rapidly, and then fluctuated around 1; the shortest curve(Yizhou-Jiaozi intersection) start to descended behind 1 rapidly, then raise up to 1.1 slowly.

We can see that the peak of the longest curve is higher than the shortest one, this showed that the saturation headway in the Hongxing-Shudu intersection is larger than the one in Yizhou-Jiaozi intersection. This is because the downstream stretching-segment could offer more space for vehicle to merge.

Besides, the speed of the longest curve is larger than the shortest one, this reflected that the storage function of downstream stretching-segment. For intersection with downstream stretching-segment, the merging points would be transferred to the downstream section, while intersection without downstream stretching-segment, vehicles would merge in the intersection, which would be easier to reach saturation.

These results can reflect that downstream stretching-segment can improve capacity of intersection compared with intersection without stretching-segment.

5 VISSIM Simulation Analysis

It is difficult to control the variable in the field research. So it is necessary to make simulation study. Based on the experimental sites, simulation model was built to analyze the impacts on signalized intersection caused by different length of downstream stretching-segment and different signal cycles.

This study assessed the capacity when the length of downstream short lane is 20m, 30m, 40m, 50m, and 60m, while taper is 20m and the signal cycle is 120s. The results were shown in table 5.

Table 5. capacity of intersection

short lane(m)	20	30	40	50	60
Inner lane(pcu/ *h*)	1593	1608	1533	1605	1598
Middle lane(pcu/ *h*)	1014	1032	1050	987	1004
Outside lane(pcu/ *h*)	945	966	918	987	1002
Total(pcu/ *h*)	7562	7654	7732	7796	7825

From table 4, we can see that capacity of the intersection will increase with the length of short lane increasing.

This study also assessed the capacity when the signal cycle is 60s, 90s, and 120s.The green time ratio would be fixed and the length of downstream stretching-segment （short lane 30m and taper 20m）would also be unchanged. The result was shown in table 6.

Table 6. Capacity of intersection

Signal cycles(s)	60	90	120
Inner lane(pcu/ *h*)	1650	1593	1548
Middle lane(pcu/ *h*)	1317	1194	1128
Outside lane(pcu/ *h*)	1134	1191	1056
Total (pcu/ *h*)	8652	8418	7881

Conclusion can be taken from table 6 that capacity would decrease with the increase of signal cycle.

6 Conclusion

Based on the field study, we can make a conclusion: downstream stretching-segment could improve the capacity of signalized intersections compared with intersection without stretching-segment.

With simulation results, we can make conclusions as follows:

(1)For intersection with downstream stretching-segment, signal cycle will take an effect on its capacity. With a certain range, capacity would descend with the increase of signal cycle.

(2)For intersection with downstream stretching-segment, the capacity will increase with the length of stretching-segment increases, but the increased speed will be lower and lower. The capacity would not change when the length of stretching-segment is longer than a certain distance.

(3) For intersection with downstream stretching-segment, the outside lane will be more sensitive.

7 Recommendations for Future Research

This survey is not very accurate because of the limited simple size. The future research will be based on larger simple sizes and make some deeper theoretical study.

Abstract: The structure of road network in a city will not only affect the spatial morphology of a city, but also have influence on the operating performance of all kinds of ground transportation and people's travel behavior. Therefore it's necessary to identify the methods and indicators to describe network structure, and analyses its impacts on the distribution of vehicle volume. The authors first used ArcGIS on road network's topological analysis, then used dual approach to abstract the stroke graph into connectivity graph, which as a result figured out the indicators of road network structure. Multiple regression and simple regression were used to analyze how road network structure impact the distribution of vehicle volume. In the end the contrasted results of the two methods lead two most representative indicators of road network structure and the distribution of vehicle volume, which are Betweenness and vehicle kilometers traveled. So the conclusion is that Betweenness and vehicle kilometers traveled shows simple linear relationship, which means the more important of a stroke in road network is, the more vehicle kilometers there will be on the stroke.
Keywords: Road network; Topology; Distribution of traffic volume; Regression analysis.

1 Introduction

In the traditional study of traffic volume distribution, traffic demand, land use and the distribution of traffic facilities' capacity are often considered, while the role of road network structure is often ignored. But as we all know, road network is the infrastructure of the city, its structure and layout can reflect the distribution characteristics of geographic features, so it has great effect on the distribution of traffic demand. At present, many researches on the structure of road network have been made on the international, and the relationship between road network structure and traffic volume distribution is preliminary discussed. Based on the study, this paper made a research on the influence of road network structure to traffic volume distribution.

The structure of tis paper is described as following. Firstly, section 2 shows the literature review which focuses on the influence of road network structure to traffic volume distribution. Then, Section 3 is a description of road network topology and its indicators. Section 4 introduces the indicators of traffic volume distribution and section 5 shows the relationship between road network structure and traffic volume distribution. The last two sections are the conclusion of this paper and proposes direction for further research.

2 Literature Review

Montis and other researchers studied the structure of the network representing the interurban commuting traffic (Montis, 2007), they also characterized quantitatively the traffic backbone and gave evidence for a very high heterogeneity of the commuter flows around large cities.

Lammer analyzed the 20 largest German cities and found that traffic strongly concentrates on only a small fraction of the roads (Lammer, 2006). The distribution of vehicular flows over the roads obeys a power law, indicating a clear hierarchical order of the roads.

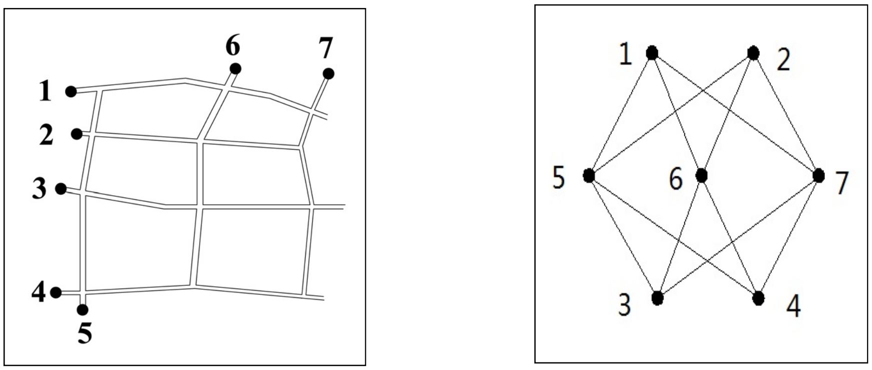
Jiang and Liu made research on Hong Kong's road network and found that vehicle flow is correlated to a morphological property of streets and suggest the topological analyses as a new analytical means for geographic knowledge discovery (Jiang Bin, 2007).

Flavio Bono and others studied the path-dependencies in closed trails and computed their global and spatial correlations with measured traffic flows (Flavio Bono, 2010). They found that the heterogeneous distribution of traffic intensity is mirrored by the distribution of agglomerate path-dependency and that high traffic roads are packed along corridors at short-to-medium trail lengths from the ensemble of nodes.

3 Road Network Topology

3.1 Brief description of road network topology

Road network topology is significant for expressing the network structure, from which way people can understand the complexity of road network more simply and intuitively. There are two main approaches to build network topology, namely the primal approach and dual approach (Jiang Bin, 2004). In the primal approach, intersections are abstracted to nodes and the roads are abstracted to connections; in the dual approach, roads are abstracted to nodes and intersections are abstracted to connections. In order to obtain scale-free networks, stroke (A series of roads that have continuity in direction) is used as the node in the dual graph (Ye Pengyao, 2008). Compared with the primal approach, the dual approach retains not only spatial relationships between strokes but also structural characteristics of transport networks, therefore it is particularly suitable for analyzing the transport routes network (Sergio Porta, 2006). So in this paper the authors will use the dual approach. Figure 1 is a dual graph which is based on dual approach.



a）Stroke network b) Network based on dual approach

Figure 1. Dual graph

3.2 Indicators of road network topology

Network centrality is often used as indicator in the analysis of characteristics of network topology (Park K, 2004). There are three main centrality indicators, namely degree, closeness and betweenness. The three indicators can be used to evaluate the importance of nodes in the network.

(1) Degree

Degree is defined as the normalization of the number of nodes which are directly connected to a particular node. Its expression is as follows:

$$C_D(x) = \frac{k_i}{N-1} \tag{1}$$

Where N is the number of nodes in the network, k_i is the number of nodes which are directly connected to a particular node. The degree can also be named as "local degree", because it only considers the number of nodes which directly connect to a particular node while ignoring the number of nodes which indirectly connect to the particular node.

(2) Closeness

The Closeness of a node is the reciprocal of the sum of the shortest topological distances from the node to all other nodes in the network. Its expression is as follows:

$$C_C(x) = \frac{N-1}{\sum_{y=1}^{N} d_{xy}} \tag{2}$$

Where d_{xy} is the shortest topological distance between node x and node y. It is not suitable for closeness to describe the structural importance of a node, because either the arterial road or the branch road, as long as the shorter the distance between road and central region is, the bigger of the road's closeness will be, but this does not mean that the road plays a more important role in the road network (M.E.J. Newman

2003).

(3) Betweenness

Betweenness is defined as the probability of shortest paths between any pairs of nodes in the network which go through a particular node:

$$C_B(x) = \frac{2g(x)}{(N-1)(N-2)} \tag{3}$$

It's easy to see from the description that betweenness is a global indicator. A stroke with a lower degree may also play an important role as "intermediary", which means it is important in communicating the entire road network.

4 Road Network Structure's Effect on The Distribution of Traffic Volume

4.1 Indicators of the distribution of traffic volume

On different roads, traffic volume shows different characteristics, therefore several indicators are needed to describe the distribution of traffic volume clearly. In this paper, road's average traffic volume (RAV) and stroke's vehicle kilometers traveled (VKT) were chosen to describe the distribution characteristics of traffic volume.

(1) Road's average volume, RAV

The road's average volume is defined as the average volume of each road in a stroke. As the number of lanes in each road may be different, which can lead to a different traffic distribution, so it is necessary to analyze the average volume.

(2) Stroke's vehicle kilometers traveled, VKT

Vehicle kilometers traveled is defined by the U.S. government as a measurement of kilometers traveled by vehicles in a specified region for a specified time period. The stroke's VKT is the sum of each road's vehicle kilometers traveled. It is easy to see that, the RAV only considers the characteristics of traffic entity, but ignoring the differences that caused by the natural properties of each road. The VKT precisely makes up for the shortcoming, it indicates the using of the stroke when the vehicles are traveling on it.

4.2 Impact analysis

In the previous section, we introduced three indicators of network topology, and qualitatively described each indicator's role in describing the importance of a stroke in the network. But it is not clear that the road network structure's impact on the distribution of traffic volume is a result of the combined action of these three indicators, or just only one certain indicator. So, multiple liner regression and simple liner regression are used to make quantitatively research on how road network structure impact the distribution of vehicle volume.

5 Case Study

The experimental data is three cities' (Deyang, Ziyang and Mianyang) road center line graphs and vehicle traffic volume. Figure 2 shows Deyang’s road network. ArcGIS, Stroke Analysis (Ye Pengyao, 2008) and Ucinet were used to calculate the indicators of road network structure, and then the indicators of road network structure and the distribution of traffic volume were matched together. Deyang’s matching result is shown in table 1.

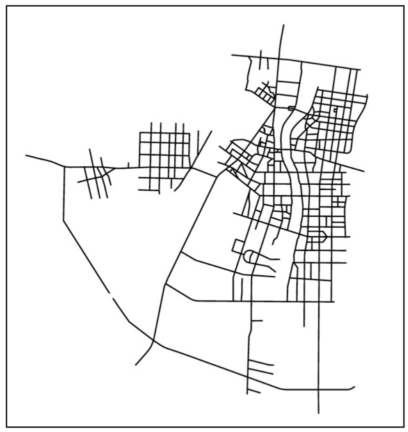


Figure 2. Deyang’s road center line

Table 1. The match result of the two kinds of indicators

Stroke ID	Degree	Closeness	Betweenness	RAV（pcu/h）	VKT（pcu·km/h）
1	0.06383	0.286585	0.050803	1057	5864.3
2	0.177305	0.287755	0.095604	1073	7452.6
3	0.219858	0.313333	0.274021	2248	25754.6

5.1 Multiple linear regression analysis

Multiple linear regression analysis was carried out on the indicators of network structure and traffic distribution. The purpose of the analysis is to quantitatively describe the influence of the structure to the distribution.

In the regression analysis, the road network structure indicators are the independent variables and the traffic distribution indicators are treated as dependent variables. Set the significance level of 0.05. The regression results of the VKT and RAV for the three cities are as follows:

Table 2. The results of multiple liner regression analysis of the VKT

Name of road network	Indicator of structure	significance	Independent variables of the function
Deyang	Degree	0.442	Betweenness
	Closeness	0.121	

	Betweenness	0.002	
Ziyang	Degree	0.158	none
	Closeness	0.956	
	Betweenness	0.712	
Mianyang	Degree	0.01	Degree Betweenness
	Closeness	0.217	
	Betweenness	0.005	

Table 3. The results of multiple liner regression analysis of the RAV

Name of road network	Indicator of structure	significance	Independent variables of the function
Deyang	Degree	0.086	Betweenness
	Closeness	0.175	
	Betweenness	0.002	
Ziyang	Degree	0.076	none
	Closeness	0.879	
	Betweenness	0.142	
Mianyang	Degree	0.198	none
	Closeness	0.542	
	Betweenness	0.177	

From the results of the regression analysis we can see that the type of indicators which have influence on VKT are different, that is to say, the type of indicators will change by different cities. While in the result of RAV, the values of significance (P-value) are all above 0.05 expect the value of Deyang's betweenness, which indicates that the structure indicators almost have no effect on RAV, so we abandon it in the next study. The multiple regression analysis cannot help to determine the type and number of the formula of the three cities, so simple regression analysis will be used in the next study.

5.2 Simple liner regression analysis

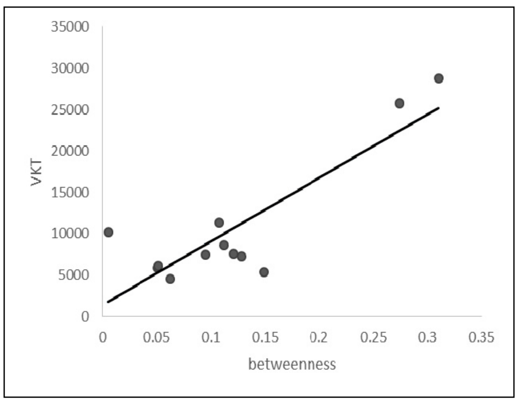
From table 2 we can see that the significance of VKT and betweenness tends to be the best, and from the definition of betweenness we can see it is a global indicator, a stroke with a lower degree may also play an important role as "intermediary", which means it is important in communicating the entire road network. Therefore, in the simple liner regression analysis, only betweenness and VKT are taken into account.

Set the significance level of 0.05, the model summary of simple liner regression analysis is showed in table 4.

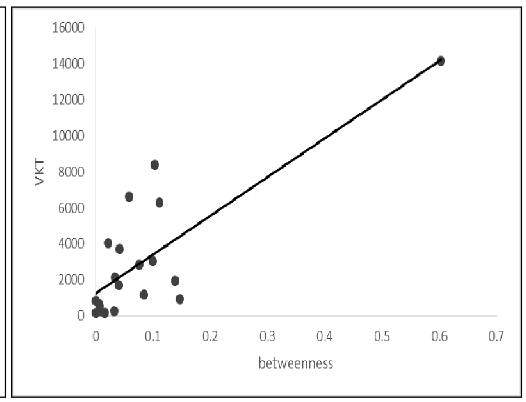
Table 4. Model summary

Name of road network	Indicators	R	R Square
Deyang	VKT betweenness	0.858	0.737
Ziyang		0.799	0.638
Mianyang		0.897	0.804

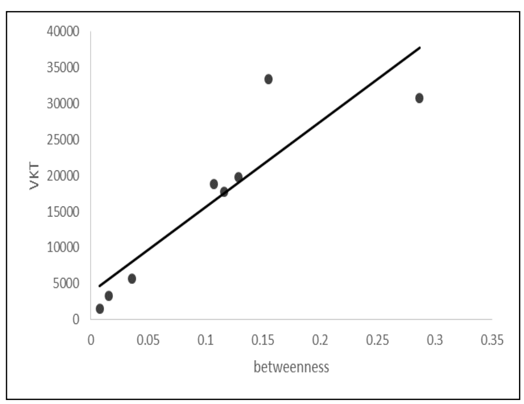
Table 4 shows that the fitting degree of VKT and betweenness are all favorable in the three cities. Figure 3 shows the three cities' scatter diagram of VKT and betweenness. Table 4 and figure 3 indicate that VKT and betweenness is proportional, that is to say the lager betweenness of a stroke is, the more VKT there will be on it.



a) Deyang



b) Ziyang



c) Mianyang

Figure 3. Three cities' scatter diagram of VKT and betweenness

6 Conclusion

Based on the study of road network topology, this paper introduced that the structure of road network will influence the distribution of the traffic, and the idea is verified by three cases. The result of multiple linear regression analysis indicates that the betweenness is the very structure indicator which has greatest influence on traffic distribution; of the two traffic distribution indicators, VKT is the very indicator which is more significant effected by the network structure. The result of simple liner regression shows that the impact of network structure on the distribution of traffic is linear.

7 Recommendations for Future Research

As we all know, the distribution of traffic volume is also affected by the traffic demand, therefore, in the follow-up studies, combined effects of traffic demand and network structure on traffic distribution will be analyzed.

Abstract: The multi-objective coordinated control strategy of tram in the intersection based on speed guidance in this article is the evaluation basis of the control strategy which is built on the basis of existing tram priority control in the intersection with the index of additional passengers' total delay time in the intersection; the tram and social vehicle can be coordination controlled by speed guidance or giving the tram passing priority in the intersection in order to minimize additional passengers' total delay time in the intersection.
Keywords: Speed guidance; Tram; Intersection; Multi-objective coordinated control.

1 Introduction

Trams (Bie Yiming, 2011) belong to the ground bus rapid transit, mostly a semi independent row form is used in space, and social vehicle drives together on the road, in the presence of plane intersection, which all will cause the tram in conflict with social vehicles at the intersection. So, in order to maintain the high efficiency of tram, using the maximum capacity of transporation. So far, most research focus on the aspect of priority control of signal at intersection in China. Mainly includes: passive priority control strategy, the absolute priority control strategy, conditional priority control strategy and real-time priority control strategy; the main methods are: the red light, green light delay and early fault phase insertion etc. But the primary goal of these strategies is to give the tram priority at intersections, not mainly considering the delay impact to other social vehicles (or the way of phase compensation to reduce the impact on other social vehicles). However, the the fundamental purpose of intersection signal control is to reduce the delay time of whole passenger at intersection, improving the traffic efficiency, so this paper is based on this for judgement, combined with the traditional research and coordinated control of the existing bus priority control, proposing a kind of tram road intersection coordination control strategy based on speed guided. Firstly, judging whether is it possible to go through the intersetion by accelerated guide in the green phase before the end, if not, setting how to minimize the intersection of additional total passenger delay time as the goal to guide the distribution of trams and social vehicles right of way and speed, so as to achieve the best efficiency of intersection traffic.

2 Determination of the Control Strategy Basis

Coordinated control strategy proposed in this paper contains the following assumptions:

The left turn phase and the yellow light phase in signal phase is not considered.

(2) Left social traffic flow is far less than the straight social flow.

(3) The tram line layout is central type.

(4) The interaction of tram platform and intersection is not considered.

2.1 Intersection planar structure

As shown in Figure 1, (Cao Chenghai,2006)central type is applied at the trolley lines, the platform is located in the middle of the road. Each import all has left, straight, right lane. Social vehicle detector is laid out at each entrance, which of the distance and intersection are L1; each the tram line of imports also emplace a tram detector, the distance from intersection is L2(the specific value L1, L2 should be determined according to the actual speed and intersection status). The width of the intersection is L4, tram length is L3, for the convenience of the subsequent calculation, making L3= L_t ,L4= L_i ,L1=L_{cd} ,L2=L_{td} .

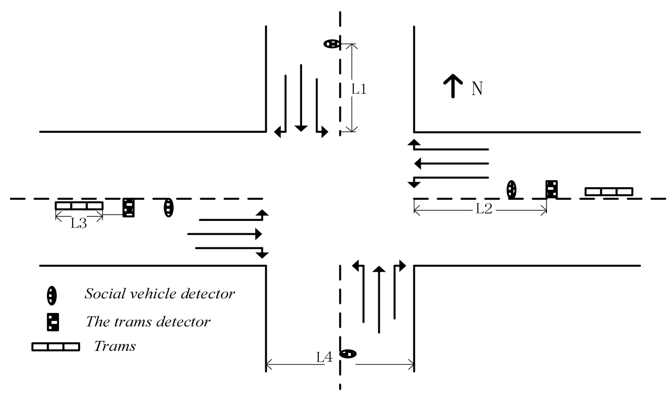

Figure 1. Planar intersection structure

2.2 Control strategy basis

In figure 1, social vehicle detector(Li Sheng,2005)collects information are: straight, left turn traffic flow, traffic flow of intersection queue number; the collected information of tram detector are: the tram reaches a detector when the time, speed, number of passengers. First of all, when detecting the tram arrived, the system will predict the tram arrived at the intersection of the moment, if it is not able to pass the intersection in the light phase, it is determined whether it should be accelerating guided through the intersection, If applicable, then calculate guiding target speed value; if not, then analysis in process shown below:

Assumption of the trams take priority control strategy (the red light, green light delay early break), social vehicles on the conflict phase using speed guide, it will produce additional delay of social vehicles on the vertical direction (Figure 1: South - North going straight and turning left vehicle), but at the same time，it will reduce the delay of tram and same phase of the straight vehicle in the cross (Fig. 1 : Middle East - West to straight vehicle). So in this case the intersection of additional total passenger delay time is as follows:

$$D_{total}^{1} = D_{NS} + D_{NL} + D_{SS} + D_{SL} - D_{WS} - D_{ES} \qquad (1)$$

In the formula: D_{total}^{1}: In case of tram priority control, intersection of additional total passenger delay time. D_{NS}: The north entrance of straight vehicle additional total passenger delay time. D_{NL}: The north entrance of left turning vehicle additional total passenger delay time . D_{SS}: South entrance of straight vehicle additional total passenger delay time. D_{SL}: The South Port Road turning left additional passenger vehicle total delay time. D_{WS}: Total corresponding reduction passenger delay time of westward entrance straight vehicle. D_{ES}: Total corresponding reduction passenger delay time of east entrance straight vehicle.

Assuming that it applies deceleration guidance to tram, instead of priority control strategy, means the intersection signal phase without any changes, then the intersection of the additional total passenger delay time is shown as follows:

$$D_{total}^{2} = D_{T} \qquad (2)$$

In the formula: D_{total}^{2}: Total delay time of additional passenger at intersection with tram deceleration guide. D_{T}: Total delay time of additional passenger at tram

So, to sum up:

When $D_{total}^{1} < D_{total}^{2}$, priority control strategy should be taken for the tram, guiding the social vehicle speed. When $D_{total}^{1} > D_{total}^{2}$, the intersection keeps the original signal phase invariant, decelerate guide should be taken to the tram.

3 Analysis of Tram Arrival Patterns

In this article, (Li Kai,2013)each red light and green light phase is divided into three stages, which are early stage, intermediate stage and later stage. The lengths of early stage and later stage are assumed to be a quarter of the corresponding phase, while the length of intermediate stage is half of the phase (Proportion of the specific time shall be determined according to actual situation intersections), which is shown in figure 2.

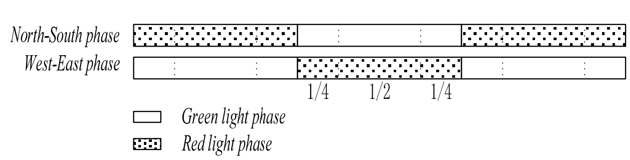

Figure 2. Phase structure

3.1 Arrival patterns

Assumes(Ma Wanjing,2009)that the average speed of tram is V_i when passing the intersection in the actual operation, time used to pass the intersection is Δt, moment to enter the intersection is T_{is}, moment to leave the intersection is T_{ie}, so:

$$\Delta t = \frac{L_t + L_i}{V_i} = T_{ie} - T_{is} \tag{3}$$

In this article, according to the arrive time detected by the trams detector, the predicted situations of the tram reaching the intersection can be divided into 9 model, which is shown in figure 3.

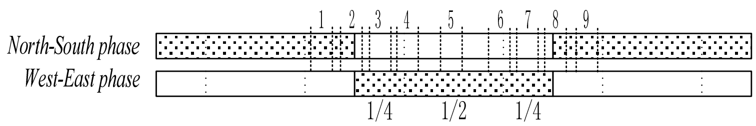

Figure 3. The tram arrival patterns

In pattern 1 and pattern 9, the moment to reach and leave the intersection of the tram are in green light phase thus they won't be considered in the following passage. In pattern 4, 5 and 6, the moment to reach or leave the intersection of the tram are in the intermediate stage of the red light phase, there will be a great influence on original phase's time series and passing efficiency if the tram is priority controlled in this condition, so speed guidance can be taken to the tram in order to decrease the stopping time.

3.2 Calculation of additional passengers' total delay time in the intersection

Pattern 2: The tram is predicted to enter the intersection in green light phase and leave the intersection in red light phase, which is shown in figure 4.

Pattern 3: The tram is predicted to enter the intersection in red light phase and leave the intersection in red light phase, which is shown in figure 5.

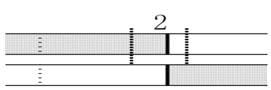

Figure 4 .Phase diagram of pattern 2

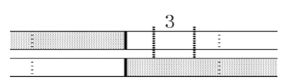

Figure 5. Phase diagram of pattern 3

If we take priority control strategy to the tram (delaying the green light), and guide social vehicles' speed, the following can obtain by formula (1):

$$\begin{aligned} D_{total}^{1} &= (Q_{NSW} + Q_{NLW} + Q_{SSW} + Q_{SLW}) \bullet \Delta t' \bullet \lambda + \\ &\frac{1}{3600}(q_{NS} + q_{NL} + q_{SS} + q_{SL} - q_{WS} - q_{ES}) \bullet \int_0^{\Delta t'} (\Delta t' - t)\, dt \bullet \lambda \\ &= (Q_{NSW} + Q_{NLW} + Q_{SSW} + Q_{SLW}) \bullet \Delta t' \bullet \lambda + \\ &\frac{1}{7200}(q_{NS} + q_{NL} + q_{SS} + q_{SL} - q_{WS} - q_{ES}) \bullet \Delta t'^2 \bullet \lambda \end{aligned} \tag{4}$$

In the formula: Q_{NSW} is the number of vehicle waiting to go straight in the north entrance; Q_{NLW} is the number of vehicle waiting to turn left in the north entrance;

Q_{SSW} is the number of vehicle waiting to go straight in the south entrance; Q_{SLW} is the number of vehicle waiting to turn left in the south entrance; q_{NS} is the traffic flow to go straight in the north entrance, pcu/h; q_{NL} is the traffic flow to turn left in the north entrance, pcu/h; q_{SS} is the traffic flow to go straight in the south entrance, pcu/h; q_{SL} is the traffic flow to turn left in the south entrance, pcu/h; q_{WS} is the traffic flow to go straight in the west entrance, pcu/h; q_{ES} is the traffic flow to go straight in the east entrance, pcu/h; $\Delta t'$ is green light delay time, s, $\Delta t' = T_{ie} - T_{rs}$, T_{rs} is the moment when the red light hits; λ is the average passenger number in each vehicle.

If we don't change the original signal phase in the intersection, just guide the tram to slow down, then:

$$D_{total}^{2} = (t_r + T_{rs} - T_{is}) \bullet N \tag{5}$$

In the formula: t_r is the duration of red light phase; N is the passenger number on the tram.

Pattern 7: The tram is predicted to enter the intersection in red light phase and leave the intersection in red light phase, which is shown in figure 6.

Pattern 3: The tram is predicted to enter the intersection in red light phase and leave the intersection in green light phase, which is shown in figure 7.

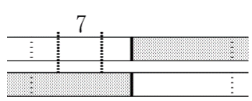

Figure 6. Phase diagram of pattern 7

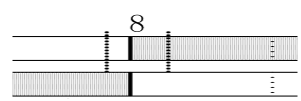

Figure 7. Phase diagram of pattern 8

If we take priority control strategy to the tram (turning off the red light early), and guide social vehicles' speed, the following can obtain by formula (1):

$$\begin{aligned} D_{total}^{1} &= \frac{1}{3600}(q_{NS} + q_{NL} + q_{SS} + q_{SL} - q_{WS} - q_{ES}) \bullet \int_0^{\Delta t'} (\Delta t' - t)\, dt \bullet \lambda - \\ &\quad (Q_{ESW} + Q_{WSW}) \bullet \Delta t' \bullet \lambda \\ &= \frac{1}{7200}(q_{NS} + q_{NL} + q_{SS} + q_{SL} - q_{WS} - q_{ES}) \bullet \Delta t'^{2} \bullet \lambda - \\ &\quad (Q_{ESW} + Q_{WSW}) \bullet \Delta t' \bullet \lambda \end{aligned} \tag{6}$$

In the formula: Q_{ESW} is the number of vehicle waiting to go straight in the east entrance; Q_{WSW} is the number of vehicle waiting to go straight in the west entrance; $\Delta t'$ is the lead time to turn off the red light, s, $\Delta t' = T_{re} - T_{is}$, T_{re} is the moment when the red light turn off.

If we don't change the original signal phase in the intersection, just guide the tram to slow down, then:

$$D_{total}^{2} = (T_{re} - T_{is}) \bullet N \tag{7}$$

4 The Determination of Guided Speed

Because social traffic flow(Wang Yizhe,2014) is composed of many single vehicles, while speed of the social vehicle is guided, this paper doesn't take the method of giving targeted speed value, but in the form of the countdown to display end time of the red light phase and green light phase. But for the tram, this paper takes the method of giving targeted speed value to guide its speed. The determination of targeted speed value of the accelerated speed guidance and decelerated speed guidance will be discussed respectively in following contents.

Accelerated guidance(Zeng Ying,2009): When tram passes the intersection at end moment of the green light phase time, the targeted speed value of the accelerated guidance is minimum. It can be determinate by following formulae:

$$T_{rs} - T_{td} = \frac{v_1 - v_0}{a_a} + \frac{v_1 - v_i}{a_d} + \Delta t^{"} + \Delta t \tag{8}$$

$$L_{td} = \frac{v_1^2 - v_0^2}{2a_a} + \frac{v_1^2 - v_i^2}{2a_d} + v_1 \Delta t^{"} \tag{9}$$

In the formula: T_{td} is the moment when tram reach the detector, v_1 is the targeted speed value of guidance, v_0 is the speed when tram reach the detector, a_a is the average acceleration of the tram, a_d is the average deceleration of the tram, $\Delta t^{"}$ is the traveling time of the tram at v_1 speed .

Note: Because the tram is affected by vehicle characteristics and safety in the process of driving, there is a threshold of the travelling speed. If the calculative guided speed is faster than top limit of the travelling speed($v_1 > v_{max}$), the accelerated guidance can't be taken.

Decelerated guidance: When tram enter into the intersection at end moment of the red light phase time, the targeted speed value of the decelerated guidance is maximum. It can be determinate by following formulae:

$$T_{re} - T_{td} = \frac{v_0 - v_1}{a_d} + \frac{v_i - v_1}{a_a} + \Delta t^{"} \tag{10}$$

$$L_{td} = \frac{v_0^2 - v_1^2}{2a_d} + \frac{v_i^2 - v_1^2}{2a_a} + v_1 \Delta t^{"} \tag{11}$$

5 The processes of the coordinated control

By above knowable, the logic process of this paper proposed coordinated control strategy is shown in figure 8:

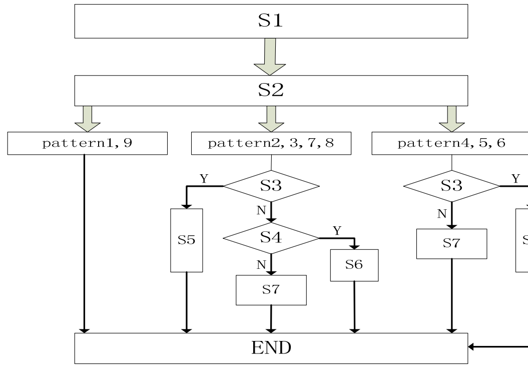

Figure 8. The processes of the coordinated control

In the figure:S1: Collect data by detector.S2: Predict the arrival time and arrival patterns of the tram.S3: Can take the accelerated guidance for the tram? S4: $D_{total}^{1} < D_{total}^{2}$? S5: Give the targeted speed value of the accelerated guidance.S6: Take the priority control strategies (delaying the green light or turning off the red light early).S7: Take the decelerated guidance and give the value of the targeted speed.

6 Conclusions and Outlook

Technically, the proposed control strategy can be a good way to solve the problem of low efficiency due to the frequent changes in the original phase of the intersection. In the subsequent study, this control strategy will be verified through the simulation and actual situation. At the same time, the condition with the existence of yellow light phase and left-turn phase will be analyzed deeply.

A Method of Intersection Traffic Volume Statistics Using Aerial Video

Yuheng Zhang; Xiaoxiang Yuan; Jusheng Tong; Yongfei Liu; and Yu Shi

School of Transportation, Southeast University, Nanjing 211189, China.

Abstract: This paper proposes a new method of detecting traffic volume of intersections from aerial video processing by software, and made a simple example. First, we use aeromodelling to get traffic flow video of target area. Then, we process the video with software we developed independently, to access data we need. The software developed on the platform of MFC and OPECV based on the C++ program. We used the mixed Gauss background difference method to identify vehicles in a single frame, and the L-K algorithm and corner detection algorithm to track vehicles in the continuous video. By this way, we extract trajectories of vehicles, and then get the speed and acceleration according to the relationship between time and displacement. On this basis, we propose a method of intersection traffic volume statistics. Proved by the experiment, the data gathered from the aerial video by our software is very accurate, and the error of intersection traffic volume is within 2%. It meets the requirements of the traffic survey well. The foreground of the software is considerable.

Keywords: Model aircraft; Traffic volume; Software.

1 Introduction

With the rapid development of China's technology and economy, traffic problems are seriously increasing. Meanwhile, the industry of transportation is gradually moving towards intelligent. The traffic volume statistics of intersections plays an essential position in the whole industry. However, due to various reasons, the intersection traffic volume still using manual statistics most of the time. Obviously, it is far from intelligent.

Among various data, the investigation on the traffic volume of intersections is being the most basic and important thing. It helps us to understand almost all aspects of an intersection in the actual working situation, such as traffic capacity, the traffic flow distribution and so on. Based on the data, we also can make an evaluation of the road intersection’s service level to provide a basis for the traffic problems diagnosis. At the same time, we also can access the information of characteristics of the road network traffic load, and determine the level of road network load. The index above is important basis for relevant departments to make decisions such as traffic jam improvement, traffic flow status prediction, and road network planning.

Therefore, the importance of intersections traffic volume survey is going without saying. However, in this information and automation age, detecting of intersections traffic volume is still not realized automation. In most cases, the method of intersections traffic volume gathering is artificial counting, which is not only squandering manpower, but very inconvenient. In order to solve this problem, based on the model view video, we developed a kind of software which can complete the intersection traffic volume statistics automatically.

2 System Introductions

We developed the hardware system and software system at the same time. The hardware system is mainly to build a model aircraft traffic observation system, by integrating the aeromodelling equipment and flight control technology, enabling it to have the air traffic observation ability. On the other hand, we developed software for the extraction of traffic targets coordinate and track, which based on the MFC and OpenCV platform, and using it for the extraction of road coordinates, speed, and acceleration of the vehicle from videos.

2 .1 Hardware system（aeromodelling system for observation）

We set up the video acquisition platform with four axis fixed wing model as foundation, which can collect the traffic streaming video, providing aerial view video material of for our software. Our aeromodelling system for observation is divided into two parts of airborne system and the ground station system.

Airborne system includes camera for aircraft, aeromodelling flight control module, receiver, data transmission module and image transmission module; the groud station includes computer, monitor, remote control, data transmission module and image transmission module.

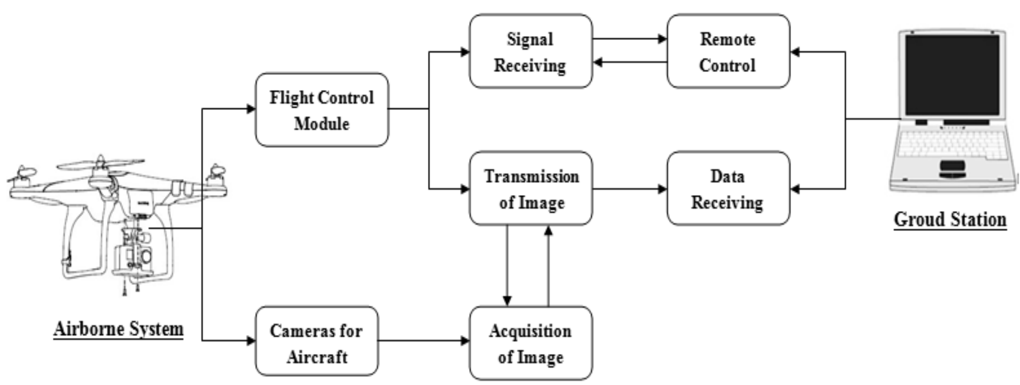

Figure 1. Schematic diagram of the hardware system

2 .2 Software system

The following is a brief introduction to part of our software's function.

2 .2 .1 The stabilization of video

For the quality of aerial videos is easily affected by wind and the user's operation, there will be different degrees of jitter in the videos. However the video's stability is a prerequisite for efficient and accurate of the software. A corner detection approach is used in the software to stabilize the jittering video. The "corner" as a feature point on the image, is the extreme point of the gray level gradient, which is easily being identified and tracked in the continuous frames in a video. The software will detect and track the static "corner" fixed on earth (usually the buildings on the roadsides). Then, the software will redefine the coordinate of the image referring to these static "corner", in order to get a more stable and easier to processing video.

2 .2 .2 Identification and tracking of traffic flow

The identification module of the software uses the mixed Gauss background difference method to segment the foreground (the traffic flow) from the background (road or highway). After eroding and dilating processing, we will get the foreground image that only contains vehicles filtering the environment noise. When the software running, there will cost a few seconds to found and accumulate the background before the identification procedure work, and the longer the software runs, the more accurate it will be.

The vehicle tracking procedure uses the L-K (Lucas & Kanade) algorithm. By identifying the corner of one contour in the foreground image (the gray level change rate between vehicles and roads is very high, and usually the boundary will be identified as the corner) and tracking it in the continuous frames, the algorithm will get the moving vehicles' coordinate information and trajectories.

2. 3 A new method of counting the intersection traffic volume

After obtaining the coordinate and trajectory information of the vehicles, we propose a statistical method of intersection traffic volume.

Aerial video is the simplification of three-dimensional scene to two-dimensional plane. It is perfectly preserved traffic volume information, with the useless terrain factors been removed.

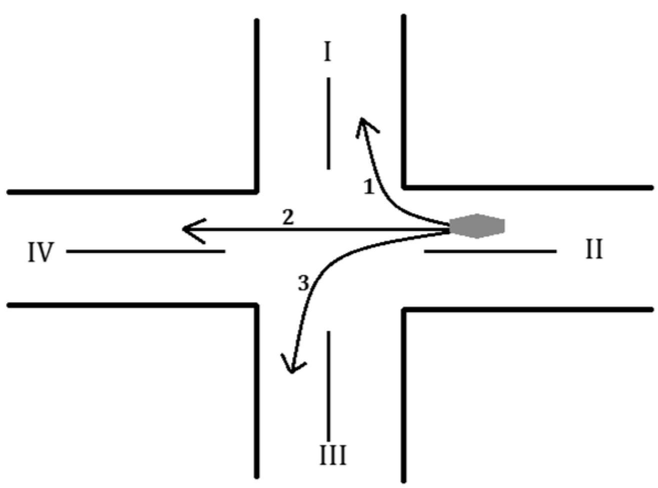

Figure 2. Schematic diagram of the hardware system

Figure 2 is the most common intersection, we numbered the four branches, respectively, I, II, III, IV.

When the vehicle enters one rectangle, the software will do the corner detection and track the trajectory information. After that, by ranking the sequence of vehicle entering the rectangle, we will get the vehicle's steering information.

When it comes to count the traffic volume, we propose a new method: using the corner detection algorithm to record the steering information, while using the area of the contours as a weight to record the quantity of traffic.

Figure 3. Result of the mixed Gauss background difference

Normally, the target can be segmented from background completely (the right of Figure 3),but under some special light, due to the reflection of the vehicle windscreen, or the color similarity between the road and cars, the case can happen that one target is segmented into two pieces (the left of Figure 3). However, using the weight to count the quantity, by comparing the standard vehicle, we will get the correct quantity of traffic volume.

3 An Example

We test the software at the intersection of Suyuan Avenue and Jiyin Avenue in Jiangning District, Nanjing city.

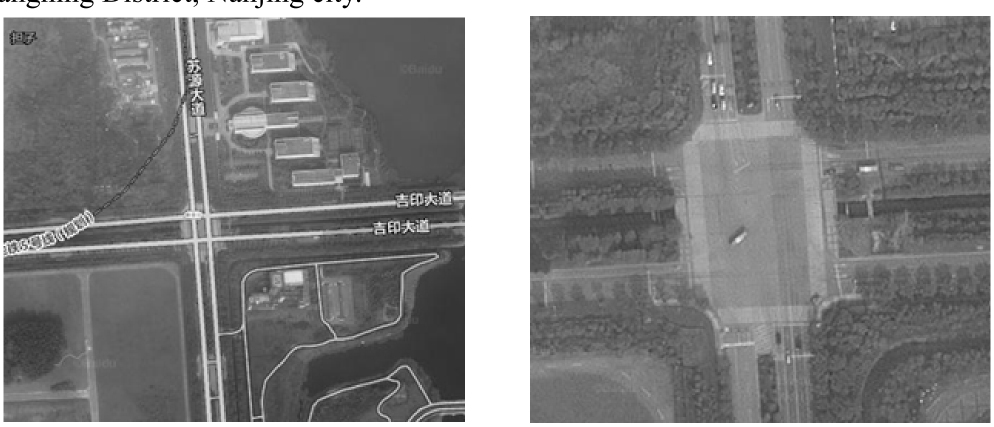

Figure 4. Schematic diagram of the hardware system

Among them, the East-West is Jiyin Avenue, to the North-South is Suyuan Avenue. The intersection is located on the Southeast University campus nine lung Lake outside the Northwest corner， Jiangning District of Nanjing City.

The two avenues are designed according to the highway design standards, more and more to assume the function of city road. They both have a design speed of 80km/h, and a forbid speed of 70km/h, and both are two-way four lane road with a broad central divider.

Due to the road shape, the intersection area is very large, so it has a wide field of vision.

There are four lanes before the intersection, is the non motor vehicle lanes, through lane, straight lane, and the left turn lane respectively. The intersection is outside of bustling area, large traffic flow only apartments during peak hours..

Since the peak period traffic in the evening is large, we chose the under time to conduct our investigation for a more representative data.

October 12, 2014, 17:00 p.m.

We are starting from 17:15 and 17:45, had twice traffic volume investigate, every time lasts 10 minutes.

Artificial statistical results of traffic volume as follows:

Intersection	Directions	Vehicle（17：15—17:25）			
of Ji Yin Avenue & Suyuan Avenue		Left	Straight	Right	SUM
	South	18	131	11	160
	North	37	50	33	120
	East	11	45	41	97
	West	36	74	8	118
Intersection	Directions	Vehicle（17：45—17:55）			
of Jiyin Avenue & Suyuan Avenue		Left	Straight	Right	SUM
	South	8	71	13	92
	North	29	43	21	93
	East	11	47	24	82
	West	37	55	14	106

Software statistical results of traffic volume as follows:

Intersection	Directions	Vehicle（17：15—17:25）			
of Jiyin Avenue & Suyuan Avenue		Left	Left	Left	Left
	South	17	129	11	157
	North	37	50	33	120
	East	11	45	39	95
	West	35	72	8	115
Intersection	Directions	Vehicle（17：15—17:25）			

of		Left	Left	Left	Left
Jiyin	South	8	69	13	90
Avenue &	North	28	43	21	92
Suyuan	East	10	47	23	80
Avenue	West	36	54	14	104

4 Data Analysis

We can assume the artificial statistics result is accurate.

The data error analysis is as follows:

	17：15—17:25	17：45—17:55
South	98.13%	97.82%
North	100%	98.92
East	97.93%	97.56%
West	97.45%	98.11%
SUM	98.38%	98.12%

By analysis, error of this software may be related to the following reasons:

I. Because the algorithm is based on the gray discriminator, a grey vehicle and similar color is not easy to be identified in the video, and leads to the occurrence of omission;

II. Time of shooting video and artificial statistical has not completely unified, they may not start and end at the same time, which resulting in the variable is not single;

III. When a non-motorized vehicle driving in motorcycle lane, if the target is large also may be identified as vehicles, causing the error formation.

5 Conclusions

From the above experimental data, the statistical results of traffic volume from software processing compared with it from artificial method, has an accuracy rate reached to 98.25%, meanwhile an error rate of 1.75%. According to our present research status, this method is convenient operation, and the intersection traffic volume survey data from software are quite accurate. So we initially considered it can replace the artificial observation.

6 Recommendations for Future Research

The traffic investigation is the basis of traffic work, but also the most crucial step. In the era of intelligent traffic, we should open up some new thoughts. The purpose of this paper is to propose a simple, convenient and accurate method of traffic volume investigation. This method combines the knowledge of traffic and computer technology, and reflects the idea of intelligent traffic very well. Its an liberation of human and material resources with a high accuracy.

Moreover, it also has broad prospects,

I. Improving the software, makes it achieved a function of the road intersections service level comprehensive after a combination with other indicators;
II. Realizing the detecting of roundabouts traffic volume which is complicated than intersections based on the present achievements;
III. Completing the development of traffic delay function based on the data has been obtained in the software. (trajectory, coordinate, velocity, acceleration)

Abstract: Based on Shanghai elevated road traffic flow, six kinds of speed-density models are calibrated by least square method for clear and rainy weather and the respective best models to estimate free-flow speed and capacity are determined. Next, the function between free-flow speed and rainfall intensity is also fitted and it is integrated into generalized speed-density models. It is found that both weather and number of lanes influence free-flow speed and capacity, and generalized speed-density models also vary with different combination of weather and number of lanes.
Keywords: Free-flow speed; Capacity; Least square method; Rainfall; Number of lanes.

1 Introduction

Lately transport system hazards due to adverse weather, e.g. traffic safety and traffic congestion, are on the rise and they will cause huge loss if not treated well. However traffic flow characteristics under adverse weather is not well studied, and because it is dependent largely on local driving behavior, so it requires more related researches carried worldwide.

The speed-density models under rainy weather, as an extension of existing traffic flow relationship studies, are gradually investigated at home and abroad. Previous studies generally take advantage of actual traffic flow and metrological data to develop different speed-density models with various categorized rainfall intensity, e.g. light rain, heavy rain etc. For example, Ibrahim and Hall (1994) observed that only the slope in linear speed-flow-occupancy model became smaller, which meant traffic flow key parameters like free-flow speed, capacity and speed-at-capacity changed under adverse weather. Unrau and Andrey (2006) analyzed variation of expressway traffic flow under light rainy weather and dry weather, and found under uncongested regime the speed-volume model is in the form of quadratic function whereas under congested regime it is in the form of exponential function. For highway or expressway traffic flow under adverse weather, Van Aerde model is most frequently used (Rakha et.al.,2008; Zhang C. et.al ,2013) as well as two-regime modified Greenshields model (Hou et.al,2013). Xiao L.(2013) maintained Underwood model is the best model to fit Beijing urban freeway traffic flow data under heavy rain. Soheil Sajjadi et.al (2014) compared Northwestern,Van Aerde, Modified Greenshields, and HCM three-regime model for expressways under rainy and snowy weather conditions, and they found that the dual-regime Modified Greenshields model estimate free-flow speed best; however, none of them can make reasonable capacity estimation. Therefore, one empirical thresholds approach is recommended in their study.

Free-flow speed is an important parameter in every speed-density model and is found to be affected by various factors such as road geometry feature, traffic composition, speed limit and weather condition (TRB,2000). In terms of weather factors, so far the relationship between free-flow speed and precipitation is described by exponential function (Lam, W.H.K., et al., 2013), power function (Jia Yuhan et al,2015) and piecewise linear function (Shi Lijuan,2012). Besides precipitation variable, the other meteorological variables like lightness, temperature, visibility, wind speed, snow layer depth are also considered in some free-flow speed regression models (Shi Lijuan,2012 and Camacho, F.J. et al.,2010).

As is seen from above, at broad highway or expressway speed-density-volume relationships were analyzed and different models were calibrated. Nevertheless, such model calibration for urban freeway is scarcely seen at home. Moreover, previous traffic flow analysis and modeling are based on lane traffic data instead of segment traffic flow, which may cover the impact of number of lanes on segment free-flow speed and capacity. Therefore this study aims to explore the impact of weather condition and number of lanes on segment traffic flow characteristics and to develop generalized speed-density models by integrating those observed impacts.

2 Data Collection

According to weather historical records, two days,ie.2012/10/18 and 2012/08/08, are chosen to represent clear weather and rainy weather respectively. It rained in nearly every hour on 2012/08/08 due to the typhoon and hourly precipitation is shown in figure 1.

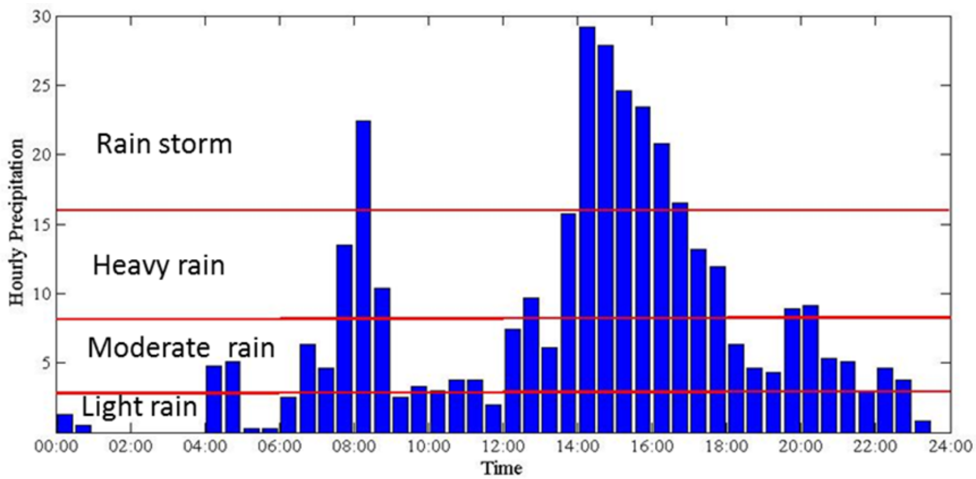

Figure 1. Rainfall classification of August 8th, 2012

The above figure indicates 24-hour accumulated precipitation reaches 175.5mm. So it belongs to heavy or stormy rain category according to China meteorological standard. Meanwhile, traffic flow data at 184 segments of Shanghai freeway are collected every 5 minutes on both days. Congested segments from A1 to A6 are used for model calibration and uncongested segments from B1 to B3 for free-flow speed model establishment. These selected segments are given in table 1. Segment name is coded using names of off/on ramps at both ends of that segment. For example, 'NBYD-DO->NBYD-DI' means eastbound road segment starting from the end Yandong off-ramp to the end Yandong on-ramp of South-North elevated road.

Table 1. Basic information about used segments

Segment Id	Segment name in database	Number of lanes	Length (m)	Freeway name
A1	NBYD-DO->NBYD-DI	2	1038	South-North elevated road
A2	NBYD-XO->NBYD-XI	2	1429	
A3	NBXJH-DO->NBXJH-DI	3	1937	
A4	NBLB-DI2->NBXJH-DO	3	1661	
A5	NBXJH-DI->NBHHZ-DO	4	1935	
A6	NBHHZ-DO->NBYD-DO	4	1288	
B1	NHZSB-NO->NHDBS-NI	2	1323	Inner Ring elevated road
B2	ZHJG-WO->ZHJG-WI	3	2117	Middle Ring elevated road
B3	ZHJG-NI->ZHZJZ-NO	4	3571	

3 Method

The six commonly used one-regime speed-density models are adopted and compared, with their respective function forms and parameters in table 2. Among all variables and parameters, v is operating speed variable; k is density variable; v_f is free-flow speed parameter; v_m is optimal speed parameter; k_j is jam density parameter; k_m is optimal density; and n is positive integer.

Table 2. Six one-regime speed-density models

Model name	Shortened Name	Model function form	Parameters
Greenshields	Gs	$v = v_f(1 - \frac{k}{k_j})$	v_f, k_j
Greenberg	Gb	$v = v_m ln\,(\frac{k_j}{k})$	v_m, k_j
Underwood	Uw	$v = v_f\ e^{(-\frac{k}{k_m})}$	v_f, k_m
Northwestern	Nw	$v = v_f\ e^{-\frac{1}{2}(\frac{k}{k_m})^2}$	v_f, k_m
Drew	Dw	$v = v_f[1 - (\frac{k}{k_j})^{n+\frac{1}{2}}]$	v_f, k_j, n
Pipes-Munjal	Pm	$v = v_f[1 - (\frac{k}{k_j})^n]$	v_f, k_j, n

Model calibration is one curving fitting problem in essence. So least square method is adopted, which can make the optimal function parameter estimation by solving one mathematical optimization problem with the help of Matlab (Xue Dingyu, et al,2004). Meanwhile, further preprocessing work is needed to obtain input data for traffic flow model. So traffic flow rate q, average spatial speed u_s, and density k are respectively converted in the following equations:

$$q = 12 \times q_{5min} \quad (1)$$
$$u_s = 1.026u_t - 1.890 \quad (2)$$
$$k = q/u_s \quad (3)$$

In addition, actual free-flow speed and capacity are also required in advance for evaluating model's estimation effectiveness. According to previous studies, free-flow speed is obtained by taking the minimum between 85th percentile of operating space speed and speed limit value (Li C., 2010);

$$v_f^{obs} = min\{v_{85}, v_{limit}\} \quad (4)$$

where v_f^{obs} is observed free-flow speed（km/h）, v_{85} *and* v_{limit} are 85th percentile of observed operating space speed and speed limit.

Capacity is obtained by taking the mean of 99th percentile of traffic flow rate (Chung E, Ohtani O, Warita H, et al，2006) and the average of the top fifth percentile of the observed flow rates (Soheil Sajjadi et al,2014; Smith B L, Byrne K G, Copperman R B, et al，2004) .

$$cap^{obs} = \frac{1}{2}(q_{99} + \frac{1}{n}\sum_{i=1}^{n} q^i) \quad (5)$$

Where cap^{obs} is observed capacity (pcu/h), q_{99} is 99^{th} percentile observed flow rate,q^i is ith of the top 5% highest flow rates and n is sample size of top 5% highest flow rates.

4 Results Analysis

4.1 Reduction in Traffic Flow Key Parameters

Using equation (4) and (5), free-flow speed and capacity of every segment are calculated both under clear weather and heavy rain weather, which are shown in Table 3.

Table 3. The influence of weather and number of lanes on key parameters

Segment id	Free-flow speed (km/h)			Capacity (vehs/h)		
	Clear weather	Heavy rain	Reduction percent	Clear weather	Heavy rain	Reduction percent
A1	69.3	69.0	0.4%	3877	3250	16.2%
A2	68.0	68.0	0.0%	3881	3263	15.9%
A3	80.0	76.0	5.0%	5150	4389	14.8%
A4	76.0	69.0	9.2%	6164	3546	42.5%
A5	69.0	67.0	2.9%	7666	4996	34.8%
A6	69.0	68.0	1.4%	6617	5767	12.8%

It can be seen from above table that under heavy rain weather, reduction of free-flow speed are respectively 0~0.4%, 5~9.2%, and 1.4~2.9% for 2-lane, 3-lane and 4-lane freeway segment. Moreover, reduction of capacity are respectively 15.9~16.2%, 14.8~42.5% and 12.8~34.8% for 2-lane, 3-lane and 4-lane freeway segment.

4.2 Model Calibration and Selection

This section presents detail results of 6 kinds of speed-density models for segments A1, A3 and A5 both under rainy and clear weather. The Drew model has two versions, Dw1 or Dw2 for parameter n being 1 or 2. So does Pipes_Munjal model, i.e., Pm2 for n being 2 and Pm3 for n being 3 respectively. Every model is labeled by linking model shorten name, segment ID and weather flag. For example, 'Gs_a1r' means Greenshields model for segment A1 under rainy weather; and 'Gs_a1c' is also Greenshields model for segment A1, but under clear weather.

In terms of 2-lane segment A1, calibration results are given in Table 4. v_f^{est} $and\ cap^{est}$ are estimated free-flow speed and estimated capacity. The other badly-calibrated models like Drew models are not given because they have negative adjusted R2 values.

Table 4. Calibration results of speed-density models for segment A1 under two weather conditions.

model	Adj_R2	v_f^{est} (km/h)	cap^{est} (veh/h)	v_f^{obs} (km/h)	cap^{obs} (veh/h)	Estimation error of v_f	Estimation error of Cap
Gs_a1r	0.95	71	3115	69	3250	2.6%	-4.2%
Gb_a1r	0.68	110	2700			59.3%	-16.9%
Uw_a1r	0.92	75	4402			8.4%	35.4%
Nw_a1r	0.97	67	2972			-3.0%	-8.6%
Gs_a1c	0.93	85	3496	69.3	3877	22.0%	-9.8%
Gb_a1c	0.69	152	3723			119.2%	-4.0%
Uw_a1c	0.87	90	5297			29.9%	36.6%
Nw_a1c	0.95	76	3476			9.1%	-10.3%
Pm3-a1c	0.81	64	4162			-7.1%	7.4%

Similarly the calibration process is carried for 3-lane and 4-lane segments, but their results are omitted due to space limit. Finally the best models to estimate free-flow speed and capacity are summarized in table 5. They are found to vary with different combinations of weather and number of lanes. So Greenshields model and Northwestern model are recommended in practice for rainy weather and clear weather condition respectively, with their estimation errors below 11%.

Table 5. Best models for key parameter estimation under different combination of weather and road condition

Weather condition	Number of lanes	model	Adj_R2	Estimation error of v_f	Estimation error of cap
Rainy	2	Gs_a1r	0.95	2.6%	-4.2%
Clear	2	Pm3-a1c	0.81	-7.1%	7.4%
Rainy	3	Uw_a3r	0.75	4.7%	6.7%
Clear	3	Nw_a3c	0.97	3.3%	0.3%
Rainy	4	Gs_a5r	0.86	-10.8%	1.8%
Clear	4	Nw_a5c	0.96	3.9%	-5.7%

Also based on calibration results, the models that have biggest R2 value are those best models for speed prediction under different weather and road conditions. It is found that for 2-lane and 3-lane segment, Northwestern model are better than the others under both weather conditions. In contrast, for 4-lane segment Underwood model performs best under rainy weather and Greenshields model under clear weather. Due to space limit, only Northwestern models at segment A3 are compared with actual observation shown in Figure 2.

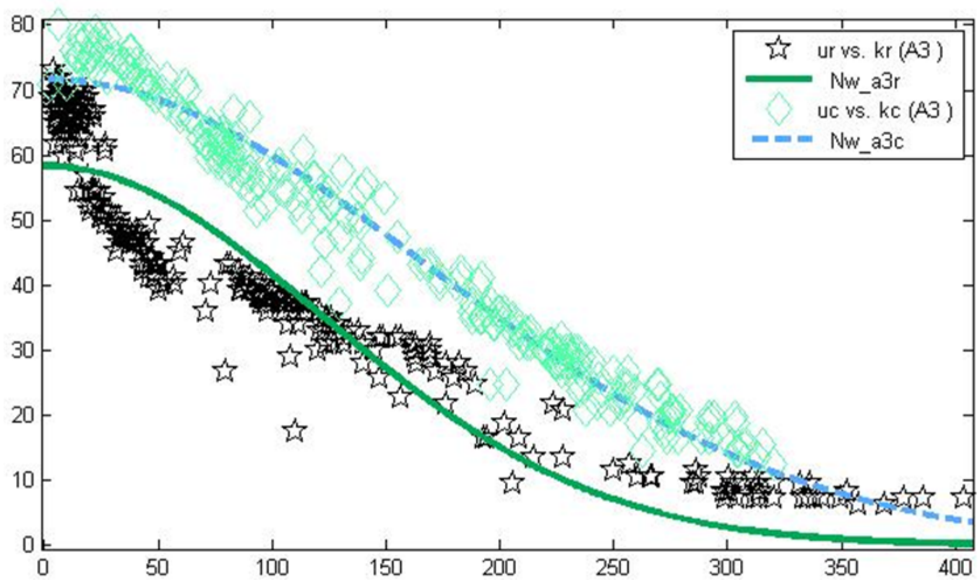

Figure 2. Fitness of Northwestern model at segment A3 under both weather

4.3 Generalized Speed-Density models for multi-lane segments

Firstly, it further to check if both weather and number of lanes have significant impact on free-flow speed using traffic flow data of uncongested segments B1, B2 and

B3. These three segments are spatially isolated and not dependent. Hourly free-flow speed and precipitation are collected from 5:00am to 19:00pm on both days. Each hourly average speed of each combination of weather and number of lanes is regarded as an experiment, and Two-Way-ANOVA test is made. From below table, the P-values for these two factors are less than 0.05, which confirms that free-flow speed is function of weather condition and number of lanes at least.

Table 6. Results of Two-Way-ANOVA test

Source of variation	SS	df	MS	F	P-value	F crit
Weather condition (4 categories)	22.068	3	7.356	9.189	0.0116	4.7571
Number of Lanes (3 categories)	37.3	2	18.65	23.297	0.0015	5.1433
Error	4.8031	6	0.8005			
Total	64.171	11				

Secondly, in order to fit the function between free-flow speed and rainfall intensity, their scatterplot is drawn in figure 3. For each segment, as rainfall intensity increase from 0 to 8mm/h, free-flow speed decreases linearly, and after that free-flow speed surprisingly increases and fluctuated. This abnormity should be cautioned because of small sample size of heavy rain and above category.

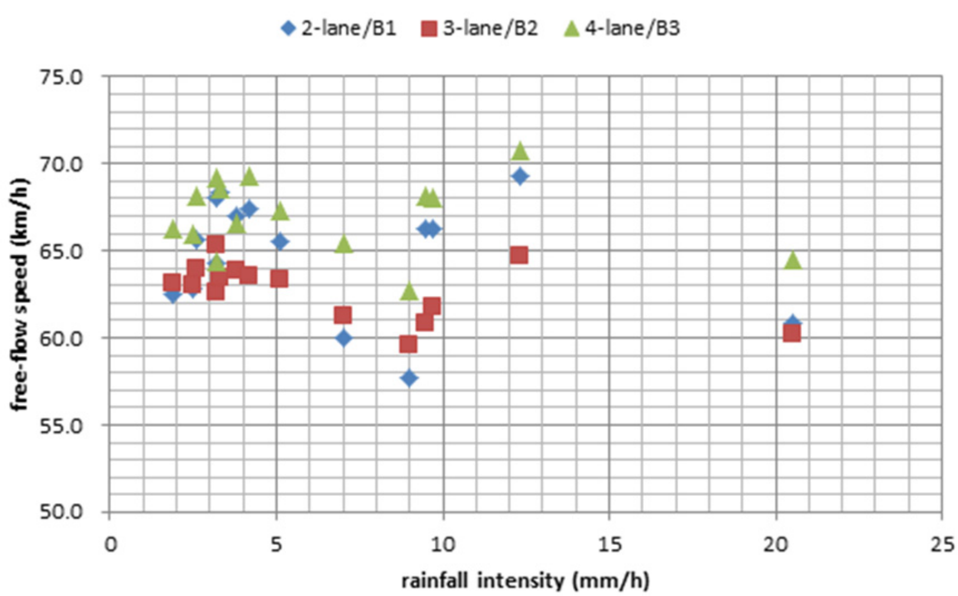

Figure 3. Scatterplot of free-flow speed and rainfall intensity by number of lanes

Therefore, the linear relationship between free-flow speed (v_f) and rainfall intensity (i) belonging to moderate rain can be fitted for segments with different number of lanes. For example, the linear model for 3-lane segment is as follows:

$$v_f = -0.3759i + 64.733, R^2 = 0.2833 \quad (6)$$

Though R-square value in equation 6 is small due to small sample size, the linear relationship can be confirmed in other study (Shi Lijuan,2012).. Last, by substituting the above function for category-related free-flow speed parameter, generalized speed-density model can be yielded and this kind of model is more suitable for on-line dynamic traffic management and control. For example, for 3-lane segment B2, according to results in section 4.2 and equation (6), its generalized Northwestern speed-density model under rainy weather can be rewritten into equation (7):

$$v = (-0.3759i + 64.733) * e^{-\frac{1}{2}\left(\frac{k}{320}\right)^2}, i \in [2.6, 8] \quad (7)$$

Where v is speed (km/h), k is density (veh/ km.3lane) and i is rainfall intensity (mm/h).

5 Conclusions

Here we may draw the following conclusions: (1) reduction in free-flow speed and capacity are affected by both weather and number of lanes; (2) the best models to estimate free-flow speed and capacity also varies with different combination of weather and number of lanes; (3) Both weather and number of lanes influence hourly free-flow speed significantly, and there exists linear relationship between free-flow speed and rainfall intensity being to moderate rain. Those conclusions shed light on selection of speed-density model under different weather and segment conditions, and also are helpful for online traffic management and control.

Short-Term Travel Time Prediction for a Car Dynamic Navigation System

Yuxi He; Renjie Du; Tong Zou; Nian Zhang; and Xunfei Gao

School of Transportation and Logistics, Southwest Jiaotong University, Chengdu 610031, China.

Abstract: This paper works on the short-term travel time prediction, aiming at predicting dynamically(or fixed-frequency) by considering dynamic road traffic index volatility and average speed, and then providing the real-time travel time prediction for users in advance. This paper improves the prediction algorithm, referenced to current traffic parameters prediction methods basing on Kalman filter, and solves the time lag and the automatic update of historical average data needed. Then this paper uses 4 evaluation indexes to make known the degree of deviation and goodness of fit between predictive value and actual value, and to verify that improved algorithm could make predictive travel time more accordant with the practical situation.

Keywords: Short-term travel time prediction; Dynamic navigation; Kalman filter.

1 Introduction

Existing travel time prediction is based on static information like road level and vehicle speed limit, offering fixed travel reference information without taking out the impact the fluctuation of traffic index have on travel time, especially during travel peak hour or traffic incident period, which is easy to provide error messages and result the delay too long. Analyzing various methods comprehensively, we selected Kalman filter method because of its simple model, easy to implement and high precision, and the Kalmen filter can use real-time section travel time to correct the state variable in prediction, also adapt to fluctuation of traffic state.

2 Methods

In this paper, the prediction model takes into account the traffic index and the actual average speed of traffic. The travel time prediction value is calculated by the actual vehicle speed and road length, and able to reflect the traffic operating efficiency of roads and network during peak hour or traffic incidents periods, which means it considers the vehicle speed of the same level roads or the same speed limitation roads is different during the actual traffic operation. The model takes real-time vehicle speed as the basis of prediction data updating.

Compared to the previous Kalman filter prediction model, this model uses the current travel time divided by its historical average travel time, which can eliminate the time lag of Kalman filter method prediction. In this paper, the calculation of historical average travel time (scilicet $\overline{q^t}(d) = \frac{\sum_{i=1}^{count} q^t(d)}{count}$) is progressively updating over time, which is no human involvement. In addition, the traffic situation is obvious different between holidays and non-holidays. Even if in non-holidays, the traffic situation on different days in a same week also have their own characteristics, called week feature, which means the traffic situation on the corresponding day in different weeks (all are non-holiday) are analogous.This paper uses the improved Kalman filter model to predict short-term travel time considering the impact of above factors, and draws the following travel time prediction model:

$$o(t+1) = p_0(t)q(t) + p_1(t)q(t-1) + p_2(t)q(t-2) + w(t) \quad (1)$$

Among them:

$p_0(t)$, $p_1(t)$, $p_2(t)$ is state coefficient; $w(t)$ is observation noise, assumed to be a zero mean white noise, and set a given value here. $o(t+1)$ and $q(t)$ are defined as follows:

$$o(t+1) = \frac{q^{t+1}(d)}{\overline{q^{t+1}}(d)} \quad (2)$$

$$q(t) = \frac{q^t(d)}{\overline{q^t}(d)} \quad (3)$$

Among them: d is {1, holiday; 2, Saturday and Sunday; 3, Monday to Friday} one kind of these three, the priority of type 1 to 3 is followed by decreasing;

$q^t(d)$: current date of target section is d type day, the travel time weight of the section in t period;

$\overline{q^t}(d) = \frac{\sum_{i=1}^{count} q^t(d)}{count}$, the historical average travel time of the target section in t period on historical d type days, this statistics is constantly updating with the advance of the date, $count$ is the number of d type days until one day before the prediction day.

3 Model Solution

In order to solve the model, given

$$\mathbf{A}(t) = [q(t), q(t-1), q(t-2)] \quad (4)$$

$$\mathbf{X}(t) = [p_0(t), p_1(t), p_2(t)]^T \quad (5)$$

$$y(t) = o(t+1) \quad (6)$$

Whereby the following equations:

$$\mathbf{X}(t) = \mathbf{B}(t)\mathbf{X}(t-1) + u(t-1) \tag{7}$$

$$y(t) = \mathbf{A}(t)\mathbf{X}(t) + w(t) \tag{8}$$

Among them: $y(t)$ is observed variables; $\mathbf{X}(t)$ is state vector; $\mathbf{A}(t)$ is observation matrix; $\mathbf{B}(t)$ is state transition matrix, set as the unit matrix; $u(t-1)$ is model noise, assumed to be zero-mean white noise, and its covariance matrix is $\mathbf{Q}$. $\mathbf{Q}$ is assumed to be a given value, scilicet the error of the model from a state to next is constant, because under normal circumstances, in a short time, the outside influence of the system will not change much. However, the calculation of $\mathbf{Q}$ should base on objective fact and statistics on large amounts of data actually, and this paper does not discuss this issue.

According to Kalman filtering theory, we found equations as follow:

Kalman filter time update equations:

$$\hat{\mathbf{X}}(t+1|t) = \mathbf{B}(t+1)\mathbf{X}(t) \tag{9}$$

$$\hat{\mathbf{P}}(t+1|t) = \mathbf{B}(t)\mathbf{P}(t)\mathbf{B}^T(t) + \mathbf{Q} \tag{10}$$

Kalman filter state update equations:

$$\mathbf{K}(t+1) = \hat{\mathbf{P}}(t+1|t)\mathbf{A}^T(t+1).(\mathbf{A}(t+1).\hat{\mathbf{P}}(t+1|t).\mathbf{A}^T(t+1))^{-1} \tag{11}$$

$$\mathbf{X}(t+1) = \hat{\mathbf{X}}(t+1|t) + \mathbf{K}(t+1).(y(t) - \mathbf{A}(t+1).\hat{\mathbf{X}}(t+1|t)) \tag{12}$$

$$\mathbf{P}(t+1) = (\mathbf{I} - \mathbf{K}(t+1).\mathbf{A}(t+1)).\hat{\mathbf{P}}(t+1|t) \tag{13}$$

In equations, $\hat{\mathbf{X}}(t+1|t)$ is the result of the next state prediction; $\mathbf{X}(t+1)$ is the best result of the next state; $\mathbf{K}(t+1)$ is Kalman gain matrix; $\mathbf{P}(t+1)$ is filtering error variance matrix; $\hat{\mathbf{P}}(t+1|t)$ is prediction error covariance matrix.

It can be seen from the definition of the above formula that this model only can begin prediction from the third time period, because the value of the first two periods are the initial parameters. This paper assume the model start at $t=1$, then the third time period is $t=3$. This model take 5 minutes as the time interval, so one day 24 hours has 288 periods. Given the initial value of the Kalman filter has a certain extent to the prediction accuracy, this paper use the methods (Lu, 1997) to calculate the initial value of $\hat{\mathbf{X}}(3)$, $\mathbf{P}(3)$, $\mathbf{Q}$. Operate the travel time weight as follow after the initial value is determined:

Firstly, calculate the time update equations, scilicet calculate the equation (9) (10).

After determining $\hat{\mathbf{X}}(t+1|t)$, we found:

$$y(t) = \mathbf{A}(t)\hat{\mathbf{X}}(t+1|t) \quad (14)$$

Further, we found road travel time predictive value is:

$$\hat{q}^{t+1}(d) = \mathbf{A}(t)\hat{\mathbf{X}}(t+1|t) \times \overline{q^{t+1}}(d) \quad (15)$$

When observed value of time $t+1$ (scilicet $y(t)$ has come), calculate Kalman filter state update equation, (11) (12) (13), to get the travel time predictive value of the next time period. If need to predict the travel time of whole network, we can base on forward calculation and operate the same method to the other road separately. Figure 1 is the shor-time travel time prediction algorithm flow chart.

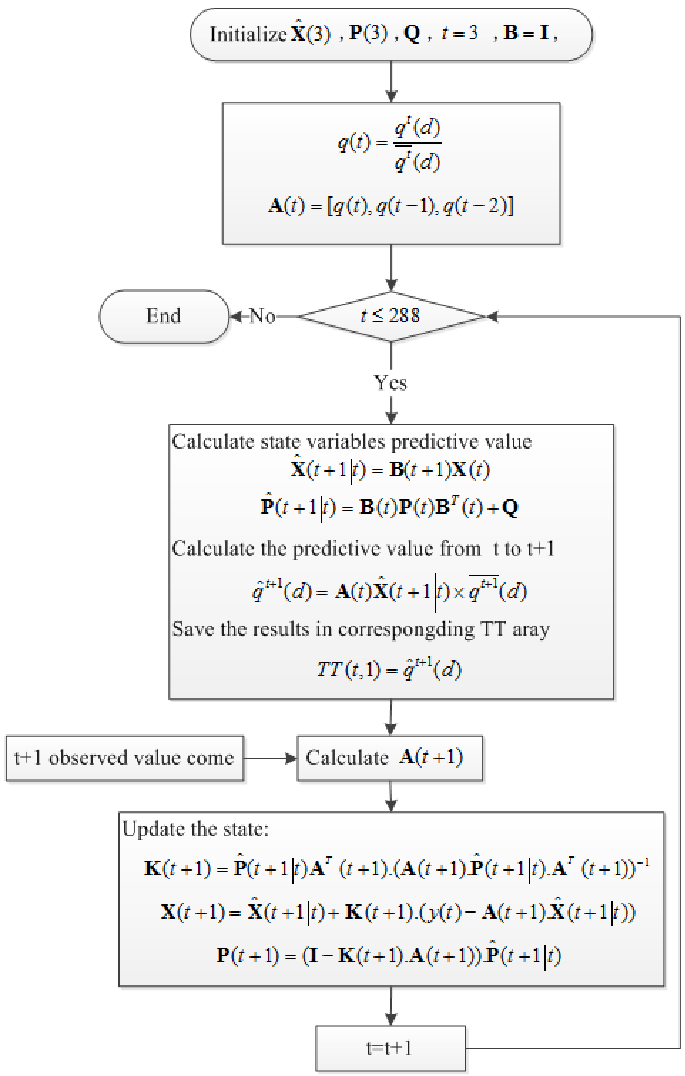

Figure 1. the shor-time travel time prediction algorithm flow chart

4 Data Analysis

To test the performance of the Kalman filter short-term travel time prediction model for car dynamic navigation system in this paper, we select the error indicators (Shen, 2011). Let $q_{pij}^{t}(d)$ be the real value and $\hat{q}_{pij}^{t}(d)$ be the prediction value, then:

Relative error percentage: $E_{PR} = \frac{\left|\hat{q}_{pij}^{t} - q_{pij}^{t}(d)\right|}{q_{pij}^{t}(d)} \times 100\%$

The average relative error percentage: $E_{PMR} = \frac{1}{288}\sum_{t=1}^{288}\frac{\left|\hat{q}_{pij}^{t}(d) - q_{pij}^{t}(d)\right|}{q_{pij}^{t}(d)} \times 100\%$

Rms relative error: $E_{RR} = \sqrt{\frac{1}{288}\sum_{t=1}^{288}\left(\frac{\hat{q}_{pij}^{t}(d) - q_{pij}^{t}(d)}{q_{pij}^{t}(d)}\right)^{2}}$

Equalization coefficients: $C_{E} = 1 - \frac{\sqrt{\sum_{t=1}^{288}\left(\hat{q}_{pij}^{t}(d) - q_{pij}^{t}(d)\right)^{2}}}{\sqrt{\sum_{t=1}^{288}\left(\hat{q}_{pij}^{t}(d)\right)^{2}} + \sqrt{\sum_{t=1}^{288}\left(q_{pij}^{t}(d)\right)^{2}}}$

This paper predicted the 10 days data separately to test the universality of the model and calculated the corresponding means of several error and equalization coefficients. This paper selected one-day data randomly from the test data of 10 days, found the following results:

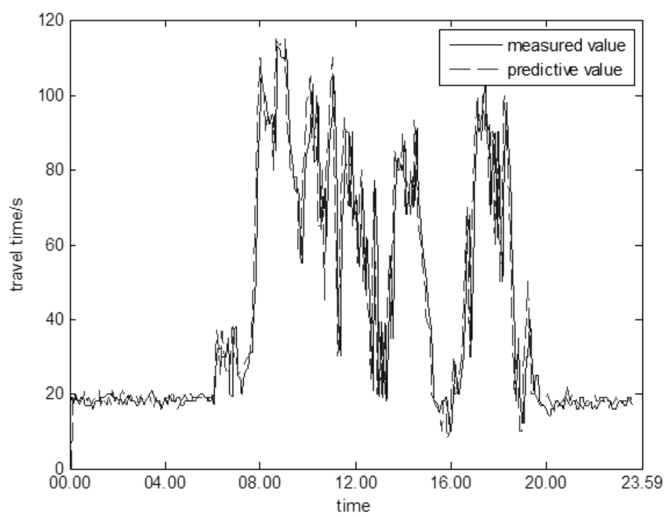

Figure 2. The predicted value and the actual value comparison

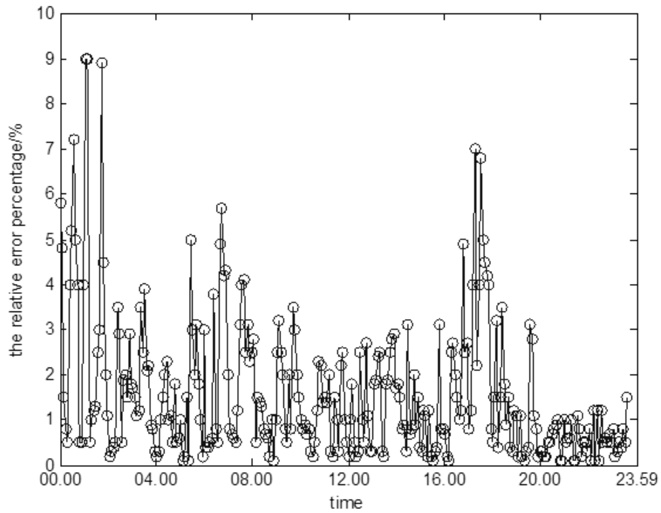

Figure 3. Relative error percentage of the prediction

5 Discussion of Results

According to the data analysis above, we found:

1. In the morning and evening peak hours, the prediction error is lager because of the greater volatility of travel time, and the error is relatively small other periods.

2. The E_{PMR} of the Kalman filter model is 5.54% in worst case, and 5.07% in average. The prediction accuracy is 1-5.07%=94.93%, and goodness of fit is 94.85% in worst case, which means it has high accuracy and good fitting results. According to Figure 1, the model has no time lag. Each average prediction index of 10 days is ideal, and not much different with the best and worst value, which means the stability and robustness is good and the model is universally applicable.

6 Conclusions

This paper selected Kalman filter method to predict, and the short-term travel time prediction model for car dynamic navigation system involves simple parameters, save the computing time and solve the time lag. The model can achieve the automatic update of the historical data, and have high accuracy and stability.

Travel Time Characteristics of Vehicles on Urban Arterial Roads Analysis Based on License Plate Data

Zhenguo Liu

China Academy of Transportation, No. 240, Huixinxijie St., Chaoyang District, Beijing 100029, China. E-mail: loe211@163.com

Abstract: As we are living in era of motorization, cities are expanding rapidly, the urban population has risen dramatically, more and more motor vehicles runs on the roads. The problem of urban transportation exacerbates. Intelligent transportation technology（ITS）is regarded as one of the best methods to solve the problem of urban traffic. A large number of traffic monitoring equipments have widely used as the development of intelligent transportation systems. With a large number of traffic monitoring system has been built, we can collect abundant operational data from the ITS systems. Mining and making good use of these data It becomes more and more important of mining and making good use of the data. License Plate Recognition (LPR) system is an important component of the intelligent transportation system. In the past, the License Plate Recognition system has been used in analysis of traffic peccancy and the tolling system. The data mining of the License Plate Recognition system is rarely been applied. The dissertation researches the theories and methods of how to analysis the time characteristics of urban vehicles based on License Plate Recognition data. With the help of real-time data which is got from license plate recognition technology of urban arterial road, we get the motor vehicle travel characteristics of vehicles by mining license plate data. In this paper, we did empirical research by using license plate data in Shenzhen. Time clustering method has been used to separate the vehicle travel behavior. By analyzing the trip frequency of the vehicles during the working day, we can extract the rigid vehicles and get travel time characteristics of vehicles on urban arterial road.
Keywords: License plate recognition; Data mining; Travel features; Vehicles.

1 Introduction

As we enter the era of motorization, intelligent transportation technology has been regarded as one of the best way to solve the problem of urban traffic. As a large number of traffic monitoring system has been built, we can collect abundance operational data from the ITS systems. Mining and making good use of these data becomes more and more important. License Plate Recognition (LPR) system is an important component of the intelligent transportation system. The data mining of the License Plate Recognition system is rarely been applied. The dissertation researches the theories and methods of how to analysis the time characteristics of urban vehicles based on License Plate Recognition data. With the help of real-time data which is got from license plate recognition technology of urban arterial road, we get the motor vehicle travel characteristics of vehicles by mining license plate data.

2 License Plate Data Overview

2.1 Features of License Plate Data

License plate number is the only tag of vehicle identity. License Plate Recognition system has become an important part of intelligent transportation management system. By using pattern recognition method for camera equipment to analyze the captured vehicle image, we get effective recognition of license plates number. Then the system can transmit data to the central processing system. The analysis of License plate recognition data is different from other data. Monitoring equipments are laid on important sections in urban arterial roads. Due to limitations of the distribution of the monitoring equipments in the city, we can only get the data from the arterial roads.

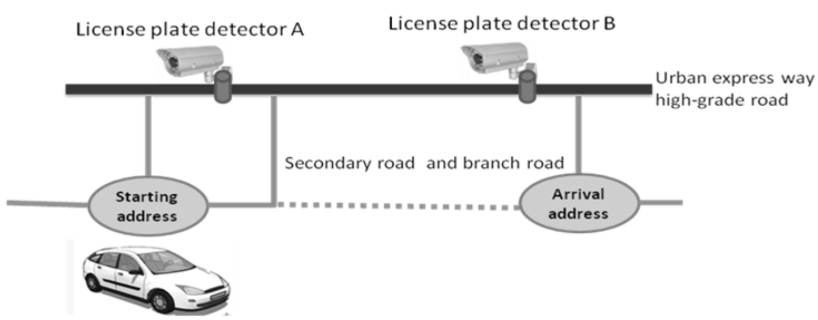

Figure 1.The position license plate detection equipment

2.2 Overview of original raw data

(1) Original data collection

We selected data from April 1 to April 30 in Shenzhen as the study time frame. The data time span is one month, which includes 22 Weekdays. Time monitoring of all road license from 00:00:00 AM to 23:59:59.PM

(2) Scale of the data

The total size of analyzed data is determined by road traffic flow and the number of monitoring equipment emplaced locations. The number of data records per day is from 2.7 to 3.6 million.

(3) The field format of original data

The original data contains multiple fields, The fields include: license plate number (PLATENO), the monitoring point number (JCDID), road lane number (LANEID), the vehicle through time (PASSTIME), license type (TYPE), square-wave length (FBCD).

Table 1. License plate recognition data format

Field	Examples	Explanation
PLATENO	YUE BN813A	License plate number
JCDID	10200402	Monitoring device number（Unique ID）
LANEID	1	road lane number
PASSTIME	2009-04-06 08：15：20	the vehicle through time
TYPE	0	Types of vehicles
FBCD	360	square-wave length

3 The vehicle travel frequency analysis

We analyzed the collected data from April 6 to April 10，and we get the frequency distribution of vehicles. 816,825 vehicles with a number of 16,842,872 records are detected in the 5 weekdays. For convenience of description, we introduce a concept called WTF（Weekday Travel Frequency）,which is the number of vehicles traveling days in weekdays from Monday to Friday. We have also introduced the concept of vehicle travel intensity in weekdays.

Vehicle weekday travel intensity = Number of vehicles*Weekday Travel Frequency.

The number of days of vehicle is recorded in the week days is 1-5, Therefore, the working frequency of vehicle trips (WTF) is 1-5. By statistical analysis of all the vehicles WTF from April 6 to April 10, we get the distribution of all vehicles in working days. The following table shows all vehicles travel distribution in Weekdays.

Table 2. Weekdays trip of all vehicle distribution

Weekday Travel Frequency (WTF)	Number of vehicles	Proportion of the number of vehicles	Vehicle weekday travel intensity	Proportion of Vehicle weekday travel intensity
1	1024824	56.41%	1024824	27.26%
2	242154	13.33%	484308	12.88%
3	162068	8.92%	486204	12.93%
4	174710	9.62%	698840	18.59%
5	213069	11.73%	1065345	28.34%
Total	1816825			

As shown in the table, 56.41% vehicles WTF are 1, which accounted for 27.26% of the total trip intensity; 9.62% vehicles WTF are 4, which accounted for

18.59% of the total trip intensity; 11.73% vehicles WTF are 5,which accounted for 28.34% of the total trip intensity.

Therefore, though the number of vehicles whose WTF are low is large, but the trip intensity is in the relatively low proportion. So it is necessary to carry out statistics of the vehicle trip frequency every workday, in order to analysis the traffic proportion of different types of vehicles WTF within a day. The results are shown in the columnar section as follows.

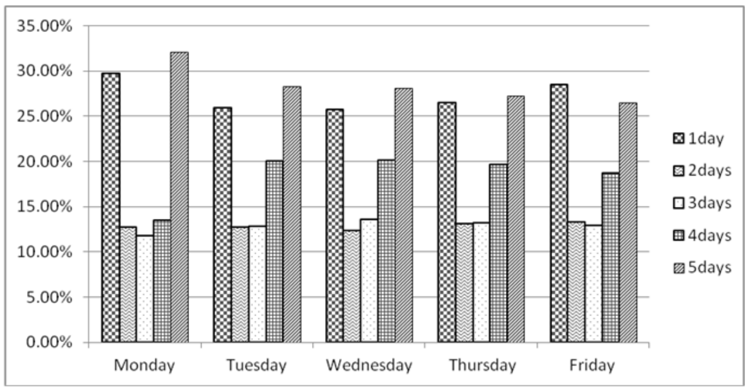

Figure 2.The proportion of vehicles with different WTF.

It is evident from figure that, the proportion of two kinds of vehicles（WTF=1 and WTF>=4） is larger. The left vehicles（WTF=2 and WTF=3）is in low proportion. This shows that the urban road network traffic flow is mainly composed of two types of vehicles in working days. One type of vehicles travel almost every day in workdays, which accounts for nearly 50% of the total traffic; Another type of vehicles are almost rarely seen in workdays, which accounts for 30% ~ 40% of the total traffic. First part of the vehicles represent "rigid" travel, analysis of travel characteristics and time-space distribution of this part of the vehicles is the key to solve the problem of urban traffic.

From the previous analysis, a large proportion of traffic flow on city road is normal travel vehicles, namely the vehicles on behalf of the is a kind of regularity travel behavior. Regularly vehicles travel in time, generally associated with commuter travel. The rigid travel which is composed of commuter travel, is the important cause leading to the urban road traffic congestion. But rigid travel is also a guarantee for normal operation of the urban social economic activities, The urban traffic system must first meet the needs of rigid travel, and also can solve the problem of urban traffic congestion.

4 vehicle travel time cluster analysis

4.1 License plate data clustering analysis method

Time consumption of single trip in cities might be within a certain range under normal circumstances. Therefore, the vehicle data will show strong time clustering features. The data whose time interval between each other is relatively small is considered to be one group. Thus, the time interval of two data are smaller recognized as a trip. In this way, we can put the data chronologically divided into several groups, each group represents a trip. For example, we get the vehicle license plate named "Guangdong BTG408" "9:36" to "21:36" 12 times at April 6 the detection recording time distribution. As shown below, we can see that the detection time has obvious clustering properties. It is apparent from the figure, the day time data clustering can be divided into five groups, that is, by separating the car license plate data we get 5 trips.

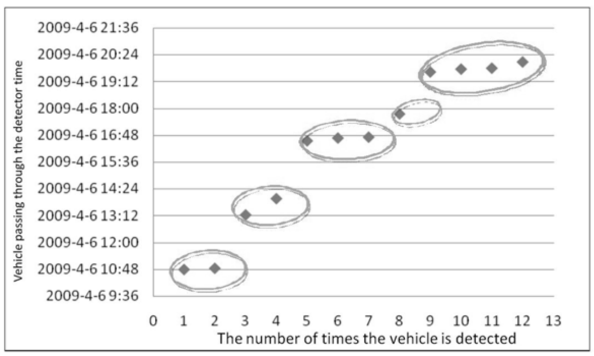

Figure 3.Time clustering analysis of vehicle license plate data

Before clustering analysis is necessary to determine the minimum threshold detection recording interval (T_{min}). If the time interval is less than the threshold T_{min}, we put the data into one group. The choice of time interval threshold value is very important, too large or too small will result in a determine error. If T_{min} value is too large, we may put different travel data recorded as a group. If Tmin value is too small, we may divide one group of travel data into two groups .Calculation procedure of time clustering method to extract vehicle travel behavior is as follows:

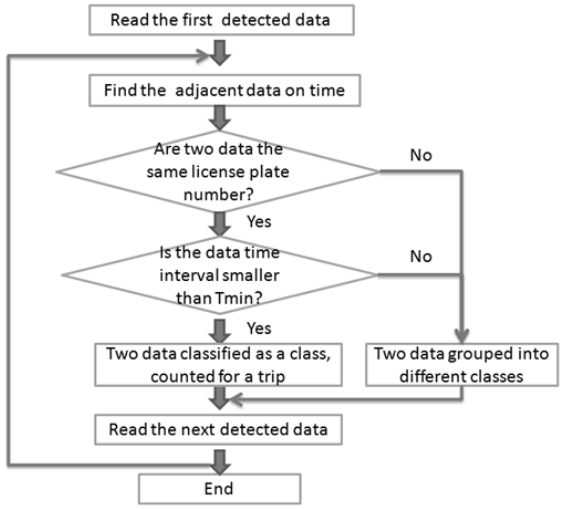

Figure 4. Analysis of motor vehicle travel time clustering process

4.2 Empirical Analysis of Shenzhen

We selected the license plate data on April 7 (weekdays) and April 12 (weekend), then analyzed the time distribution of the vehicles. We can see that:

(1) The rigid trip vehicles in the morning peak periods slightly higher than the proportion of the overall level; Shows rigidity travel is more concentrated in the morning rush hour. The morning rush hour is later than our everyday perception, it may be because the data collection points are located on high level roads.

(3) It is worth noting that the number of vehicles detected is small, peak-hour factor is only 8% to 9%. Travel characteristics described in this way may not fully reflect inhabitants.travel survey characteristics This phenomenon is partly due to travel license plate detection error data; on the other hand may also not part of the rigid commuter travel-related travel.

(4) The rigid travel feature is significant different in weekdays and weekend. There are two travel time peaks in the morning and evening on weekdays, the traffic distributed more evenly 8:00 to 18:00 on weekends

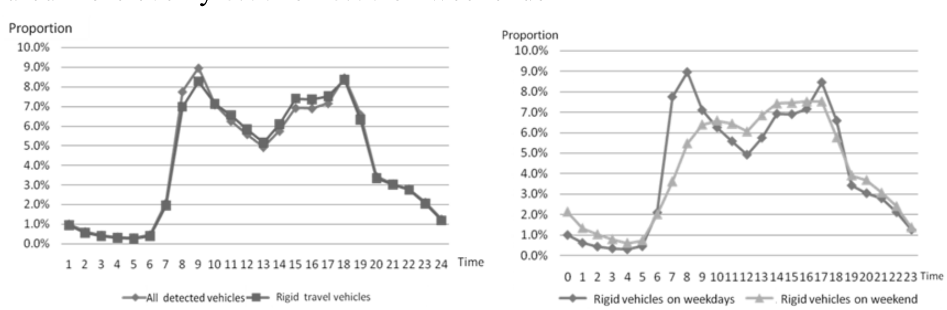

Figure 5.Time characteristics of rigid travel vehicles

5 Conclusions

Based on the Shenzhen vehicle license plate data analysis, we found the urban traffic flow is composed of two types of vehicles on weekdays-- rigid trip vehicles and occasional trip vehicles. And we proposed time clustering method to separate the travel behavior of each trip. And data in Shenzhen has been verified, you can run out of the rigid rules of the vehicle traveling on the arterial roads. We use Shenzhen data verify this method, so we can get the operation characteristics of the rigid vehicles on the arterial roads.

Abstract: The paper establishes the speed guidance model of urban expressway based on meso-simulation traffic flow model, which can provide the role of speed control and short-term traffic prediction according to the real-time severe weather. And the model regards gross vehicle travel time as the objective function and the weather condition as influence factors to optimize the design of model and be implemented by C++. Then, it simulates and analyses the results based on the east line of the southern section of Shanghai North-South Elevated road. Simulation result shows that both speed variance and speed mean square error decrease remarkably. The speed guidance control reduces the overall difference of speed of the traffic flow that can improve traffic safety and the model is effective.
Keywords: Meso-simulation model; Severe weather; Speed guidance model; Zone algorithm; Urban expressway.

1. Introduction

With the increase of the vehicle, the operating efficiency of urban expressway is decreasing and it causes the growing problems of traffic jam and safety, especially, under adverse weather conditions (MA Jian, 2011). In order to better ensure the unobstructed traffic and traffic safety, the speed guidance is the most widely used method in recent years (Wang W., 2008). The primary factors affecting traffic safety are mainly wind, rain, fog, snow, and high and low temperature (Berhanu, G., 2000). Statistical data shows, with the gradual increase of adverse climatic conditions, the share of traffic accidents occur under adverse weather conditions is increasing. Traffic accidents on roads in China, 50% occurred under poor weather conditions. And 71% of major accidents and 65% of the direct economic losses occurred under adverse climatic conditions (Ministry of Transport, 2006). Traffic safety enhancement and traffic accident prevention have become essential under adverse weather conditions.

Speed guidance is a rational way and effective means to solve this problem. The paper establishes the speed guidance model of urban expressway based on meso-simulation traffic flow model, which can provide the role of speed control and short-term traffic prediction according to the real-time severe weather. Furthermore, it simulates and analyses the results based on the east line of the southern section of Shanghai North-South Elevated road. Simulation results demonstrate the validity and practicality of the model.

2. Meso-traffic simulation model of considering the compression and viscous properties

Figure 1 describes a kind of traffic state in the car-following scenario. $x_n(t)$ is the position of vehicle n at t. $x_{n+1}(t)$ is the position of vehicle $n+1$ at t. $s(t)$ is the time spacing between the front of the vehicle at t. T_r is the relaxation time. d_1 is the driving distance of vehicle $n+1$ within T_r. d_2 is the braking distance of vehicle $n+1$. d_3 is the braking distance of vehicle n. L is the safe distance of stopping.

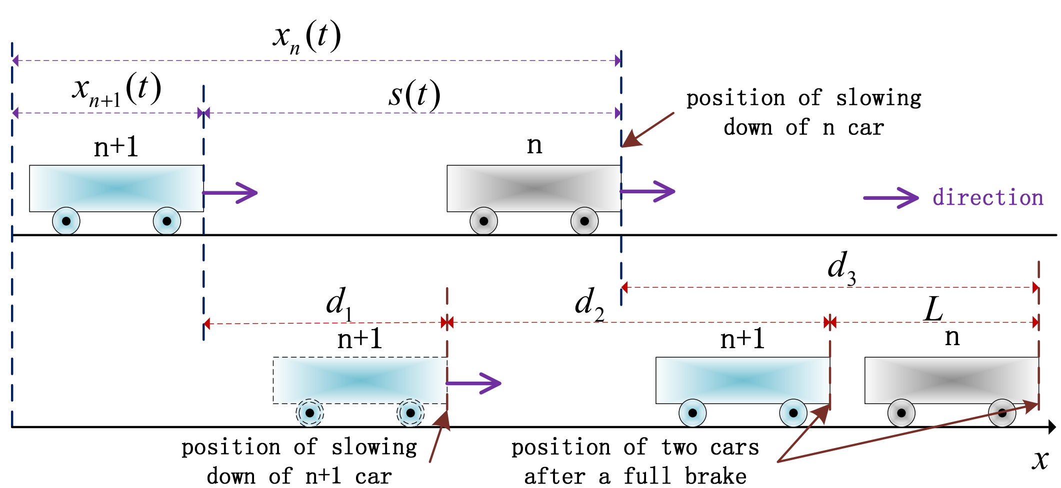

Figure 1. Comparisons of average speed

The paper builds the macro-traffic simulation model considered the properties of traffic compression and viscous based on the car-following model. The macro-model is represented as shown below.

$$\frac{du(x,t)}{dt}=\frac{\partial u}{\partial t}+u\frac{\partial u}{\partial x}=\frac{u_e(k)-u(x,t)}{T_r}+\frac{\Delta x}{\tau}\frac{\partial u}{\partial x}-W \tag{1}$$

$$\frac{\Delta x}{\tau}=-ku_e'(k)\equiv a(k)>0 \tag{2}$$

$$W=(\delta_{w1}+\delta_{w2}) \tag{3}$$

$$\delta_{w1}=\mu\cdot k\cdot\Delta u\cdot u\cdot S_z/S_j \tag{4}$$

$$\delta_{w2}=\alpha\cdot k\cdot\Delta u\cdot u\cdot S_z/S_j \tag{5}$$

$$\Delta u=u_i-u_{i+1}\begin{cases}\Delta u & \Delta u>0\\ 0 & \Delta u=0\text{或}\Delta u=\varepsilon\\ 0 & u<0\end{cases} \tag{6}$$

$$\frac{\partial k}{\partial t}+\frac{\partial q}{\partial x}=g(x,t) \tag{7}$$

Wherein k is traffic density, q is traffic flow, u is velocity, x and t represent space and time respectively. $g(x,t)$ represents traffic flow when vehicles in and out of the roads researched, known as source sink term, if there is no vehicle in and out of the road, set to zero. $\frac{\Delta x}{\tau}$ is the speed of sound. W is the transport characteristics item. δ_{w1} is the transport viscosity characteristics item. δ_{w2} is the transport compression characteristics item. τ is the required time of the disturbance propagating backward Δx distance. α is the compression coefficient. μ is the viscosity coefficient, the unit is $m/(veh\cdot s)$. S_z is the braking distance, the unit is m. S_j is the viewing distance, the unit is m.

The meso-traffic simulation model derives from the macro-traffic simulation model based on the analysis of traffic compression and viscous properties(MA Jian,2013). Based on the above macro-model, the paper establishes the meso-traffic simulation model. Figure 2 is the schematic diagram of general grid partition for the simulation scenario.

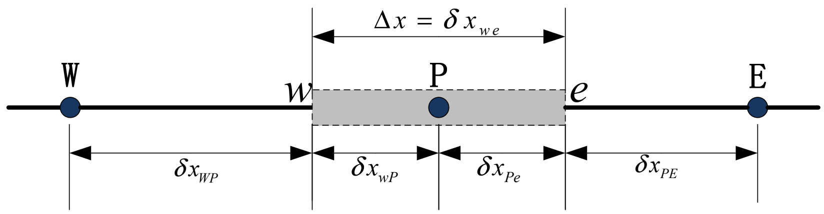

Figure 2. Schematic Diagram of General Grid Partition for The Simulation Scenario

For a one-dimensional control volume, in the time interval from t to $(t+\Delta t)$, the integral volume control equation:

$$\int_{t}^{t+\Delta t}\int_{\Delta v}\frac{\partial k}{\partial t}dvdt+\int_{t}^{t+\Delta t}\int_{\Delta v}\frac{\partial q}{\partial x}dvdt=\int_{t}^{t+\Delta t}\int_{\Delta v}g(x,t)dvdt \tag{8}$$

$$\int_{t}^{t+\Delta t}\int_{\Delta v}\frac{\partial u}{\partial t}dvdt+\int_{t}^{t+\Delta t}\int_{\Delta v}u\frac{\partial u}{\partial x}dvdt=\int_{t}^{t+\Delta t}\int_{\Delta v}F(k,u)\frac{\partial u}{\partial x}dvdt+\int_{t}^{t+\Delta t}\int_{\Delta v}\frac{u_e-u}{T_r}dvdt+\int_{t}^{t+\Delta t}\int_{\Delta v}G(k,u)dvdt \tag{9}$$

The followings can be gotten according to the Gauss–Ostrogradsky theorem.

$$\int_{\Delta v}\left(\int_{t}^{t+\Delta t}\frac{\partial k}{\partial t}dt\right)dv+\int_{t}^{t+\Delta t}[(Aq)_e-(Aq)_w]dt=\int_{t}^{t+\Delta t}\bar{g}(x,t)\Delta vdt \tag{10}$$

$$\begin{aligned}&\int_{\Delta v}\left(\int_{t}^{t+\Delta t}\frac{\partial u}{\partial t}dt\right)dv+\int_{t}^{t+\Delta t}a[(Au)_e-(Au)_w]dt=\int_{t}^{t+\Delta t}F(k,u)[(Au)_e-(Au)_w]dt\\&+\int_{t}^{t+\Delta t}\int_{\Delta v}\frac{u_e-u}{T_r}dvdt+\int_{t}^{t+\Delta t}\int_{\Delta v}G(k,u)dvdt\end{aligned} \tag{11}$$

Wherein A is control volume surface area, in one dimension, A=1; Δv is control volume, $\Delta v = A \cdot \Delta x$,where Δx is control the length of volume Δx_{we} ; $\overline{g}(x,t)$ is the average intensity of the source term.

3. Optimal design of control parameters under severe weather

According to the figure 1, the paper optimizes the design of control parameters of the traffic simulation model under severe weather(Samba, D.,2010, Watkins, K. E.,2010).. The following is parameters expressions.

$$d_1 + d_2 \le x_n(t) + d_3 \tag{12}$$

$$d_1 = v_{n+1} \cdot t \tag{13}$$

$$d_2 = v_{n+1}^2 \big/ [254(f - i)] \tag{14}$$

$$d_3 = (t_1 + t_2)v_n \big/ 3.6 \tag{15}$$

Wherein v_n is the velocity of vehicle n. v_{n+1} is the velocity of vehicle $n+1$. t is the braking reaction time of the driver of the vehicle $n+1$. f is the road adhesion coefficient. i is the gradient of the road. t_2 is the braking time of the rear vehicle $n+1$.

4. Speed Guidance Control Model

According to meso-simulation model of short-term traffic flow prediction of Urban Expressway and dynamic control of speed guidance, total vehicle travel time is as the objective function Z, thus:

$$Z = T\sum_{k=1}^{M_1}[\sum_{i=1}^{M_2}\rho_i(k)L_i\lambda_i] \tag{16}$$

Where, i is section number(1, ……, M_2); k is data collection interval number(1, ……, M_1); M_2 is maximum link number of sections; M_1 is maximum data collection time interval number; T is data collection cycle; L_i is the length of section i; λ_i is lane number of cellular road i; $\rho_i(k)$ is the density of the road section i at time k.

5. Case study

5.1 Simulation Scenarios

This paper chooses the east line of the southern section of Shanghai North-South Elevated road as the research object. This section is 8.45 km in length, with a total of 10 entrance ramps and 11 exit ramps. Actual testing data adopt the September 22, 2009 detector data, with the sampling frequency of 60 seconds.

The main parameters of the model are set as follows:

Ramp parameters:

$Q_0 = 2100veh/h$, $k_{\max} = 140veh/km/lane$, $k_{critical,u} = 40veh/km/lane$;

Mainline parameters: $\Delta t = 60s$, $k_{u,1} = 33.5veh/km/lane$, $u_{free} = 80km/h$, $u_{critical,i} = 45km/h$;

Viscous and compression parameters: $\alpha = 0.5$, $\mu = 0.5$, $S_z = 100m$, $S_j = 1000m$;

Weather influencing parameters $t = 0.3s$, $f = 0.45$, $i = 0.005$, $t_2 = 2s$;

Initial value of the total flow of the section ramp entrance: $Q_{in} = 585veh$;

Probability of section ramp export flow:

$$P_{out,i} = \{0,0,0.2,0,0.15,0,\{0.3,0.35\},0,0.2,0,0,\{0.5,0.4\},0.2,0,\{0.2,0.7,0.1\}\},$$

$$\rho_0(i) = \begin{cases} 0.025 & 1 \le i \le 5 \\ 0.02 & 6 \le i \le 10 \\ 0.018 & 11 \le i \le 15 \end{cases} ; \text{ Unit: } veh/m;$$

T is 300 simulation steps, the section length is 8.45km. Evaluation indexes include Variance and Mean Square Error.

5.2 Analysis of Simulation Results

Figure 3 is average speed comparison diagram under the conditions of no control and speed guidance on urban expressway. As we can see from this figure, in most of the sections, the average speed of the traffic flow in the situation of speed guidance are higher than the situation without control. At the same time, speed changes in the situation of speed guidance are smoother than that in the situation without control.

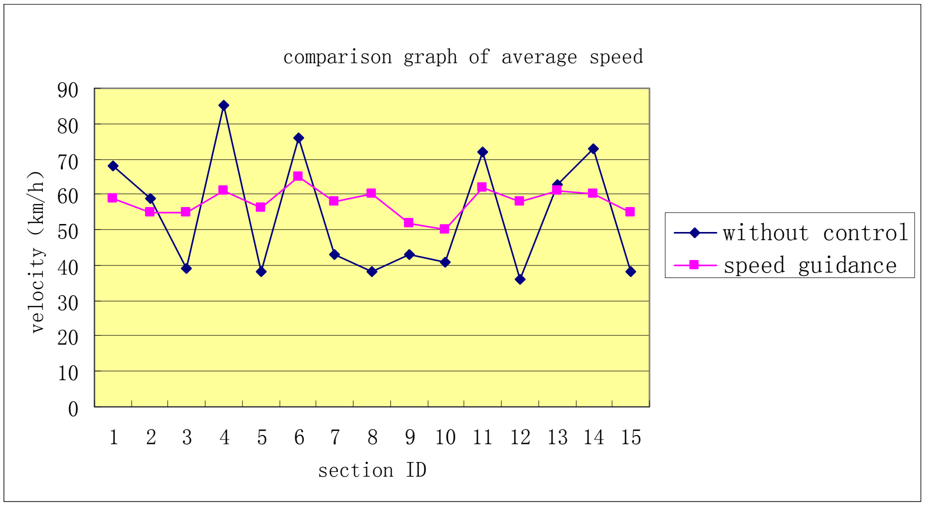

Figure 3. Comparison diagram of average speed

Table 1 is the comparison of speed variance and mean square error of all sections under different control conditions. As we can see in the table 1, after the implementation of speed guidance control, speed variance dropped from 297.12 (km/h) 2 to 15.89 (km/h) 2, the speed mean square error dropped from 17.24 (km/h) to 3.99 (km/h). It suggests that, compared with no control, speed guidance control has reduced the total speed difference of traffic flow and improved the traffic safety in the research sections.

Table 1. Comparison of speed variance and mean square error of all sections under different control conditions.

Items	Value
Speed variance of all sections without control $(km/h)^2$	297.12
Speed variance of all sections with guidance $(km/h)^2$	15.89
Mean square error of all sections without control (km/h)	17.24
Mean square error of all sections with guidance (km/h)	3.99

6. Conclusions

The paper presents a speed guidance control in urban expressway under adverse weather conditions. A meso-simulation traffic flow model of considering the compression and viscous properties is established on that basis. The simulation research and comparing analysis of the east line of the southern section of Shanghai North-South Elevated road shows that compared with no control situation, speed guidance control has reduced the overall speed difference of traffic flow and improved the traffic safety.

Abstract: The study of online diagnosis based on testability models has been greatly concerned, due to the advantages of generality, real-time performance, intuitive modeling and high efficiency. The paper presents a technique of the vehicle's online diagnosis based on testability models. Firstly, a basic algorithm is proposed, and a universal machine is designed for real-time performance. To fulfill the demands of online application, a reasoning prototype is developed with the embedded platform of VxWorks. The experimental results prove the performance and effectiveness of the universal real-time reasoning machine. Such a technique of online diagnosis can be applied to other equipments of traffic and transportation.
Keywords: Testability; Online diagnosis; Reasoning machine; VxWorks.

1 Introduction

This paper analyzes the issue of online diagnosis, which is of great significance for a vehicle's long-term operation. Currently, the strategies of fault diagnosis can be categorized as the sequential and the concurrent (Yan, 2012).

The sequential diagnostic method is to perform the process of fault isolation in a certain order. In essence, that is to execute a test, determine the system's status, and guide people to the next test of the most meaningful. The method mainly focused on how to generate or optimize the diagnostic rules in the last decade, and solved a lot of theoretical and practical problems (Pattipati, 1990; Tu. 2003; Yang, 2008; Zhang, 2013). The sequential diagnostic method is most suitable for a deep diagnosis in an offline way, taking the case of maintenance operations. Under that circumstance, a clear diagnosis timeliness requirement is usually not necessary. Thus, real-time embedded sensors and testing informations should be considered.

Concurrent diagnosis refers to a one-off reasoning of the health status from all the acquired testing data. Usually, an alarm is triggered with the help of real-time monitoring of operating parameters when an exception occurs. The possible drawn exception sites can be located to provide reference informations for reconfiguration of the system. A real-time diagnosis method can quickly detect the presence of failure, reducing "can-not reproduce" problems (Deb, 2000). That is significant for online applications demanding for high safety, for example, a complex vehicle, which involves multi-energy domains, multi-system couplings, special environments, and possible catastrophic consequences after a failure (Kurtoglu, 2008).

Usually, the online diagnostic systems can be constructed in different ways, such as model-based, data-driven or rule-guided, to achieve real-time performances. With the increasing complexity of modern vehicles, the diagnostic technique which is based on testability model has become widely accepted. The method will make full use of design information of testability, optimize and re-allocate measuring points. That will greatly improve the fault coverage at the vehicle design stage, and also the effectiveness of fault diagnosis. What’s more, the model is relatively standard and unified, which will help to improve the versatility of fault diagnostic systems.

Currently, one of the most widely marketed real-time reasoning toolkit is QSI TEAMS-RT, which provides an excellent diagnostic machine based on testability modeling way of multi-signal flow graph (Mathur, 1998). TEAMS-RT is part of the famous TEAMS tools, which has a long-term history of development (Deb, 1997). However, it’s not open-source and restricts to its specific model file format, which indeed greatly limits the possible domestic applications with different embedded platforms, especially for special fields of vehicle. Thus, there exists urgent demands for developing high-performance reasoning machine with independent intellectual copyrights. This paper is intended to investigate a universal method and application of real-time diagnostic embedded system based on testability models, including the design of reasoning algorithm, the development of embedded diagnostic machine under VxWorks platform. Finally, the software/hardware architecture and operation performance is analyzed, outlining its possible prospects.

2 Algorithm

The diagnostic process is to analyze any defective states of the vehicle, based on the test results obtained and pre-implanted testability models from the interface files. An online diagnostic system is used to monitor the normal process, and ensure the critical safety of operation. Thus, there exists a great demand for real-time reasoning algorithm with high performance, especially for a large-scale system. The diagnostic results are also expected with accuracy.

As we all know, sets operations in Mathematics have a great efficiency by way of Boolean calculation basics. Accordingly, the development of a real-time reasoning machine can be achieved by way of set operations to improve the execution speed by computers. The basic algorithm is as follows:

Algorithm Input: (1) Normal and abnormal testing data, processed as 0/1
(2) Testability model interface file (correlation matrix)

Algorithm output: Normal, faulty, suspicious and unknown sets,

(Note: each module will be classified into one set.)

Algorithmic process:

Step one: all modules are marketed suspicious objects;

Step two: process the normal tests (binary 0);

Find out all the associated modules in the correlation matrix from the testability model, and mark them as normal, and update the different sets.

Step three: similarly, process the abnormal tests (binary 1);

Removed the normal modules from the abnormal sets, which is associated with the abnormal tests in the correlation matrix. If the remaining number of modules is only 1, mark it into the faulty set. Otherwise, keep it unchanged.

3 Real-time Diagnostic System under VxWorks

The VxWorks operating system is owned by Wind River System (WRS) of USA. The company designed VxWorks in 1983. It can be greatly customized according to the vehicle, and has a strong real-time performance on the target. The advantages include the sustainable development, efficient kernel and user-friendly environment. Currently, it is widely used in the fields with real-time requirements, i.e. aviation, aerospace, communications and other sophisticated circumstances (Liu. 2009).

A prototype is developed to demonstrate the online diagnostic application, and verify the real-time performance. The reasoning machine is developed with VxWorks, the popular embedded platform. The system configuration is shown in Figure 1.

The target VxWorks platform parameters are: 500MHz, PPC7410CPU, 512MB RAM. Experimental results show that the diagnostic results from the reasoning machine are consistent with the expected by simulation. The prototype machine has a high precision, giving that the reasoning time is proportional to the system size (the correlation matrix of the number of elements). For example, an analysis with a 1000 × 1000 system (i.e. 1000 failure modes and 1000 tests) is presented in Table 1. The parameter of matrix density describes the proportion of 1-element in the correlation matrix, and a larger density usually means a higher cost of mathematic calculations.

As is shown, the performance of the prototype is quite excellent. Diagnostic results are always proved correct by simulation, under the conditions of a single fault and multiple faults. The reasoning speed is very fast, and the time costs are obviously scoped in the scale of "hundred" milliseconds. The performance is no less than that of QSI TEAMS-RT (Mathur. 1998). Even for the worst case that most of the testing data are abnormal (for example, matrix density of 30%, 10 faults implanted), the reasoning speed is still quite fast. It's believed to be suitable for online diagnosis of the large-scale systems.

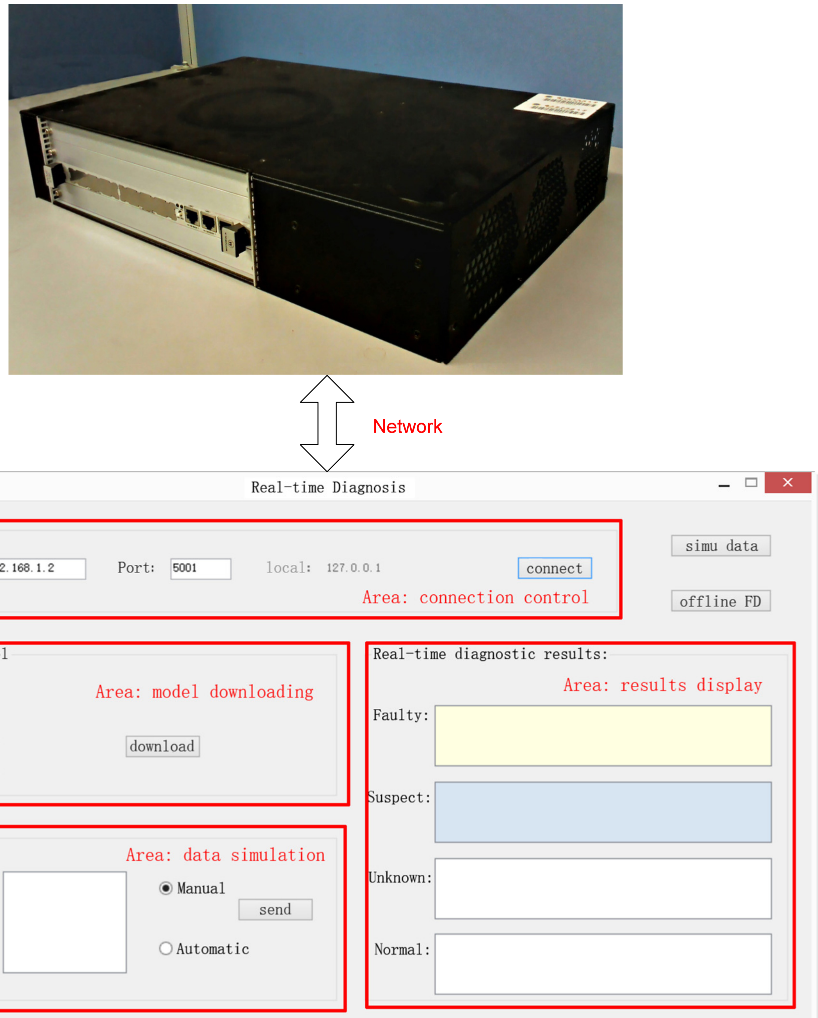

Figure 1.VxWorks target server and PC client

Table 1. Prototype performance of 1000 × 1000 system

Matrix density	Number of faults	Number of passed tests	Faulty modules (reasoning)	Suspect modules (reasoning)	Fault identify rate	Time cost (ms)
1%	1	991	1	0	100%	85
	2	979	2	0	100%	87
	5	955	5	0	100%	89
	10	914	10	0	100%	92
10%	1	898	1	0	100%	88
	2	807	2	0	100%	98

	5	606	5	0	100%	124
	10	369	10	0	100%	164
20%	1	803	1	0	100%	97
	2	635	2	0	100%	115
	5	326	5	0	100%	167
	10	104	10	0	100%	229
30%	1	705	1	0	100%	104
	2	514	2	0	100%	131
	5	183	5	0	100%	204
	10	42	10	0	100%	262

4 Conclusions

Real-time diagnosis is significant to ensure safe operation of the vehicle. This paper presents an online fault diagnosis method based on testability model, and also a systemic description of the prototype. Basic steps of the reasoning algorithm are discussed. The general architecture of the reasoning diagnostic system is summarized. A VxWorks target machine is developed and analyzed in detail by way of simulation. The performance, effectiveness and efficiency are finally proved by the experimental results. Such a diagnostic system is applicable to different traffic and transportation equipments, for example, power devices, satellites, aircrafts, vehicles, and so on. A further research on robust real-time algorithms and more applications of such an online diagnosis technique will be expected.

Abstract: The objective of this paper is to develop a new computational method of friction power loss of the spiral bevel gears transmission system of the helicopter tail reducer. At first, the velocity and force of the meshing point were analyzed during meshing process. Then a computational model of friction power loss for spiral bevel gear was established based on the principle of meshing and tribology theory, considering the effects of actual contact ratio and time-variant factors. This model considered the effects of actual contact ratio and time-variant factors including mesh point relative sliding velocity of mesh point, normal load, friction coefficient, etc.
Keywords: Computational method; Friction power loss; Spiral bevel gears.

1 Introduction

The spiral bevel gears transmission system is the key part of the helicopter tail reducer. In its operation process, the heat generated by the gear and bearing friction deforms the parts of the transmission due to its temperature rise, which will decrease the transmission performance. Especially in the case of insufficient lubrication and cooling, the great amount of frictional heat easily cause the serious failure phenomena such as teeth bonding, bearing raceway burns, cage fall even gear stuck and bearing axle etc. Thus, the computational methods of friction power loss and temperature field distribution of spiral bevel gears transmission system are very important for thermal characteristics analysis and lubrication design.

The computational method of gear friction power loss are the testing method, the look-up table method and the direct computational method (Diab, 2006). The test method is long and costly, and the look-up table method is estimated from the mechanical manual but not universal. In the direct computational method, the gear friction power loss model is established, and the result is more reasonable. In recent years, many authors have been used the direct computational method to analyze different cases of the gear friction power loss (Handschuh, 1996). Su H (Su, 2000) analyzed the speed and force of the meshing point and has obtained the friction power loss based on gear meshing and contact analysis theory. However, the meshing point velocity and loadings are very difficult to determine due to the complex nature geometry of the spiral bevel gear tooth surface and the method is complicated to compute. Yu D J (Yu, 2005) used Anderson-Loewenthal equation (Anderson, 1981) of spur gear power loss model to simplify the model, and calculated the spiral bevel gear friction power loss. But its method did not consider the relative sliding velocity, normal load, friction coefficient of meshing points, which varied with the meshing position. Besides, only 1/4 length of the meshing line of the frictional meshing points was taken as the average gear friction power loss and the computational results were not accuracy.

In view of the above problems, the objective of this paper was to develop a new computational method of the temperature field of the spiral bevel gears transmission system of the helicopter tail reducer in the normal lubrication. In the first part of this paper, the velocity and force of meshing point are analyzed based on meshing theory. Then, a computational model of friction power loss will be established based on gear meshing and tribology theory. This model considered the effects of actual contact ratio and time-variant factors including mesh point relative sliding velocity of mesh point, normal load, friction coefficient, etc.

2 Velocity and force analysis of meshing point

2.1 Equivalent theory of spiral bevel gear

The relative sliding velocity of mesh point, normal load and friction coefficient are three important factors during meshing of the spiral bevel gears. In this part, the velocity and force of meshing point are firstly analyzed based on equivalent spur gear meshing theory. Effects of instantaneous sliding friction is then deeply investigated under different lubrication conditions.

The space meshing theory of the spiral bevel gear is complicated, so the friction power loss is difficult to be directly calculated. If the spiral bevel gear was equivalent to the equivalent spur gear on the promise of the constant velocity and normal load of the equivalent gear midpoint, the problem could be simplified(Zeng, 1989), as shown in Fig.1. In that case, the spiral bevel gear is firstly transferred to the equivalent spur gear, and the structural parameters are shown in Tab.1.

2.2 Meshing velocity analysis

The velocity and force of the meshing point were then analyzed based on meshing theory. Fig.2 shows the velocity analysis of the spur gear meshing point, in which P is pitch point, C is transient meshing point, r_1 and r_2 are pitch radius of driving and driven gear, r_{a1} and r_{a2} are outside radius, N_1N_2 is meshing line in theory, r is the distance from axle center O_1 to meshing point C, α is the pressure angle of pitch circle, α_c is the pressure angle of meshing point C, T is input torque, ω_1 and ω_2 is the angular velocity of driving and driven gear, B_1 is the initial meshing point , B_2 is the end meshing point, and B_1B_2 is the actual meshing line(Yang, 1999).

Table 1. Structural parameters of spiral bevel gear and its equivalent spurgear

Gear type	pitch cone angle		number of teeth		pitch cone distance midpoint	spiral angle	pitch radius	
	driving gear	driven gear	driving gear	driven gear			driving gear	driven gear
Spiral bevel gear	δ_1	δ_2	z_1	z_2	R	β	——	——
Equivalent spur gear	——	——	$\frac{z_1}{\cos\delta_1 \cos^3\beta}$	$\frac{z_2}{\cos\delta_2 \cos^3\beta}$	——	——	$\frac{R\tan\delta_1}{\cos^2\beta}$	$\frac{R\tan\delta_2}{\cos^2\beta}$

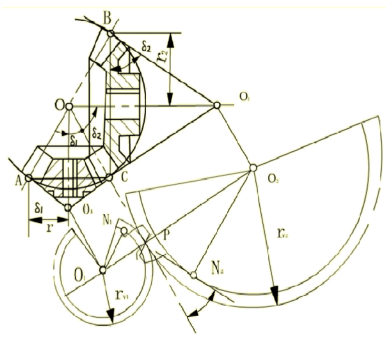

Figure.1 Equivalent spur gear theory

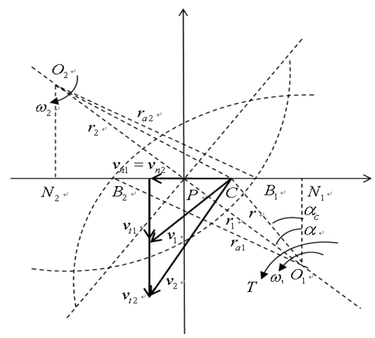

Figure. 2 Velocity analysis on meshing point

The velocity of meshing point C following the driving gear is separated to normal and tangential velocity, and the tangential velocity $\vec{v}_{t1}$ can be expressed as:

$$\vec{v}_{t1} = \vec{v}_1 \sin\alpha_c = r\omega_1 \sin\alpha_c = |N_1C|\omega_1 \tag{1}$$

Similarly, the tangential velocity of driven gear $\vec{v}_{t2}$ can be expressed as:

$$\vec{v}_{t2} = |N_2C|\omega_2 \tag{2}$$

In that case, the relative sliding velocity is deduced as follows:

$$v_s = |\vec{v}_{t1} - \vec{v}_{t2}| \tag{3}$$

And the entrainment velocity is expressed as:

$$v_t = \frac{|\vec{v}_{t1} + \vec{v}_{t2}|}{2} \tag{4}$$

2.3 Force analysis of meshing point

The spiral bevel gear is a certain approximate to its equivalent gear in movement, but the meshing force of the two cannot be equivalent. To assure the accuracy of the friction power loss in computational model, the normal force of the tooth breadth midpoint of spiral bevel gear must be equal to the equivalent spur gear. The force equations on the reference circle of the tooth breadth midpoint of spiral bevel gear are shown in reference (Zeng, 1989).

The normal force of gears is determined on basis of the force principle of the equivalent spur gear meshing point and force computational equations in Table.2, and the normal force F_n is defined as:

$$F_n = \frac{F_t}{\cos\alpha_c} \tag{5}$$

where $F_t = \frac{T}{r}$, $r = \frac{r_1 \cos\alpha}{\cos\alpha_c}$.The reference pitch p_b and overlap ratio ε_α of spur gear are defined as[10]:

$$p_b = \frac{2\pi r_1 \cos\alpha}{z_1} \tag{6}$$

$$\varepsilon_\alpha = \frac{|B_1B_2|}{p_b} \tag{7}$$

If the overlap ratio was equal to 1($\varepsilon_\alpha = 1$), only a pair of gears is meshing at the same time. In practice, the overlap ratio is always above 1, and a plurality of teeth were meshing simultaneously. If $1 < \varepsilon_a < 2$, the single and double teeth is alternative meshing. The normal force variation of a single teeth is shown in Fig.4. In the single meshing area B_4B_3, only a pair of gears bears the normal force. But, the two pairs of gears must bear the normal force in the double meshing area B_1B_3 or B_4B_2. The relationship between the meshing length and meshing ratio is expressed as:

$$B_1B_3 = B_4B_2 = B_1B_2 - P_b = (\varepsilon_\alpha - 1)P_b \tag{8}$$

Generally, the normal force was assigned in two teeth in average. In this case, the normal force should be assigned in the two simultaneous meshing teeth, and the normal force F_n can be expressed as:

$$F_n = \begin{cases} \dfrac{T}{r_1 \cos\alpha} & \text{single} \\ \dfrac{T}{2r_1 \cos\alpha} & \text{double} \end{cases} \tag{9}$$

3 Computational model of friction power loss

3.1Transient sliding friction coefficient

The gear sliding friction coefficient is related with many factors, such as the structural parameters of gears, meshing position, normal load, rotational speed, the tooth surface roughness, lubrication condition, oil viscosity and temperature effects et.al. The thickness ratio of lubrication oil-film λ[14] is defined as:

$$\lambda = \frac{h_{\min}}{\sigma} \tag{10}$$

$$\sigma = \sqrt{\sigma_1^2 + \sigma_2^2} \tag{11}$$

where $h_{\min}$ is the minimum oil-film thickness between teeth surfaces, σ is the average roughness of the tooth surface, and σ_1 and σ_2 are the roughness of the contact two teeth surfaces.

Many scholars have studied different methods to determine the sliding friction coefficient based on the elasto-hydro-dynamic lubrication(EHL) theory (Tallian, 1973). In Martin K's papers (Martin, 1978), the sliding lubrication conditions can be divided into three types: the fully EHL state($\lambda > 2$), the mixed EHL state($0.2 < \lambda < 2$), and the boundary lubrication state($\lambda < 0.2$). Therefore, different computational model of the sliding friction coefficient should be established due to different lubrication conditions. In that case, Wen S J (Wen, 1992) developed an equation to calculate EHL thickness,

$$h_{\min} = 6.67\mu^{0.53}(\eta v_t)^{0.75} E^{-0.06} R^{0.41} F_L^{-0.16} \tag{12}$$

where μ is the pressure-viscosity coefficient of lubrication oil(m^2/N), η is the dynamic viscosity coefficient of lubrication oil($Pa \cdot s$), $E = 2\big/\left(1-\nu_1^2/E_1 + 1-\nu_2^2/E_2\right)$ is the equivalent Young's modulus(Pa), E_1 and E_2 are the Young's modulus of driving and driven gears, ν_1 and ν_2 are the Possion ratio of driving and driven gears, $R_{eq} = R_1R_2/(R_1+R_2)$ is the equivalent curvature radius(m), $R_1 = |N_1C|$ and $R_2 = |N_2C|$ are the curvature radius of driving and driven gear meshing point(m), $F_L = F_n/L$ is the unit force of contact length(N/m), and L is contact length(m). The sliding friction coefficient of the fully EHL state was then calculated by Winter and Michaelis:

$$f_m = 0.0607(\frac{F_L}{v_s R})^{0.2} \eta^{-0.05} \left(\frac{\sigma}{d_1}\right)^{0.25} \tag{13}$$

3.2 Model of friction power loss

The friction between the meshing tooth are sliding friction, rolling friction and internal friction caused by metal plastic deformation during meshing process. And the rolling friction and internal friction are in small proportion, often negligible. Generally, only sliding friction is considered to compute the power loss (Su, 2000).

When the degree of contact ratio is $1<\varepsilon_\alpha<2$, the transient friction power loss of the single gear meshing zone B_4B_3 is,

$$q_c = f_1F_{n1}v_{s1} \tag{14}$$

And, the transient friction power loss of the double gear meshing zone B_1B_4 and B_3B_2 are,

$$q_c = q_{c1}+q_{c2} = f_1F_{n1}v_{s1}+f_2F_{n2}v_{s2} \tag{15}$$

where f_i is the friction coefficient of the i^{th} gear tooth meshing point, F_{ni} is the normal load of the i^{th} gear tooth meshing point, v_{si} is the relative sliding velocity of the i^{th} gear tooth meshing point, and $i=1,2$ represent the front and rear pairs of simultaneously meshing teeth respectively.

In a meshing cycle, the total friction heat are,

$$Q=\int_{t_{B1}}^{t_{B2}} q_c dt = \int_{t_{B1}}^{t_{B3}} \left(f_1F_{n1}v_{s1}+f_2F_{n2}v_{s2}\right)dt + \int_{t_{B3}}^{t_{B4}} f_1F_{n1}v_{s1}dt + \int_{t_{B4}}^{t_{B2}} \left(f_1F_{n1}v_{s1}+f_2F_{n2}v_{s2}\right)dt \tag{16}$$

where $t_{Bj}=\dfrac{\alpha_{Bj}-\alpha_{B1}}{\omega_1}$ is the time from the beginning meshing point B_1 to B_j, and $j=1,2,3,4$.

Thus, the computational model of the average friction power loss of the teeth is,

$$q_m=\frac{Q}{t_{B2}} \tag{17}$$

4 Conclusions

(1) In this paper, a friction power loss calculation model of spiral bevel gear was established. In this model, the spiral bevel gear is equivalent to the equivalent spur gear, and the gear meshing point during the relative sliding velocity, normal load, friction coefficient time-varying factors et.al are considered. In that case, the analysis model could be easier, and the calculation results could be more reliable.

(2) The friction power loss calculation model of spiral bevel gear, established in this paper, could be taken as the reference to thermal analysis of spiral bevel gear drive system and heat calculation in the lubricating design.

City Transit Ridership Forecasting Based on Weather Conditions—Case Study of the Chicago Transit Authority (CTA)

Wenqiao Sun[1] and Luyu Zhang[2]

[1]Department of Civil and Environmental Engineering, Northwestern University, Evanston, IL 60201. E-mail: wenqiaosun2013@u.northwestern.edu
[2]School of transportation and logistics, Southwest Jiaotong University, No. 111 North 1st of Second Ring Rd., Chengdu, Sichuan, China. E-mail: bettyzly@163.com

Abstract: Chicago Transit Authority (CTA) total ridership data is analysis considering weather data of the weekday. The results that lower temperature influences the transit ridership a lot and the influence reduces when the mean temperature goes higher are discovered. Different weather factors are analyzed to see how they affect the total ridership. In addition, a logistical regression model is generated based on the January 2014's weekday data.
Keywords: Transit forecasting; CTA; Weather condition.

1 Introduction

During the past 30 to 40 years, the transit share of total travel has been declining. More and more people live at suburban area but work at downtown, which provides great challenges for public transportation system. Therefore, how to maintain transit ridership and what operation strategies to use are problems facing by many transportation agencies today. One of the key issues to solve these problems is to figure out what factors affect the transit ridership.

One of the most famous strategies to forecast the ridership is Logit model based on census data. However, census reports are published very five years by the government and it is based on questionnaire. Transit ridership could change significantly through the five years' period based on the employment situation, transit development, government policies, climate changes and some other factors.

A lot of researchers studied travel demand forecasting in past several decades but with little of them take the weather as a factor which influences the transit ridership. In order to better understand the characteristics of transit ridership, a further analysis of transit ridership and a model that can reflect changes in transit ridership corresponding to changes in factors affecting ridership is needed.

The Chicago Transit Authority (CTA) operates the second largest public transportation system in the United States, and covers the City of Chicago and 35 surrounding suburbs. Approximately 1.7 million rides are taken on the CTA on an average weekday. (http://www.transitchicago.com/about/overview.aspx)

The objective of this paper is to examine potential variables that may have effects on CTA transit ridership and to develop a mathematical model to forecast ridership as a function of weather factors without census data. The rest of the paper is organized as follows. Section 2 offers a literature review on ridership forecasting. Section 3 analyzes existing ridership and weather data. Model analysis is described in section 4. Finally, section 5 presents the final conclusions as well as directions for future work.

2 Literature Review

Methodologies of transit ridership forecasting began to blossom in the 1970s and 19080s. Some scholars developed techniques to forecast system-level or route-level transit ridership in 1980s, either through a modified four-step travel model (Ulberg 1982; Levinson 1984; Horowitz 1985; Levinson 1985), or regression models using combination of population, employment, automobile ownership, etc.

(Menhard, 1983) summarized route-level ridership prediction techniques and characterized four of them, which are ‘Professional judgment; Noncommittal or stated-preference surveys; Cross-sectional models, ranging in sophistication from similar routes and rules of thumb to regression analyses; Time-series models, including elasticity-based approaches and trend analysis’. Those techniques were ranked subjectively based on some factors, but summarized that ‘insufficient information was available to address accuracy and transferability’ (Boyle, 2006). (Stopher, 1992) proposed a model to forecast ridership changes - based on route extensions, headway changes, service span changes, route shortenings, new routes, short-lines on existing routes, or a combination of actions – at route and time-of-day levels. (Peng, 1997) developed a ridership model that incorporated transit demand, supply, and inter-route factors on a route level by time-of-day and direction. The study realized that it is likely to cause a ridership decrease on competing or parallel routes lately, when ridership on a given route increased by service improvement.

(Lane, 2006) proposed a ridership-forecasting tool on a sketch-level for light and commuter rail. This model was improved by (Parsons, 1996) through taking into account service-related variables like travel speed, midday headways, and fare, as well as by introducing reverse commutes trips. (Marshall, 2006) presented a sketch level transit planning model that sensitive to land usage, matches suburban transit ridership better, and cost less than the traditional four-step model.

3 Data Analysis

The CTA ridership data is from CTA website and the dataset shows system-wide boardings for both bus and rail services provided by CTA, dating back to 2001. There are three kinds of day types, weekday, Saturday, and Sunday/holiday. The weather data comes from “weather underground” website contains high, average and low data for temperature (F), dew point (F), Humidity (%), sea level press (In), wind (mph) and events (fog, rain, snow etc.).

Figure 1 shows total ridership in January 2013. It is easy to see that there are huge gaps between weekdays and weekends. In this paper, weekday data is used to analysis how the weather influences the transit ridership. Because total commute trips in weekday will not change a lot in different weather conditions. By analysis weekday data, we could not only know how transit ridership changes in different weather condition but also how the transit share considers the weather.

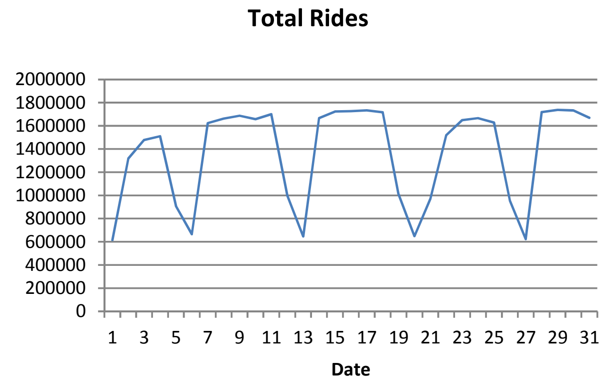

Figure 1. CTA Total Ridership in January 2013

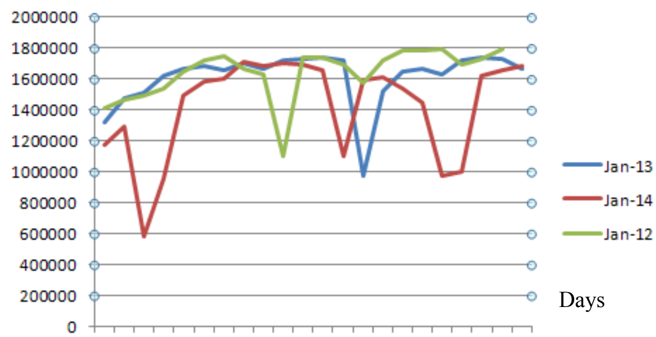

Figure 2. CTA Total Weekday Ridership in January 2012, 2013 and 2014

Figure 2 shows CTA Total Ridership in January 2012, 2013 and 2014. It is clear that ridership in January 2014 is much lower than in 2012 and 2013. From the weather data, we could know that the temperature in Chicago area is much lower in January 2014 than in January 2013. Figure 3 shows the relationship between mean temperature of a day and the total CTA transit ridership in January 2014. It is quite straightforward that when the average temperature of a weekday is quite low, the ridership of the transit is also very low.

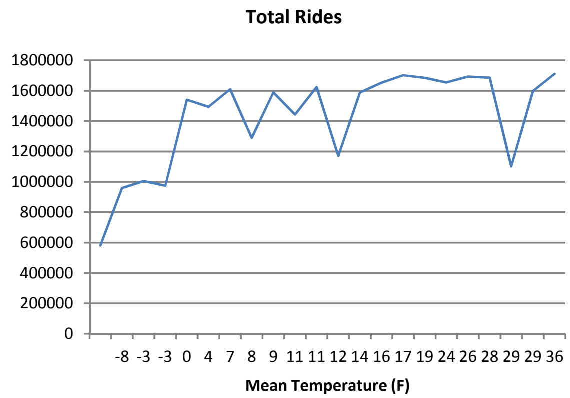

Figure 3. Relationship between Mean Temperature and Total Weekday Ridership in January 2014

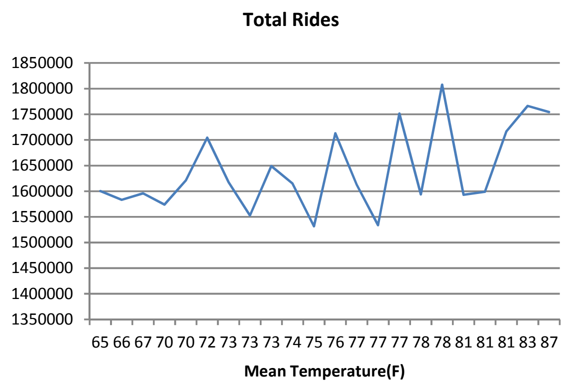

Figure 4. Relationship between Mean Temperature and Total Weekday Ridership in August 2013

Figure 4 displays how ridership changes due to the mean temperature changes of the weekday in August 2013. The ridership does not change as much as in January 2014. Even though the total ridership fluctuates, the trend goes up as temperature going up.

To sum up, it is clear that the CTA ridership on weekday is influenced by the mean temperature of the day. Next section will discuss the mathematical relationship between transit weekday ridership and weather condition (temperature, humidity, wind and events like fog, rain, snow etc.).

4 Model Analysis

First we tried logistic regression contains all weather factors to see which factors influence the weekday ridership significantly. The regression result shows in figure 6 based on the weather and weekday CTA total ridership data in January 2014.

As we forecasted before, mean temperature of the day is a very important factor of the transit ridership. Besides, mean wind speed and mean humidity also affect the ridership more or less. When we considered only mean temperature and mean wind speed to do the logistic regression, the result shows that mean wind speed is not significantly influence the total ridership. The regression model of transit ridership will only consider the mean temperature of the day which is easy to get the data and affects the ridership significantly. The regression output is displayed in figure 7 and the model is the following: Total CTA Ridership = 1172764 + 16870 * (Mean Temperature of the day/F).

Figure 7. Logistical Regression Result Consider Mean Temperature Only (Jan 2014)

Here the problem comes, the regressions above based on the data in January 2014, the month Chicago has the lowest average temperature in the past twenty years. However, in January 2013, the mean temperature is from 13F to 45F, which are much higher than in January 2014. The regression results for January 2013 and August 2013 show that mean temperature is not as significant as in 2014. The logistic regression outcome shows in figure 8.

```
Call:
glm(formula = total_rides ~ Mean.TemperatureF, data = d)

```

Figure 8. Logistical Regression Result Consider Mean Temperature Only (Aug 2013)

5 Conclusion

By comparing the CTA ridership data and Chicago weather data, we find that the mean temperature of a weekday influences the transit ridership significantly especially the temperature is low. When the temperature is not low like in January 2013 and August 2013, the mean temperature also influence the transit ridership a lot but not as significantly as in January 2014. The trend is when the temperature is higher the transit ridership is also higher. It might because that many people do not want to take transit to school or work in an extreme weather condition especially when they have alternative choices.

A logistic regression model is also given based on the January 2014 data which is Total CTA Ridership = 1172764 + 16870 * (Mean Temperature of the day/F). We can forecast the CTA total ridership in extreme cold weather based on this model and change the operation strategy to serve residents better.

There are still a lot of things need to do in the future. First, the importance of factor temperature varies when the temperature level is different. A parameter should add to interpret this variance. Second, we did not verify the model with other data and sensitivity analysis to check the model performance. Furthermore, this model only considered the weather data. Usually the transit ridership also affected by the land use, transit routes, transit accessibility, household characters and so on. And the weather data could be included in the error term of the model to influent the total ridership. Hence, model comparison should be done in the future to compare different model performances and analysis the error term as well to see how weather conditions influent the error term and total transit ridership.

Abstract: In general, traffic demand regression analysis is conducted independently on a certain path of transport corridor with little consideration about the effects from other adjacent paths which have the same directions. Separate multivariate linear regression analysis and that of multiple dependent variables are conducted respectively based on research data of two paths of traffic corridor between Shenyang and Shanhaiguan. Analysis results indicate that associative regression prediction has higher accuracy than separate regression prediction. Research results of this paper provide a more accurate theoretical calculation method for transport corridor traffic demand prediction in practical engineering projects.
Keywords: Transport corridor; Traffic demand prediction; Multivariate regression.

1 Introduction

Predictions separately in each direction or OD-based four-step prediction method are usually adopted to forecast traffic demand in regional transport corridors. Prediction values of the former method are prediction values of perspective traffic of corridors under planning research which are aggregated from quantitative predictions of basic traffic, diverted traffic and induced traffic of the corridors in future years. However, interaction effects among several paths of a corridor are not taken into consideration in predictions separately in each direction. Four-step prediction method is a prediction method which developed during studying urban transportation planning and is widely utilized in urban transportation planning, but it is not suitable for corridor traffic demand prediction because of the significant difference between urban traffic and regional transport corridor traffic. To be specific, directional distribution of traffic flow in urban traffic is complicated with high divergence where traffic flow in corridor has simple directional distribution. Besides, numerous paths from O to D are available for travelers to select in urban traffic systems where the paths in corridor are commonly fixed with little choice for traveler.

In previous studies, with adequate consideration about influence factors on traffic demand, Li (2006) determined correlations between traffic demand and influences on it such as social events and economic development, forecast gross traffic demand according to the correlation coefficient, and obtained traffic volumes of feasible paths using attracting weight and logit assignment method. Zhu (2007) studied common methods of passenger traffic demand prediction and introduced thought, methods and models of corridor passenger traffic demand prediction based on the special characteristics of corridor passenger traffic. He also developed game theory model and fuzzy synthetic evaluation model through corridor competition analysis. Li et al. (2013) built a prediction model on diverted traffic and induced traffic of freeways under reconstruction and expansion. Based on the actual situation, PHAN et al.（2009）combined advantages with the existing freeway y traffic forecasting, respectively according to the original channel within the traffic demand of natural growth, induced by the new high-speed traffic and other traffic in the path of the transfer of these 3 aspects of forecasting, and made different sensitivity analysis on current toll level on expressway. Multivariate linear regression prediction of multiple dependent variables will be adopted to forecast traffic demand of transport corridors in this paper.

2 Model development

2.1 Models

In this paper, Transport corridor is comprised of several paths sharing the same origin and destination, serving large traffic flow and passing through almost the same locations according to the definition giving by Zhu (2007).

Influence factors on traffic demand need to be determined before forecasting traffic demand of transport corridors. Consulting general influence factors on traffic demand (Wang, 2007) and considering requirements of this study and characteristics of transport corridors, the following factors are selected to do regression analysis:

- Road grade

Multiple paths with the same origin, destination, and direction are the study targets which have particular correlation when forecasting traffic demand. Road grade has such significant influences on traffic demand that it needs to be considered.

- Area

Different areas between the origin and destination passed by a path don't always raise the same traffic demand. Thus, effects on traffic demand caused by areas should not be neglected.

- Population

People is one of basic elements of transportation. It is inevitable that the variation of resident population could affect aggregate traffic demand.

- GDP

Transportation is a category of derived demand, a large proportion of which belongs to productive and working transportation demand. Higher regional economic development level could generate larger demand of these categories. Besides, regional economic development influences income and consumption level of inhabitants which cause variation of living transportation demand. Thus, regional economic development level has great impacts on traffic demand. Generally, GDP is adopted to estimate the economic development level.

- Lanes

Lanes have direct effect on traffic demand. Specifically, more lanes could provide larger service traffic volume and less lanes may result in less traffic demand.

- Distance from location of data detector on the road to downtown

In addition to resident population and regional GDP, distance from downtown (areas with high population density and economic level) to location of data collectors on roads has an impact on path selection propensity of travelers.

- Others

Large number of unknown factors affecting traffic demand of corridors makes it unable to list them in detail. One variable is used here to represent all other unknown influence factors.

In traffic demand prediction, regression prediction method is to establish regression equations through discovering statistical regularities among prediction objects and their influence factors. As a relatively scientific prediction method, it could analyze major influence factors of prediction objects concretely and do statistical tests on rationality of models and reliability of prediction. The precondition of applying regression models is that traffic volumes have high sensitivity to explanatory variables. With inappropriate explanatory variables, fake regressive phenomenon would arises easily and multicollinearity could exist in multivariate linear regression. This study is based on sufficient data from two paths of traffic corridor between Shenyang and Shanhaiguan and conducts separate and associative multivariate linear regression analysis.

2.2 Model development

A hypothesis is made that the multivariate linear regression equation, which traffic volume of Path 1 and its road grade, number of lanes, regional resident population, regional GDP, and distance from downtown satisfy, is Eq.(1). The equation that Path 2 satisfies could be expressed as Eq.(2). Eq.(3) denotes the associative multivariate linear regression equation that Path 1 and Path 2 satisfy.

$$y_1 = b_{10} + b_{11}x_{11} + b_{12}x_{12} + b_{13}x_{13} + b_{14}x_{14} + b_{15}x_{15} + \varepsilon_1 \quad (1)$$

where: y_1 = traffic volume of Path 1;

$x_{11} \sim x_{15}$ = respectively represents road grade, number of lanes, regional resident population, regional GDP, and distance from downtown of Path 1;

$b_{10} \sim b_{15}$ = undetermined coefficients;

ε_1 = random error, $\varepsilon_1 \sim N(0,\sigma^2)$.

$$y_2 = b_{20} + b_{21}x_{21} + b_{22}x_{22} + b_{23}x_{23} + b_{24}x_{24} + b_{25}x_{25} + \varepsilon_2 \quad (2)$$

where: y_2 = traffic volume of Path 2;

$x_{21} \sim x_{25}$ = respectively represents road grade, number of lanes, regional resident population, regional GDP, and distance from downtown of Path 1;

$b_{20} \sim b_{25}$ = undetermined coefficients;

ε_2 = random error, $\varepsilon_2 \sim N(0, \sigma^2)$, ε_2 and ε_2 are independent of each other.

$$\begin{cases} y_1 = b_{10} + b_{11}x_{11} + b_{12}x_{12} + b_{13}x_{13} + b_{14}x_{14} + b_{15}x_{15} + \varepsilon_1 + \theta \\ y_2 = b_{20} + b_{21}x_{21} + b_{22}x_{22} + b_{23}x_{23} + b_{24}x_{24} + b_{25}x_{25} + \varepsilon_2 + \theta \end{cases} \quad (3)$$

where: θ = the variable that represents all other unknown variables which affect correlations between y_1 and y_2. Its value varies with variation of areas. $\theta \sim N(0, \sigma_\theta^2)$. Concrete meanings of other variables are the same with above but ε_1 and ε_2 are not independent of each other.

Obviously, $y_1 \sim N(\beta_1 x_1, \sigma_1^2)$, $y_2 \sim N(\beta_2 x_2, \sigma_2^2)$, where $\beta_1 = (b_{10}, b_{11}, b_{12}, b_{13}, b_{14}, b_{15})$, $x_1 = (1, x_{11}, x_{12}, x_{13}, x_{14}, x_{15})$, $\beta_2 = (b_{20}, b_{21}, b_{22}, b_{23}, b_{24}, b_{25})$, $x_2 = (1, x_{21}, x_{22}, x_{23}, x_{24}, x_{25})$. The value of θ varies upon different areas and the corresponding estimated values of y_1 and y_2 varies as well. y_1 and y_2 obey associative bivariate normal distribution, which is given as $(Y_1, Y_2) \sim N(\mu_1, \mu_2, \sigma_1^2, \sigma_2^2, \rho)$.

3 Model calculation

On the basis of field data of over the years, separate and associative multivariate linear regression analysis are conducted respectively between traffic volumes of two paths and their road grades, numbers of lanes, regional resident population, regional GDP, and distances from downtown, with 5% significance level. Regression calculation results are illustrated in Table 1and Table 2.

As shown in Table 1, the correlation coefficient of associative multivariate linear regression equation is 0.8628, which means that multivariate linear regression equations of two paths have high correlation with 5% significance level. Judging from parameters prediction results, x_{22} is ruled out due to the absence of prediction value of b_{22}, which indicates that there is no significant linear relation between traffic volume of Path 2 and its number of lanes since Path 2 has the same number of lanes in all field research areas. Positive value of a coefficient indicates a positive correlation between traffic demand and these parameters where negative value indicated a negative correlation. To be specific, the traffic volume of Path 1 rises with the increase of its road grade, number of lanes, and regional *GDP* as well as the decrease of regional resident population and distance from downtown. Besides, the traffic volume of Path 2 rises with the increase of its road grade and regional *GDP* as well as the decrease of regional resident population and the distance from downtown. Note that traffic demand reduces with the growth of regional resident population of areas where a path passes through. Fig.1 illustrates the scatter diagram of traffic demand and resident population. A conclusion could be drawn that traffic demand and resident population have no significant linear relation but a general negative correlation. It is the major reason for this distortion that there is no large population in the area where

b_{25}	-4.892	17.79	-41.11	-4.88	29.53

The segment with the highest traffic demand of the path. This distortion manifests as high traffic demand in areas with little population and low traffic demand in areas with large population. Apart from this, regional resident population continues to increase with decreasing growth rate. Traffic demand of paths are influenced by multiple factors, contributing to wider fluctuation. Thus, it is believable that regression models have relatively high reliability with introduction of θ and other influence factors.

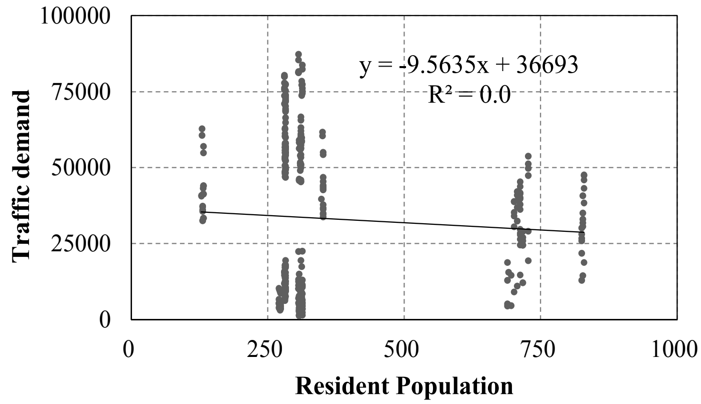

Figure 1. The scatter diagram of traffic demand-resident population

4 Regression prediction and comparative analysis

Traffic demand predictions are conducted using the associative multivariate linear regression equation obtained from Table 1. The comparative analysis results of predicted values and measured values are shown in Fig.2; Traffic demand predictions are conducted using separate multivariate linear regression equations obtained from Table 2. The comparative analysis results of predicted values and measured values are shown in Fig.3. According to Fig. 2 and Fig.3, the square of the correlation coefficient of the prediction results of the associative regression equation and measured values R^2=0.9095, which is approximately 1(when prediction values exactly match to measured values). It suggests that the prediction results of the associative multivariate linear regression equation are in good agreement with the measured value. Whereas, the square of the correlation coefficient of the prediction results of separate regression equations and measured values R^2=0.8368, which shows relatively poor prediction performance. The accuracy of associative prediction can be computed as *e*=1-|predicted value- measured value|/measured value =1-0.305955349=0.694044651 and the accuracy of separate prediction can be computed as *e* =1-0.362926922=0.637073078. Thus, applying associative prediction could improve prediction accuracy by 5.7%.

5 Conclusion and prospect

This paper firstly analyzes influence factors of regional transport corridor traffic demand and establishes the separate multivariate regression model and associative multivariate regression model based on those factors. Then calibration of regression models are conducted with field data of two paths of traffic corridor between Shenyang and Shanhaiguan. Calibrated models are applied finally to forecast traffic demand. Results of comparative analysis indicates that associative regression prediction has higher prediction accuracy than separate regression prediction. Only part of influence factors are selected in the analysis and numerous unknown factors have impacts on accuracy of regression prediction and correlation among multiple paths. To obtain higher accuracy, more influence factors will be analyzed and taken into consideration of model development in sequential studies. In practical engineering application, there are always multiple paths in a corridor in multiple traffic modes and what effects the correlations among various traffic modes have on demand prediction will be proposed in another paper.

Transport Priority and Economic Growth in China's Ethnic Area: A Case Study of Guizhou Province

Zhongxing Cheng

Southwest Jiaotong University, Sichuan University, Chengdu City 610013, China. E-mail: chengzhongxing@swjtu.edu.cn

Abstract: It is an important item to assess the effects of west transportation improvement on economic growth in China's Ethnic Area. Our findings show that local economy growth doesn't benefit from transportation improvement in Guizhou ethnic area. That is to say, the effects of transportation improvement are fully spilled. Although the transportation costs of households and firms are reduced by transportation improvement, the flow of production factors (population mobility & movement of goods) are one-way from ethnic area to developed region. On this condition, transportation improvement has negative spatial spillover effects to the economic development in ethnic area.

Keywords: Transportation improvement; Economic growth; Spatial spillover effects.

1 Introduction

The ethnic area in Guizhou Province is a typical Karsts region in southwestern China. which are not littoral or riparian or border areas. The dirt road and mountain road have been the bottleneck of local development.

As transport priority in western development strategy has been implementing, the transportation infrastructure construction in Guizhou ethnic area has acquired a real breakthrough. Fixed asset investment across the region totaled 4006.95 trillion Yuan during ten years (2001 to 2011). The total mileage of highway reached up to 80145km and all the countries and villages have been connected by the oil way or high way. In particular, the total mileage of expressway are from 0km on 1988 to 1978km on 2014. For example, 234 townships in Qiannan autonomous prefecture have been connected by oil, accounting for 97.1 percent of total 241 townships. and 796 villages have been connected by oil, 1542 villages have been connected by highway, accounting for 33.6 and 98.94 percent of total 2363 villages respectively (Tao Mouli, 2014). The huge transport investment and the strong economic growth did not existed in history, the accessibility and the convenience level have been improved significantly in all ethnic areas.

At the same time, the economy in Guizhou ethnic area grew rapidly. GNP are rising from 314.49 trillion Yuan on 2000 to 1560.5 trillion Yuan on 2011. For example, PGDP in Qiannan autonomous prefecture break through the $1000 mark firstly on 2010, and GDP increased to 312.57 trillion Yuan with average annual growth rate of 12.7% during the period of "the 11th five year plan", which is 2%

higher than the rate in the period of "the 10^{th} five year plan" and exceeded the average growth level of the corresponding period in Guizhou province.

However, to what extent did the economical growth benefit from the transportation improvement in Guizhou ethic area? it is no doubt that this question is the crucial issue for people.

It is well known that the development economical theory which used to be popular, such as "big-push" theory (Rodan, 1943), "economic take-off" theory (Rostow., 1960) regard transportation improvement as the precondition of economical growth in less developed region. World Bank Report also pointed out that transportation improvement was pioneer capital for economic development in developing country (World Bank, 1994). Furthermore, Aschauer (1989) once computed the output elasticity of transportation improvement for economical growth using neoclassical economical model, and the result was 0.39.

However, Tatom (1991) and Holtz-Eakin (1994) had queried if the result is reasonable. They thought that diversity in different cross-section data were not involved in neoclassical economical growth model, so it was inappropriate when computing output elasticity based solely on time series data. Banister and Berechman (2001), their research shown that transport infrastructure investment acted as a complement to other more important underlying conditions, including economic externalities, investment factors, and political factors, which must also be met if further economic development is to take place.

In a word, the relationship between transportation improvement and economical growth is neither unidirectional causality nor simple linearity. Thus how about the relationship in Guizhou ethnic area? It is no doubt that this question has unique meaning in theory and reality especially on the day when Go-west Campaign has last more than one decade.

The organization of the paper is as follows. Section 2 gives 6 key variables to measure transportation improvement and economical growth, and presents its statistical descriptions. Section 3 are data analysis, including co-integration analysis and Granger Causality Test. Section 4 draw main conclusions.

2 Variable , Data and Description

In this paper we set 6 variables: Passenger-Kilometers (PK,10,000) and Freight Ton-kilometers (FTK) are used to measure transportation improvement. Primary industry GDP (GDP1), Secondary industry GDP (GDP2), Tertiary industry (GDP3) and Total GDP (GDP), those variables are used to measure economical growth. All data comes from Guizhou Statistical Yearbook (1992-2011) and Transport Yearbook (1992-2011). So why we choose these variables and the period from 1992 to 2011? the reasons are just as the data of variables is continuous and 2000 is the time when western development strategy was issued. To describe above 6 variables, time series plot were given as Figure1, Figure 2, Figure 3.

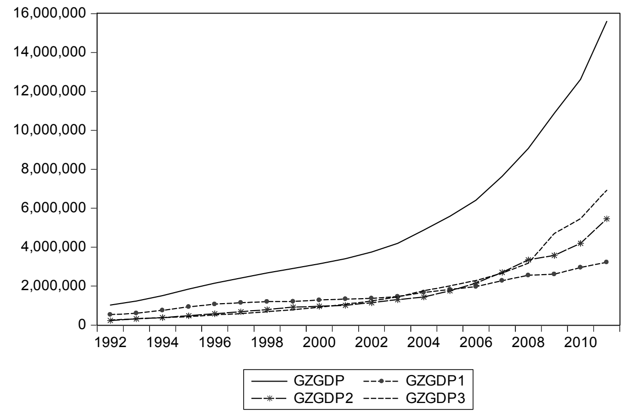

Figure 1. Time Series Plot of GDP

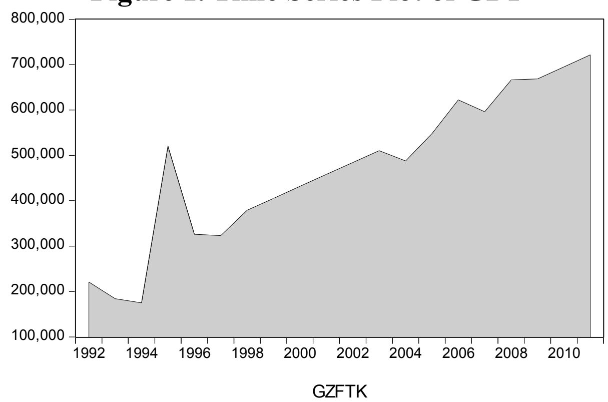

Figure 2. Time Series Plot of FTK

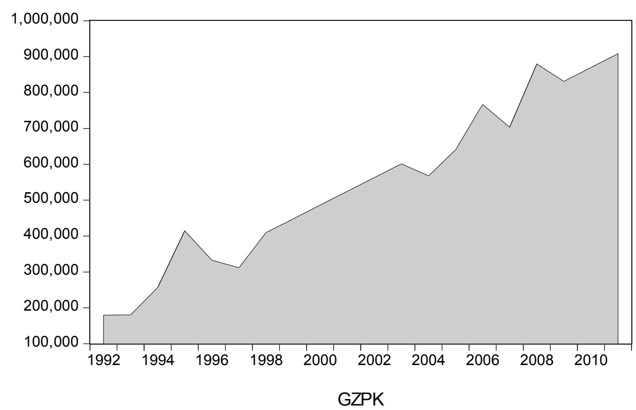

Figure 3. Time Series Plot of PK

From figure1, figure2 and figure3, we can speculate that all the time series are not stationary.

3 Data Analysis

3.1 Unit root test

As time series are not stationary, So unit root test should be used firstly. To make time series more stationary, we take logarithm of variables and record them as LogFTK, LogPK, LogGDP1, LogGDP2,LogGDP3, LogGDP. we apply ADF to test whether a time series is stationary by Eviews 7.0 (similarly hereinafter). the estimated results of ADF test as follows:

Table 1. ADF Test of LogFTK& LogPK

Null Hypothesis: D(LOGFTK) has a unit root				Null Hypothesis: D(LOGPK) has a unit root			
Exogenous: Constant				Exogenous: Constant			
Lag Length: 1 (Automatic - based on SIC, maxlag=4)				Lag Length:1 (Automatic - based on SIC, maxlag=4)			
		t-Statistic	Prob.*			t-Statistic	Prob.*
ADF test statistic		-5.987927	0.0002	ADF test statistic		-4.973256	0.0012
Test critical values:	1% level	-3.886751		Test critical values:	1% level	-3.886751	
	5% level	-3.052169			5% level	-3.052169	
	10% level	-2.666593			10% level	-2.666593	

*MacKinnon (1996) one-sided p-values.

Table 2. ADF Test of LogGDP1& LogGDP2

Null Hypothesis: D(LOGGDP1) has a unit root				Null Hypothesis: D(LOGGDP2) has a unit root			
Exogenous: Constant				Exogenous: Constant			
Lag Length: 4 (Automatic - based on SIC, maxlag=4)				Lag Length: 0 (Automatic - based on SIC, maxlag=4)			
		t-Statistic	Prob.*			t-Statistic	Prob.*
ADF test statistic		-3.776448	0.0151	ADF test statistic		-3.126374	0.0425
Test critical values:	1% level	-4.004425		Test critical values:	1% level	-3.857386	
	5% level	-3.098896			5% level	-3.040391	
	10% level	-2.690439			10% level	-2.660551	

*MacKinnon (1996) one-sided p-values.

Table 3. ADF Test of LogGDP3& LogGDP

Null Hypothesis: D(LOGGDP3) has a unit root				Null Hypothesis: D(LOGGDP，2) has a unit root			
Exogenous: Constant				Exogenous: Constant			
Lag Length: 0(Automatic - based on SIC, maxlag=4)				Lag Length: 0 (Automatic - based on SIC, maxlag=4)			
		t-Statistic	Prob.*			t-Statistic	Prob.*
ADF test statistic		-3.979571	0.0078	ADF test statistic		-3.059262	0.0493
Test critical values:	1% level	-3.857386		Test critical values:	1% level	-3.886751	
	5% level	-3.040391			5% level	-3.052169	
	10% level	-2.660551			10% level	-2.666593	

*MacKinnon (1996) one-sided p-values.

The results indicate that the time series variables are non-stationary in their levels but stationary in the first differences except for GDP, which is stationary in second differences. That is to say, FTK&GDP1/GDP2/GDP3 or PK &GDP1/GDP2/GDP3 are integrated of order one [I(1)] and confirms the possibility of long run equilibrium relationship between them.

3.2 Co-integration analysis

One aim of this paper is to find whether there are relationships of co- integration between transportation improvement and economical development in Guizhou ethnic area. how to verify co-integration between FTK and GDP1/GDP2/GDP3 or between PK and GDP1/GDP2/GDP3?

Generally, Johansen test and E-G test are two popular methods: The former applies to two variables, and the later applies to multiple variables. This paper test the co-integration between two variables, so chose E-G test:

Do regressions analysis:LogGDP1/logGDP2/logGDP3 as dependent variable, LogPK (or LogFTK) as independent variable, then get time series of residual as following:e1、e2、e3、 e4 、e5、 e6:

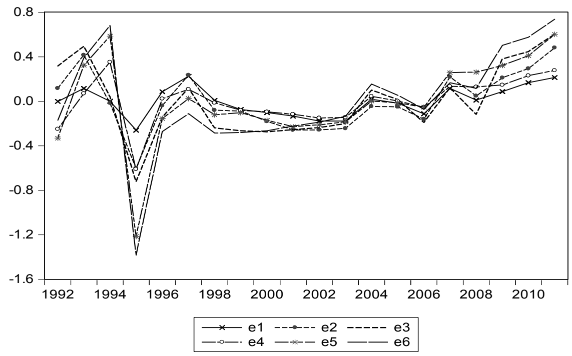

Figure4 Time Series Plot of e1/e2/e3/ e4/e5/ e6

The second step is to test residual to find if they have unit root (Table4-6):

Table 4. Unit root Test of e1/e2

Null Hypothesis : $e_1$has a unit root				Null Hypothesis: $e_2$has a unit root			
Exogenous: None				Exogenous: None			
Lag Length: 0 (Automatic - based on SIC, maxlag=1)				Lag Length: 0 (Automatic - based on SIC, maxlag=1)			
		t-Statistic	Prob.*			t-Statistic	Prob.*
ADF test statistic		-2.533560	0.1237	ADF test statistic		-2.294100	0.1835
Test critical values:	1% level	-3.831511		Test critical values:	1% level	-3.831511	
	5% level	-3.029970			5% level	-3.029970	
	10% level	-2.655194			10% level	-2.655194	

*MacKinnon (1996) one-sided p-values.

Table 5. Unit root Test of e3/ e4

Null Hypothesis: $e_3$has a unit root				Null Hypothesis: $e_4$has a unit root			
Exogenous: None				Exogenous: None			
Lag Length: 0 (Automatic - based on SIC, maxlag=1)				Lag Length: 0 (Automatic - based on SIC, maxlag=1)			
		t-Statistic	Prob.*			t-Statistic	Prob.*
ADF test statistic		-2.130237	0.2359	ADF test statistic		-4.283164	0.0039
Test critical	1% level	-3.831511		Test critical	1% level	-3.831511	

values:	5% level	-3.029970		values:	5% level	-3.029970	
	10% level	-2.655194			10% level	-2.655194	

*MacKinnon (1996) one-sided p-values.

Table 6. Unit root Test of e5/ e6

Null Hypothesis: $e_5$has a unit root				Null Hypothesis: $e_6$has a unit root			
Exogenous: None				Exogenous: None			
Lag Length: 0 (Automatic - based on SIC, maxlag=1)				Lag Length: 0 (Automatic - based on SIC, maxlag=1)			
		t-Statistic	Prob.*			t-Statistic	Prob.*
ADF test statistic		-0.953440	0.7447	ADF test statistic		-3.104423	0.0433
Test critical values:	1% level	-3.886751		Test critical values:	1% level	-3.831511	
	5% level	-3.052169			5% level	-3.029970	
	10% level	-2.666593			10% level	-2.655194	

*MacKinnon (1996) one-sided p-values.

Table4-6 show that the co-integration relationship only exist between FTK and GDP1 (p=0.0039) or between FTK and GDP3 (p=0.0433).

Lastly, establish error correcting model (ECM). the dependent variable is the first difference of GDP1 or GDP3, the independent variables are the first difference of FTK and error correction item e4 $_{（t-1）}$ or e6 $_{（t-1）}$ .then we get the ECM as follows:

$$D\log gdp1 = \text{-3.82E-17} + 1.07\, D\log ftk + e_{4(t-1)} + v_t$$

（p=0.9557）（p=0.0000）（p=0.0000）

$$D\log gdp3 = \text{8.48E-15} + 2.01\, D\log ftk + e_{6(t-1)} + \varepsilon_t$$

（p=0.0018）（p=0.0000）（p=0.0000）

3.3 Granger casualty test

The other aim of this paper is to investigate the direction of causation in the Granger sense between transportation improvement and economical development in Guizhou ethnic area. Table7 show the result of Granger Causality test: no Granger cause between FTK and GDP1/GDP3.

Table7. Granger Causality Test between GDP1/GDP3and FTK

Sample: 1992 2011			
Lags: 2			
Null Hypothesis:	Obs	F-Statistic	Prob.
GDP1 does not Granger Cause FTK	18	3.73564	0.0523
FTK does not Granger Cause GDP1		0.00755	0.9925
GDP3 does not Granger Cause FTK	18	1.53045	0.2530
FTK does not Granger Cause GDP3		0.10864	0.8979

4 Conclusions

All above studies clearly show a paradoxical relationship between economical growth and transportation improvement. Although the co-integration relationship exist between FTK and GDP1 or GDP3. there are no Granger cause between them. In another word, the transportation improvement has no direct effect on local economic growth. the effects of transportation improvement in Guizhou ethnic area are fully spilled. The conclusion suggests that it is a prime topic to turn the negative spatial spillover effects to positive.

Abstract: The possibility of spatial spillover effects of transport infrastructure on economic growth was examined in Northwest China, which is analyzed based on spatial spillover theory and Cobb - Douglas production function, using panel data from 1990~2012. The results show that: (1) The output coefficient of local road infrastructure on economy in the Northwest is 0.1325, which means that local highway infrastructure plays a significant role in promoting local economic growth. (2) The output coefficient of ecdemic highway infrastructure on local economy is 0.1512, comes to the conclusion that there is a significant positive spillover effect of ecdemic highwayinfrastructure on local economic growth.

Keywords: Highway investment; Economic development; Spatial spillover effects; Northwest China.

1 Introduction

Transport infrastructure investment is a very important means of economic regulation by the government, and important transport infrastructure can cause significant changes in the pattern of economic space, so that the relationship between transport infrastructure and economic growth is still a research focus to economists. The national economy of Northwest China has been developed rapidly since the implementation of the Western Development Strategy, but it is still lagging behind compared with the eastern part of China. With the proposition of Silk Road Economic Belt Strategy, economic and social development of the Northwest region has been concerned widely，however，there is a huge gap between the economic development level of the Northwest and its economic circles at both ends due to the inconvenience of its transport and the poor natural environment. As its complex international environment, highway in Northwest China plays an important role in national economic growth.

Spatial Spillover Effects describes the mechanism of polarization of economic growth in different regions from the aspects of cumulative circulation of supply and demand, which is proposed by New Economic Geography in these years. GDP in all surrounding areas are added together to measure the size of the potential demand of a region's products and services, and is taken as the market potential to examine factors affecting wages in this regions (Gregory, 1994). Holtz-Eakin and Schwartz (1995) firstly started to study the spatial spillover effects of transport infrastructure on economic growth, they built spatial weights matrix and added infrastructure variables in adjacent areas to traditional production function, however, they didn't confirm the existence of the spatial spillover effects. Mas，Maudos (1996) tried to look for spillover effects of infrastructure on regional economic growth using the comparative output elasticity method. Boarnet (1998) collected panel data from 1968~1988 of counties in California and defined different spatial weight matrix, he indicated that there was a strong spatial spillover effects of highway transport infrastructure between adjacent areas. Joseph，Ozbay (2006) verified the spillover effects of transportation of US states, administrative cities and counties using the space measurement methods, he thought that the directly affect of transport infrastructure decreased and the spillover effects of transportation increased with the decrease of the geographical scale.

These years, many domestic scholars studied the spatial spillover effects of transport infrastructure. HU Angang, LIU Shenglong（2009）considered that the annual contribution rate of the sum of direct contribution of China's transport investment and external spillover effects is 13.8%. ZHANG Zhi and ZHOU Hao（2012）pointed out that the spillover effects of China's transport infrastructure worked more through economic ties. LI Fengyue（2013） analyzed the mechanism of spillover effects of transport infrastructure taking counties in Zhejiang province as examples, and explained the way of spillover effects from three dimensions, residents, businesses and regions.

These studies always take the whole China and some developed provinces as research objects, confirms the spillover effects of transport infrastructure on economic growth from different aspects. However, little studies has been down for some backward-developed areas. As for the Northwest region, where economy develop is lagging behind and the strategic position is very important, transportation development relies more on highway which is of high level in accessibility. With the proposition of Silk Road Economic Belt Strategy, an urgent need for economy development is put forward, which makes it an urgent problem to be clear of the model and degree of the impact of transport infrastructure on economic growth. As a result, it is very significant for guiding the layout and construction of highway and is very meaningful for social and economic development in the Northwest to study on the promotion of highway transport on economic growth and revealing its spillover effects.

2 Basic model

2.1 Basic model theory

Cobb-Douglas production function is used to analyze the relationship between highway transport infrastructure and economic growth. Capital investment (K) is decomposed into two parts, one is the highway infrastructure investment in the region (K), another is the capital investment except the highway infrastructure stock in the region (TR). In addition, highway infrastructure investment in other regions (OTR) is also joined in to build Cobb-Douglas production function, which is converted to the following relationship formula:

$$\ln Y = \alpha_1 \ln L + \alpha_2 \ln K + \alpha_3 \ln TR + \alpha_4 \ln OTR + C + \varepsilon_t \qquad (1)$$

In this formula, Y stands for output within the region, which reflects the economic growth in the region; L stands for local human capital investment, α_1 stands for elasticity of labor force output; α_2 stands for elasticity of capital output except highway transport infrastructure in the region; α_3 stands for elasticity of input and output of highway transport infrastructure in the region; α_4 stands for elasticity of input and output of highway transport infrastructure in other regions.

An only-individuals-affected panel data model including time dummy variables is built as follows:

$$\ln Y = \alpha_1 \ln L_{it} + \alpha_2 \ln K_{it} + \alpha_3 \ln TR_{it} + \alpha_4 \ln OTR_{it} + C + \varepsilon_t \qquad (2)$$

ε_t is assumed as classical error term: the mean value is zero and the variances are the same, there is no relevant sections of related time series. That is to say, there is no correlation exists when the error term is between different individuals or at different times.

2.2 Model verification method

Panel data structure is built to analyze time series of the five provinces in the Northwest in different years. The sample contains information in three directions, individual, indicators and time (Balgagi, 2001). Variable intercept model is often used to represent the individual differences existed in individual causes when building the model. Individual effects is divided into two forms, the fixed effects and the stochastic effects. The impact is analyzed using the fixed effects estimation method and the stochastic effects estimation method. F Test is used to decide whether to use the hybrid model or the fixed effects model, then Hausman Test is used to make sure whether to establish a random effects model or a fixed effects model.

3. Variables selection and data processing

3.1 Variables selection

Relevant variables are used as substitutions in order to study the spatial spillover effects of highway transport infrastructure on economic growth in Northwest China.

GDP is taken as output value as it stands for the value of all final goods and labor force produced by the economy in a region or a country.

The number of overall employments, which can be obtained directly from Statistical Yearbook, is taken to represent labor force investment of a region.

In traditional Cobb-Douglas production function, highway equivalent mileage is obtained by weighted conversion based on traffic volume. However, as different levels of highway have different functions and service objects, this method can't reflect the differences of the proportion of GDP produced by different levels of highway to transport, also can't reflect the investment of highway infrastructure accurately (Jeffrey, 2010). As a result, the amount of highway infrastructure investment is accumulated annually to get the capital stock of highway infrastructure in the current year. In data processing, annual highway investment is transformed into constant prices of 1990 to calculate the highway infrastructure investment in the Northwest from1990~2012.

The whole social capital stock (removal of the part of highway infrastructure stock) is taken to represent capital investment except the capital stock of highway infrastructure.

3.2 Calculation of spatial weight matrix

Based on the purpose of the study, the binary adjacency matrix of the five capitals in the Northwest is built.

Referring to the relevant researches, the binary adjacency matrix is built as follows: If two provinces are contiguous (sharing a common boundary length), the corresponding weight element value is 1; On the contrary, if they are not (no common border length), then the corresponding weight element value is 0.

$$w_{ij} = \begin{cases} 1 & \textit{when} \text{ i and j are contiguous} \\ 0 & \textit{when} \text{ i = j or they are not contiguous} \end{cases}$$

In which, $i, j \in [1, N]$, i, j are serial numbers of space unit, N is the quantity of space unit.

The first row to the fifth row represents Gansu, Shaanxi, Qinghai, Ningxia, and Xinjiang respectively, then the matrix is standardized so that the sum of the elements in every row is equal to 1. The final matrix is as follows.

$$w_{ij} = \begin{bmatrix} 0 & \frac{1}{4} & \frac{1}{4} & \frac{1}{4} & \frac{1}{4} \\ \frac{1}{2} & 0 & 0 & \frac{1}{2} & 0 \\ \frac{1}{2} & 0 & 0 & 0 & \frac{1}{2} \\ \frac{1}{2} & \frac{1}{2} & 0 & 0 & 0 \\ \frac{1}{2} & 0 & \frac{1}{2} & 0 & 0 \end{bmatrix}$$

4. Empirical analysis

According to the previous modeling analysis, the sectional data of GDP, labor investment, highway infrastructure investment and capital investment except the capital stock of highway infrastructure in the Northwest from 1990 to 2012 are collected. Then the consolidated data series are established by EViews, and the compiled data are analyzed using regression method. The results are shown in Table 1.

Table 1. Results of the analysis of spatial spillover effects based on the binary adjacency matrix in the Northwest

Dependent Variable: Q		Method: Pooled Least Squares		
Sample: 1990 2012		Included Observations: 23		
Cross-sections included: 5		Total pool (banlanced) observation: 115		
Variable	Coefficient	Std.Error	t-Statistic	Prob
L	0.517083	0.569726	0.907637	0.3669
K	0.206349	0.180790	1.141373	0.2573
TR	0.132547	0.132032	1.003860	0.3178
OTR	0.151206	0.265161	0.570102	0.5703
C	-0.120751	3.596924	-0.033571	0.9733
Fixed Effects(Cross)				
_GS-C	-0.254403			
_SX-C	0.199262			
_QH-C	-0.380281			
_NX-C	-0.25989			
_XJ-C	0.461410			

The results are calculated by panel data OLS, the fixed effects and the stochastic effects. The conclusion is that the fixed effects should be used. The estimation results are shown in Table 2.

Table 2. Estimation results of the binary adjacency matrix model (1990~2012)

spillover effects	variables	panel data OLS	panel data fixed effects	panel data stochastic effects	test results
W_{con}	labor	0.358619 3.095739	0.517133 0.907687	0.378333 3.121823	From the result of fixed effects model Wald, stochastic effects model L and test Huasman , fixed effects should be used.
	Capital stock except for highway	0.281929 3.229871	0.206349 1.141373	0.278346 3.153858	
	Highway investment	0.363875 5.184601	0.132516 1.003670	0.336984 4.697073	
	W_{con}	-0.289798 -4.972228	0.151150 0.570032	-0.263612 -4.264511	
	Constant term	1.301204 3.180545	-0.120751 -0.033571	1.192487 2.679655	
	R^2	0.868028	0.946806	0.843112	

Model estimation results:

$$\ln Y = 0.517083 \ln L + 0.206349 \ln K + 0.132547 \ln TR + 0.151206 \ln OTR - 0.120751$$

（0.907637） （1.141373） （1.003860） （0.570102）
（-0.033571）

$R^2 = 0.946806$ $\overline{R^2} = 0.927209$ F=48.31221

The model estimation results indicate that when the assuming of other variables is constant, GDP grows 0.517083% when labor force input increases 1%; GDP grows 0.206349% when capital stock increases 1%; GDP grows 0.132547% when local highway infrastructure investment increases 1%,; and GDP grows 0.151206% when ecdemic highway infrastructure investment increases 1%. From these results we can see that highway infrastructure investment plays an important role in promoting local economic development, and the spillover effects of ecdemic highway infrastructure investment on local economic development is also obvious.

Goodness of fit can be obtained from the regression model results: $R^2 = 0.946806$, corrected coefficient of determination is $\overline{R^2} = 0.927209$, which shows that the sample fits the model well.

As to H_0: $\beta_2 = \beta_3 = \beta_4 = 0$, the given significant level is $\alpha = 0.05$, and the critical value of freedom k-1=3 and n-k=18 identified in the F distribution table is F(3,18)=3.16. Based on the F=48.31221 in the table, F> F(3,18)=3.16, therefore the null hypothesis is rejected, which means that the regression equation is significant. As a result, labor force input, capital stock and highway infrastructure stock together have a significant effect on GDP.

5. Conclusion

Here we may draw the following conclusions.

(1) As an important part of social capital stock, local highway infrastructure plays a significant role in promoting local economic growth. The output coefficient of local road infrastructure on economy in the Northwest is 0.1325, which is higher than the results obtained by economists using panel data of China. It's mainly caused by the relatively backward infrastructure capital stock of Northwest China.

(2)There is a significant positive spillover effect of ecdemic highway infrastructure on local economic growth. The output coefficient of ecdemic highway infrastructure on economy is positive, which mainly works between neighboring provinces. The higher the supply capacity of national and provincial highway between them is, the stronger the positive spillover effect will be, and the higher the correlation about economic growth between them will be.

Abstract: At present, China's urban public transport development cannot adapt to economic and social development, the majority of urban public transportation proportion is low with accelerating urbanization, growing urban population, the trend of an integral of urban and rural has become more and more obvious and the problems of urban public transport are increasingly prominent. And improving legal system of urban public transport is the basic guarantee for the healthy development. This paper will study the legislation of China's urban public transport administrative regulations in depth.

Keywords: Public management; Public transport priority; Legislation of China Urban Public transport.

1 Introduction

At present, China's urban public transport development cannot adapt to economic and social development and people's travel needs, the majority of city public transportation proportion is low. In order to fundamentally ease traffic congestion, travel inconvenience, environmental pollution, contradiction, must establish the public transport priority development ideas. Bus priority is the important content of current our country to determine the city traffic development strategy, it is the inevitable choice to solve the traffic problems in our city. Implementation of bus priority development is the important content of government public management, but how to implement, implementation of bus priority, the city government is still in the exploratory stage.

2 Legislative principles

Legislation of China urban public transport is benefit for people. In order to ensure the correct direction of public transportation development of book industry, public transportation legislation should adhere to the following basic principles .

(1) The principle of unity of coordination

Because of the laws and regulations of our country is composed of legal norm effectiveness rating of multi-level, each are not identical, this is no exception in field bus legislation. Therefore, public transportation legislation must pay attention to the harmonization and unification of the whole system of laws and regulations, except the. Level coordination between unified legal norms.

(2) The principle of social justice

Urban public transportation legislation in particular should highlight the principle of social justice. Its connotation includes two aspects: On the one hand, generation fair; On the other hand, intergenerational equity. By emphasizing the importance of the priority development of public transport, promoting low carbon travel, protect the natural ecological environment, maintenance of the earth quality, so that future generations of people can enjoy fairly and contemporary people of earth mass.

(3) The principle of public participation

In order to make the public development truly realize "people-oriented", "public transportation legislation process must follow the principle of public participation, to keep the Democratic legislation. In the United States, in order to ensure public participation in the content of the adoption and enforcement of good government provisions, any traffic (including public transport project to obtain), federal government capital funding, we must ensure that the project is to attract the public and stakeholder participation, is a comprehensive, coordinated and continuous the planning process.

3 Legislative system

At present, in the field of traffic is not independent and complete public transportation method. About public traffic regulations are relatively more, such as the "Ministry of construction on the development of urban public transport priority views" (Ministry of construction, 2004), the "urban public steam tram passenger management approach" (Ministry of construction, 2005), "on the development of urban public transport priority of several economic policy advice" (Ministry of construction and other ministries. "The State Council on 2006), the urban public transport priority development guidance" (State Council, 2012), these rules are introduced to guide China's urban public traffic construction plays an important role in guiding policy.

Because our country is vast in territory, the urban development is great, can not solve all the problems of urban public transport regulations by a public transportation method, thus the public traffic law should include the guiding opinions and suggestions to the local public transport regulations, so as to provide basis for the formulation of laws and regulations of local government policy. The main should be reflected in the local laws and regulations of the content, depth equirements, such as the bus operating range, quality of service, freight, specific measures of administration of authorization.

4 The content of legislation

Mature foreign legislative experience of public traffic, and fully consider the present situation and development of China's public transit legislation situation, city public transportation legislation in China should include the following several aspects.

(1) The nature and status of urban public transit industry

Should the public nature of clear city public transportation. In the city traffic system, as the public transport has the advantages of high efficiency, environmental protection, economy, fairness properties, has a major role in alleviating traffic congestion in the city, to meet the public demand for travel, Protect environment, energy conservation, the promotion of city traffic sustainable development. Therefore, we should establish the priority of city public traffic in city traffic development, as well as its in passenger traffic of city of the dominant position in the overall city public traffic mode; clear requirements, form the core principles.

(2) Authority government and administration functions,

Should be the main leading responsibilities clear government on the development of bus priority and bus industry, clear the authorities and responsibilities of urban public transport sector, coordination mechanism of decision making clear of transit priority. At the same time, the relevant departments to deal with the transit priority rights to make limited, to ensure the healthy and orderly development of urban public transit industry.

(3) The priority development of public funds from the security mechanism

Clear the public transportation development into the government public finance priority protection, definite proportion sources and investment funds (public transport expenditure of public finance expenditure ratio), the establishment of long-term security mechanism, clear sustainability bus priority development of fund input.

(6) The overall principle of bus lines operation and management

The main task is to the provisions of the urban public transport operation managers and their responsibilities and management right is obtained, the rights and obligations of operators. Encourage public transport operating orderly competition and limited competition, market development of the principle of public traffic. In addition, the bus operating quality, price and other content clear macro guiding principles.

(8)The subsidy policy loss mechanism of bus

To clarify the public traffic industry policy loss of content and category, accounting mechanism; clear the policy loss of subsidies, subsidies model, and the related supervision, auditing system.

(9) bus service standards and supervision mechanism

On public transport enterprises, different bus hall type service norms, establishing a fair and impartial service standards; supervise and inspection, regular inspection for bus services, a clear corporate responsibility and obligation, ensure passenger satisfactory bus service.

(13) The legal liability and penalties

Clearly in violation of public traffic law provisions of punishment and enforcement provisions; to implement the main responsibility of public transit priority setting to investigate the mechanism of corresponding.

(1) The duties and rights of operation main body

As the passengers to provide basic services for urban residents, public transit enterprises have a bounden social responsibilities and obligations. City bus operation main body should be operating in good faith oriented, committed to providing passengers with safe, efficient, convenient, punctual, comfortable bus service, satisfy all sorts of transit demand residents growing city, guarantee the efficiency and vitality, promote the rapid development of city social economy. On the other hand, as a part of urban public transit industry, every bus operation main body should the whole industry interests, compliance with industry regulations, abide by the industry norms, and orderly competition, and seek common development, promote the healthy development of public transport industry.

Single bus operation main body development, the general enterprise economy's inalienable right, these basic rights include: the right to operate independently, provide the product right, profit, to the market development and expansion of enterprise scale and other rights. Needs to be pointed out is, because of the particularity of public transportation, bus operation main body in the enjoyment of those fundamental rights at the same time, will also be more strict government control than other industries and enterprises, in order to ensure the correct direction of the development of the public transport industry. However, the bus operation main body in accepting the control at the same time, should also enjoy the financial support and policy support provided by the government, which is also of special interest in other industries can not enjoy the. Can say, the rights of the main body of public transportation operation with more particularity compared with the enterprises in other industries, this is also reflected in the specific requirements of the development of public transport industry.

(2) The rights and obligations of passengers

Bus companies charge a fee to provide bus service between the passengers and the public transit operators have formed a relationship of rights and obligations, and is restricted and legal protection. Passenger bus service is the object and the core, the bus service should establish the supremacy of passengers, passengers for this concept, to provide passengers with safe, convenient, stable service. Enjoy the bus enterprise high quality service is the basic right of publication of passengers, including time, space and quality of service requirements, such as safety, stability, on time. At the same time, every passenger has the service level of public transportation enterprise and service quality - supervision rights, when their legitimate rights are harmed, have the right to make reasonable compensation requirements.

Urban public transport service has universality and fairness, both men and women, young and old, should emphasize the wealth, health, urban and rural residual have enjoy the bus service to the right, the government and the enterprise has the obligation to provide a fair public services for all citizens and foreign staff. The bus service should pay attention to humanistic care, with relatively low fares so that the majority of wage earners can afford, to people with low incomes, old and young, the disabled and other subgroups give preferential subsidies, to provide special services for persons with disabilities, is the responsibility of the government, is the part of the special groups enjoy the basic rights issue.

Abstract: The study of the changes the Freight Organizational Reforms brings to the freight demand network are important for development of railway freight traffic as it is the most source of income. This paper presents the changes through the demand network. Firstly, the collected data is used to analysis the demand of the transport market changes. This is one of the important reasons for the implementation of Freight Organizational Reforms. Secondly, by constructing virtual transport network, the differences are analyzed about the changes that transportation reforms have brought. The freight transportation reform loses the requirements of goods transport. This makes the origins and destinations of goods on the network become diverse. Accompanied by the reform, the flow and volume of traffic and goods are more complicated than pre-reform period. Before and after the reforms, comparing the range of network and wagon destination, as well as the possible path of the goods, we can draw on the conclusion that the demand network is more complicated and competitive in the future. How to organize the transport of goods more convenient and economic after reform is a serious problem.
Keywords: Freight organizational reforms; Demand changes; Demand network changes; Goods transport path problems.

1 Introduction

This paper analyzes the impact on freight demand network from the Freight Organizational Reforms. First, Freight Organizational Reforms is to adapt to changes of demand in freight transport market, to better meet customers' transportation needs and to improve competition of rail freight in transport market.

Second, Freight Organizational Reforms is the reform of transport organization of the railway transport enterprise, which is in order to change the conduct situation of freight market and to reduce freight transport deficiencies at the current process (ZHAO Xueyou, 2014).

The main connotation about the reforms includes two aspects. One is the overall objective of Freight Organization Reforms. The other is the tasks of the reforms. Among them, the overall goal of Freight Organization Reforms covers the stability of bulk material transport and the other goods (YANG Wenxi, 2014). For the former material, the protocol approach should be taken. And for the latter, the railway companies should guarantee to meet customer’s demand, the quality of transport services and the standardization of the management fees. The main task of the Freight Organizational Reforms can be divided into three parts. The first part is mainly about the innovation of the operation ways that freight organizational uses. The second part is the implement of the real goods system and the last part is railway freight transport developing to modern logistics.

Third, due to Freight Organizational Reforms, the railway freight in the operation process is different than before. An open carriage and full acceptance expanded scope of railway freight service supply area, which causing freight demand network compared with the network before is changed. Such changes include the increase of the demand network nodes, the wagon flow path, and the expansion of freight service scope, etc.

2 Freight Market Demand Changes

Economic development makes the transportation needs change a lot, which contributed to the rapid growth of the need in modern logistics industry (CUI Yaqiong, 2014). The transportation demand of small parts and items, express transportation, and some daily necessities are growing fast in recent years (DING Chuang, 2014).

About 70% income is from freight rail transport. Due to the form of macroeconomic malaise, railway freight volume continued to decline. In 2013, the national railway freight, the growth index almost decreased and presented to negative in each months except for January. Railway freight is decreased, but the logistics of the whole society achieved higher growth. Railway freight data (collected form the internet) from January to June in 2013 is as follows:

Table 1. Freight volume of six months in 2013

	Months					
	Jan	Feb	Mar	Apr	May	June
Freight Volume(10 kilo-tons)	34443	30980	33984	31218	32420	313048
Grand Total Freight Volume(10 kilo-tons)	34443	65423	99407	130625	163044	194348
Cumulative YoY Growth (%)	1.6	0	-0.9	-2.3	-3.1	-2.8
YoY Growth (%)	1.6	-1.8	-2.4	-6.5	-6.5	-0.7

Table 1 shows the exact data about the freight volume in 2013. According to table 1, we can draw the trends of freight volume in Figure 1 as follows:

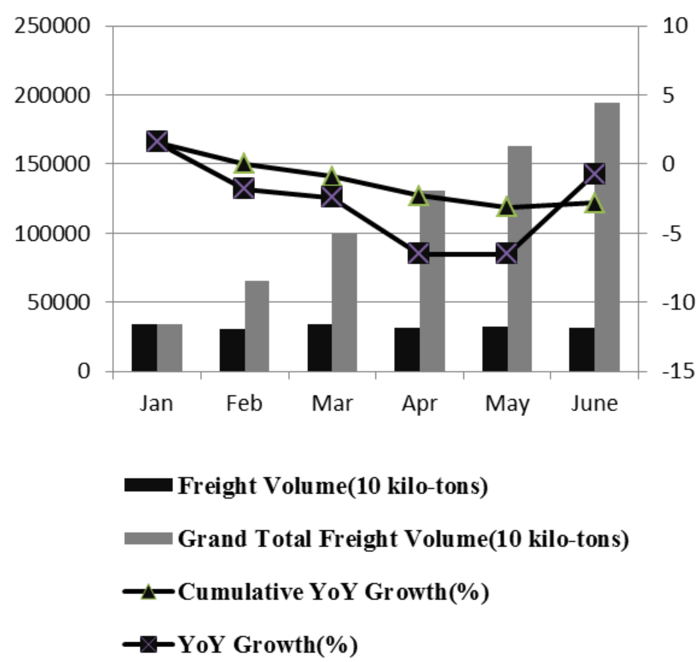

Figure 1.The trends of freight volume of six months in 2013

In the railway freight services, there is a complicated procedure in application for goods transport, which makes transport organization out of touch with the market demand. Non-standard transportation fees and capacity allocation issues also caused goods lose. After the reforms, railway transport companies fully considered all the stations and its generating demand for freight transport, which makes the increased needs of scattered white goods transportation in small and medium enterprises.

3 Demand Network Changes Analysis

In order to analyze the impact of reform, the following simple visual railway network graph is constructed. Suppose there are n stations. Among them, the freight source generating points are represented as the node set of O, and the destination stations are represented as the node set of D. In the set of O suppose that o_i (i=1, 2, 3, •••, n) refers to the non-fulcrum stations, O_i refers to fulcrum station. While the d_j (j=1, 2, 3, •••, n) and D_j refers to the non-fulcrum stations and fulcrum stations in the set of D. The bold lines and bold dashed lines represent the volume in these path are larger than the other lines.

(1)The network before Freight Organizational Reforms

Railway freight business is mainly to supply the approval to large loading points, namely adequate supply compared to the surrounding small freight stations for relatively concentrated flows. For the generated supply of the non-fulcrum station, it should be transported between the major sites. Some non-fulcrum stations will even be ignored. This kind of network is as follows:

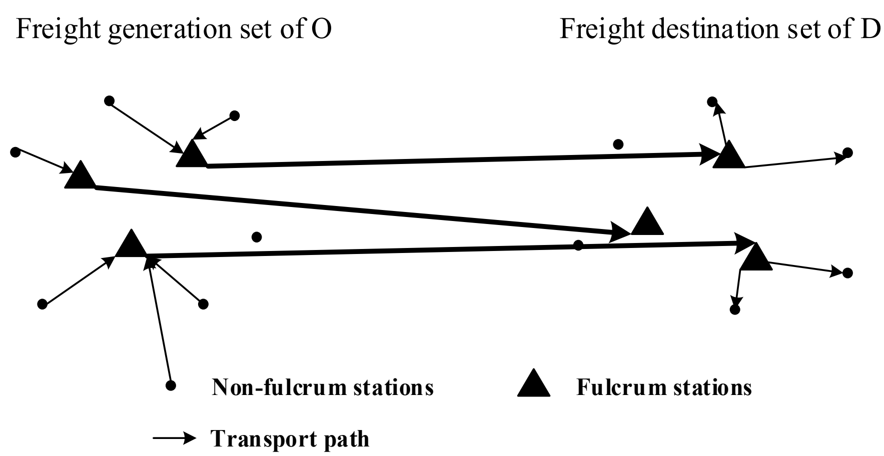

Figure 2.The railway networks before freight organizational reforms

(2) The network after freight organizational reforms

After the railway Freight Organizational Reforms, there is a comprehensive open acceptance for freight demand. For non-fulcrum stations, the supply that generated not only can be directly carried and transported to the destination, but freight sources can cycle between fulcrum and non-fulcrum stations. Therefore, the status of non-fulcrum stations has improved after the reforms, which directly led to an increase in the number of generation and disappeared sites.

Transport of goods does not to pass through the fulcrum stations on condition that the origins to the destination stations have adequate transport volume and the goods flow is concentrated. This means the origin station to destination transport is more economic than the transport path which goods must transport to fulcrum stations first.

The changes of the network are as follows:

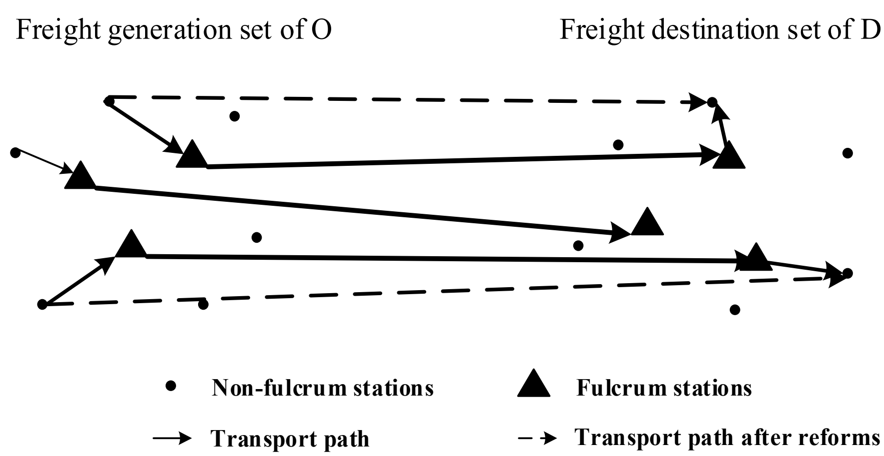

Figure 3.The railway networks after freight organizational reforms

The transportation path should be chosen from the consideration of transport cost, the shortest path and other objections. Finally, the chosen path must meet the multi-objections.

4 Discussions of Results

(1)Problem definition and description

We define the directed graph as G= (V, A). Every node $v \in V$ represent the original (or the destination) station. The arc set A define as the route, which freight train transport path contained. Each arc on the graph has a corresponding nonnegative real number W, which represent the weight of arc. The weight refers to the quantitative index related to the arc (WU Fei, 2014). P for graph G is a transport route of goods from the origins to the destinations. The path P contains a set of nodes which represent the stations the path contained. The nodes in P represent the order that goods be transported. And the shortest route can be represented as follows:

$$W(P^*) = \min\{W(P)\}$$

With the length of the P is called as follows:

$$W(P) = \sum_{a \in P}(a)$$

(2)Results analysis

Before Freight Organizational Reforms, some non-fulcrum stations are ignored because of the less freight volume generated. And some non-fulcrum stations' freight volumes which are taken into considered must be transported to fulcrum stations first. Then through the origin fulcrum stations and destination fulcrum stations, the goods can finally arrive at their place. So the possible paths can be enumerated as follows:

P (voi, v0i, vDj, vdj)
P (v0i, vDj, vdj)
P (voi, v0i, vDj)
P (v0i, vDj)

After the reforms, all the non-fulcrum stations are considered no matter how small freight volumes they generated. The reforms promoted the non-fulcrum stations status. At the same time, the numbers of the original non-fulcrum stations are increased. Therefore, in one hand the goods circulate between the non-fulcrum stations and the fulcrum stations. In other hand, goods can also be transfer directly between two non-fulcrum stations. As the result, the possible paths of the goods are enumerated as follows:

P (voi, vdi)
P (voi, v0i, vDj, vdj)
P (voi, vDj)
P (voi, v0j, vdj)
P (voi, v0i, vDj)
P (v0i, vDj, vdj)
P (v0i, vDj)
P (v0i, vdj)
P (voi, vDj, vdj)

The enumerated paths list all possible paths that goods can be transported. For different condition of goods transport, the chosen path should meet the objective function. All the analysis on this paper is based on the hypothesis of sample visual transportation network which discussed above.

5 Conclusions

Here the following conclusions can be made.

(1) It is observed that the network has changed since the Freight Organizational Reforms. Not only the scope of the service and the range of wagon destination are more lager than before, but the number of the stations that must be considered is increased.

(2) It is also observed that the path and the wagon routing have a lot of choices. The goods can be transported between the non-fulcrum stations and the fulcrum stations. Also, the origin and destination stations of the path are not just at the fulcrum stations, it can be non-fulcrum as well.

6 Recommendations for Future Research

Goods transport path problem and rail network problem are important to study so that it can be more detailed in rail freight transportation situation. And the model can be more close to the actual, such as the objective function of the path, the constraints of path chosen and routing problem. The constraints that contain the capacity constraints, flow direction, flow volume, and the demand of customer should be considered in the future research.

Abstract: This paper is based on the analysis of the rail freight demand and problems, by conducting SP survey for the owner of the demand in the freight market and using cluster analysis to segment the freight market to obtain differentiated needs of each owner. And combining product hierarchy theory, this paper analyzes the design elements of frail freight products. Finally, from the perspective of the unitized rail transport product, the paper analysis three kinds of modes of transportation, including truckload, LTL, container transport, and designs and develops the form of the rail freight transport products on the internet of things. This research considering the characteristics of our railways and the market demands to create some unitized transport products in the application environment of the internet of things, which ispersonalized, diversified, and meeting the needs of shippers.
Keywords: The internet of things; Unitization; Railway product design; Clustering analysis; Market segmentation.

1 Introduction

Under the planned economy, the traditional rail freight product refers to spatial displacement of goods through the process of transportation, it is calculated in units of tonne-kilometers (Jiguang. G, 2005). With the development of market economy, multiple transportation modes system gradually improved, substantial changes occurred in the connotation of freight product. It caused a huge impact for the development of the traditional railway cargo transportation product. In order to change the situation that rail transport market rate is gradually decline, some scholars carried out a series of studies about rail transport product design and development. Literature (Yan. Z, 2014) on the basis of analysis of current situation of China's railway freight product design, based on the CS strategy, proposed a ideas about rail freight product optimization. Literature (Yuhua. G, 2011) on the basis of the rail freight market survey forecast, from a marketing point of view, use the concept of the overall product to design railway cargo transportation product. Above studies lay a solid foundation for more theoretical studies, but its products were not really designed to achieve transparency in the transport process and product tracking real time. Rise and application of the Internet of Things technology lay an important foundation for solving the problem. So this paper is based on the analysis of the rail freight demand and problems, by conducting SP survey and cluster analysis knowing the different need of shipper, and from the perspective of the unitized rail transport product,designing and developing the forms of the rail freight transport product on the Internet of things. This research for enhancing the competitiveness of rail transport, consolidating and expanding market share, improving the economic and social benefits has a great significance.

2 Internet of Things technology and its application in railway freight transport

2.1 outlined of the Internet of Things

Things English name is "The Internet of Things". Abbreviation: IOT. Known by name, the Internet of Things is " the Internet that things linked." It has two meanings: First, the core and foundation of the Internet of Things is still the Internet, and it is an extension and a network based on the Internet; Second, its client extends to any goods to exchange information.

Therefore, the definition the Internet of Things is through radio frequency identification (RFID) devices, sensors, global positioning systems, laser scanners and other information sensing device, according to the agreed protocol, to make anything connect with the Internet, and to exchange information and communication, in order to achieve intelligent identification, positioning, tracking, monitoring and management of a network (Xin. Z, 2011).

2.2 application in railway freight transport

According to the requirements of the railway cargo transportation, railway cargo transportation applications in Internet of Things technology should be independent electronic label design, things were constructed corresponding application system to adapt to different forms of freight requirements. The core problem is that RFID technology designed to identify the goods, mainly electronic tags include RFID, ZigBee, Beidou recognizes.

Applications of three types of RFID technology of The Internet of Things in railway freight transport firstly need to achieve a unit, which is the application of stereotypes storage containers, such as pallets, containers, bulk bags, baskets and other container forming a cargo unit, for different cargo units designed appropriate electronic tag, information intelligent recognition technology and PC application software development, eventually forming the corresponding The Internet of Things applications.

3 Rail freight market segments

3.1 Rail freight needs analysis

There is a big difference in the species, volume, speed between shippers, and the Rail freight demand is different. So the survey for the need of shipper and cluster analysis for the Rail freight market for rail transport product' design and research has important significance.

When shippers choose the transport products, they mainly consider the following effects factors:

(1) Freight volume. Shippers when choosing mode of transport, freight volume as an important limiting factor is essential. Because of different size cargo, its optional mode of transportation is not the same.

(2) Economy. Economic factors are important when selecting the mode of transportation, especially for the level of low-value bulk goods transportation and under the condition that various other factors are same, economic factors often play a role as the first factor.

(3) Security. the impact and consequences caused by damaged goods, can not compensate by the money, so the safety of the transport of goods is very important, especially for high value-added goods.

(4) Transport speed. Timely delivery of goods is very important for investment and conversion marketing plan, therefore, the owner of the requirements for the transportation rate is also increasing.

(5) Convenience. Freight-related procedures are or are not simple and convenient, relevant job is simple and efficient, becoming increasingly important factor when the user selects products.

(6) Transparency during transport. In a market economy,Master cargo status and location, configuration, and management to improve the level of corporate resources play an important role.

(7) Service. With the continuous development of additional products, services indicators such as "door to door" may also become a considering factor when selecting.

3.2 SP survey of the rail freight demand

According to analyzing influencing factors, using SP survey (Stated Preference Survey) method (Lianhua. T, 2013), access to cargo demand information through questionnaires, we use the principle of sampling in shen yang railway bureau' qi qi ha er freight station for each owner of the 105 questionnaires, 100 valid questionnaires were obtained.

In order to verify the reasonableness and reliability of the questionnaire design, 'use KMO and Bartlett test of sphericity test methods to verify (Ya. Z, 2014), the test results are shown in Table 3.1.

Table 3.1 KMO and Bartlett's test

KMO and Bartlett's test	
Adequate sampling of the degree of Kaiser-Meyer-Olkin	.727

Bartlett's test	The chi-square approximation	191.106
	df	21
	Sig	.000

Table 3.1 shows the KMO and Bartlett test results, which KMO value is 0.727> 0.7, indicating good validity; Bartlett spherical test results Sig value of 0.00, less than the significance level of 0.05, and therefore reject the null hypothesis Bartlett test of sphericity, validity think good fit to continue to do factor analysis.

3.3 Cluster analysis based on the rail freight market segments

China's existing rail freight transport is divided into three types, namely, truckload, LTL, containers. Transport product design and development should be combined with the owner's needs, based on the original three forms. so, in this paper, freight volume, economy, transparency, security, transportation speed, convenience, transportation, and service these seven factors as the classification index, using K-means clustering analysis method, due to sample size constraints, in this paper, decided to divided100 samples into three categories, the final clustering results are shown in Table 3.2**.**

Table 3.2 K-means final clustering center

	Cluster		
	1	2	3
Freight volume	9	3	4
Economy	8	7	8
Security	7	5	8
Transport speed	8	7	8
Convenience	7	7	7
Transparency during transport	7	8	8
Service	6	6	7

Through inter-class variance and intra-class error mean square analyzing for each impact factor, obtained significant differences between the various categories, reasonable clustering results.

3.4 Characterization of the various market segments

After the railway freight market segments, each of these factors need to be broken down to study the general characteristics of each segment of the market, in order to distinguish the different needs of various market segments of travelers. Factors in the various market segments are distributed as follows Table 3.3.

Table 3.3 Distribution of shippers' demand in the various market segments

Index	Demand / Market	Unimportant	Less important	General	More important	Important
Freight volume	Ⅰ type	0.00	0.00	0.00	36.80	63.20
	Ⅱ type	26.00	69.60	4.40	0.00	0.00
	Ⅲ type	0.00	51.30	48.70	0.00	0.00
Economy	Ⅰ type	0.00	0.00	2.60	84.20	13.20
	Ⅱ type	0.00	4.40	21.70	69.50	4.40
	Ⅲ type	0.00	0.00	5.10	58.90	36.00
Security	Ⅰ type	0.00	0.00	2.60	84.20	13.20
	Ⅱ type	0.00	0.00	4.40	30.40	65.20
	Ⅲ type	0.00	0.00	15.10	48.90	36.00
Transport speed	Ⅰ type	0.00	5.30	7.90	71.10	15.70
	Ⅱ type	0.00	4.40	21.70	56.50	17.40
	Ⅲ type	0.00	0.00	0.00	56.40	43.60
Convenience	Ⅰ type	0.00	2.60	36.80	60.60	0.00
	Ⅱ type	0.00	0.00	47.80	47.80	4.40
	Ⅲ type	0.00	0.00	15.40	71.80	12.80
Transparency during ransport	Ⅰ type	0.00	0.00	11.10	71.10	17.80
	Ⅱ type	0.00	0.00	8.70	60.90	30.40
	Ⅲ type	0.00	0.00	0.00	81.30	18.70
Service	Ⅰ type	0.00	15.80	50.00	34.20	0.00
	Ⅱ type	0.00	17.40	26.10	56.50	0.00
	Ⅲ type	0.00	0.00	12.80	84.60	2.60

Through analyzing the following diagram can be obtained, freight volume in class Ⅰ market more than the other market, were 100%, it can be explained mostly bulk cargo transport market, at the same time, in such markets, the speed of transportation and transparency during transport is relatively high proportion, were 97.4%, 97.4% and 88.9%, which can be seen for bulk cargo shippers valued economy and security of the modes of transportation, in addition, the requirements for transparency during transport is relatively high; Ⅱ type of market factors that affect the safety of the biggest, 95.6%, thus indicating that the market can focus on cargo security; in Ⅲ type of market, transparency during transport were the largest share of 100%, followed by economic factors accounted 94.9%,while the service is more than other markets, and Freight volume' proportion were smallest. Therefore, it can speculate that the market should be small pieces, LTL, the owner pay more attention to the state of real-time control for the transport of goods, and focus on transport prices and transportation services.

4 Unit of rail transport product design and development in the environment of The Internet of Things.

According to the above freight market segments and the requirements of the railway cargo transport unit, combined with the existing truckload, LTL, three freight containers in the form of rail, on the basis of the existing railway products designs and developsrail transport product in the environment of The Internet of Things.

4.1 Unit of vehicle transportation products

(1) Unit of the fast-specific bulk cargo originating direct trains. For the type of supply is fixed, stable volume of bulk cargo such as grain, cotton, mineral running specific, direct, fast trains, while a train as a unit to add electronic tags, using The Internet of Things technology for cargo location tracking, achieve transparency requirements during transport.

(2) Unit of the Cape-speed direct-specific bulk cargo originating trains. Such products are also great for freight volume shippers, but the transport speed is relatively low, these products relative to specific bulk cargo fast direct trains has low price.

(3) Unit of vehicle transportation transit trains. Such products for freight volume is relatively small, not enough to gather a direct train. while a car is a transport unit to add electronic tags, to achieve the positioning of each type of cargo tracking, to provide convenient services to shippers.

4.2 Unit of container transportation products

(1) Unit of the container transport fast trains. This column is the product for the stable supply of container transportation shippers, major transport precision, precious, fragile goods, running rapid transit trains containers, while a container for a transport Unit to add an electronic tag.

(2) Unit of the Cape-speed container transport trains. Such products compared to the previous one in terms of products, more slowly, but the price is cheaper.

(3) Unit of regular direct containers trains. This train fixed, fixed-line, regular, fixed vehicle, pricing, circulation runs between two base stations, without regrouping. so it has high speed and efficiency.

4.3 Unit of LTL product transportation products

(1) High-speed Unit of LTL transportation product. This is mainly for small-volume, high value-added transportation time demanding LTL, per packaging unit for a transport unit for tracking the goods, to ensure safe transport of goods, with the option to provide "door to door" transport services, for the owner to provide convenient.

(2) Cape speed Unit of LTL transportation products. These products mainly include transportation to the time limit is not required, according to sources, waitingthe consolidation, assembly and other job completed, running alone trains transport products.

5 Conclusions

Faced on the increasing competition in freight market and the increasingly diverse needs of shippers, rail freight market ushered in new opportunities and challenges. Given a rail shipper of product design issues, combined with the main trend of the logistics network technology development and applications, create personalized, diversification, meeting the necessary demand of shippers Unit of transport product, is the necessary development trends of rail freight market, and this is of great significance for the consolidation and expansion of rail freight market share, and the economic and social benefits improved.

Abstract: This paper introduces the systematic strategy of car-following (CF) models with three aspects. The general reality description is firstly used to analyze whether the CF models can describe the overall longitudinal driving behaviors really. Then the individual reality description is applied to analyze the ability of simulating individual behaviors precisely of diverse CF models. Finally, the inter-driver and intra-driver heterogeneity are analyzed for that good models can minimize the discreteness. In general, it is convenient for researcher to use the systematic strategy to evaluate the CF models.
Keywords: Car-following models; Evaluation; Systematic strategy.

1 Introduction

Car-following (CF) models, which describe the longitudinal interactions of vehicles, have been developed for almost half a century. In the early stage, the studies of CF models are focused on the model establishment. Many models are developed when researchers figure out that the existing models cannot describe some specifically macroscopic phenomena. In this period, a large number of models are proposed by researchers due to their intuitive senses. And the rule of CF models evaluation is whether the model can describe the real traffic phenomenon. However, the parameters of various CF models cannot be estimated precisely because of the lacking of measured data, especially the microscopic data. Several researchers attempt using vehicle experiments to calibrate the parameters, leading to a doubt about the quantity and quality of the data (Brackstone, 1999).

Technological advances in the field of microscopic data-collection methods have caused a considerable increase in the number of studies using trajectory data to calibrate CF models accurately (Pipes, 1953; Gazis, 1959; Herman, 1959; Brockfeld, 2004). During the calibration, two mathematical principles are widely applied: Least squared errors (LSE) and maximum likelihood (ML), and these two principles are identical in some degree. Arne (Ranjitkar, 2004; Hoogendoorn, 2005) and Wang (Wang,2010) use the value of the LSE as the standard of evaluating the CF models. And the smaller errors between simulated and measured trajectories mean better model performances. Hoogendoorn (Ossen, 2006) adopt the value of ML in the model estimation and use the likelihood-ratio test to cross-compare CF models with different complexity.

In general, the methods of using mathematical value to evaluate model performances, which represents the fitting degree of simulated and measured microscopic trajectories, are widely developed in recent years.

These methods which provide a convenient cross-comparison of different models, however, result in the deviation from the initial goal of CF models' establishment. A great CF model is one that can describe the real microscopic longitudinal behaviors precisely and the actual macroscopic phenomena accurately, not one with the maximum or minimum mathematical value. Therefore, the systematic evaluation strategy of CF models, which accord to the initial goal, is still lacked.

The main contribution of the present study is the introduction of a systematic evaluation strategy of CF models, which focuses on the model description on real behavior. And the next section will proposed the strategy in detail and the section 3, 4 and 5 will introduce the different rules of model evaluation belonging to the strategy system separately. Conclusion will be drawn and further studies will be introduced in the last section.

2 Systematic Strategy

The initial goal of CF models' development is to describe the reality of the longitudinal behaviors. Thus the basic principle of the systematic strategy of CF models evaluation is reality description. There are two methods of reality description analysis: the first one is general reality description, which describes different individual drivers with the identical parameters; the second one is individual reality description, which models individual drivers separately with the independent parameters. These two methods represent different aspects of CF models evaluation, with the same principle—reality description although.

Besides the basic principle, there is another goal focused on by some researchers and should become the developed principle—adaptation analysis. The adaptation analysis is more and more vital when the CF models are applied to a large number of individual drivers. These drivers have diverse driving styles which are called the inter-driver heterogeneity, and the same driver has distinct styles which is called the intra-driver heterogeneity. A good model should cover the inter/intra-driver heterogeneity simultaneously with great robustness. Therefore, the developed principle of adaptation analysis is inevitable.

3 Generalized CF models

The CF models can be expressed in discretized form as follows:

$$v_i(t_{k+1}) = f[h, y_i(t_k), y_i(t_k - \tau)|\theta] \tag{1}$$

Where θ denotes the set of parameters describing the car-following models; h denotes the time step used for discretization; $v_i(t_k)$ denotes the velocity of driver i at time instant t_k; $a_i(t_k)$ denotes the acceleration of driver i at time instant t_k; and $y_i(t_k)$ denotes the state that is relevant for driver i at time instant t_k.

The state of $y_i(t_k)$ includes all stimuli present in the CF models, and can use the following specification:

$$y_i(t_k)=f[v_i(t_k),\Delta x_i(t_k),\Delta v_i(t_k)] \tag{2}$$

Where $\Delta x_i(t_k)$ denotes the distance between the vehicle i and the leading vehicle; $\Delta v_i(t_k)$ denotes the velocity difference between the vehicle i and the leading vehicle.

And the calibration is to minimize the difference between the measured state $y_i^{obs}(t_k)$ and the simulated state $y_i^{sim}(t_k)$, which can be expressed as follows:

$$\begin{aligned} y_i^{obs}(t_k)&=f[v_i(t_k),x_{i-1}(t_k)-x_i^{obs}(t_k),v_{i-1}(t_k)-v_i^{obs}(t_k)] \\ y_i^{sim}(t_k)&=f[v_i(t_k),x_{i-1}(t_k)-x_i^{sim}(t_k),v_{i-1}(t_k)-v_i^{sim}(t_k)] \end{aligned} \tag{3}$$

Where $x_i^{obs}(t_k)$ denotes the measured position of vehicle i at time instant t_k; $x_i^{sim}(t_k)$ denotes the simulated position of vehicle i at time instant t_k; $v_i^{obs}(t_k)$ denotes the measured velocity of vehicle i at time instant t_k; $v_i^{sim}(t_k)$ denotes the simulated velocity of vehicle i at time instant t_k;

4 Calibrating methods

There are two main mathematical approaches to formulate the calibration problems: Least squared errors (LSE) and maximum likelihood (ML).

The LSE is one of the regression methods which can be expressed as following simply:

$$S(\theta)=\sum_{1}^{n}(Y_i^{sim}(\theta)-Y_i^{obs})^2 \tag{4}$$

Where Y_i^{sim} denotes the simulation predictions at point i, i = 1, . . . n; Y_i^{obs} denotes the data point i, i = 1, . . . n; and this reduces the calibration problem to a multi-variate nonlinear optimization problem:

$$\boldsymbol{\theta} = \arg\min S(\theta) \tag{5}$$

The ML method uses the likelihood function as the joint probability that the CF model predicts all data points:

$$L(\theta)=prob(Y_1^{sim}(\theta)=Y_1^{obs},\ldots,Y_n^{sim}(\theta)=Y_n^{obs}) \tag{6}$$

$$L(\theta)=\prod_{i=1}^{n} p(Y_i^{obs}|\theta) \tag{7}$$

When the log-likelihood function is used as follows:

$$L(\theta)=\sum_{i=1}^{n} Ln\ p(Y_i^{obs}|\theta) \tag{8}$$

And the parameters can also be solved:

$$\boldsymbol{\theta} = \arg\max L(\theta) \tag{9}$$

4.1 General reality description

For the general reality description, the CF models are calibrated for all drivers with the following approach: the measured data of the leading vehicle is served as inputs for the models. The longitudinal models calculate the acceleration of the follower, and get the velocity and position. In that case, the models can simulate the movements of each following car. Comparing the measured data points and the simulated data points, the error term can be calculated generally for all drivers, as shown in the following :

$$Error(\theta)=\frac{1}{n}\sum_{1}^{n}\frac{\sqrt{\sum[Y_i^{obs}-Y_i^{sim}(\theta)]^2}}{\sqrt{\sum[Y_i^{obs}]^2}} \tag{10}$$

Where n denotes the number of vehicles.

Considering the calculating error in the optimization, the optimal process is repeated for several times to get the distribution of the parameters θ. And in the general reality analysis, the parameters should be in the normal range, which is in line with the actual driving behaviors. If there is any parameter that is not consistent with the range, the general reality description is not good and the model cannot describe the overall longitudinal driving behaviors really.

4.2 Individual reality description

For the individual reality description, the CF models are calibrated for each driver separately with the following approach: the measured data of the leading vehicle is as inputs for the models. The longitudinal models calculate the acceleration of the follower, and get the velocity and position. In that case, the models can simulate the movements of each following car. Comparing the measured data points and the simulated data points, the error term can be calculated separately for individuals, as shown in the following :

$$\varepsilon(\theta) = \frac{\sqrt{\sum[Y_i^{obs} - Y_i^{sim}(\theta)]^2}}{\sqrt{\sum[Y_i^{obs}]^2}} \tag{11}$$

The calibrating errors are also considered and the calibration should be repeated for several times. The average values of the parameters θ are used in the simulation of the car-following behavior. Comparing the measured microscopic trajectory separately with the simulated one, the individual reality can be evaluated, with the little difference means the great individual reality description.

4.3 Heterogeneity analysis

Heterogeneity is widespread, for that human drivers are not deterministic automata. And there two aspects of longitudinal driving behavior heterogeneity: inter-driver heterogeneity and intra-driver heterogeneity.

Inter-driver heterogeneity is the diverse driving styles among different drivers, and can be figured out when the individual reality description is applied. When the different parameters of distinct drivers are compared, the discreteness of these parameters can be used as the inter-driver heterogeneity analysis. In general, the large discreteness means the large inter-driver heterogeneity and the defect of the CF model.

Intra-driver heterogeneity is the difference during the different periods of driving. For intra-driver heterogeneity analysis, the data of all the leader-follower combinations are split into two parts equally in the first. Then the part I and part II are calibrated with the method mentioned in the calibration for individual reality description. For each vehicle in the two part, the error term is defined as follows:

$$\varepsilon_J(\theta) = \frac{\sqrt{\sum[Y_i^{obs} - Y_i^{sim}(\theta)]^2}}{\sqrt{\sum[Y_i^{obs}]^2}} \tag{12}$$

Where J belongs to part I or Part II.

And through comparing the difference of $\varepsilon_I(\theta)$ and $\varepsilon_{II}(\theta)$, the intra-driver heterogenetiy can be figured out. Generally, the large difference of the distinct driving period means the model cannot simulate one driver precisely. Therefore, the intra-driver heterogeneity can also be the vital aspects in the CF models evaluation.

5 Conclusion and future work

The systematic strategy of car-following models is developed for the three levels. Firstly, the general reality description is used to analyze whether the CF models can describe the overall longitudinal driving behaviors really; secondly, the individual reality description is used to analyze the ability of simulating individual behaviors precisely of diverse CF models; finally, the inter-driver and intra-driver heterogeneity are analyzed for that good models can minimize the discreteness. For using the systematic strategy, the evaluation of the CF models can be more convenient and feasible. In the future, the specific case of several CF models evaluation should be studied and the process need to be further refined.

Abstract: The rail transportation has been gradually becoming a main way for the urban public transportation in China. The rail transit, as a kind of large capacity, high speed, safety and punctual transportation, not only improves the accessibility of the urban traffic, but also raises the new commercial circle. It brings a huge impact to the development of urban commercial space. In recent years, with the rapid development of Zhuhai, the government has started the constructions of the rail system and the north station TOD project in order to alleviate the traffic congestion in the downtown of Zhuhai. Based on the north station TOD projects, the relationship between the rail transit and the urban commercial space had been analyzed. The rail transit impact on development of commercial space had been studied.
Keywords: TOD; Urban commercial space; Rail transit; Catalyst.

1 Introduction

In China, the cities are facing many developing problems with the development of economy, the industrial structure adjustment and the urbanization. The continuous expansions of city bring about the intense traffic demand and the serious traffic pressure. The congestion has being more and more serious. In major cities, though a variety of measures having been implemented, but it is difficult to fundamentally solve the congestion problems. In the other way, facing the grim problems of energy and land, many big cities in the developed countries almost without exception had chosen the rail transportation as the main mode of transport. Comprehensive analysis of the current social economic development and urbanizational development goals has found that the urban rail transit system basically established the leading position of the future transportation in cities.

The rail transit is not only changing the pattern of the city, but also bringing the value-added land for the rail transit site periphery. The infinite business opportunities and vitality had been brought by the formation and development of business circle. The change of traffic pattern, caused by the rapid public bus or rail transit, had brought the new pattern for domestic business development. For example, the transit-oriented development (TOD) will play a key role to promote the development of urban commercial space.

The paper analyzed the rail transit impacts on the urban spatial structure and the development of commercial space according to the Zhuhai north station TOD project according to the TOD theory and the theory of urban catalyst.

2 Related Theories

2.1 Urban Rail Transit System

Urban rail transit system is a special line public transportation system with continuous orientation ability. Its characteristic is a whole special track that is not mixed with the motor vehicles. For example, there is no any intersection, any pedestrian crossing, and any bicycle way or vehicle line. Usually, urban rail transit systems were built in the underground or above viaduct. The special pattern made the train run in the rail line freely. Urban rail transit system can run in the fully automatic operation mode. In addition, the urban rail system is divided into two kinds, heavy subway and light rail (Sebastien, 2009).

2.2 TOD

A TOD is a mixed-use residential and commercial area designed to maximize the access to public transport. A TOD neighborhood typically has a center with a transit station or stop (train station, metro station, tram stop, or bus stop) surrounded by the relatively high-density development blocks, with which the lower-density development blocks progressively spread outward from the center. TODs generally are located within a radius of one-quarter to one-half mile (400 to 800 meters) from a transit stop because it is considered to be an appropriate scale for pedestrians. Thus the last mile problem is solved.

Eight principles of design a TOD (Peter, 2014) are:

(1) Designing suitable for walking the streets and pedestrian scale blocks.
(2) The bicycle network is preferred.
(3) Improving the road network density.
(4) Developing a high quality public transport system.
(5) Using a mixture of blocks.
(6) According to the city's public transport capacity to determine the density.
(7) Through the quick commute to establish some compact urban areas.
(8) Adjusting the parking areas and the road use to increase mobility.

A typical TOD is mainly composed of the following functional structures of land use: Bus stops, core business district, office district, residential districts, and public open space (Lu).

2.3 Urban Catalyst

The theory of urban catalyst (Jin, 2006) is that the original spot catalyst integrates with new elements to form a urban large spot catalyst, or along the river or the traffic route to form a line catalyst as well as a plane catalyst that would make the design project affect a larger city area. The influence would eventually produce a reaction mechanism with the urban development.

In terms of urban design project itself, a specific construction project that can be used as a start point or a catalyst to stimulate the urban design implementation. The spot catalyst is important for the decision of implementing a phased

3 The Impacts of the Rail Transit on the Urban Space

This chapter analyzed the impacts of the rail transit on the urban space according to the urban structure and the urban commercial space. Including, the axial development of urban space, the overall urban space form changement, the rail transit has two efficacies of the agglomeration and diffusion on the urban structure, and the urban population spatial distribution change. By the joint effect of the agglomeration and the diffusion, the urban commercial space will be an urban catalyst pattern.

3.1 The Impacts of the Rail Transit on Urban Space Structure

3.1.1 Axial development of urban space

Urban development axis is mainly composed by the centrifugal effect traffics, such as railway, highway, rail transit lines, which drive the development of the surrounding land. The development axis type, quantity, direction, length, and stretching speed directly constitute all kinds of city external forms, which determined some phased development characteristics of the city developing form. The rail transit as a fast high-volume traffic type guided the urban development along the rail transport, which the corridor effect made the city construction along the rail transit line be a high density axial city development. Rail traffic impacts the urban spatial structure by the stations or sites. These stations constitute an axis, along which the urban high-density development and dotted construction have been done with a continuously expansion. Eventually, the axial development of urban space is finished and the corresponding rail transit lines have also become a city's developing axis (Bao, 2012).

3.1.2 Overall urban space form change

The different forms of rail transit network have very different impacts on the whole urban space. The grid network makes an evenly distributed urban space. The radial network has a strong center district. The ideal form is a ring network with some radial lines, which is helpful for realizing the sustainable development of urban space.

3.1.3 Urban spatial agglomeration and diffusion

Rail transit guides the spatial distribution of a city's important flow of people, logistics and economy, which has taken the role of agglomeration and diffusion for the urban space. The convenience of rail transit makes people in the industry that is on the outskirts of the city concentrate to the downtown of the city. The heavy development of land and the high density agglomeration of commercial offices and other public facilities constructed in a large-scale construction impact area have brought the agglomeration form of the urban spatial structure, which the stop station is the center. It not only helps stimulating the city's vigour and keeping a strong central region, but also promotes the formation and development of the city's secondary center. "Agglomeration" effect has some impacts on the land price. The related industries that want to improve their profit will make some decisions on the land cost and transportation cost. There are quite a number of industries and population which will spread to outside. It is called the city industry "diffusion" effect (Bao, 2011).

3.1.4 Urban population spatial distribution change

The rail transit can make the urban population migrate to the new town or the edge area of a city, which alleviates the pressure of the central downtown and drives the development of the new town or the edge area. It will ease the pressure of downtown population.

3.2 The Impacts of the Rail Transit on Urban Commercial Space

The construction of rail transit has an important impact on the location of urban commercial space which is decided by three factors including the market, the distance and the competition. The urban commercial space can be changed dramatically by the joint effect of the agglomeration and the diffusion. The impacts on the urban commercial space structure can be some gradual developing forms according to the points, the lines and the planes (Cai).

The motivation of commercial spatial structure evolution is mainly the location change of the business, which is caused by a collection effect of the market, the distance and the competition. The factor of market is the combination of consumers. The factor of distance includes the traffic conditions and the space distance. The factor of competition is mainly the number and capacity of distribution in a same industry among the commercial and radical scope (Xin Fei).

4 The Rail Transit Construction Impacts on Zhuhai's Commercial Space

Zhuhai is located in the southwestern coast of the Pearl River mouth, which is adjacent to Macau and Hong Kong. It has a population of about 2.5 million. Zhuhai's climate is warm and humid. The coastline with continuous mountains is long and beautiful. Now the current population center of Zhuhai is to the southeast of the north station, which is near the Pearl River estuary.

The Zhuhai north station TOD project is designed by the Peter Carl Thorpe who is the author of the concept of TOD design. The north station TOD project is located in Tangjiawan, 15 kilometers north to the Zhuhai downtown, where is adjacent to the southern section of Zhongshan city, Guangdong province, China.

The south and west border of the project is a mountain with rich vegetation. The east of the project is the Pearl River estuary. There are a large number of transport infrastructures in the internal layout of the project, which maintain a convenient contact with other area. The transportation infrastructure is also a part of the strategy that Zhuhai is a core developing area for future in Guangdong province.

Peter designed eight subjects for the project place, of which one subject is developed around the local and inter-city public traffic stations, including a rail transit through the project area.

There will be three kinds of public transportation including inter-city light railway, rail transit and traditional bus. The most important parts are the intersection between the rail transit and the light railway and the intersection between the rail transit and the traditional bus. This area is the highest density of development among the area in future including commercial and retail service and some residential district. A series of square and park will increase the public space along the roads.

The rail transit stations along the public transportation road will provide the transfer function with the traditional bus. The transfer stations will also be a high density area for employment, which are convenient public traffic services for people. In addition, the community services, shops and restaurants are located within a walking distance. The bus rapid transit (BRT) lines are generally perpendicular to the bus lines or along the crescent bay edges. This will provide convenience for local residents who want to go to all local or other tourist destinations in the city (Ning).

According to the project plan, the inter-city railway, the local rail transit and the BRT will converge together in the north station, which provides a convenient transportation. The north station will become a large TOD community. In this area, where will be the most urbanized area, there will be a high density of commercial, retail and high-rise residential area. There also will be a series of square, parks and other public spaces. The TOD community relying on the north station will become the point catalyst that drives the development of entire regional area.

The rail transit line extended from the downtown of Zhuhai is the most important public transportation trunk from the TOD project base to the downtown of Zhuhai. It is the main axis in the base area, which forms a line catalyst to connect the different level TODs. Along the lines, the mixed development will drive the whole project base development. Along with the economic power's increasing of the TOD base, the developing focus will shift to the secondary area of the TOD and the areas that are encircled by different public traffic lines. By spreading outward from the axis, a plane catalyst will take shape in the north station area. It is called an integral space growth pattern from point to line, then from line to plane (Yao Yafang).

The following figure shows the layout of the rail transit lines including the Line 1 and the Line 2 in Zhuhai.

Figure 1. The layout of rail transit lines in Zhuhai

5 Conclusions

The rail transit is an important part of urban public transportation, which can drive the commercial development and restructure the commercial space layout. Through the analysis of the development of Zhuhai urban rail transit and the relationship between the rail transit and the commercial space, we can draw the following conclusions:

(1) The development of rail transit has an important impact on the development of urban commercial space. The construction of rail transit will bring new business districts. The functions of the traditional business districts or the center business district (CBD) will be weakened because the rail transit changes the regional commercial status of the hub site near downtown.

(2) The development of rail transit will lead to the evolution of the urban commercial pattern, which is from point to line and from line to plane.

(3) During the rail transit construction, we should take advantage of the certain project plans and policies to guide the rail transit along the peripheral to form a good business environment.

Abstract: Port city is a kind of special economic region with inner inevitable connection essentially, which determines its development practice need the integration between port and port city. Based on the studies of the economic impact of port cluster on city, especially the integration process, integration effect and integration tendency with each other in the economic development, this paper proposes that the set composed of a port cluster and city should be regarded as a large-scale system and puts forward a dynamic port economic impact model based on system dynamics, providing applied theory and methodology for the economic operation mode of port cluster and port city.
Keywords: Economic integration; Port cluster; System dynamics.

1 Introduction

With the tendency of global economy integration strengthening, the influence of port on global economic development has become increasingly strong, and the changing functions of port have made the relationship between port and urban economy get closer. As a consequence, the careful studies of the role of port cluster and its correlative development with urban economy can become the essential basis for solving a series of significant issues. Although the theory and application study on the integration of port industry and national economy in contemporary academic field is gradually deepened and has made some process, there is obviously still blank in the research on the integration process, integration effect and integration tendency between port cluster and city in the economic development. Therefore the complete analysis of the economic impact of port on the urban economy from the perspective of port cluster and the systematic analysis of the integration between port and city from the perspective of city can lay a research foundation for the applied theory of the economic operation mode of port cluster and port city.

2 Port Cluster

2.1 Defining a port cluster

It is because of the unique geographical position and the relevant business that the cluster phenomena of port industry have become more and more clear. There are acknowledged port clusters in Rotterdam, the Lower Mississippi and Durban, which shows that the cluster theories can be used as a tool to analyze the development status of port and port-related industry. Haezendonck defined a port cluster as 'the set of interdependent firms engaged in port related activities, located within the same port region and possibly with similar strategies leading to competitive advantage and characterized by a joint competitive position vis-à-vis the environment external to the cluster (Haezendonck, 2001) '. By studying the experts' advice comprehensively, a port cluster is defined as 'a population of mutually related business units, associations, universities, research institutes and public (-private) organizations centered around a distinctive economic specialization, engaged in port related activities, located within the same port region with similar strategies leading to competitive advantage and characterized by a joint competitive position vis-à-vis the environment external to the cluster'.

2.2 Constructing a port cluster

The first step to identify a port cluster is to decide on the economic specialization of the cluster. In the case of seaports the core specialization is the arrival of goods and ships. All activities related to the arrival of goods and ships are included in the port cluster.

The second step is to identify the business organizations and non-business organizations included in a port cluster. Business organizations consist of at least five broad groups in a port cluster: cargo-handling firms, transport firms, logistics firms, manufacturing firms, trading firms, etc. Non- business organizations consist of associations and public (-private) organizations.

The third step is to identify relevant port cluster region. All clusters have 'geographical borders', even though in many cases these are not well defined. The relevant region generally includes the primary port area, the business district of the port city, secondary nodes in the proximity of the primary seaport (Klink, 1995) and municipalities in the vicinity of the port with a concentration of port service activities.

2.3 Measuring a port cluster performance

The issue of how the performance of port clusters can be measured is important for cluster scholars. The net present value of the future value added generated in the cluster is the best indicator of the performance of a port cluster. This indicator cannot be calculated. However, once time series of the value added generated in a port cluster become available, the influence of various variables on the performance of clusters can be analyzed. For instance, variables such as expenses for harbor administration, and the number of new port establishments are likely to influence the future value added generated in the cluster. The value added generated in year t can be written as:

$$VA_p(t) = \sum_{i=1}^{n} Va_i(t) \qquad for \quad i = \{1 \ldots n\} \tag{1}$$

Where: VA is the total value added of a population P consisting of n firms,
Va_i is the value added of firm i in the cluster P.

The performance of the cluster can be written as:

$$CP_p(t) = VA_p(t) + \frac{VA_p(t+1)}{1+r} + \cdots + \frac{VA_p(t+n)}{(1+r)^n} \tag{2}$$

Where r is the discount rate used to calculate the net present value over the period t to n.

3 The Economic Integration Analysis of Port Cluster and Port City

3.1 Port cluster activities with industry classifications

According to the industry standard, the port cluster activities with industry classifications are shown as Figure 1.

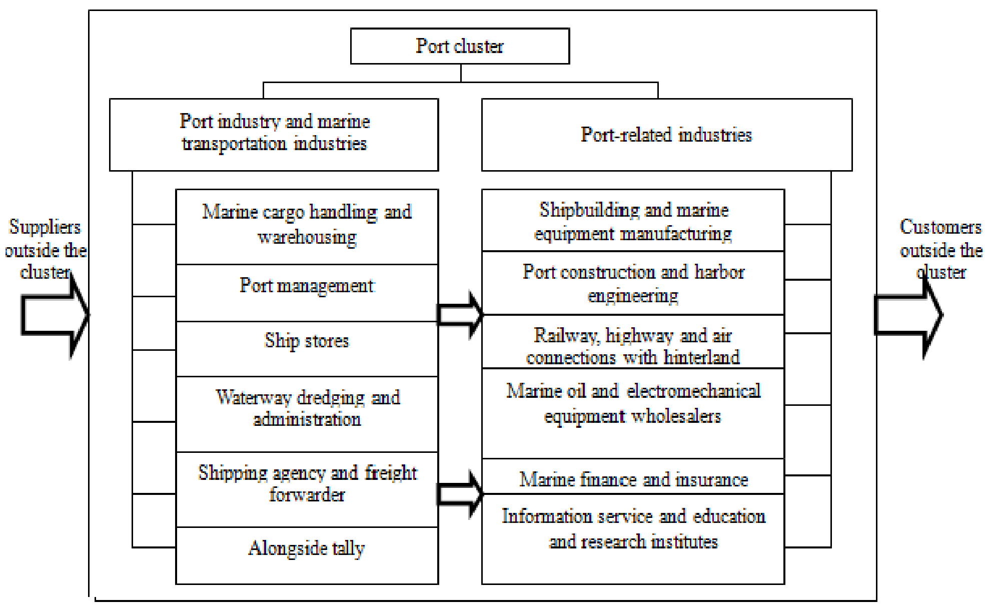

Figure 1. Port cluster activities with industry classifications (SISIRC, 1999)

3.2 The economic impact of port cluster on port city

In general, the total impact of a port cluster on the local urban economy can be divided into the direct, indirect and induced impact. The direct impact is referred to the economic impact generated by port itself and marine related activities on the local and national economy, which mainly arises from local port user industries. The indirect impact is generally defined as all activities in the region which are economically dependent on the primary activity (Davis, 1983), which comes from port capital spending on new port construction, expansion or rehabilitation projects. The induced impact includes economic activity that comes from household purchases of goods and services made possible because of wages generated by the direct and indirect activities.

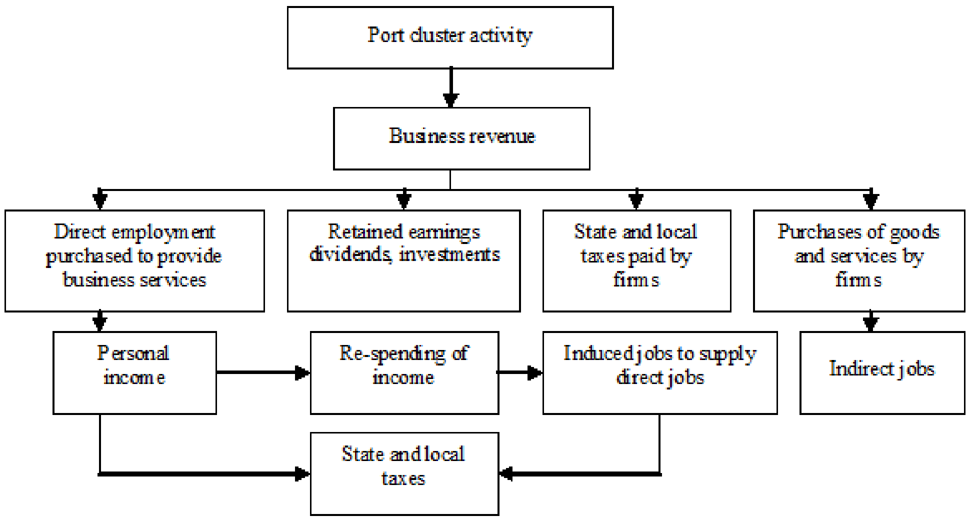

Figure 2. Flows of economic impacts through the economy

Figure 2 graphically demonstrates how seaport activity impacts urban economy. As indicated, the marine cargo and vessel activity initially generate business revenue to the firms supplying marine services. This revenue is used to purchase employment (direct jobs) to provide the services, to pay stockholders and for retained earnings, and to purchase goods and services from local firms, as well as national and international firms (creating indirect jobs with these firms). Businesses also pay taxes from the business revenue. Furthermore the employees hired by the firms receive wages and salaries (personal income), a portion of which is saved, while another portion is used to buy goods and services such as food, housing, clothing, health care, etc. These purchases create a re-spending impact throughout the economy, known as the personal income multiplier. As a result of these local purchases, additional jobs (induced jobs) are created in the local economy. Finally, taxes are paid by individuals employed with the firms providing the services for the marine terminals.

3.3 The economic integration analysis of port cluster and port city

Engaged in the retrospect of port development process, we will be aware of the reason why the scholars come to attach weight on the degree of relationship between port and city, the significant effects produced by port on urban and regional economies, as well as the integration between each other during the economic development. Also it must be admitted that the supporter of prosperous ports should be the growth of urban and regional economies, which embodies the development strategies of 'prospering city on the port and making port serve the city'. Given the close linkage between port and urban economy, the followings should be emphasized to well deal with the economic integration between port cluster and port city: (1) it is essential that the idea of 'port cluster serving urban economy' should be demonstrated clearly and port cluster operation should take the development of urban and regional economies as final goal; (2) a unblock and high-effective integrated transportation system around the port should be established in the city. It has been approved by lessons in the transportation practice all over the world that the construction of port should be carried out in accordance with that of integrated transportation system; and (3) there is much necessity to definite the port development direction where the construction of modern logistics hub is a strategic target.

4 Methodology of Economic Integration of Port cluster and Port City

4.1 Research review of methodology

After discussing the economic integration of port cluster and city, the next step is to find an appropriate methodology to estimate the impacts. However, there is no standard methodology that accurately measures the economic impact of a port cluster. It has been observed that the economic impact of port cluster on city is clearly characteristic of dynamic. As time goes by, some integration factors will enlarge, transfer or disappear due to the social and economic effect, such as the advance of technology, the difference of government policy orientation and the adjustment of industrial structure. Thus there will be a corresponding change in the economic impact of port cluster on city, and all needed is to analyze the changing tendency and find out its inherent law. What's more, it is evitable that the integrated supplement effect between port and urban economy will lead to the existence of abundant nonlinear relation in the integration with each other, and the application of system analysis is required to solve the problem because the accumulated effect caused by the correlation is non-additive.

4.2 Dynamic model based on system dynamics

System dynamics (SD) is a methodology for studying and managing complex feedback-control systems. In fact it has been used to address practically every sort of feedback system. System dynamics provides a common foundation that can be applied wherever we want to understand and influence how things change through time, which uses concepts drawn from the field of feedback control to organize available information into computer simulation models. A digital computer as a simulator, acting out the roles of the operating people in the real system, reveals the behavioral implications of the system that has been described in the model in order to see how the structure and decision-making policies in a system create its behavior. Hereby we regard a port cluster and the city as a large-scale system, and the analytic procedures on principle of system dynamics stimulation model are as follows:

(1) Definition of system objectives. The objectives of establishing the dynamic economic impact model are to study the dynamic changes of the economic impact of a port cluster on the city and the economic integration with each other.

(2) Identification of system boundary. There are two types of variables in the model, one is the state variables —— gross domestic product, port throughput volume, port throughput capacity, cluster natural resource, port pressure and fixed assets investment to cluster, and the other is the supplementary variables —— cluster-generated gross domestic product (GDP), cluster-generated employment, cluster revenue and cluster itself investment.

(3) Ascertainment of causality. The essence of model establishment is to analyze the causality, only through which can we understand the whole structure of the system and as a result find out the correlation among variables (Figure 3.).

(4) Establishment of system dynamics model. The causality diagrams and flow diagrams are presented through causality analysis of system elements, forming the model by means of the software of VENISM (Renan Jia, 2002) which is the special software package for system dynamics.

(5) Computer simulation. The results of model test on computer can be used to analyze the approaches to system improvement or to draw up several alternative plans as reference for decision-makers.

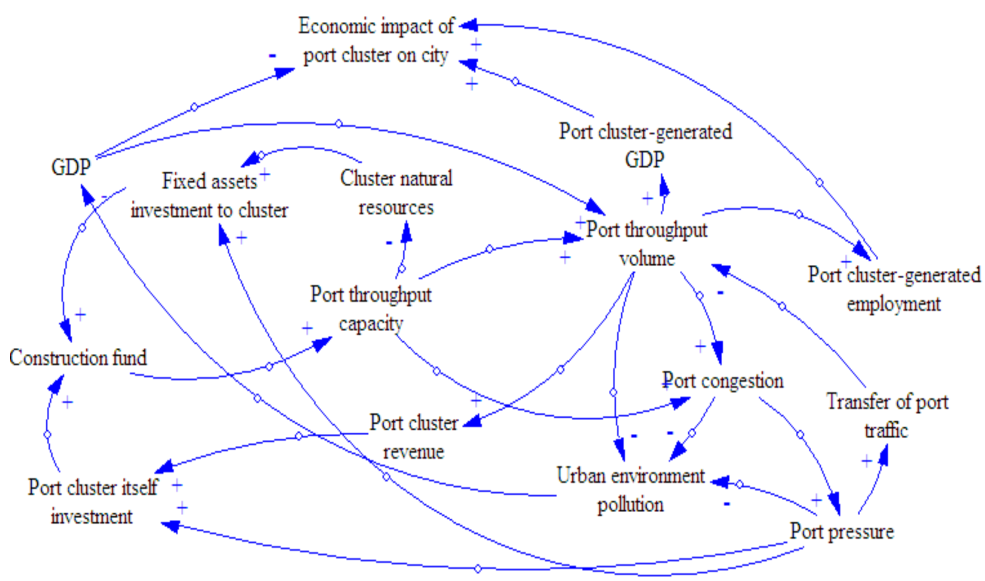

Figure 3. The total causality of economic integration between port cluster and port city

5 Conclusions

A good integration is the key to develop port cluster and urban economy, so further study on the operation mode of port cluster, the effective models and algorithms measuring the economic integration between port cluster and city, and then the definition of applied theory for the economic operation mode of each other are both of academic and practical significance, especially for the development of port resources and improvement of port competitiveness.

Abstract: The aging of population has become a global trend, and the traffic problem of the older people has become the focus of the society. With the large-scale network of the urban rail transit, there is a certain gap between the existing station facilities and the traffic demand of aging society. This article analyzed travel characteristics of older people through surveys and questionnaires. Based on the characteristics and travel demands, service quality index system for urban rail transit station is established. The service quality of the several stations in Shanghai is evaluated through comprehensive evaluation model. Finally, in order to improve the safety and convenience for older people's travel, some suggestions for improving facility and services of station are proposed.
Keywords: Urban rail transit station; Characteristics of the elderly; Evaluation of service quality.

1 Introduction

Since 1980s, Shanghai has been the oldest city in China. By the end of 2013, the population of aged 60 and above accounted for 27.1% of the total population. The degree of the ageing is nearly twice that of china's national average. According to the prediction of Population and Development Research Institute of Shanghai Academy of Social Sciences, the peak of aging population will appear in the 2030s. And then the elderly population in Shanghai is expected to be more than 5,000,000. With the implementation of free public transport service, the frequency of elderly traveling is increased. The proportion of elderly to take rail transit is also increased. Mao Haixiao and Ren Futian analyzed the travel characteristics of older people. They proposed some suggestions from development of public transportation and construction of barrier free facilities for the elderly (Mao Haixiao and Ren Futian, 2005). Zhang Zheng gave the travel behavior characteristics of the elderly in Beijing city. He predicted the effect of aging population on future structure of residents travel in Beijing (Zhang Zheng, 2009). Yue Xiang studied the universal design of public transport facilities in Berlin, and proposed some special design advice for the disabled and elderly people (Yue Xiang, 2013). But there was little research about how to improve the quality of serving aging people in urban rail transit stations. So this article studied the related problems of service quality in urban rail transit station based on the characteristics and travel demands of the elderly.

2 Travel Behavior and Travel Problems of the Elderly

We investigate some elderly people in Yangpu district and Hongkou district. And the elderly around Siping Road station, Wujiaochang station and Hongkou football stadium station are the main surveying people. The research results are as follows.

2.1 Travel characteristics of the elderly

(1) Psychological and physiological characteristics of the elderly

The old people cannot be as intensive as young people. Their response to the outside world is slow and their action is not flexible. They are easily in danger even in ordinary circumstances. For the psychological aspect, the elderly are more likely to feel they are failures. They want to be taken care of, but they have strong self-esteem. They don't want to be despised because of age and physical reasons.

Action ability and endurance of the elderly are not as good as that of the young (Zhang Zheng, 2009. Xu Zhiyong, 2012). When solving the problems of safety and convenience of elderly travel, we should consider the psychological and physiological needs of the elderly.

(2) Traffic characteristics of the elderly

As for the trip purpose, the elderly travel gradually from survival to enjoying good quality of life (Mao Haixiao and Ren Futian, 2005). Exercise, food shopping and sending their children to school accounted for higher proportion in numerous travel purposes. And then, going to hospital and visiting friends are as follows. The purposes of travel by rail transit are mainly shopping, visiting friends, participating social activities and going to the hospital.

2.2 Existing problems of the elderly travel

On the basis of research data, there are a lot of difficult matters for the elderly in rail transit station, such as walking up and down stairs, standing trouble in platform, going in and out of toll gate machine, listening to broadcast, finding the corresponding export etc. The ratio of various difficulties can be found in Figure 1.

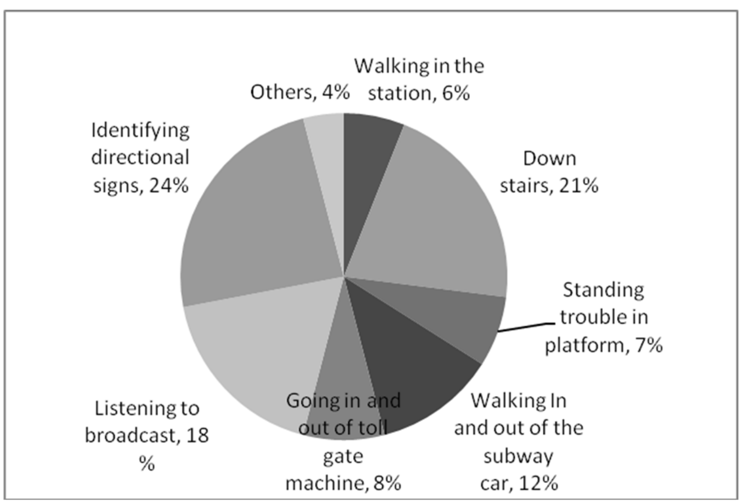

Figure 1. Behavioral difficulties of the elderly

3 Establishing Evaluation Index System

Through the above analysis of the existing problems on the travel characteristics of the elderly, we established the evaluation index system of service quality of urban rail transit station. The index systems is also combined with the relevant experts' advices (Fan Qianqi, Pu Qi and Yin Congcong, 2013; Zhao Ye, Wang Jinsong and Chen Fa'an, 2013). It is divided into three layers. The first layer is comprehensive index A. Safety index B_1、convenience index B_2、speed index B_3 and amenity index B_4 are the second layer. Each of the second level indicators can be divided into the third level indexes of C_{11}-C_{14}, C_{21}-C_{25}, C_{31}-C_{33}, C_{41}-C_{43}. All the indexes are shown in Table 1.

Table 1. The evaluation index system of service quality

The First layer	The second layer	The third layer	
The evaluation index system of service quality of urban rail transit station based on characteristic of elderly A	safety index B_1	C_{11}	setting rationality of barrier free lift
		C_{12}	setting rationality of safety handrail
		C_{13}	skid resistance surface
		C_{14}	safety in waiting area on platform
	convenience index B_2	C_{21}	convenience of ticket checking machine
		C_{22}	layout rationality of guiding sign
		C_{23}	visibility of electronic information
		C_{24}	toilet position in station
		C_{25}	convenience of information consultation
	speed index B_3	C_{31}	walking time
		C_{32}	transfer time at station (for transfer station)
		C_{33}	ticket waiting time
	comfort index B_4	C_{41}	cleanliness at station
		C_{42}	layout rationality of seat and its number
		C_{43}	comfortable at station queuing area

4 A Case Study of Service Quality Evaluation at Urban Rail Transit Station

Considering multiple factors, this study uses AHP to analyze the problem. This method is systematic, simplicity and practicality. It can analyze the nature and influence factors of complex decision problems. And quantitative information is taken into account to make thought process mathematical, so as to provide a simple decision-making method for multi-objective, multi-criteria problems.

4.1 Computing the index weight

By consulting the experts in the field of urban rail transit, we establish the comparative judgment matrix (A-B, B_1-C, B_2-C, B_3-C, B_4-C). These judgment matrixes present the situation of the comparative weight of this layer's relative factors, aiming at some factors of the upper layer. AHP adopts the 1~9 marking method, brought forward by Satie, to constitute the judging matrix. And then we calculate the weight of each index, along with the consistency check of judging matrix.

The judgment matrix of the A-B is as follows (Table 2).

Table 2. A-B judgment matrix

A	B_1	B_2	B_3	B_4
B_1	1	3/2	4	3
B_2	2/3	1	8/3	2
B_3	1/4	3/8	1	3/5
B_4	1/3	1/2	5/3	1

Calculating the maximum characteristic value of judgment matrix by using MATLAB software, we get $\lambda_{\max} = 4.006$.

Then, we calculate the consistency index C.I. of judgment matrix (formula 1), and get the the consistency ratio C.R. using the following formula 2.

$$C.I. = \frac{\lambda_{\max} - n}{n-1} \tag{1}$$

$$C.R. = \frac{C.I.}{R.I.} \tag{2}$$

In the function, n is the order of matrix. The random consistent index R.I. is shown in Table 3. When the $C.R. \leq 0.1$, we think the judging matrix has satisfying consistency. Otherwise, we should adjust it.

Table 3. The average random consistent index R.I.

N	*1*	*2*	*3*	*4*	*5*	*6*	*7*	*8*	*9*	*10*	*11*	12
R.I.	0	0	0.58	0.90	1.12	1.24	1.32	1.41	1.45	1.49	1.52	1.54

The calculation process is as follows.

$$C.I. = \frac{\lambda_{\max} - n}{n-1} = \frac{4.006 - 4}{4-1} = 0.002;$$

$$C.R. = \frac{C.I.}{R.I.} = \frac{0.002}{0.9} = 0.0022 \langle 0.1$$

So we think the judging matrix has a satisfying consistency. Therefore, the weight vector of each indicator using MATLAB software is $A = (0.443, 0.295, 0.105, 0.156)^T$

With the same methods, we establish the other judgment matrix B_1-C, B_2-C, B_3-C, B_4-C. The results of weight are as follows:

$B_1 = (0.213,0.262,0.346,0.179)^T$; $B_2 = (0.208,0.281,0.228,0.109,0.174)^T$

$B_3 = (0.625,0.238,0.136)^T$; $B_4 = (0.167,0.333,0.500)^T$

The final index weights are as follows:

W=(0.0944,0.1161,0.1533,0.0793,0.0614,0.0829,0.0673,0.0322,0.0513,0.0656, 0.0250,0.0143,0.0261,0.0519,0.0780)^T

4.2 Computing the index score

Taking Siping Road Station as an example, this paper studies the evaluation method for service quality. Siping Road Station is the transfer station of line 10 and line 8, where is heavy traffic. Among the indicators in the third level of index system, 3 indicators are quantitative indicators, while 12 indicators are qualitative indicators. The scores of the quantitative index are got by survey at the station. The scores of the qualitative indicators are got from the data of questionnaire for the elderly passengers.

The walking speed is about 0.9m / s for the elderly. The average walking time is about 2min18s from Exit 1 or Exit 2 to platform (excluding ticketing time). According to early study and practical situation of stations in Shanghai, the score of walking time is shown in Table 4 (Zhao Ye, Wang Jinsong and Chen Fa'an, 2013).

Table 4. Scores of walking time index

Walking time	Score	Walking time	Score
0 min 00 s ~ 1 min 00 s	10	3 min 00 s ~ 3 min 30 s	5
1 min 00 s ~ 1 min 30 s	9	3 min 30 s ~ 4 min 00 s	4
1 min 30 s ~ 2 min 00 s	8	4 min 00 s ~ 5 min 00 s	3
2 min 00 s ~ 2 min 30 s	7	5 min 00 s ~ 6 min 00 s	2
2 min 30 s ~ 3 min 00 s	6	>6min 00 s	1

As for internal transfer time, score of each index is valued at the same way with Table 4. And the total transfer time from Line 10 to Line 8 is 42s at the walking speed of 0.9m / s for the elderly.

As for ticket waiting time, the average ticket waiting time is 52s based on field research on the elderly without Bus Card. The score of various ticket waiting time is shown in Table 5 (Zhao Ye, Wang Jinsong and Chen Fa'an, 2013).

Table 5. Scores of ticket waiting time index

Ticket waiting	Score	Ticket waiting	Score
0 min 00 s ~ 0 min 30 s	10	2 min 30 s ~ 3 min 00 s	5
0 min 30 s ~ 1 min 00 s	9	3 min 00 s ~ 3 min 30 s	4
1 min 00 s ~ 1 min 30 s	8	3 min 30 s ~ 4 min 00 s	3
1 min 30 s ~ 2 min 00 s	7	4 min 00 s ~ 5 min 00 s	2
2 min 00 s ~ 2 min 30 s	6	>5min 00 s	1

The sores of the other 12 qualitative evaluation indexes are scored by passengers one by one during the questionnaires. Using the same ten score system, the highest score is "10". The elderly gives the score according to their degree of satisfaction. Then we analyze the overall data of the investigation and get the final score. Combined with the above quantitative indicators, the scores of different indexes of this station are summarized in Table 6.

Table 6. Service quality evaluation of Siping Road station
(For the elderly passengers group)

Index	Score	Index	Score
setting rationality of barrier free lift	3.5	convenience of information consultation	7
setting rationality of safety handrail	8.5	walking time	7
skid resistance surface	9	transfer time at station (for transfer station)	10
safety in waiting area on platform	9.5		
convenience of ticket checking machine	9	ticket waiting time	9
layout rationality of guiding sign	8	cleanliness at station	9
visibility of electronic information	8.5	layout rationality of seat and its number	7.5
toilet position in station	8	comfortable at station queuing area	9

So we get the score of service quality of Siping Road Station for the elderly is 8.019. According to the value of evaluation, the service quality of Siping Road station is good.

The service quality of other stations can be evaluated by this method. So we can find the gaps between the service quality and the demands of the elderly. Some measures should be taken so as to provide better services for the elderly. The measures include improving the convenience of barrier free elevators, setting non-skid floor and sitting area at the right position. Guiding signs should be designed more scientific and reasonable. The amount of information, text size, pattern and color should also be considered. At the same time, we should enhance the public awareness of respecting the elderly through media publicity. Subway staff and passengers in the station are willing to help the elderly so that the elderly travels smoothly by urban rail system.

5 Conclusions

Population aging is the inexorable trend of economic development and social progress. This paper made a quantitative evaluation for the service quality of urban rail transit station based on characteristics of the elderly, taking Siping Road station as an example. Some related suggestions are put forward. With the increase of the elderly travel frequency, there are still many issues need to be further studied. We hope to create a humanized travel environment for the elderly.

Abstract: Inappropriate planning and operation of bus system in small and medium-sized cities has severely hampered the development of the public transport industry. This paper takes the public transport system of Luotian county of Hubei province as an example, and uses game theory to analyze the behavior of the government, the bus company and the bus owner's under uncertain information. Basically, this paper provides a method for better solving the distribution contradiction problems of buses owners interest group under the new operating system. Study results also have a reference value for small and medium-sized cities of our country. This paper also provides a decision support system for the reform of public transport system of small and medium-sized cities.

Keywords: Public transport system reform; Asymmetric game patterns; Luotian county.

1 Introduction

The urban public transportation is an important infrastructure of city which related to the sustainable development of the city and the people's interests. As the increasing population and the rapid growth of the car ownership, the urban traffic has become a more serious problem.

With the improvement of government reform and the socialization process, the traditional public transport operation mode is clearly unable to respond to the needs of society effectively. At present bus operation and management of small and medium-sized cities in our country are worrying as follows: 1. Policies are hysteretic and law enforcement cannot find strong evidence. 2. Each department acts on its own and responsibilities are not clear, which lead to low efficiency and poor macro-control ability. 3. Integration of government administration with enterprise which lead to the competition is not strong. 4. The bus fare mechanism is not scientific and the service quality is not high. 5.Law frame and compensation mechanism of finance are still not perfect.6.Lacking of effective supervision mechanisms (CHEN Pu, 2012).

The main reason caused these problems is that the public transport operating system does not appropriate, at the same time the government did not play a dominant role. So many cities began to explore the reform of the public transportation operation model. The key to reform is adequately introduce the competition mechanism.

2 Social Conditions for Reform Are Gradually Mature

The social conditions here are on a perspective of a wide range, including factors such as government, enterprises and the public.

In terms of government, the main factor that affects it's functional transformation is financial burden. How to reduce the governmental financial burden and arrange the limited funds to where the need is greatest becomes a direct reason why the government returned partly public service supply power to enterprises.

In terms of the public, the public transport is running monopoly by the state-owned enterprises which lead to low bus service quality and the poor efficiency. It not only can't meet the demand of the public travel but also often operates at a loss, thus the government has to increase financial support.

Therefore, in the cases of international economic environment gradually open, in order to guarantee the quality of bus transportation service and at the same time to intensify competition of private enterprises, it is necessary to introduce the privatization mechanism to bus operation to achieve the optimal allocation of resources.

3 Public Transport System Reform of Luotian

The thoughts of the Luotian public traffic operation reform is to transform from the original affiliated management mode to share-holding management mode. Through the reform to establish relative state-owned control and enhance the government leadership and control force to the development of the bus company. At the same time, establishing and improving market access and exit mechanisms to realize the return of the vehicle ownership and management rights. Then making uniform standard and unified management for all vehicles and drivers. Rights and interests are redistributed and signed up in the process of reform. Whether the interests of all parties can realize game balance or not is critical to the success of a reform （ZHANG Shuquan,2012）.

According to the ideas of the game theory in this paper, a model of the information uncertainty will be established to analysis the behavior regularity the government, the bus company and the original buses owner.

3.1 Model assumption.

Assumption 1: For convenience of analysis , the model assumes that the bus reform relates to two different groups, one is profit group which get more profits under the original system, the other is none profit group which get less. In this case, affiliated bus owners are belong to profit group and bus company is belong to none profit group. Assumption 2: None profit group preferential make choose in reform. And assume that the both game players to take some strategy has nothing to do with the proportion of the decision makers.

Assumption 3: Both sides are free to give selection strategy, and there is no external intervention force .

Assumption 4:Both sides are bounded rational. They can calculate their own cost effectiveness, and there does not exist the possibility that one side accepted the game because of cheat. In addition, both the game sides achieve equilibrium only for their expected income and cost of one reform policy.

To facilitate the research, all of these assumptions are ideal.

3.2 The establishment of non-symmetrical game model.

Under the condition of the above assumptions, using the non-symmetrical game models structure to set up a model as shown in figure 1.（HE Chaoping，2006）. Profit group 1 stands for bus company and fist choose to reform or not.

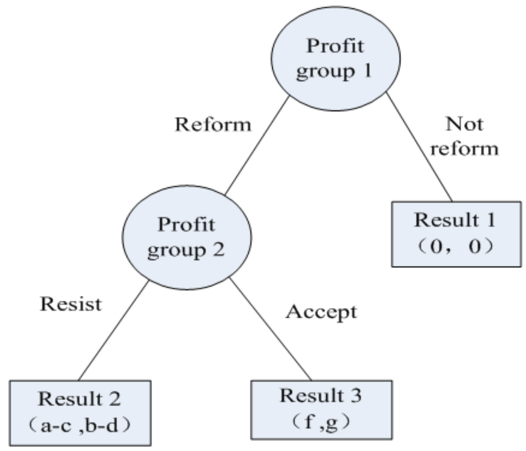

Figure 1. Non-symmetrical game model of bus reform

Assuming that the original utility of both the interest groups are 0. "a" stands for the utility that brought about if group 1 chooses to reform. "b" stands for the utility that brought about if group 2 resists the reform. "c" stands for a loss group 1 suffered when group 2 resists the reform. "d" stands for cost of resistance. "f" and "g" each stands for the utility of profit group 1 and 2.

The probability of profit group 1 chooses the reform strategy is x($0<x<1$).The probability of profit group 2 chooses the resistance strategy is y($0<y<1$).Utility of both game players as shown in table 1:

Table.1 Utility of both game players under non-symmetrical game model

utility	Game player 2	resist	accept
Game player 1	probability	y	1-y
reform	x	(a-c, b-d)	(f, g)
not reform	1-x	(0, 0)	(0, 0)

According to the table.1, it can be calculated that the expected utility of player 1 when it took reform strategy is:

$$E_{1m} = y(a-c)+(1-y)f = (a-c-f)y+f$$

The expected utility of player 1 if it didn't take reform strategy is:

$$E_{1n} = 0$$

The average expected utility of player 1 is:

$$\overline{E_1} = xE_{1m} + (1-x)E_{1n} = x[(a-c-f)y + f]$$

The expected utility of player 2 if it resisted the reform is:

$$E_{2\mathrm{m}} = x(b-d)$$

The expected utility of player 2 if it accepted the reform is:

$$E_{2\mathrm{n}} = xg$$

The average expected utility of player 2 is:

$$\overline{E}_2 = yx(b-d) + (1-y)xg$$

According to the replicated dynamic equation formula of the asymmetric evolutionary game model, it can be calculated that the replicated dynamic equations of two players' expected utility are (MIAO Ruili, 2012) :

$$F_{1(x,y)} = \frac{d(x)}{d(t)} = x(E_{1m} - \overline{E}_1) = x(1-x)[f + (a-c-f)y] \qquad (1)$$

$$F_{2(x,y)} = \frac{\mathrm{d}(y)}{d(t)} = y(E_{2m} - \overline{E}_2) = y(1-y)x(b-d-g) \qquad (2)$$

3.3 Discussion and results of model

game player 1. For Eq. 1, if a-c>0, then a-c-f>-f ; and 0≤y≤1, so f+(a-c-f)y＞0 always stands up. And because of 0≤x≤1, the solution of $F_{1(x,y)}=0$ is x=1.The game player 1 choose the evolutionary stable strategy.

If a-c≤0, when f+(a-c-f)y=0, then y= -f/(a-c-f); that means if y= -f/(a-c-f) , no mater what value the x is,$F_{1(x,y)}=0$ permanent stands up,and it is an evolutionary stable strategy. If y≠-f/(a-c-f), x=0 or x=1 is the evolutionary stable strategy. To be specific, x=1 is the evolutionary stable strategy when 0<y< -f/(a-c-f), and x=0 is the evolutionary stable strategy when -f/(a-c-f)<y<1.

game player 2. For Eq. 2, if b - d > g, it will eventually converge to (0, 1) no matter how the initial state is, so the game 2 will eventually in the condition of resistance, and all the game player 1 will not reform. In the end, the new system can not be applied.

If b - d < g, it will eventually converge to (1, 0) no matter how the initial state is, namely the game player 1 will eventually in the state of reform, and the player 2 will accept reform. When b - d - g = 0, $F_{2(x,y)}$ always equal 0, it will be evolutionary stable strategy no matter what value y is. The phase diagram of asymmetric evolutionary game is in figure.2.

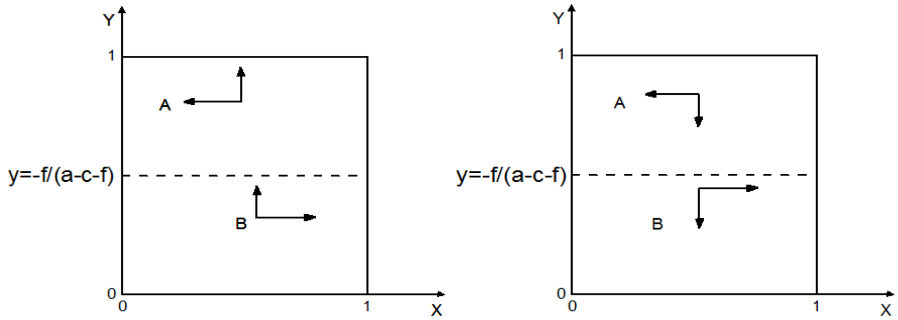

Figure 2. Phase diagram about asymmetric evolutionary game for b-d>g and b-d<g

4 Conclusion

Through the analysis and discussion of the model, three conclusions are summarized.

1. If new public transport operation patterns could bring profits to both the bus company group and the original buses owners group, the reform would be easy to get success. It is apparent even without the game model. While it gives an inspiration that government must first consider whether the new system is beneficial to non-profit group, this is the most basic prerequisite for a successful reform. At the same time if the new system can improve the profit group interests than under the original system, it will contribute to the success of the reform.

2. If the affiliated owners get more profits when they boycott the application of a new system than accept it, they will not accept the reform, so the reform will be met with resistance. Even if the bus company could get more profits under the new system and the government took forced reform measures, affiliated buses owners will take strike and other boycott measures to block the public transportation reform. Such bus reform is failure, even threaten the social stability.

3. Raising the cost of boycott or giving preferential policies to affiliated owners who accepted the reform will enhance the success of reform. For example, government can stop giving financial subsidies to opponents, or give economic compensation and higher priority of route selection to the supporters. These steps can accelerate reform to a great extent.

Abstract: Although the Passenger Railway has developed rapidly, the ticketing is still on a first come, first served basis. Gradually, we find it always induced the seats unoccupied and reduced the system rewards because of the halfway-station requests. This paper presents the Railway Passenger Ticketing Optimization Model based on Semi-Markov Decision Process (SMDP) to increase the system rewards. Especially, we propose "the seats risk-rewards" to indicate the system value at risk by different ticketing decisions. Furthermore, this study provides not only the optimal strategy of the seats utilization, but also the system maximum long-term rewards.
Keywords: Ticketing decisions; Semi-Markov Decision Process (SMDP); The seats risk-rewards; System rewards.

1 Introduction

With the massive Passenger railway constructed and operated, the demands of passengers continue to increase and a large number of new technologies have emerged (Liang et al., 2011; Liang et al., 2010). In this work, our research focuses on the seats reusing (Mao et al., 2004; Zhou et al., 2003) and the system rewards improving in Passenger railway. In general, we classify the ticketing requests services in two categories: Long Distance Requests and Short Distance Requests. We accurately defined the economic gain of railway passenger as system rewards as well.

In the development history of the railway passenger, there are three important phases. Firstly, Railway Ticketing System (RTS) has facilitated passengers travel (Feng, 2009). However, the RTS has not implemented the intelligent decision. Secondly, Tickets Distribution Plan (TDP) generated to assist the railway passenger (Ma et al., 2001). It is a strategy to allocation a number of tickets to every station along the way to sale. According to the principle Tickets Distribution Plan, the long-distance passengers' demands have priority over short-distance demands, which permits to effectively combine the short-distance demands in order to improve the load factor. Under the TDP, the essence of ticketing is based on a strategy of first come-first serve. Intelligent decision is also not applied in the tickets sale process. Thirdly, Revenue Management is successfully applied in the aviation field (Goasvi et al., 2002). However, because of the complex railway network, multi-site, travel distance different and other characteristics, it is necessary for railway to combine with its own characteristics in order to improve the system rewards.

Generally, the railway economic revenue is primarily from tickets sale (Zhang et al., 2006). However, little literature gives the intelligent optimization strategy about seats utilization to enhance railway economic revenue. In this paper, we discuss a kind of optimal decision model by dynamic analyzing the possible tickets array for one seat along the whole way in order to maximize the system rewards, in the period of tickets sale.

To describe briefly and accurately, we propose "seats risk-rewards" to indicate the system value at risk (Zhou et al., 2008). Seats risk-rewards mean the value of the remainder short-distance tickets. It can be explained that a long-distance ticket is cut into several short-distance tickets to sale. After one of these short-distance tickets has been sold, the seats risk-rewards indicate the summation of all the remainder short-distance tickets value. System rewards can be presented by tickets-rewards subtracting seats risk-rewards.

According to the above analysis, our work is organized as follows. The ticketing strategy and procedure is described in Section II. In Section III, we presented the optimization model. The specific analysis of the Semi-Markov Decision Process model (SMDP) for Railway Passenger Ticketing is in Section IV. The simulation with analyze about the optimal model is in Section V. Finally, we summarized the research in this article and presented future work in Section VI.

2 Ticketing Strategy and procedure

In terms of first come first serve, the seats are liable to lead to vacant. Because short-distance passengers occupied tickets, the demands of long-distance passengers rarely could be content. In comparison to the conventional way, our strategy based on the SMDP is effective for the ticketing decision.

This paper provides a number of assumptions: every station which uses the optimal model is controlled by its own virtual station, receptively. The virtual station records the number of the remained tickets in real time. Moreover, it makes the decisions about all the purchase requests. Besides this, we suppose that: no ticket reservation been canceled, no request been postponed scheduled, no refund request, all passengers had to buy one ticket for once request, the person who was denied would be directed to purchase other trips ticket, and all the demands would be treated sequentially by virtual station. There are two levels of tickets: long-distance (h) and short-distance (l).

Figure1 shows that the procedure of the purchase requests in station A. In the primary stage, each ticketing agent transmitted every ticket purchase request to virtual station to process. The virtual station handles only one request at one time. It will array a series of requests randomly which generate simultaneously and are treated sequentially. Except for the limited capacity for a train, the available tickets are also limited. In regard to the different O-D demands, the new tickets will be generated by the seats reusing. It can effectively enhance the tickets-rewards and the tickets utilization. The main idea of our Semi-Markov Decision Process model (SMDP) for Railway Passenger Ticketing Model is to decide whether to accept or not a purchase request from a passenger at a time for effectively utilizing the value of all the seats. In this study, not only we have considered traffic volume, but also analyzed the system rewards in an optimal decision.

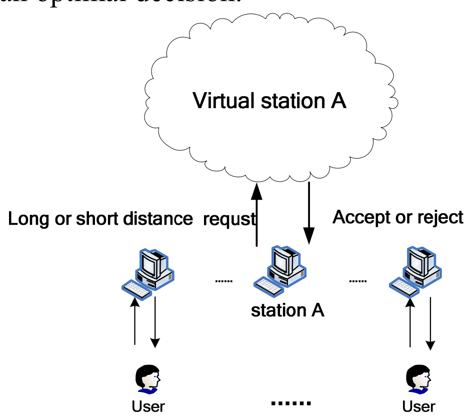

Figure 1. The ticketing procedure in station A

3 Optimization Model

Before we throw out the specific model, there are several definitions need to be described.

(1) In our model, the optimal model is applied only in the originating station.

(2) We define the destination-station which is not the Terminal station as halfway-station. We denote the number of halfway-station as Z, $Z \geq 1$.

(3) The destination-station which is affiliated in one local Railway Bureau is considered as short-distance (l).

(4) The destination-station which crosses Railway Bureaus is considered as long-distance (h).

In our model, two basic kinds of requests are provided, namely, short-distance and long-distance requests. For brevity, four stations (z_1~z_4) are set along the whole line. We consider only one class of seats and the unlimited station are z_2 and beyond. In comparison to the traditional ticketing policy in station z_2~z_4, the originating station z_1 uses the optimal model to sale tickets. As the following descriptions, we focus on the ticketing optimal decision in station z_1.

Figure 2 explains the characteristic about the four stations. Because of station z_2

affiliated in one local Railway Bureau, the request type is short-distance when the destination is station z_2. The travel from z_1 to z_3 and z_4 is regarded as long-distance, since z_3 and z_4 are cross Railway Bureaus. In order to comply with the Rail Tickets distribution principle, the demands which destination is terminus station (z_4) will be directly received. Thus, we only analyze the travel in which the destination except z_4. The arrival rates of requests l or h follow the Poisson distribution with mean rates λ_l and λ_h, respectively.

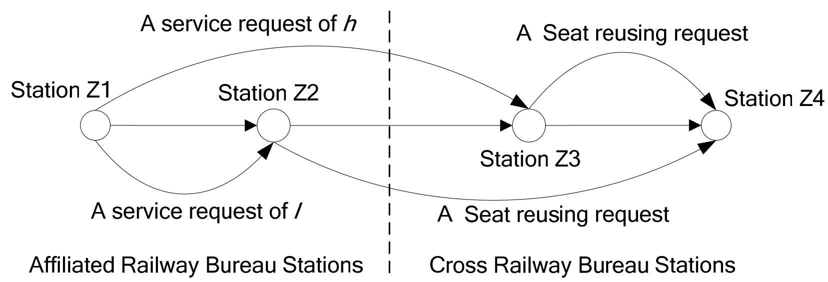

Figure 2. Illustrate about the stations and seats reuse

In order to understand the relationship between the halfway-station (z_2 and z_3) requests and the seats reuse, we give the explanation as follows. When a halfway-station request was received, a new ticket was generated which from the halfway-station to beyond (Shi et al., 2009; Shi et al., 2008). The whole process of the optimal policy decisions can not only control the seats reuse, but also improve the load factors and system rewards.

4 SMDP-Based optimization policy decisions

4.1 System states

We present request-events as well as the system states in this section. The system states can reflect the system rewards impacted by ticketing decisions. A request of purchase tickets l or h can be considered as an incoming event. Thus, in the system model, we define two events:

(1) Receive or reject a long-distance request (e.g. A passenger want to go from z_1 to z_3), denoted by e_h;

(2) Receive or reject a short-distance request (e.g. A passenger want to go from z_1 to z_2), denoted by e_l;

The number of purchase request l and h which has been received are denoted as n_l and n_h, respectively. Thus, the system states can be expressed as following:

$$S = \{ s \mid s = < n_l, n_h, e > \} \quad (1)$$

Where $e \in \{ e_l, \quad e_h \}$ indicates the collection of all the events.

4.2 Decision-making

It is critical for our model to make ticketing decision. When a passenger arrived at a ticket window and proposed a particular type of ticket request, two type of decisions can be selected by the model: reject and receive, which are denoted by $a(e)$=0 ,and $a(e)$=1 . Accordingly, the decisions can be expressed by a set:

$$A = \{ a_{\langle s,e \rangle} \mid \quad a_{\langle s,e \rangle} \in \{0,1\} \}$$

4.3 System rewards

In this study, the seats risk-rewards caused by the short-distance tickets is particularly problem resolved by our optimized model. With the following discuss in this section, we focus on Single trains to research system rewards, which contains two factors: The ticket-rewards and seats risk-rewards.

Let $x(s,a)$ as the ticket-rewards, when the system selects decision *a* with state *s*. $x(s,a)$ is shown as follow:

$$x(s,a) = \begin{cases} 0, & e \in \{ e_h, e_l \}, a = 0 \\ R_h, & e = e_h, a = 1 \\ R_l, & e = e_l, a = 1 \end{cases} \quad (2)$$

Where $R \in \{ R_l, \quad R_h \}$ denote the value of a ticket, as an *l* or *h* purchase request is accepted, the system can obtain income R_l or R_h .

The seats risk-rewards can be evaluated based on the probability of the various seats reuse array and the corresponding rewards, denoted by *q* and β , respectively.

Consequently, we have

$$y(s,a) = q \bullet \beta \quad (3)$$

Let the parameter $\tau(s,a)$ indicates the time duration between two adjacent policy decisions and it follows an exponential distribution. Therefore, the average rate of passengers arriving for tickets can be computed as:

$$\gamma(s,a) = \tau(s,a)^{-1} = \lambda_h + \lambda_l \quad (4)$$

According to above analyses, the Semi-Markov Decision Process (SMDP)-Based Optimization Model, the whole system rewards $z(s,a)$ in the duration of $\tau(s,a)$ can be built as following:

$$z(s,a)=x(s,a)+y(s,a) \tag{5}$$

Where $x(s,a)$ and $y(s,a)$ are already defined in the previous.

Applying the system rewards equivalent (5), we can deduce the maximum long term rewards as following:

$$v(s)=\max\left\{z(s,a)+\eta\sum_{i\in S;i=s-1}p(i\mid s,a)v(i)\right\} \tag{6}$$

Where $\eta=\dfrac{\gamma(s,a)}{\varphi+\gamma(s,a)}$, φ indicates the discount rate. Denote $p(i\mid s,a)$ as the state transition probability, with the decision *a* and the current state *s*.

According to these equivalents above, the ticketing failure probability $P_{failure}$, defined as the ratio of the number of rejected requests and the total number of requests, is thus given by

$$P_{failure}=\frac{\sum_{n_l}\sum_{n_h}\left(\left(1-a_{j1}\right)\pi_{j1}+\left(1-a_{j2}\right)\pi_{j2}\right)}{\sum_{n_l}\sum_{n_h}\left(\pi_{j1}+\pi_{j2}\right)} \tag{7}$$

where a_{j1}, $a_{j2}\in A$ are the decisions adopted at states $\langle n_l,n_h,e_l\rangle$ and $\langle n_l,n_h,e_h\rangle$, respectively. The short-distance and long-distance requests steady-states probabilities can be indicated as π_{j1} and π_{j2}, respectively, with $j1=\langle n_l,n_h,e_l\rangle$, $j2=\langle n_l,n_h,e_h\rangle$.

5 Performance evaluations

In this section, we will provide the performance of our optimal model using a simulator written in matlab. In the simulation, we set the requests arrival rates of requests *l* and *h* are 3 and 5 per unit time, respectively, and the discount factor φ=0.1.

The ticketing failure probability of request *h* under various arrival rates of purchase requests are shown in fig.3. We have evaluated the ticketing failure probability of long-distance passengers under different number of total tickets (K=600 and K=1000) with different arithmetic: SMDP and Greedy. By using Greedy arithmetic, it always adopted any kind of requests without considered the risk probability. We further increase the total number of tickets from 600 to 1000. We can gain better results by the higher number of tickets. A higher ticketing failure probability is achieved when the long-distance request arrival rate increases. For example, we need reserve some tickets for the requests which want to terminal station. Compared with Greedy arithmetic, the ticketing failure probability is lower by using SMDP, when we set a same total number of tickets. It can be seen that the SMDP is an efficient optimal model which can reasonably allocate *l* and *h* tickets.

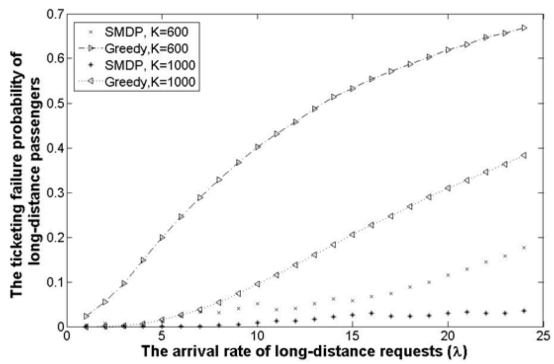

Figure 3. The ticketing failure probability of request *h* under various arrival rates

In fig 4, we can easily find the distinguished performance in system rewards by using the SMDP optimal model compared with the Greedy arithmetic. The change of the number of total tickets affects the system rewards with the same arrival rate. With increasing arrival rate for request *h*, the system rewards are enhanced by an exponential distribution for both SMDP and Greedy. Although, the SMDP model could get more excellent results than Greedy did.

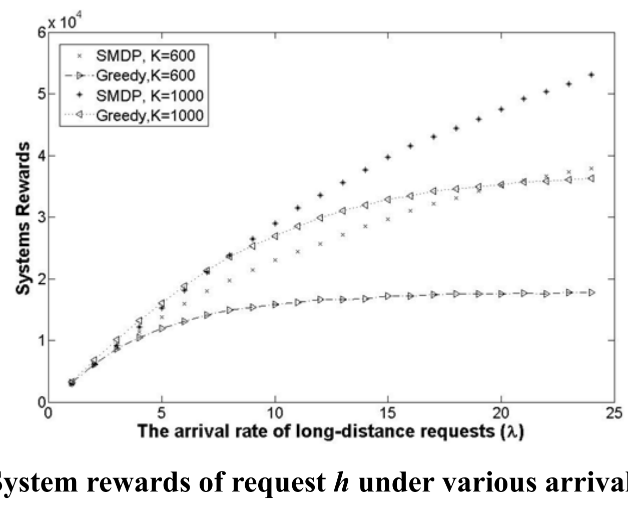

Figure 4. System rewards of request *h* under various arrival rates

6 Conclusions

In this paper we have proposed a new idea to provide insight to formulate an optimal Railway Passenger Ticketing model based on SMDP for the problem of seats reuse of the tickets from origin station to halfway point. By simulation with matlab, we have obtained the ticketing failure probability of long-distance (h) passengers and the whole system rewards considering the seats risk-rewards with various arrival rate of request h. Further study will focus on deducing the details of the seats risk-rewards on different optimal decisions. In addition, we will investigate the ticketing and travel guidance in railway passenger traffic passage.

Abstract: In order to prevent social instability of rail transit construction projects effectively, 15 factors caused rail transit social risk were extracted. Using the integration of decision-making trial and evaluation laboratory (DEMATEL) and the interpretive structure model(ISM), a structural model of risk cause system was established. The causes were divided into 4 categories: root causes, controllable causes, key causes, direct causes. The results show that safeguarding the fundamental interests of the masses is the key to control the social risk of the rail transit construction.
Keywords: Rail transit; Social risk; DEMATEL; ISM; Causes.

1 Introduction

In recent years, rail transit construction projects bring great benefits for society. Meanwhile, since the complexity of the project and the management, the construction also brings a lot of problems especially social conflicts, which seriously affects social stability. Social risk assessment work will play an important role. Domestic research on social risk all concentrate on risk assessment method aspect, e.g. Wu put forward a comprehensive evaluation method of the combination of entropy weight and AHP method to evaluates the social risk of city transportation construction projects (Wu et al. 2009), and Yang set up a social risk evaluation index system of critical projects with three levels (Yang, Luo 2010), while quite a few research mentions about social risk causes.

The occurrence of risks is the result of multiple combined forces and to some extent corresponds with the complex environment. Relationship of each element in the risk causes system is the premise and foundation of social risk evaluation. Therefore, 15 factors caused rail transit social risk were extracted. In order to study the risk causes relationship of each element in the system further, using the integration of decision-making trial and evaluation laboratory and the interpretive structure model, a structural model of risk cause system was established, to provide the reference for the social risk assessment and risk management in the future.

2 Analysis of Social Risk Causes System of Rail Transit Construction Projects

The rail transit construction projects are large-scale projects with the characteristic of high workload, long duration, high technique, complex construction and management condition, and various interest groups involving, hence it leads to the perplexing relationship among factors, and forms an open, complex, stochastic and dynamic system.

To accurately analyze the social stability risk causes in the system, this paper studies social risk events that have occurred in the procedure of project construction, combining with the characteristics of rail construction projects, and comprehensive analysis of the relevant research results, 15 factors which cause the social risk were extracted from the four aspects of social environment, economic, ecological environment and system. (See Table 1)

Table 1. Social risk cause of rail transit construction projects

Social Risk Cause of Rail Transit Construction Projects	
Ecological Cause	S_1: Pollution from construction
	S_2: Soil and water loss
Economical Cause	S_3: Unemployment caused by project
	S_4: Low compensation of land expropriation
Social Cause	S_5: The wage arrears of workers
	S_6: Traffic risks caused by project
	S_7: High rate of Construction safety accident
	S_8: The resettlement difficulties
	S_9: National cultural conflict
	S_{10}: Negative public opinion
	S_{11}: Low degree between construction and opinion fusion
	S_{12}: Social conflicts caused by project
System Cause	S_{13}: Untimely and Opaque Information publicity
	S_{14}: Imperfect social risk management system
	S_{15}: Imperfect accountability system

3 An Integrated Modeling Method Based on DEMATEL-ISM

DEMATEL, also known as the decision-making trial and evaluation laboratory, is developed by the American Bastille National Laboratory (Li, Zhang 2014). It builds the direct influence matrix using the logical relationship between elements, suitable for studying the interactions between factors of complex systems. Interpretative Structural Modeling, which is to use known but messy relationships between system elements to reveal the internal structure of the discrete, unordered, static system (Jiang 2013), is also a method for complex system research (Zuo et al. 2012).

Plenty of researches suggest that the effectiveness of the hierarchical division of system structure is obviously weaker than ISM approach while applying DEMATEL method solely. However, large amount of computation exist when there are many factors in the system while using the ISM method alone. In view of the fact that there are many similarities between the DEMATEL and the ISM method, the combination of the two can not only reduce the complexity of computation, but also create a clear hierarchical structure to analyze complex system (Xie 2014). Zhou Dequn (Zhou, Zhang 2008) first put forward the construction method of hierarchical structure of the integrated DEMATEL-ISM system, and gives the theoretical basis and algorithm of the integration. According to Zhou Dequn's (Zhou, Zhang 2008) research, the modeling steps are as follows. (Figure 1)

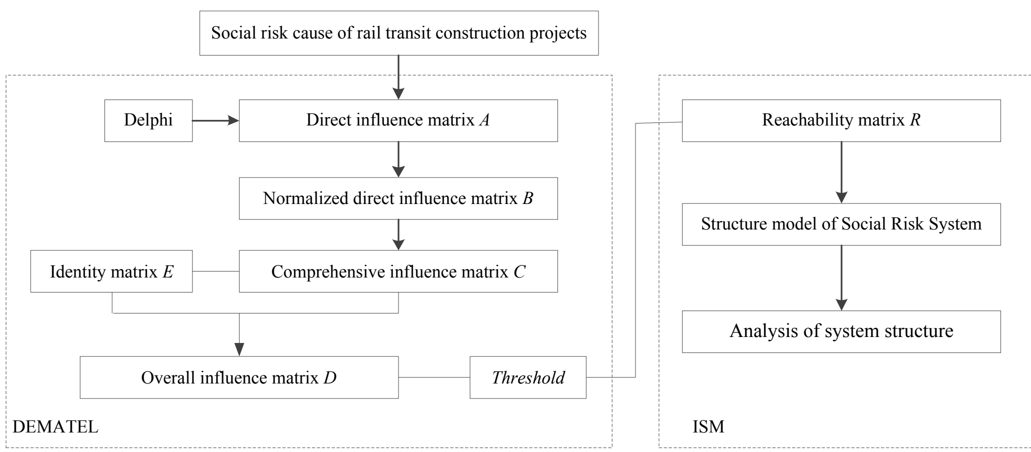

Figure 1.Modeling steps

3.1 Establishing Direct Influence Matrix

15 factors of causation system in table 1 are scored using Delphi by 20 experts in Rail transport Construction area. They compared each factor in pairs and scored them from 0 to 3 according to the degree of direct influence, representing no direct relation, weak relation, general relation and strong relation. Relations between factors were defined according to formula 1.Then the influence matrix A was established; $A = \left(a_{ij}\right)_{n \times n}$.

$$a_{ij}=\begin{cases}3, & \mathrm{k}\geq 13\\ 2, & 7\leq \mathrm{k}\leq 12\\ 1, & 1\leq \mathrm{k}\leq 6\\ 0, & \mathrm{k}=0\end{cases} \tag{1}$$

with k : number of person who holds that S_i impacts S_j .

$$A=\begin{pmatrix}
0&2&0&0&0&0&0&0&0&1&1&2&0&0&0\\
0&0&0&0&0&0&0&0&0&1&1&2&0&0&0\\
0&0&0&0&0&0&0&3&0&2&2&3&0&0&0\\
0&0&0&0&0&0&0&3&0&1&1&2&0&0&0\\
0&0&0&0&0&0&0&0&0&2&0&2&0&0&0\\
0&0&0&0&0&0&0&0&0&1&1&1&0&0&0\\
0&0&0&0&0&0&0&0&0&1&2&1&0&0&0\\
0&0&0&0&0&0&0&0&0&0&1&3&0&0&0\\
0&0&0&0&0&0&0&2&0&0&1&3&0&0&0\\
0&0&0&0&0&0&0&0&0&0&2&2&0&0&0\\
0&0&0&0&0&0&0&0&0&0&0&3&0&0&0\\
0&0&0&0&0&0&0&0&0&0&0&0&0&0&0\\
0&0&0&0&0&0&0&0&0&3&3&0&0&0&0\\
0&0&0&1&1&0&2&0&0&0&0&0&2&0&0\\
0&0&0&0&0&0&3&0&0&1&0&0&0&2&0
\end{pmatrix}$$

3.2 Establishing Comprehensive Influence Matrix

Normalize direct influence matrix then we get normalized direct influence matrix B .

$$B=\left(b_{ij}\right)_{n\times n}=\left(\max_{1\leq i\leq n}\sum_{j=1}^{n}a_{ij}\right)^{-1}A \tag{2}$$

According to matrix A , summation of the third row elements is biggest. Based on matrix B , comprehensive influence matrix C can be defined using formula 3;

$$C=B+B^2+\cdots B^n \tag{3}$$

consider $\lim_{n\to\infty}\left(B\right)^{\mathrm{n-1}}=0$, so

$$C=B\left(E-B\right)^{-1}=\left(c_{ij}\right)_{n\times n} \tag{4}$$

Then comprehensive influence matrix can be defined using MATLAB programming, when E represents identity matrix.

$$C=\begin{pmatrix}
0 & 0.200 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.120 & 0.144 & 0.307 & 0 & 0 & 0\\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.100 & 0.1200 & 0.256 & 0 & 0 & 0\\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.300 & 0 & 0.200 & 0.270 & 0.511 & 0 & 0 & 0\\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.300 & 0 & 0.100 & 0.150 & 0.355 & 0 & 0 & 0\\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.200 & 0.040 & 0.252 & 0 & 0 & 0\\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.100 & 0.120 & 0.156 & 0 & 0 & 0\\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.100 & 0.220 & 0.186 & 0 & 0 & 0\\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.100 & 0.330 & 0 & 0 & 0\\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.200 & 0 & 0 & 0.120 & 0.396 & 0 & 0 & 0\\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.200 & 0.260 & 0 & 0 & 0\\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.300 & 0 & 0 & 0\\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0\\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.300 & 0.300 & 0.1680 & 0 & 0 & 0\\
0 & 0 & 0 & 0.100 & 0.100 & 0 & 0.200 & 0.030 & 0 & 0.110 & 0.135 & 0.132 & 0.200 & 0 & 0\\
0 & 0 & 0 & 0.020 & 0.020 & 0 & 0.340 & 0.006 & 0 & 0.152 & 0.113 & 0.108 & 0.040 & 0.200 & 0
\end{pmatrix}$$

3.3 Defining Overall Influence Matrix

Comprehensive influence matrix shows the degree of influence and relation between factors in the causation system. And the influence of each factor to itself can be shown by identity matrix E. Overall influence matrix D can be defined using formula $D = C + E = \left(\mathrm{d}_{ij}\right)_{n\times n}$.

3.4 Defining Reachability matrix

Based on overall influence matrix D, reachability matrix can be defined as $R = \left(r_{ij}\right)_{n\times n}$. And according to practical situation of Rail Transport Construction, consider threshold $\lambda = 0.15$. When $\mathrm{d}_{ij} \ge \lambda$, $r_{ij} = 1$; while $\mathrm{d}_{ij} < \lambda$, $r_{ij} = 0$.

$$R=\begin{pmatrix}
1&1&0&0&0&0&0&0&0&0&0&1&0&0&0\\
0&1&0&0&0&0&0&0&0&0&0&1&0&0&0\\
0&0&1&0&0&0&0&1&0&1&1&1&0&0&0\\
0&0&0&1&0&0&0&1&0&0&1&1&0&0&0\\
0&0&0&0&1&0&0&0&0&1&0&1&0&0&0\\
0&0&0&0&0&1&0&0&0&0&0&1&0&0&0\\
0&0&0&0&0&0&1&0&0&0&1&1&0&0&0\\
0&0&0&0&0&0&0&1&0&0&0&1&0&0&0\\
0&0&0&0&0&0&0&1&1&0&0&1&0&0&0\\
0&0&0&0&0&0&0&0&0&1&1&1&0&0&0\\
0&0&0&0&0&0&0&0&0&0&1&1&0&0&0\\
0&0&0&0&0&0&0&0&0&0&0&1&0&0&0\\
0&0&0&0&0&0&0&0&0&1&1&1&1&0&0\\
0&0&0&0&0&0&1&0&0&0&0&0&1&1&0\\
0&0&0&0&0&0&1&0&0&1&0&0&0&1&1
\end{pmatrix}$$

3.5 Establishing Structural Analysis Model

The reachable set R_i, the antecedent set A_i, and intersection 错误!未找到引用

源。 in the causation system can be calculated by using ISM while the reachability matrix is defined. Then factor S12 can be defined according to formula $R_i \cap A_i = R_i$. Remove the corresponding rows and columns of the reachability matrix in order to find new summit factors in the reachability matrix left. Followed by analogy we can get an analytical result of the hierarchy of the reachability matrix in order to establishing a structural analysis model in the end. As shown in Figure 1.

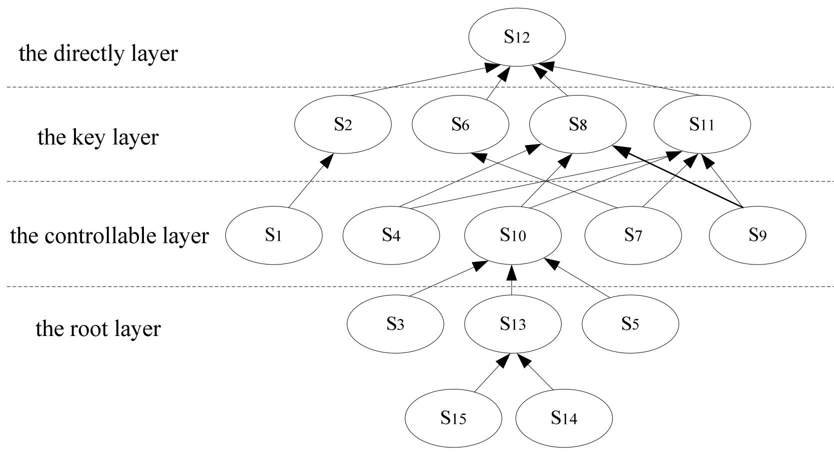

Figure 2.Structure Model of Social Risk System

4 Analysis of System Structure

Social risk causes system of rail transit construction projects with multilevel hierarchical structure can be divided into 4 layers from bottom to top: the root layer, the controllable layer, the key layer, and the directly layer (as shown in Figure 2).

(1)From root layer to controllable layer

As can be seen from Figure 2, imperfect accountability system (s_{15}) and risk management system (s_{14}) is likely to cause the manipulation, opaque information publicity (s_{13}), and the spread of negative public opinion (s_{10}). Although from different aspects of the factors, both unemployment caused by projects (s_3) and the wage arrears of workers (s_5) are the public opinion direction, and their result may lead to the negative opinion (s_{10}).

(2)From controllable layer to key layer

We also can be seen from Figure 2, negative public opinion (s_{10}) and low compensation of land expropriation (s_4) might affect the public mood, reduce the resettlement difficulties (s_8) and low degree between construction and opinion fusion (s_{11}).

Pollution from construction (s_1), such as water pollution and garbage pollution, would cause soil and water loss (s_2). Construction safety accident (s_7) may trigger traffic risks (s_6). National cultural conflict (s_9) can increase the resettlement difficulties (s_8). Construction and opinion fusion (s_{11}) also be affected by the construction safety accident (s_7) and national cultural conflict (s_9).

(3) From key layer to directly layer

As shown in Figure 2, social conflicts (s_{12}), the most direct manifestations of social risk, are influenced by all the factors in the key layer. Concretely, oil and water loss (s_2) will trigger the conflicts (s_{12}) between projects owner and the local environmental protection department; the contradiction (s_{12}) between projects owner and the traffic department may arise by traffic risks (s_6); the resettlement difficulties (s_8) would make projects owner conflict (s_{12}) with local people; the backlash of the masses may be initiated by low degree between construction and opinion fusion (s_{11}), and reduce social conflicts (s_{12}).

5 Conclusions

By the thinking of system analysis, this paper uses the method of integrated DEMATEL and ISM, puts forward the multilevel hierarchical structure and the relationship within the social risk causes system of rail transit construction projects. At the same time, root causes, key causes, controllable causes and directly causes of the social risk system were proposed. The results show that safeguarding the fundamental interests of the masses is the key to control the social risk of the rail transit construction.

The method of integrated DEMATEL and ISM not only avoids the subjectivity of the traditional analysis methods, such as fault tree analysis and analytic hierarchy process, but also ensures the system structure hierarchical and unambiguous. It should be noted that the judgments of relationship between factors in the system are based on experts' experience, and there is still a certain amount of subjectivity. The focus of future research is to realize objective relation judgment of the factors.

[2]School of Traffic and Transportation, Southwest Jiaotong University, Chengdu, Sichuan 610031.

Abstract: In this article, we studies the optimal trade credit term decision under the centralized decision making in an extended economic ordering quantity framework. We divide the trade credit policy into two parts: $T \le M_j$ and $T > M_j$. The objective of this research is to determine the optimal credit term to maximize the joint total profit per unit time. Furthermore, numerical study and sensitivity analysis are presented to illustrate the results of the proposed model and to draw managerial insights.
Keywords: Trade credit; Credit term; Centralized decision; Sensitivity analysis.

1 Introduction

In business operations, due to the uncertainty of the procurement, production and sales aspects, business will be a shortage of funds. China's small and medium -sized enterprises have capital constraint, it is difficult to solve this problem. This will not only hinder their own development, also affect the profit of other companies in the supply chain. Now, there are two common ways: First is the bank credit; the second is trade credit. The first study is a bit of more, the second way is relatively lake. So, this paper studies of the second way.

Trade Credit is an important coordination mechanism between manufacturers and retailers. It can share the cost, transfer the risks and regulate the benefits. Trade credit term is the length of time allowed retailer to delay payment, it is the core concern of credit term decisions. This paper study the issue of trade credit term decision under a centralized decision-making, how to set the optimal trade credit term to make the supply chain system's profit maximization, and the sensitivity analysis of trade credit term.

2 Literature review

When the buyers and suppliers exchange goods/services, they usually have to agree on trade terms. These trade terms consist of delivery and prices and payment conditions. Now trade credit for goods/services is a very common business practice, the optimal length of trade credit is the core concern of credit term decisions.

Shi and Zhang (2010) incorporated default risk into the supplier's decision. Numerical study suggested that the optimal trade credit term increases with the buyer's capital cost, and decreased with the supplier's capital cost, the demand rate, the probability of default, and the buyer's inventory holding costs. Abad and Jaggi (2003) introduced cooperative behavior, modeled a set of Pareto-efficient solutions. The particular solution depended on a profit-sharing parameter that the supplier and the retailer establish through negotiation. Jaber and Osman (2006) relaxed the lot-for-lot assumption. Jaggi et al. (2008) investigated the supplier and the retailer both offer trade credit. Assuming the supplier's credit period as given, they presented an algorithm to jointly determine the retailer's optimal cycle time and credit period. Kouvelis and Zhao (2012) modeled no cooperative behavior but introduced stochastic demand. Using a capital-constrained newsvendor model, the authors found that trade credit was always advantageous for the supplier. Gupta and Wang (2009) formulated a model to investigate the relationship between cash discount and discount period. A smaller cash discount implied a longer discount period. Charharsoogi and Heydari (2010) introduced cooperative behavior and uncertain lead times. Sarmah et al. (2007) compared trade credit and quantity discount contracts in an economic order quantity framework. Trade credit was more efficient if the supplier's cost of capital is lower than the buyer's cost of capital; otherwise quantity discounts were more efficient. Lee and Rhee (2010) considered quantity discount, buy backs, two-part tariffs, and revenue sharing in a newsvendor framework.

In these literatures, the trade credit term were considered as the unilateral decision problem of manufacturer rather than from the perspective of the entire supply chain. Therefore, this paper sets up a two-echelon supply chain that contains single manufacturer and a single retailer to study the optimal trade credit term decision under the centralized decision making.

3 The mathematical model

3.1 Assumptions and notation

The following assumptions were made in developing the proposed model:

(1)There is a single supplier and a single buyer in this model.

(2)The production rate is greater than the demand rate and shortages are not allowed.

(3)The supplier adopts a lot-for-lot policy.

(4)The retailer has no initial money, but his/her sales revenue can put in the bank to obtain interest. When the time to pay supplier for goods, the retailer's sales revenue less than need to pay ,he/she should take stock pledge measure to pay.

(4)The supplier cost of capital is less than the retailer, this ensures that manufacturers have the ability to provide the trade credit.

(5)The retailer holding cost is less than the purchase cost, if the holding cost is higher than purchasing cost, the retailer don't want to keep any inventory.

Notation:

D - Retailer's demand rate per unit time

h - Retailer's unit stock holding cost of good quality items per unit time excluding interest charges

A - Supplier's setup cost per setup

S - Retailer's ordering cost per order

M_j - The length of the trade credit period offered by the supplier

T - The length of replenishment cycle of the retailer

I_e - Retailer's interest earned per dollar per unit time

I_p - Retailer's interest charged per dollar in stocks per unit time

I_m - Supplier's capital opportunity cost per dollar per unit time

π_j - Retailer profit, supplier profit and total profit($j = r, s, 1, 2$)

p, w, c - Retailer selling price, supplier wholesale price, supplier production cost($p > w > c$)

Then assumption that $I_p > I_e$, $I_p > I_m$, $pI_e > wI_m$.

3.2 Modeling

In the trade credit, as the credit term is longer or shorter than the length of replenishment cycle of the retailer, we have the following two possible cases:① $T \le M_j$ and ② $T > M_j$. These two cases' inventory and capital model for the retailer are depicted in Figure.1.

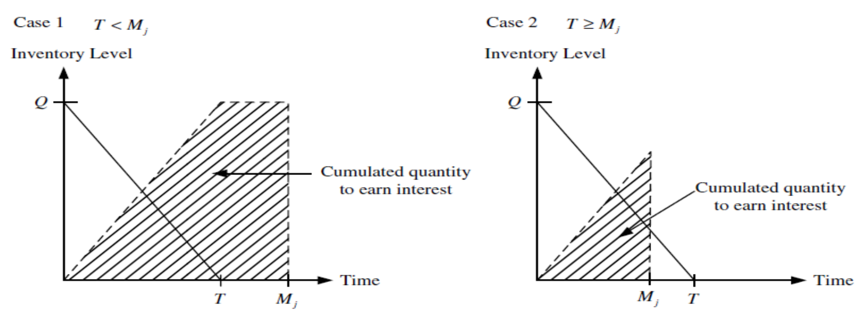

Figure 1. Inventory and capital model for the retailer under trade credit

Profit function of the retailer:

Retailer's profit= sales revenue- ordering cost – inventory cost –cost of financing+ interest of sales revenue

$sales\ revenue\ = (p-w)D$, $ordering\ cost\ = S/T$, $inventory\ cost\ = hDT/2$.

When the $T \le M$, retailer dose not financing so has no cost of financing, $interest\ of\ sales\ revenue\ = pDI_e(M - \frac{T}{2})$

When the $T > M$, $cost\ of\ financing\ = \frac{wD(T-M)^2 I_p}{T}$,

$$interest\ of\ sales\ revenue\ = \frac{pDI_e[M^2 + (T-M)^2]}{2T}$$

Retailer's profit:

$$\begin{cases} T \le M, & \pi_r = (p-w)D - \dfrac{S}{T} - \dfrac{DTh}{2} + pDI_e(M - \dfrac{T}{2}) \\ T > M, & \pi_r = (p-w)D - \dfrac{S}{T} - \dfrac{DTh}{2} - \dfrac{wD(T-M)^2 I_p}{T} + \dfrac{pDI_e[M^2 + (T-M)^2]}{2T} \end{cases} \quad (1)$$

Profit function of the supplier：

Supplier's profit = sales revenue - opportunity cost -set-up cost

$$\text{Supplier profit}: \pi_s = (w-c)D - wI_m MD - A/T \quad (2)$$

Total profit function of the system：

$$\begin{cases} T \le M, & \pi_1 = (p-c)D - \dfrac{A+S}{T} - \dfrac{DTh}{2} + pDI_e(M - \dfrac{T}{2}) - wI_m MD \\ T > M, & \pi_2 = (p-c)D - \dfrac{A+S}{T} - \dfrac{DTh}{2} - \dfrac{wD(T-M)^2 I_p}{T} + \dfrac{pDI_e[M^2 + (T-M)^2]}{2T} - wI_m MD \end{cases} \quad (3)$$

3.3 Solution procedure

According to the total profit function of the system (3), we can get the first derivative and the second derivative of the function as following:

$$\frac{d\pi_1}{dT} = \frac{A+S}{T^2} - \frac{Dh + pDI_e}{2} \quad (4)$$

$$\frac{d^2\pi_1}{dT^2} = -2\frac{A+S}{T^3} < 0 \quad (5)$$

$$\frac{d\pi_2}{dT} = \frac{A+S+DM^2(wI_p - pI_e)}{T^2} - \frac{Dh}{2} + \frac{D(2pI_e - wI_p)}{2} \quad (6)$$

$$\frac{d^2\pi_2}{dT^2} = -2\frac{[A+S+DM^2(wI_p - pI_e)]}{T^3} < 0 \quad (7)$$

By (5) and (7) shows that the profit function's second derivative is below zero, we can know that the total profit function of the system is a concave function. Furthermore, from(4)and(6)we get the $\frac{d\pi_1}{dT}|_{T=M} = \frac{d\pi_2}{dT}|_{T=M}$, therefore the profit function in the $T > 0$ is a concave function rather than piecewise concave function.

Setting $\frac{d\pi_1}{dT} = 0$ and $\frac{d\pi_2}{dT}$=0, we can get the optimal replenishment cycle time when $T \le M$ and $T > M$.

$$\begin{cases} \dfrac{d\pi_1}{dT}=0, & T_1^*=\sqrt{\dfrac{2(A+S)}{Dh+2pDI_e}} \\ \dfrac{d\pi_2}{dT}=0, & T_2^*=\sqrt{\dfrac{2[A+S+DM^2(wI_p-pI_e)]}{Dh+2D(pI_e-wI_p)}} \end{cases} \quad (8)$$

In the case $T \le M$, due to $pI_e < wI_m$, we can know that the longer the credit term, the system's profit will be smaller, so the optimal M is

$$M_1^* = T = \sqrt{\frac{2(A+S)}{Dh+2pDI_e}} \quad (9)$$

In the case of $T > M$, we can get the $T > M \Rightarrow M < \sqrt{\dfrac{2(A+S)}{Dh}}$, therefor the optimal credit term is

$$M_2^* = (I_p - I_m)\sqrt{\frac{2(A+S)}{D}} * \frac{1}{\sqrt{hI_p{}^2 + wI_pI_m(2I_p - I_m)}} \quad (10)$$

By the above get:

$$\begin{cases} T \le M\text{时}, & \pi_1^* = [p-c+M(pI_e-wI_m)]D-\sqrt{2D(A+S)(h+2pI_e)} \\ T > M\text{时}, & \pi_2^* = [p-c+wM(I_p-wI_m)]D-\sqrt{(h+wI_p)[2D(A+S)+wI_pM^2\mathrm{D}^2]} \end{cases} \quad (11)$$

4 Numerical studies

In this section, we solve the problem described in this paper, for numerical study with the parameters set as follows: $D=100$, $A=100$, $S=90$, $p=100$, $w=40$, $c=20$, $h=5$, $I_e=0.01$, $I_p=0.06$, $I_m=0.05$.

According to the(11)get the relationship between credit term and total profit of entire channel is depicted in Figure.2. So we can get the optimal trade credit term is $M^*=0.12$, the maximum profit is $\pi^*=7472$ and the optimal replenishment cycle time is $T^*=0.72$. This result is consistent with the section 3. Under the trade credit financing, business can increase the order to increase its sales revenue, but the cost of financing also increase, so businesses need to proceed from the total profit to give the optimal trade credit term.

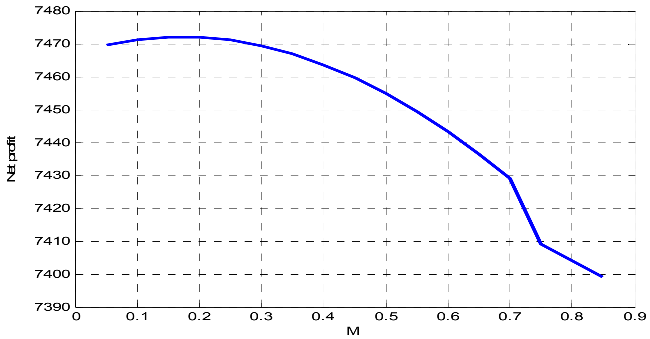

Figure 2. The relationship between credit term and total profit of entire channel

On this basis, we use sensitivity analysis to investigate the impacts of some factors on trade credit term decisions. These factors contain h, D, I_p and I_m, we let h, D, I_p and I_m within a reasonable range by a certain step change, then analyze these variables how affect trade credit term decisions.

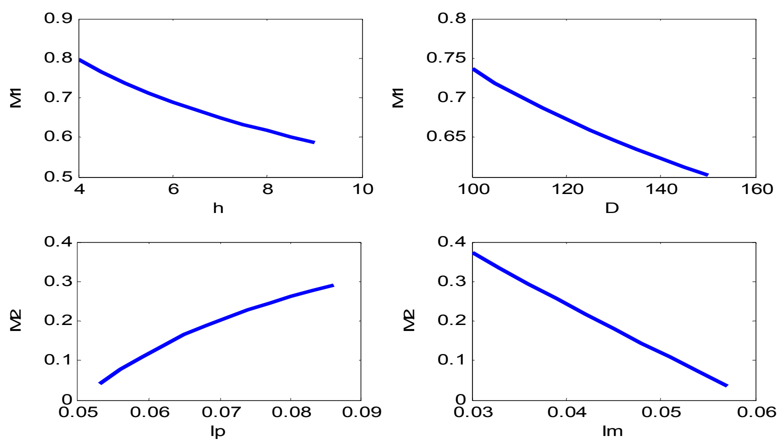

Figure 3. Credit term sensitivity analysis of h, D, I_p and I_m

The sensitivity analysis results are shown in Fig.3, We can draw the conclusions from Figure.3 as following:①Retailer holding cost impacts the retailer's ordering, in response to the supplier's credit term. So a higher holding cost leads to a shorter term, because the retailer’s inventory cost increases with his holding cost, a longer term in the case of a higher holding cost. ②A higher demand rate leads to a shorter credit term. We argue that a longer term for retailers with a higher demand rate, may bring in more orders, but it also leads the supplier to a greater level of default risk, so a shorter term will be preferred.③The retailer has a higher capital cost, which indicates his financing is more constrained, the supplier has to grant a longer term in this case. ④The supplier with greater financing capacity tends to grant longer term.

5 Conclusions

Trade credit is a major component of short-term financing for business all over the world, and the optimal length of trade credit is the core concern of trade credit term decisions. This paper studies the optimal trade credit term decision in an extended EOQ framework, and makes the numerical study. We get the relationship between credit term and total profit of entire channel and the sensitivity analysis of h, D, I_p and I_m .

As for future research, our model can be extended to decentralized supply chain, multi-echelon supply chains. Also, it can consider deteriorating items and default risk into the proposed model.

Abstract: Production function is the econometric model used to study the business relationship between input and output. In this paper, it uses Cobb-Douglas (C-D) production function as based model, and it uses regression analysis and Solow residual as the theoretical support. It simulates the production function model of railway transportation. Through the empirical study and quantify the railway transport enterprise production function analysis, we can reveal factors affecting investment in the railway transport enterprise output volume. This research is helpful for future.

Keywords: Transportation economy; Production function and cost function.

1 Introduction

Our country has vast land and rich resources, but the allocation of resources are out of balance, so we should develop the railway transportation industry. Because it can provide strong service, it can support for last development of our country's economy and society. We research the relationship between the national economy and the production factors of rail transportation. It can provide guidance for scientific advice in the development of railway transport. It discusses the application of the production function in analysis, forecasting and investing. At last it can provide a reference for the production and management decision-making.

2 Cobb-Douglas production function (C-D)

C-D production function is very widely used in economic production function model, and it is very suitable for the analysis and research of the production development of large enterprises. C-D production function was originally by American mathematician Cobb and economist Paul Douglas, they studied the capital of the United States between 1899 to 1922 impact on national income and labor force by historical material. When the assumption of constant technology is the same, we can simulate for the output and the relations of capital and labor force.

2.1 The mathematical model of C-D production function

The first winner of the Nobel Prize economics professor J.Tinbergen thinks that as time progresses, the production function's curve should exhibit a trend to move to the right level. That is the same number of labor force and the amount of capital should get the output as time increase, the level of technology should be varied. Based on the above, an enterprise may be increasing, decreasing or the same, then the C-D production function as follows:

$$Y = A(t)L^{\alpha}K^{\beta}\mu \qquad (1)$$

Y: the output of an enterprise; $A(t)$:Comprehensive technical level, change over time; L: the number of input labour; K: the amount of capital invested, generally refers to the net value of fixed assets; α:Law firms; β:Law firms; μ:Random perturbation terms, including in addition to comprehensive technical level, the number of labor, the capital of three factors, all other unpredictable factors influence on output, in order to simplify the model, this article does not consider random perturbation terms.

Type (1) is a common C-D production function model. The model adopts the comprehensive technical level of change, and it didn't make any assumptions on law firms, so it is usually referred to as free schema model.

2.2 C-D Production function of the basic indicators

This paper uses one of the most basic margin analysis to analyze C-D production function in economic. The main factors of production are marginal product, elasticity and returns to scale, as follows:

(1) The marginal output of labor MP_L

$$MP_L = \lim_{\Delta L \to 0}\frac{\Delta Y}{\Delta L} = \frac{\partial Y}{\partial L} = \alpha A(t)L^{\alpha-1}K^{\beta}\mu = \alpha\frac{Y}{L} \qquad (2)$$

(2) The assets of the marginal output $\mathrm{MP_K}$

$$\mathrm{MP_K} = \beta\frac{Y}{K} \qquad (3)$$

(3) Labor unit of output MP_{LM}

The average wage of railway transportation industry in our country as the SA_L RMB, the investment on labor each unit of currency can be output to labor unit of output:

$$MP_{LM} = \frac{MP_L}{10^4 \bullet SA_L} \tag{4}$$

(4) Asset unit of output MP_{KM}

$$MP_{KM} = \frac{MP_K}{10^8} \tag{5}$$

(5) The marginal rate of substitution of labor for assets

In the C-D production function, the work of the marginal rate of substitution of capital MRS_{LK} refers to in the case of the production/output unchanged, an additional unit of labor can reduce the inventory of fixed assets, at this time because the output Y is constant, K can be assets as function of labor L:

$$MRS_{LK} = -\lim_{\Delta L \to 0} \frac{\Delta K}{\Delta L} = -\frac{\partial K}{\partial L} = \frac{\alpha K}{\beta L} \tag{6}$$

(6) The output elasticity coefficient of labor and assets EL 、 EK

$$EL = \frac{\frac{\partial Y}{Y}}{\frac{\partial L}{L}} = \frac{\partial Y}{\partial L} \bullet \frac{L}{Y} = MP_L \bullet \frac{Y}{L} = \alpha \tag{7}$$

$$EK=\beta \tag{8}$$

(7) Scale reward change

Assume that labor and fixed assets and to expand the production of lambda times to Y

$$\frac{Y'}{Y} = \frac{A(t)(\lambda L)^{\alpha}(\lambda K)^{\beta}}{A(t)L^{\alpha}K^{\beta}} (\lambda > 1) \tag{9}$$

3 Railway transportation production function simulation

Railway transport is a large service companies, and its production function is key function that relationship between output and input key. In this section, we use C-D production function as the basis model. It can be used as railway transport simulation and test, and it also can calculate and analyze the related indicators.

3.1 Railway transportation C-D production function

（1）Y：Output, railway transportation industry output value can be a transportation revenue or reduced turnover, consider conversion turnover H is the railway transportation industry to meet the national economy development the most visible expression of transport demand, this paper USES it as the full value of the railway transportation industry.

（2）A（t）: Comprehensive technical level, the management level, labor force quality, the introduction of advanced technology such as decision, type (10) adopted the comprehensive technical level of change, considering the research period, remained stable development of national economy and railway transportation in our country, think comprehensive technical level A (t) and over time, steady development using the type function as A comprehensive technical level of development:

$$A(t) = A_0 * \gamma' \tag{10}$$

A_0: The base of comprehensive technical level; γ': Comprehensive technical level of the average development speed; t: Relative to the time span of the base period during the reporting period.

（3）L: Labor number, generally the number of employees or staff total wages, considering the research period, our country labor force decline of railway transportation, and increasing its total wages, these two indicators were used respectively to simulate and compare.

（4）K: Fixed assets, the use of railway transportation industry of the net value of fixed assets each year.

（5）μ: Random disturbance, to simplify the model, μ=1

Based on the above, the free mode, railway transportation, the normal form of the C-D production function is:

$$H = A(t)L^{\alpha}K^{\beta} = A_0 * \gamma' L^{\alpha}K^{\beta} \tag{11}$$

Under the condition of constant scale reward, railway transportation, the normal form of the C-D production function is:

$$H = A_0 * \gamma' L^{\alpha}K^{1-\alpha} \tag{12}$$

3.2 Railway transport simulation of C-D production function

Based on the index data, production function to simulate and test of the railway transportation industry, briefly describes its principle is as follows.The simulation of the C-D production function

According to the constant return free mode and scale (actual it is the size of remuneration changes due to the change of the comprehensive technical level) in the two cases, introduces the following two methods respectively.

(1) Direct estimate method

Direct estimation refers to completely based on the historical data, not to any scale returns hypothesis, according to certain mathematical method to estimate parameters, a brief introduction to its steps are as follows.

Transform the C-D production function:

In order to get the function of linear form, type (11) on both sides for logarithmic transformation, have to function as follows:

$$\ln H = \ln A_0 + \ln \gamma * t + \alpha * \ln L + \beta * \ln K \tag{13}$$

$$\begin{cases} Y = \ln H \\ a = \ln A_0 \\ b_1 = \ln \gamma \\ b_2 = \alpha \\ b_3 = \beta \\ x_1 = t \\ x_2 = \ln L \\ x_3 = \ln K \end{cases} \tag{14}$$

Type (13) can be turned into:

$$Y = a + b_1 x_1 + b_2 x_2 + b_3 x_3 \tag{15}$$

Type (15) as a ternary linear function, can take advantage of the multiple linear regression of related theory and method to estimate its parameters.

Estimated parameter: similar to a yuan linear regression, multiple linear regression parameter estimation is also based on the least squares principle, go into the derivation process here.

Reduction simulative function parameters: according to the type (13), through a simple reverse, easy type (11) of each parameter of the experience value is:

$$\begin{cases} \tilde{A}_0 = e^{\tilde{a}} \\ \tilde{\gamma} = e^{\tilde{b}_1} \\ \alpha = \tilde{b}_2 \\ \beta = \tilde{b}_3 \end{cases} \tag{16}$$

Free mode, the railway transportation industry experience C-D production function of the sample regression function is:

$$\tilde{H} = e^{\tilde{a} + \tilde{b}_1 \bullet t} L^{\tilde{b}_2} K^{\tilde{b}_3} \tag{17}$$

(2) Strength form estimate method

Strength form estimation is in a constant scale reward ($\alpha + \beta = 1$) conditions, the type (12) on both sides of the exponential, it turned into a binary linear function, on the basis of drop yuan, according to the principle of least squares estimate parameter, the specific steps similar to direct estimation method, go here, its experience regression function are as follows:

$$\tilde{Y} = \tilde{\alpha} + \tilde{b}_1 x_1 + \tilde{b}_2 x_2 \quad (18)$$

$$\tilde{H} = e^{\tilde{a} + \tilde{b}_1 \bullet t} L^{(1-\tilde{b}_2)} K^{\tilde{b}_2} \quad (19)$$

4 Conclusions

This paper describes parameter estimation and hypothesis testing that free mode and constant returns to scale method. Then few years of study can be selected, it uses the railway converted turnover as output value, and it uses the number of employees in the transportation industry employees, total wage and net fixed assets as input elements. At last it uses SPSS software for the production of railway transportation function model to simulate and test. According to the test results of the two models, it selected constant returns to scale case studies as a basis for the subsequent. Then it calculates the relevant indicators and draws the relevant conclusions. For example, it can research the number of employees employed for transportation and net fixed assets; and it also research the comparison of fixed assets brought into outputs and inputs to bring the total wages; at last it research on the labor force relationship between the size of elastic modulus than the elastic coefficient assets.

Implications of Foreign Policy to the Development of Railway Freight

Jingjing Bao; Yingcan Li; and Yanping Cui
China Academy of Railway Sciences, Institute of Transportation and Economy, Beijing 100081.

Abstract: According to foreign study on the policy development of railway freight transportation, this paper present that the developed countries adjust transportation structure and encourage various transportation modes to balanced develop by laying down integrated transportation and environmental protection policy. On the basis of analysis on current situations of the railway freight market and referring experiences of the foreign policy of integrated transportation, tax policy and transport subsidy, it introduces a strategy on promoting the development of China railway freight transportation.
Keywords: Freight turnover; Railway freight transportation; Transportation policy.

1 Introduction

Along with variety of industrial structure and the increasing competitiveness of other transport modes, the railway freight transportation maintains the steady growth in the volume and turnover volume. Nevertheless, the railway freight transportation facing severe challenges because of the decreasing of transportation market share. Besides, the sustained growth of car ownership contribute to the serious traffic congestion to many countries, uncoordinated development of transportation structure, which bring obstacles to the sustainable development of transportation. Therefore, we can learn and reference the methods of solving these issues form those countries, such as providing subsidy to environmental friendly transportation modes, increasing the tax on vehicle transportation, limiting vehicle transportation development and so on.

Table 1.2002-2012 the trend of Chinese freight market share change

Year	Railway	Road	Waterway	Airlift	Pipeline
2002	13.82%	75.25%	9.56%	0.01%	1.36%

2012	16.80%	34.26%	47.02%	0.09%	1.83%

2 Integrated Transport Policy in Foreign Countries

Most of the countries keeping the similar objectives of integrated transport policy, which are speeding up transportation development for promoting economy, raising transportation efficiency, ensuring social equality, developing backward areas, protecting environmental and using resource more efficiently. To achieve the objectives, the developed countries pay much attention to the balanced development of various transportation structures. From the view of sustainable development of transportation, the railway is widely accepted because of more environmental protection and energy saving.

The White Paper On European Transport Policy For 2010 emphasized on comparison of different modes of transport especially mentioned the waterway and railway should occupy a larger market share. Finally to break the strong situation of road transport, create comprehensive transportation system with coordinated development of various modes of transport, and solve various transportation issues. In order to achieve the goal of sustainable development and social equality, the European Union provides support to the transport mode which helps to the goal. At the same time, gradually adjust the transport policy along with the deeper understanding on developing law of transportation and social economy.

The UK proposed the concept of low carbon transportation in the white paper of Our Energy Future Creating A Lowcarbon Economy in 2003, which is worldwide accepted. In decade, the UK focuses on the study of low carbon emission transportation. Compare with the other transportation modes, the railway transportation is hardly affected by weather conditions and low pollution, which is the lowest carbon and most efficient transportation way thus acquire to a large number of policy support.

Japan's Transport Ministry published a paper The Direction of Integrated Transportation Policy on The Basis of Long-term Prospect in 1980. The objective of the paper is that developing overall public transportation system to instead the vehicles society. The main measures are speeding up the railway on mail lines, developing urban rail and aviation network, and making full use of the railway, shipping and other transportation systems.

From the foreign comprehensive transportation policy that we can see, abroad countries pay more attention to balanced development of various transport modes. Moreover, the transportation policy is adjusted constantly along with the social and economic changes. They attaching importance to railway development, meanwhile, ensure the sustainable development of transportation.

3 Foreign Tax Policy

Tax is the regulation of the economy running. Through to increase or decrease tax can affect the economic interests of the various modes of transportation, which guiding transport enterprise or individual economic behavior.

In German, the overall level of burden is less than one percent of the income of transportation even though the enterprises undertake the full amount of tax. There are mineral oil taxes, ecological protection tax, vehicles tax and road use fees in the German transportation tax. The railway transportation did not need to pay the vehicle tax and road use fees. To restrict road transportation, German government decides the vehicle tax to large trucks according to the weight, the discharge of harmful substances and noise emissions, and the highway use fees to heavy truck according to the using time.

The main taxes that the U.S. freight railway undertaking are corporate income tax, fuel tax and property tax. For the fuel tax, the federal and state offer some privilege to railway and levy lower tax rate.

There are three added-value tax standards in Italy, 21% standard rate, 10% beneficial tariff and 4% special beneficial tariff. Italy rail transport implement 10% beneficial tariff, and in some special cases it can be tax-free. The passenger and freight railway transport within the international and European Union are both duty-free.

The UK takes the lead in levying climate change tax by 2011 Finance Act. The article stipulates that beside electricity for residents, it must pay the climate change tax to all electricity using. To support the railway transportation, the act clear that the British treasury has the power to extend the passenger and freight railway operators' climate change immunity.

4 The Foreign Policy of Subsidies

Because railway freight transportation undertake the transport of life necessities and key material, which has public good characteristics. The most obvious manifestation of railway public good is the transport prices deviate from the transportation value, need government subsidies to make up for the loss. Beside, along with the concept of environmental protection is gradually strengthened, many countries pay more attention to the development of low carbon transportation. Environmental subsidies are the most direct means to encourage low carbon transport.

4.1 Public welfare subsidy

Transportation companies are the business entities of the transport sector; meanwhile it is taking the busy transportation task. It not only hopes to gain profit from transport activities, but also to complete the public transport service requirements. Therefore, the companies could not fully charge in accordance with market principles.

Russia affords the transportation companies subsidies on the transportation of ensuring national security, disaster relief, emergency transportation and other necessary personnel and material transport that having completely social significance. To the transportation that government supporting for food, pesticides, fertilizers and other materials, the railway charges the regular fare, and to the part which needs policy relief, the government directly give subsidies to the carrier.

After the Dutch railway reformed, the allowance was decreasing yearly. Instead of the objective of profit, the railway service has social benefits. The new mode is that the government provides the allowance according to the contract which signed with operators. Moreover, Dutch also provide the allowance to the projects which having significant effect about economic and social development. For example, the specialized freight railway line between Dutch and Germany border which receive 150 million-250 million euro operating subsidy per year from the government.

The Sweden government first isolated profit line and losses line. As the representative for losses line, the local government implemented concession that received appropriate subsidies. Such approach achieved a clearly definition about public railway service and commercial service.

4.2 Environmental subsidies

The EU Transport Commission is the coordinating agency of various transport modes in Europe. Since the organization was founded, one of the main businesses is constantly engaged in lay down the integrated transport policy from the level of the overall European Union and the concrete implementation. According to the statistics at that time, the proportion of road traffic CO2 emission occupies 84% among all the transportation modes. Thence, the European Union started to pay more attention on the development of Eco-friendly transportation mode.

The Marco Polo program directly support to non-automotive transportation in the form of subsidies, which have significant effect on transportation modes transfer. At present, the program has funded more than 150 projects, of which transportation modes transfer projects occupy 83%. The Marco Polo program affirmed environmental benefits of rail and waterway transportation, that is the most directly and efficiency measure to promote transportation modes transfer in Europe.

In the initial stage of the railway reform, there are three allowances of UK government providing, freight facilities subsidy, line usage fee subsidy fund and company-neutral income support fund. Among the three allowances, the major objective of freight facilities subsidy is encouraging the freight transportation to transfer from roadway to waterway. Switzerland was the first country to establish an integrated transport infrastructure fund which imposes high tolls to heavy freight trucks. Most of the income earned is included in integrated transport infrastructure fund to the new railway line project investment.

Since the 1970s and 1980s, the rapid development of road traffic in Japan. It brings environmental and energy crisis, while accompanied by the negative impact of traffic accidents, road congestion and so on. The Japan government carried out a transportation preferential policy. The purpose of the policy is to promote the transfer from long-distance freight transport to take railway and waterway transportation modes, which supporting the development of railway freight transportation from the level of national aspect. The Japan Railway Freight company think of that the supporting from national policies bring into play affect to construction of high density of Japan freight corridor.

There are some other mainly subsidies around the world. For instance, after twentieth Century 80 years, the U.S. derate the tax which are necessary but unprofitable rail lines, meanwhile encouraged to sell the unprofitable rail lines to subsidize the main business line; in order to mitigate the traffic congestion, traffic accidents, air pollution and reduce the road noise, the French government decided to provide the allowance to support the development of railway. After calculation, the number of subsidy is about equal to the effect of energy saving and environmental protection.

5 Freight fare policy

In the fierce competition of the transport market, freight fare not only reflect the value of freight transport product, but also regulate the relationship between supply and demand, which is the most direct factor of owners choosing the transportation modes.

The railway freight fare in Italy is completely decided by the cargo transportation department of the national railway group of Italy independently. Railway Company has relatively high autonomy on freight fare.

The freight fare making and adjustment of French railway is completely by French state-owned railway company, it has high autonomy. The freight fare is made by according to its category, feature, characteristics and transportation condition, the French railway freight fare is the price by agreement, if the customer agrees, the company can sign agreement with the customer, and there is no need for approval by other departments. Flexible price making mechanism is the guarantee of stable development of railway cargo transportation.

American railway cargo transportation has several forms such as price by agreement, freight fare released, combined transportation freight fare and local line freight fare. Price by agreement is the main form of American railway cargo freight, 80% of the UP's volume is agreed by contract, On the basis of basic freight fare, Railway Company can negotiate and sign transportation contract with the consignor. When the consignor disagrees with the railway company, freight fare released can be used, which can also be adjusted, National Transportation Safety Board has certain appropriate regulations on freight fare which is mainly used on the cargo lacking competition, for those competitive cargo, policy regulations are much less.

In Brazil after the privatization of railway, freight fare by agreement is implemented, transportation service price cap is set by making transportation agreement and is duly adjusted by according to the change in inflation rate. On the premise of effective competition, operator has the right to make its price autonomously, different freight fare can be adopted by different transportation demand of different consignors, franchised operators are allowed to sign transportation agreement freely with the consignors under special circumstances by different demand and margin cost pricing.

In 2003, the Russian Government enacted Transportation Development Strategy of Russian Federation, in which it states Russian Railway Company should change the methods of changing freight fare and adjusting price list in order to adapt to the need of market development. On the aspect of cargo transportation, for the cargo imported and exported, the sea port fare rate should be emphasized and freight fare comprehensive adjustment method should be made.

6 The enlightenment of transportation policy abroad to China

The sustainable development of transportation modes is very dependent on the support of national policy. Because the railway has advantages of large volume, high stability, small influence by climate, and low carbon and environmental protection, so it received lots of national attention. Currently, Chinese government provide certain orientation to support the railway transportation, but lack specific support policies and measures, which is one of the main factors to contribute to the low share in the railway freight market.

6.1 Comprehensive transportation policy in China

In China, the research on comprehensive transportation system came later, Ministry of Transportation of the People's Republic of China was established in 2008, which represents comprehensive transportation system development in China has entered organizational and institutional phase, but Ministry of Railway is always independent of other four transportation forms until march, 10, 2013, by according to organizational reform and functional transformation of the State Council, government functions are separated form enterprise, the administrative function of drafting railway development planning and policy which belonged to Ministry of Railway was handed over to Ministry of Transportation, since then China has really initiated the comprehensive transportation system research and management.

The comprehensive transportation policy making can refer to the practices abroad, thoroughly consider various transportation forms from the perspective of comprehensive transportation system. Transportation development fund should be collected and used, the usage of this fund shouldn't be confined on construction, which should always be used to subsidize operation, all transportation forms should be encouraged to develop in balance. Furthermore, on the aspect of environmental protection, the term of encouraging environmental transportation should also be made, ensuring sustainable development of transportation.

6.2 China's railway taxation policy

China put an emphasis and support the construction and development of railway, the taxation policy was implemented in 1994 which exempt corporation income tax of some railway state owned enterprises with multiple businesses, but in 1998 the taxation policy was reinstated. In 2001, to support the development of western region, during the construction period or Qing Zhang Railway, corporation income tax was also being exempted. During the process of railway funding institution reform, for supporting Daqin company reconstruction and IPO, 7.9 billion RMB corporation income tax it should pay was exempted. But in recent years, the favorable policy given to the railway company has been less and less, there is rarely any tax preference regarding railway operation.

Under the circumstances of emerging green transportation concept, railway transportation as low carbon transportation form should be supported and preferred. The investment and technology transformation are concerning environmental protection, safe operation, energy saving and emission reduction, in taxation deduction and exemption policy can be increased in the projects of railway investment, more social capital can be attracted to the investment of railway, promoting the development of railway transportation. On operation, due to the effect of energy saving and environmental protection the fuel tax exert, thus fuel tax can be collected from road transportation and other forms, slow down their development and create a space of development for railway transportation.

6.3 Railway subsidy policy in China

Railway transportation shoulder the transportation mission of public interest, basic return of investment can almost not be realized. Due to the features of public interest, cross-subsidies are adopted inside the railway, subsidizing the loss of public interest transportation by operational transportation profit, but the government has not specific subside policy on public interest railway., which causes that the operational target, financial boundary and assessment criteria are not specific, there is no direct connection between operational activities and performance, operational effectiveness is low, effective stimulation, supervision and assessment mechanism cannot be established which hinders the organizational reform of railway cargo transportation. Indian railway didn't separate the governmental functions from the enterprises, which undertook enormous public interest transportation tasks, for balancing and lowering the consumer prices, regarding the necessities of fruit, vegetables, papers, cotton and organic fertilizer, Indian railway offered a freight fare which was lower than its cost. In result, the economic loss for transporting those cargo is 0.5672 billion Rupee.

As an entity in the market, railway transportation companies undertake public-interest transportation task which doesn't comply with corporate behavior, government should define the commercial and public-interest features of railway cargo transportation, the economic loss due to public-interest transportation should be subsided. Different loss should be assigned to different entities, the loss of supporting agricultural cargo should be subsided by Ministry of Agriculture and the loss due to relief supplies should be shouldered by Ministry of Civil Affairs. The source of subsidies funding could also refer to foreign practices, tax and fees should be collected from the transportation mode which has negative effect on environment such as road transportation.

6.4 Railway freight fare policy in China

To avoid monopoly and promote the healthy development of national economy, in the initial period after the founding of this nation, under the planning economy system, administrative method was adopted to make and adjust railway cargo transportation freight fare, which management was centralized and uniform freight fare was implemented, under the market economy system, uniform freight fare does not reflect the true value of service of railway transportation products, the transportation department which has the right to make price cannot allocate the transportation resources by adopting market mechanism, the price level loses its function of adjusting the demand and supply of cargo transportation, compared with flexible and diversified road transportation mechanism, railway transportation losing its market share is inevitable .

Freight fare is the most significant factor which affects railway cargo transportation, flexible price making policy can correct the defective relations between transportation cost and freight fare, transportation enterprise should have the right of appropriately floating the freight fare, strategy of multiple forms of freight should be implemented. When it was put into practice, certain period, certain region certain cargo could be allowed to operate in market-oriented way, gradually open it up all around after learning the lessons.

7 Conclusions

The supports from government policies play an important role on the development of railway freight transportation. However, it was difficult to achieve the goal of high freight turnover if only relayed on the policy support. Except the policy support, the railway transportation has gained success on the aspects of infrastructure planning and construction, Operation organization mode and freight product marketing. It should closely follow the cargo transport market and logistics trend to constantly improve market competitiveness in the future.

Particular Cultivation for Outstanding Talent in the Transportation Industry

Tingying Ju

School of Political Science, Southwest Jiaotong University, No. 111, North Section 1, Erhuan Rd., Chengdu 610031, China. E-mail: jtying@home.swjtu.edu.cn

Abstract: Transportation industry is basic industry and service industry of the economic and social development, transportation outstanding talent is the fundamental guarantee to support the development of transportation, the realization of the scientific development of transportation relies on sufficient amount, structural optimization, excellent quality and reasonable distribution of professional talent team. As a featured college, that provides service for the rapid developing transportation industry, should take the initiative to serve the country's strategic needs and the needs of industries and enterprises, support and play its leading role in developing the national economy to meet the urgent need of transportation industry outstanding engineering talent. Aiming at current common existing problems of talent development and personnel training, systematically analyze training excellence transportation needs and quality standards of excellence talents, explore and summarize the terms of the training objectives, training programs and training model to build transportation training excellence system that is able to provide a good reference for transportation training excellence.
Keywords: Transportation; Excellent talent; Cultivation system.

1 Introduction

Transportation industry is the basic industries and service industries of economic and social development. With emphasis on the construction of comprehensive transportation system, accelerating the development of transportation industry is an important material prerequisite for the accelerated development of the urbanization and the sustained and healthy development of economic society. The next decade is a critical period of national transportation strategy transformation and accelerating the development of modern transportation, transportation development will face a very arduous task, until 2020, we should have greatly enhanced the quality and efficiency of development, have vigorously promoted the ability and level of service, and have built a safe, smooth, convenient, green and economical transportation system.

Transportation outstanding talent is the fundamental security to the support of the transportation industry, to achieve scientific development of transportation relies on the adequate amount, structural optimization, good quality, reasonable distribution of talent team, strengthening the construction of transportation industry outstanding talent team and enhancing the guarantee capacity of outstanding talent will profoundly affect the progress and efficiency of the development of modern transportation. The development of the transportation industry puts forward higher requirements and challenges to our country's higher education, especially higher engineering education. Faced with the country's economic and social development needs of transportation excellence talent, As a featured college, that provides service for the rapid developing transportation industry, should shoulder the responsibilities and tasks, play its supporting and leading role, cultivate outstanding talent of transportation industry which is in the urgent need in the development of national economy.

Transportation industry talent team construction should be closely combined with the feature of industry development stage and talent demand characteristics of regional economic development, and fully in accordance with the new situation and new development of modern transportation requirements, aiming at prominent problems existing in talent development, overall planning, highlight the keystone, promote steadily and enhance the relevance and global transportation industry talent development. Cultivating excellence talents should fully follow the law of growth, working institutional mechanisms of innovation and talent, with emphasis at the urgent need of talent, high-level and highly skilled talent, as a whole to promote all types of talent team construction, construct a all-round, multi-level, professional, international transportation professional talent team with high-quality.

2 Current problems in talent development and cultivation in transportation industry

Transportation engineering education in China has good foundation after years of development, has formed a reasonable transportation industry education structure and system. Basically meet the large demand for various levels of society, various types of engineering and technical personnel. We have made great achievements in the development of service industry. At the same time, many problems still exists in transportation industry talent development and talent training.

The problems of talents development in transportation industry currently can be summarized as the following three aspects: firstly, the relative shortage in advanced and skilled personnel. In the face of increasingly complex natural conditions and even more serious resources and environment restriction, solve the relative scarcity of talented person in major transportation engineering construction, transport services, security, energy conservation and environmental protection science and so on; A serious shortage of high-skilled talents, high-skilled talents with technicians and more than skill level is much lower than the national average and the goals. Secondly, the professional and regional distributions are not reasonable. Existing talent, especially with senior professional and technical positions, mainly focused on the field of traffic engineering technology research and development, design and construction. However, these talents in the conservation and management, transportation services, security and environmental protection and other areas are failing. Thirdly, the use of high-level talent is unreasonable. The phenomenon that "Executive" and "official position" lead to the invisible drain of talent is serious; the sustainable development of the talent problem is outstanding.

Taking characteristic university in high levels of transportation industry as a case study, there are some problems of talent training showing in four aspects: firstly, the course system setting can't meet the requirements of cultivating innovative talents. Professional backbone course is weak, and the organic link is not enough. It focus on a single course of systematic, specificity and specific laws, but of course, the connection between the integrity and common law have been neglected, and lacking of knowledge integration and integrated applications is difficult to meet the system requirements of innovative talents knowledge system. Secondly, single training model, training methods behind. Especially the teaching mode and teaching method are still "force-feeding", dominated by teachers, take the student as the main body of research teaching mode has not been fully established; Lack of effective implementation of the operational level, driving force is not enough. The majority of students learn passively rather than actively, this way of imparting knowledge imprisoned the students' thinking and development, it is difficult to effectively stimulate students interest in learning, leading to students' initiative and energy is not enough. Third, the comprehensive quality education still needs to intensify. On ability training, we design more about what we learn, but why and how to design is relatively less, lack of systematic education of Disciplines and scientific research methods, lack of scientific research training system. On the engineering quality training, lack of overall design of engineering quality training from the perspective of professional. Fourth, the Industry-university joint training in engineering education is insufficient. Especially the higher education system reform, industries and enterprises are unable to effectively participate in the training process, resulting in the physical practice is absent or weak.

3 The requirements and quality standards

3.1 Transportation talents training demand

Our road to brand-new industrialization with Chinese characteristics, building an innovative country, reinvigorating China through human resource development and other series of major strategic made an urgent request of higher engineering education reform and development. The urgent need is to train a large number of engineering talents with the capacity of support industries development, innovation and international competitiveness. Transportation is the basic industries and service industries of the economic and social development. Over the next decade is the critical period for the national transportation strategy transformation and accelerate the development of modern transportation. To greatly enhance the quality and efficiency of development as well as the ability and level of service, the aim is to build a safe, smooth, convenient, green and economical transportation system. In order to achieve transportation scientific development, we need to rely on adequate quantity, reasonable structure and excellent quality of talents. Transportation development is faced with a very arduous task, which made an urgent demand for transportation talents training.

Transportation talents' training is to strengthen the awareness needs of active service for national strategic and industry business. It requires establishing the concept of training talents with morality first, capacity importance and all-round development. And it also requires innovation the mechanism of the universities and industry and enterprises in joint training, reforming the talents training model of the engineering education, enhancing the ability of students' engineering practice, creative capacity and international competitiveness. Transportation professionals needs to master basic theory and method of transport organization, which equip them with strong engineering application capability to undertake transportation production work in various positions. And also they must be capable of responding quickly to principle and method of operation of new technologies and equipment, which enable them to make the application of innovation based on the new technologies and equipment. In addition to master the transportation expertise, it also needs to be familiar with management, economics, safety engineering control theory, information theory and other disciplines' basic theory and method, so that they have an integrated transportation systems thinking and have the need of the ability to actively adapt to social and economic development and transportation continued rapid.

Transportation talents training on the basis of summarize the national historical achievements of engineering education and reference the foreign experience is to identify the importance of national transportation area talents training strategy which is focused on: first, we must pay more attention to engineering education in severing national development strategies. Second, we must pay more attention to work closely with industry. Third, the more attention should be paid to overall quality and social responsibility. Fourth, the internationalization of engineering talents training also should be paid corresponding attention. The integration and cross of the transportation professionals' knowledge with management science, economics, security science and computer science needs to be taken fully account of when training the transportation professional talents. These enable students to form a transportation professional knowledge system based on the ability to disciplinary. The students should be strengthened in the general education model of professional training, which improved their overall quality and innovation and enhanced students' social adaptability.

3.2 The quality standards of cultivation for transportation talents

"National Long-term Education Reform and Development Plan" takes the "excellent engineer education training program" as a strategic important task in new era about the reform and development of higher education. Through the closed cooperation of education and industry, the universities and enterprises, in the background of practical engineering, as the main line of the engineering technology, the engineering awareness and engineering quality as well as the ability of engineering practice of students are improved. Training a large number of many types of excellent engineers who are creative to adapt to business development demand, rapid economic and social development, and can meet the international requirements of technology and engineering application.

The primary issue of the higher engineering education is to clear the quality standard of training the excellent engineering, namely to solve the problem of what human should be cultured. Higher engineering education is not yet created by "excellent engineer", but to create "excellent engineer" for the potential to build a good foundation. The so-called "excellence" is the pursuit of the development of quality standards and a concept, its basic characteristics reflected in the talents training objectives, training an important element of the specifications, organizational processes and pathway in the way of education. Excellent idea can be summarized to reflect goal of quality education concept, a wide range of the positioning, the "student-centered" model concept and the approach view of the characteristics of school.

(1)The goal of quality education

The quality of traditional knowledge and the once popularized ability quality concept are converted into a comprehensive view of the quality which included the knowledge and capability. That is to say, the personnel training is focus on the ultimate goal that to promote the overall development of students.

(2)A wide range of positioning

As a high level of industry characteristics universities, outstanding engineering talents training specifications positioning, not only to cultivate creative talents of various projects, but also to develop academic, engineering and management of complex interdisciplinary top creative talent. The development needs of the industry and business should be met in training talents to adapt to the country's economic and social development, and the need of internationalization and globalization should also be accomplished.

(3)The "student-centered" model concept

In reaching a variety of external training objectives and specifications location, the contribution about students' self-development must be taken as the core, so as to implement a wide range of training mode, highlight the dominant position of students, promote students' personality expertise and student self-development.

(4)The characteristics of school of approach concept

The featured high-level university not only to cultivate innovative talents as the fundamental tasks, but the functional disciplines should be reflected, so as to highlight the scientific research and social service functions that should be carried out tightly around personnel training. It is necessary to guide the teaching with scientific in training of personnel. The research-based training approach will be run through the entire process of personnel training, which means that it advocates "explore", "question", "advocating" and "hard-work and pioneers" to improve students' ability to learn, practice and innovation ability.

4 The cultivation system for excellent students in transport industry

The key point of training excellent students lies in how to train good persons. This means what kind of training modes and training pathways should be taken, and also means the design and innovation of training elements such as personnel targeting, training programs and training modes.

(1)The scientific training objectives

The training objectives and positioning is the guiding principle of training programs. With the rapid development of transportation, the demand for excellent students in different types and levels is increasing. The majors relating to transportation should fully understand and grasp the characteristics of the industry trends and this demand. Combined with their characteristics and level types, these majors should set and improve the distinctive training targets on the basis of reflecting the students' competence.

Students are required to master the basic theory and a relatively broad knowledge in their area, to have the ability to solve practical engineering problems with innovation and research capabilities for engineering and technical work to assume senior professional or managerial jobs. On this basis, the training system aims at the rail transportation industry's urgent demand for innovative talents, closely tracking the forefront of rail transportation, and vigorously educating the engineering, complex and research-oriented creative students. The integrated key technologies and management requirements shall be taken into account such as bridge and tunnel stations around the line, EMU and overloaded trains, traction power supply, communication signal, operations and scheduling, etc.

(2)Systematical and matching training program

Training program takes the achievement of training objective as basic guiding principle, decomposes the capacity according to the capacity target matrix and capacity achievement matrix, takes the project awareness, the practical ability and innovation on the basis of general engineering education as priority, optimizes the specific curriculum, and updates the teaching content. Transportation Excellent Training Program shall highlight the characteristics of this industry, relying on long-term research cooperation, taking bilateral advantages, and designing the curriculum content, the training process models, as well as the pathway of students' self-learning and personality development all together. From the perspective of universities, the key is to grasp the rules of personnel training and students' growth.

(3) Innovative and diverse cultivation mode

Cultivation mode plays a key role in cultivation process for excellent talent in transportation industry. The single cultivation mode with course inculcation as principle is necessary to be broken through, in the cultivation process for excellent talent. The coalition of college and enterprise is carried out to make sure the cultivation is open to enterprise, society and world. Based on the combination strategy with production, teaching and research, the diverse cultivation mode is jointly created with question-inquiry, research-training and engineering-practice as orientation. The diverse cultivation mode ensures the development of individual strong point, and enforces the capability to study initiatively, exploring and research, engineering practice and innovation, which broadens their internationalization visions.

5 Conclusions

Transportation outstanding talent is the fundamental guarantee to support the development of transportation, the realization of the scientific development of transportation relies on sufficient amount, structural optimization, excellent quality and reasonable distribution of professional talent team. Enhancing the guarantee capacity of outstanding talent will profoundly affect the progress and efficiency of the development of modern transportation. The development of the transportation industry puts forward higher requirements and challenges to our country's higher education, especially higher engineering education. With economic and social development needs for transportation excellence talent, the featured college providing service for the rapid developing transportation industry, should shoulder the responsibilities and tasks, play its supporting and leading role, cultivate outstanding talent of transportation industry which is in the urgent need in the development of national economy.

Transportation talents' training is to strengthen the awareness needs of active service for national strategic and industry business. It requires establishing the concept of training talents with morality first, capacity importance and all-round development. Transportation industry talent team construction should be closely combined with the feature of industry development stage and talent demand characteristics of regional economic development, and fully in accordance with the new situation and new development of modern transportation requirements, aiming at prominent problems existing in talent development, overall planning, highlight the keystone, promote steadily and enhance the relevance and global transportation industry talent development. Excellent idea can be summarized to reflect goal of quality education concept, a wide range of the positioning, the "student-centered" model concept and the approach view of the characteristics of school. The scientific objectives, systematical and matching training program and innovative besides diverse cultivation mode are the basic elements of effective cultivation system for excellent talent in transportation industry.

Customer Satisfaction Evaluation of Rail Door-to-Door Transport Service

Yinying Tang[1,2] and Jiaxin Sun[2]

[1]National United Engineering Laboratory of Integrated and Intelligent Transportation, Chengdu 610031, China.
[2]School of Transportation and Logistics, Southwest Jiaotong University, Chengdu 610031, China. E-mail: ssunny02566@sina.com

Abstract: The customer satisfaction evaluation characteristics of rail door-to-door transport service is analyzed in this paper. Establishment of timeliness, charge, goods integrity, complaint, information, order acceptance, cargo taken, cargo delivery, other service to the first-level indexes of satisfaction evaluation indexes system by LSQ model for reference. Fuzzy comprehensive evaluation method and the relevant parameters are combined on processing evaluation result. Finally, the feasibility of value calculation method is verified according to evaluate rail freight point Y.
Keywords: Door-to-door service; Evaluation index; Evaluation method.

1 Introduction

Rail door-to-door transport service is coordinated to promote rail logistics development and well satisfy customer demand. It takes rational utilization of nonmetal resource, improvement for take-distribution network as well as active expansion to their business (Wang, 2014).It extends service into management, also blend rail freight and logistics together as a complete business process, not only to broaden business thoughts, but to increase transport market share. Due to its conduct is guided under customer demand. There provides reference for service improvement. In addition, current rail service-related indexes are overly one-sided or lack of market to participate, difficult to reflect difference in evaluation object and service environment. On the great of significance for the customer satisfaction evaluation in rail door-to-door service.

2 Rail Door-to-door Service Customer Satisfaction Characteristics

Rail door-to-door transport service as the third-party logistics, mainly has the following characteristics evaluation of customer satisfaction:

(1) The comprehensive evaluation index; which can accurately reflect the satisfaction of customers. Rail door-to-door transport service possess inseparable feature of general logistics service, namely the production and consumption is at the same time. So it is reasonable to select indexes based on service process.

(2) Service results; since the rail transport door-to-door service is the logistics service extends the arrival end to the sending. It focuses on convenience, accuracy

and standardization, makes reducing customer perception for service. Comparing with process, customers are more concerned about service completion.

(3) Information; since the reduction of customer perception, makes it possible to deliver service information to customer, which is an important factor for evaluation.

(4) Different customer evaluation; the service must adhere to the customer voluntary principle. Customers are divided into shipping and receiving, only being able to enjoy the "arrival gate", "station-to-door" service, namely service and corresponding service object according to the flow of goods.

3 The Construction for Evaluation Indexes

Rail door-to-door transport refers the whole process, begins with collection in designated place, transportation, until delivery to the consignee (Ye,2011). There order acceptance, cargo taken, goods in transit transport, cargo delivery, also charge, information, complaint, claim service based on the general service process. While it considers the inseparability, lacks evaluation indicators about service result. Relatively complete customer logistics service evaluation is LSQ model at present, in which nine indicators are summarized based on the investigation in numbers of the United State large third-party logistics companies. That is staff communication, order release amount, information quality, order process, goods accuracy rate, cargo soundness, goods quality, error processing, timeliness (Mentzer,2001). Combined with the concrete conditions of China's rail door-to-door service, selected the indexes from process and results, specific analysis shown in Figure 1.

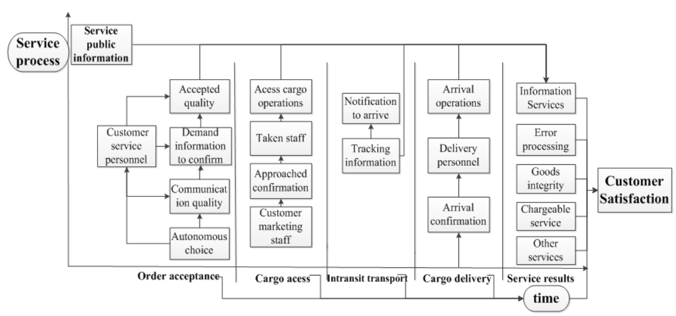

Figure 1.The process for constructing satisfaction evaluation indexes

The first-level indicators selected are timeliness, chargeable service, goods integrity, complaint, information, order acceptance, cargo taken, cargo delivery, other service. According the service process to continue and refine first-level into second-level indicators, each indexes and interpretation as shown in Table1.

Table1. Rail door-to-door service satisfaction indexes and interpretation

First-level	Second -level indexes	Interpretation
Timeliness	1Order processing 2Cargo taken 3Cargo delivery 4Claim processing 5Complaint 6Information release	Timeliness is reliable to fulfill cargo transportation. It is the core element for customer evaluation overall service. Second-level indicators are selected according to timeliness requirement.
Charge	1 Channel 2 A quotation	The door-to-door transport service-related charge and a quotation are established by using a one-time charge ticket to facilitate customer payment, also to fairly charge the transport supervision fees.
Goods integrity	1Delivery-arrival integrity 2 Claim way 3 Claim result	It is decisive to get service result and propose cargo damage or loss based on cargo integrity. It reflects rail error handling capability.
Complaint	1 Complaint channel 2 Complaint way 3 Complaint result	If the commitment and actual transportation generate deviation, it would raise questions even complaint. Customer satisfaction is decided on the treatment, the important factors of evaluation quality.
Information	1Public information 2 Check-track inquiry 3 In transit transport inquiry 4 Cargo arrival notice	Information is customer requirement to modern service as well as rail public, marketing platform. Rail main provide public information and arrival notice, not only to facilitate customer to get transport and arrival information, but to reflect error processing convenience.
Order acceptance	1Communication quality 2Demand confirmation 3Formalities 4Autonomous choice	Customer can raise demand on network and on-site orders, etc. The staff handles the request though communication, negotiation and other remedies. Order acceptance is the accuracy factor to build image in entire service process.
Cargo taken	1Contact service 2Handling operation 3 Metering service 4 Ticket transfer	There are three aspects, logistics order processing. Second is contact process, reflecting the response to customer demand. Third is logistics service process, main including loading and unloading, metering, ticketing transfer operations, customers can directly feel the specification and accuracy, embody the sender service capabilities.
Cargo delivery	1Contact service 2 Handling operation 3 Ticket transfer	Delivery service process includes handling, ticketing transfer operations. It is the terminal of entire service process, reflecting the rail in the "last mile" service capabilities.
Other service	1Warehousing 2Pack 3Agency 4 Handling 5Distribution	Rail door-to-door service also provide other logistics service. But rail logistics in the development stage, over here evaluating together.

According to the characteristic of customer difference evaluation, evaluating between sending and arrival terminals, on the one hand to facilitate calculation, on the other hand, to clearly analyze evaluation results. Distinguish the evaluation index into consignee and shipper, shown in Figure 2, Figure 3.

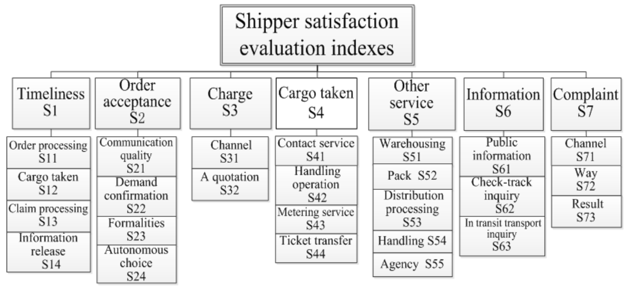

Figure 2.Shipper satisfaction evaluation indexes

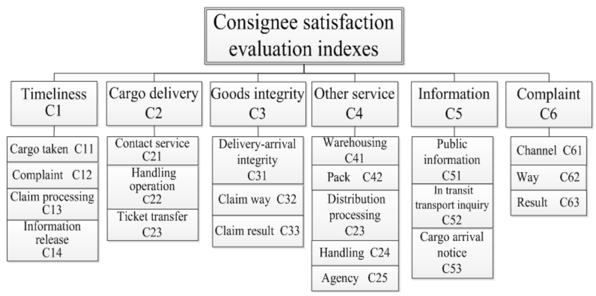

Figure 3.Consignee satisfaction evaluation indexes

4 Evaluation Method of Rail Door-to-door Service Customer Satisfaction

This text uses mature fuzzy comprehensive evaluation method to obtain result. Compared with others, it is suitable for indirectly quantitative indicators, while the indicators in the paper mostly are difficult to quantify. In addition, each evaluation values of indicators can be analyzed by fuzzy relevant parameters. It is conducive to understand customer evaluation and propose corresponding suggestions.

Each indicator is quite different on the importance extent. Therefore, it is critical to get weight. In order to simplify the calculation process and reduce confusion judgment, making customers to give the weight directly to reflect the wish. The indicators are divided into the shipper and consignee, weights got from investigation.

The five reviews table $V=\{v_i\}=\{v_1,v_2,v_3,v_4,v_5\}=\{10,8,6,4,2\}$. The survey results are normalized to obtain membership fuzzy evaluation matrix. Refer to equations by (1), $\sum_{i=1}^{7} r_{ijt}^{s}=1$;

$$R_i^s=\begin{bmatrix} r_{i11}^s, r_{i12}^s, r_{i13}^s, r_{i14}^s, r_{i15}^s \\ \cdots\cdots\cdots \\ r_{iM1}^s, r_{iM2}^s, r_{iM3}^s, r_{iM4}^s, r_{iM5}^s \end{bmatrix} \tag{1}$$

Weight fuzzy sets $w_i^s=\{w_1^s,w_2^s,w_3^s,w_4^s,w_5^s,w_6^s,w_7^s\}$; and fuzzy synthetic B_i^s evaluation vector, that is $B_i^s=W_i^s\circ R_i^s$, $\circ$ for the fuzzy composite operator.

After evaluating the above calculations, the result is a vector $B_i^s = [b_{i1}^s, b_{i2}^s, b_{i3}^s, b_{i4}^s, b_{i5}^s]$. In order to more clearly understand the result to obtain a specific value, then use the comprehensive parameters. While highlight the role of the rank, using the square of membership power b_{i2}^s can obtain weighted evaluation parameters, namely

$$\alpha_i^s = \frac{\sum_{t=1}^{5} (b_{it}^s)^2 v_t}{\sum_{t=1}^{5} (b_{it}^s)^2} \tag{2}$$

Refer to equations in the text by (2), α_i^s for shipper satisfaction evaluation index value.

These results can be clearly seen that each values of the shipper satisfaction first-level indicators. Considering the impact on the results, the processing method that is first-level indexes multiplied corresponding weights, to obtain the total evaluation value, as:

$$\alpha^s = \sum_{i=1}^{7} w_i^s \cdot \alpha_i^s \tag{3}$$

5 Analysis of Example

Survey shipper and consignee data of rail freight point Y, get 92 effective weight evaluation on network on-site and etc, half of shipper.100 customers selected to evaluate, 94 are valid, 49 are shipper, 45 are consignee, while cargo taken, cargo delivery and complaint service according be chosen whether or not, making investigation and assessment. Since calculating the membership terms, there is no significant impact on the results. Survey results are summarized in Table 2.

Table 2.Evaluation index weight values and corresponding scores

Respondent	Shipper																								
First-level	S1				S2				S3		S4				S5					S6			S7		
Weight	0.177				0.162				0.145		0.157				0.139					0.121			0.099
