List of contributors

Victor Aboyans MD, PhD
Hospital Physician, Department of Thoracic and Cardiovascular Surgery, and Angiology, Dupuytren University Hospital, Limoges, France

Sonia S. Anand MD, PhD, FRCPC
Professor of Medicine, McMaster University, Hamilton, Ontario, Canada

Jeffrey L. Anderson MD, FACC, FAHA, MACP
Professor of Internal Medicine, University of Utah School of Medicine; Associate Chief of Cardiology and Vice Chair for Research, Intermountain Medical Center, Salt Lake City, UT, USA

Craig Anderson MBBS, PhD, FRACP, FAFPHM
Director, Neurological and Mental Health Division, Professor of Stroke Medicine and Clinical Neuroscience, The George Institute for International Health, University of Sydney and the Royal Prince Alfred Hospital, Sydney, Australia

Paul W. Armstrong MD
Distinguished University Professor, University of Alberta, Edmonton, Alberta, Canada

Stephanie Atkinson PhD
Professor and Associate Chair (Research), Department of Pediatrics, Associate Member, Department of Biochemistry and Biomedical Science, McMaster University, Hamilton, Ontario, Canada

Colin Baigent BM, BCh, FFPH, FRCP
Professor of Epidemiology, University of Oxford, Clinical Trial Service Unit and Epidemiological Studies Unit (CTSU), Oxford, UK

Adrian Baranchuk MD
Kingston General Hospital, Queen's University, Kingston, Ontario, Canada

Conor D. Barrett MD
Instructor in Medicine, Harvard Medical School, Cardiac Arrhythmia Service, Massachusetts General Hospital Heart Center, Boston, MA, USA

Elisabeth Bédard MD
Adult Congenital Heart Centre and Centre for Pulmonary Hypertension, Royal Brompton Hospital, London, UK

David G. Benditt MD, FACC, FRCPC, FHRS
Professor of Medicine, Co-Director, Cardiac Arrhythmia Center, University of Minnesota Medical School, Minneapolis, MN, USA

William E. Boden MD, FACC
Professor of Medicine and Preventive Medicine, University at Buffalo, School of Medicine and Public Health; Clinical Chief, Division of Cardiovascular Medicine, University at Buffalo; Chief of Cardiology, Buffalo General and Millard Fillmore Hospitals, Buffalo, NY, USA

Barry A. Boilson MD, MRCPI
Fellow in Cardiac Transplantation Medicine, Mayo Clinic, Rochester, MN, USA

Robert H. Boone MD, FRCPC, MSc(Epi)
Clinical Assistant Professor, Interventional Cardiology, St. Paul's Hospital, Providence Health Care, University of British Columbia, Vancouver, BC, Canada

Morgan L. Brown MD
Research Fellow, Division of Cardiovascular Surgery, Mayo Clinic, Rochester, MN, USA

Brian H. Buck MD, MSc, FRCPC
Assistant Professor, Division of Neurology, Department of Medicine, University of Alberta, Edmonton, Alberta, Canada

Christopher E. Buller MD, FRCPC
Professor of Medicine, University of British Columbia; Head, Division of Cardiology, Vancouver General Hospital, Vancouver, BC, Canada

David J. Burkhardt MD
Texas Cardiac Arrhythmia Institute, St. David's Medical Center, Austin, TX, USA

John A. Cairns MD, FRCPC
Professor of Medicine and Former Dean, Faculty of Medicine, University of British Columbia, Vancouver, BC, Canada

A. John Camm MD
British Heart Foundation Professor of Clinical Cardiology, Head of Cardiac and Vascular Sciences, St George's University of London, London, UK

Blase A. Carabello MD
Professor of Medicine, Vice-Chairman, Department of Medicine, WA Tex and Deborah Moncrief Jr. Center, Baylor College of Medicine, Medical Care Line Executive, Veterans Affairs Medical Center, Houston, TX, USA

Matthew Chan FANZCA
Department of Anaesthesia and Intensive Care, The Chinese University of Hong Kong, Hong Kong Special Administrative Region, China

Chi Keong Ching MBBS, MRCP (UK)
Consultant Cardiologist and Electrophysiologist, Department of Cardiology, National Heart Centre Singapore, Mistri Wing, Singapore

Clara K. Chow MBBS, FRACP, PhD
Senior Research Fellow, Population Health Research Institute, McMaster University, Hamilton, Ontario, Canada

Victor Chu MD, FRCS(C)
McMaster University, Hamilton Health Sciences, Hamilton, Ontario, Canada

Michael Colquhoun BSc, FRCP, MRCGP
Honorary Lecturer, School of Medicine, Cardiff University, Cardiff, UK

Patrick J. Commerford MD
Cardiac Clinic, Department of Medicine, University of Cape Town, Groote Schuur Hospital, Cape Town, South Africa

Stuart J. Connolly MD, FRCPC
Director, Division of Cardiology, McMaster University, Hamilton, Ontario, Canada

Heidi M. Connolly MD
Professor of Medicine, Mayo Clinic, Rochester, MN, USA

Leslie T. Cooper Jr MD
Professor of Medicine, Mayo Clinic College of Medicine; Chief, Section of Vascular Medicine, Mayo Clinic, Rochester, MN, USA

Michael H. Criqui MD, MPH
Professor and Chief, Division of Preventive Medicine, Department of Family and Preventive Medicine, University of California, San Diego School of Medicine, La Jolla, CA, USA

Michael S. Cunnington BMedSci, MB BS (Hons), MRCP
British Cardiovascular Society/Swire Research Fellow, Institute of Human Genetics, Newcastle University, Newcastle-upon-Tyne, UK

Dawood Darbar MBChB, MD, FACC
Associate Professor of Medicine and Pharmacology, Director, Vanderbilt Arrhythmia Service, Vanderbilt University School of Medicine, Nashville, TN, USA

Tirone E. David MD
Professor of Surgery, University of Toronto, Head of Cardiovascular Surgery, Peter Munk Cardiac Centre, Toronto General Hospital, Toronto, Canada

Philip J. Devereaux MD, PhD, FRCP(C)
Departments of Clinical Epidemiology and Biostatistics and Medicine, McMaster University, Faculty of Health Sciences, Hamilton, Ontario, Canada

Luigi Di Biase MD
Electrophysiologist Research Fellow, Department Dean of Medicine, University of Texas Medical Branch at Austin, Texas Cardiac Arrhythmia Institute, St. David's Medical Center, Austin, TX, USA; Department of Cardiology, University of Foggia, Foggia, Italy

Kim A. Eagle MD, MACC
Albion Walter Hewlett Professor of Internal Medicine, Chief of Clinical Cardiology, Director, Cardiovascular Center, University of Michigan, Ann Arbor, MI, USA

John Eikelboom MBBS, MSc, FRACP, FRCPA, FRCPC
Associate Professor, Department of Medicine, McMaster University, Hamilton, Ontario, Canada

Claude S. Elayi MD
Assistant Professor of Medicine, Division of Cardiovascular Medicine, Gill Heart Institute, University of Kentucky, Lexington, KY, USA

Perry M. Elliott MBBS, MD, FRCP
Reader in Inherited Cardiac Disease, University College London, London, UK

Jonathan R. Emberson BA, MSc, PhD
Senior Statistician, University of Oxford, Clinical Trial Service Unit and Epidemiological Studies Unit (CTSU), Oxford, UK

R. Alan Failor MD
Clinical Professor of Medicine, Division of Metabolism, Endocrinology and Nutrition, University of Washington, Seattle, WA, USA

Ernest L. Fallen MD, FRCPC
Professor Emeritus, McMaster University Faculty of Health Sciences, Hamilton, Ontario, Canada

Shafie S. Fazel MD, PhD
Senior Resident, Division of Cardiac Surgery, Peter Munk Cardiac Center, Toronto General Hospital, University of Toronto, Toronto, Canada

Francisco Fernández-Avilés PhD, MD
Professor of Medicine, Head of the Department of Cardiology, Hospital General Universitario Gregorio Marañón, Complutense University, School of Medicine, Madrid, Spain

David Fitchett MD, FRCPC
Director, Cardiac ICU, St. Michael's Hospital Toronto, Associate Professor of Medicine, University of Toronto, Toronto, Ontario, Canada

Keith A. A. Fox BSc (Hons) MBChB, FRCP, FESC, FMedSci, FACC
FACC Professor of Cardiology, Centre for Cardiovascular Science, University of Edinburgh, Edinburgh, UK

Curt D. Furberg MD, PhD
Professor, Division of Public Health Sciences, Wake Forest University School of Medicine, Winston-Salem, NC, USA

Michael A. Gatzoulis MD, PhD, FACC, FESC
Professor of Cardiology, Congenital Heart Disease and Consultant Cardiologist, Adult Congenital Heart Centre and Centre for Pulmonary Hypertension, Royal Brompton Hospital, and the National Heart & Lung Institute, Imperial College, London, UK

Jacques Genest Jr MD, FRCPC
Professor, Faculty of Medicine, McGill University, Novartis Chair in Medicine at McGill University, Director, Division of Cardiology University Health Center/ Royal Victoria Hospital, Montreal, Quebec, Canada

Bernard J. Gersh MB, ChB, DPhil
Consultant in Cardiovascular Diseases and Internal Medicine, Mayo Clinic; Professor of Medicine, Mayo Clinic College of Medicine, Rochester, MN, USA

List of contributors

Hertzel C. Gerstein MD, MSc, FRCPC
Division of Endocrinology and Metabolism, Population Health Research Institute, Department of Medicine, McMaster University and Hamilton Health Sciences, Hamilton, Ontario, Canada

Raymond J. Gibbons MD
Arthur M. and Gladys D. Gray Professor of Medicine, Division of Cardiovascular Diseases, Mayo Clinic, Rochester, MN, USA

Michael M. Givertz MD
Cardiovascular Division, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA

Paul J. Hauptman MD
Professor of Internal Medicine, Saint Louis University School of Medicine, St. Louis, MO, USA

Jeffrey S. Healey MD, MSc, FRCP(C)
Associate Professor of Medicine, McMaster University, Hamilton, Ontario, Canada

Mark A. Hlatky MD
Professor of Health Research and Policy & Professor of Medicine (Cardiovascular Medicine), Stanford University School of Medicine, Stanford, CA, USA

Rodney Horton MD
Texas Cardiac Arrhythmia Institute, St. David's Medical Center, Austin, TX, USA

Marjan Jahangiri FRCS
Professor of Cardiac Surgery, Department of Cardiothoracic Surgery, St. George's University of London, London, UK

Prabhat Jha MD, DPhil
Centre for Global Health Research, St. Michael's Hospital, University of Toronto, Toronto, Ontario, Canada

Michael Joy OBE, MD, FRCP, FACC, FESC, FRAeS
Professor of Clinical Cardiology, Postgraduate Medical School, Surrey University, Guildford, and, Cardiologist, Medical Department, UK Civil Aviation Authority, West Sussex, UK

Prince Kannankeril MD, MSCI
Assistant Professor, Vanderbilt, Department of Pediatrics, University Medical Centre, Nashville, TN, USA

Clive Kearon MB, MRCPI, FRCPC, PhD
Professor of Medicine, McMaster University, Hamilton, Ontario, Canada

Bernard D. Keavney MD
Professor of Cardiology, Institute of Human Genetics and Department of Cardiology, Newcastle University, Newcastle-upon-Tyne, UK

Rohit Khurana BMBCh, PhD, MRCP
Fellow, Interventional Cardiology, Vancouver General Hospital, Division of Cardiology, University of British Columbia, Vancouver, BC, Canada

Michael Klein MD
Clinical Professor of Medicine, Boston University, School of Medicine, Boston, MA, USA

Kornelia Kotseva MD, PhD, FESC
Senior Clinical Research Fellow, Consultant Cardiologist, Cardiovascular Medicine, National Heart and Lung Institute, Imperial College, London, UK

Stavros Kounas MD
The Heart Hospital, University College London, London, UK

Antonios Kourliouros MD
Department of Cardiothoracic Surgery, St George's University of London, London, UK

Sudhir Kushwaha MD
Associate Professor of Medicine, Mayo Clinic, Rochester, MN, USA

Malcolm Law FRCP, FMedSci
Professor of Epidemiology and Preventive Medicine, Centre for Environmental and Preventive Medicine, Queen Mary School of Medicine and Dentistry, Wolfson Institute of Preventive Medicine, London, UK

Lori-Ann Linkins MD, MSc, FRCPC
Associate Professor, McMaster University, Thromboembolism/Hematology, Hamilton, Ontario, Canada

Fei Lu MD, PhD, FACC, FHRS
Associate Professor of Medicine, Director, Cardiac Electrophysiology Laboratories, Cardiac Arrhythmia Center, University of Minnesota Medical School, Minneapolis, MN, USA

Andrew J. Lucking BMedSci(Hons), MBChB(Hons), MRCP
Clinical Research Fellow, University of Edinburgh, Edinburgh, UK

Benedito Carlos Maciel MD
Full Professor of Medicine, Division of Cardiology, Department of Internal Medicine, Medical School of Ribeirão Preto, University of São Paulo, Ribeirão Preto, Brazil

Brendan P. Madden MD, MSc, FRCPI, FRCP
Professor of Cardiothoracic Medicine, St George's Hospital, London, UK

Sunil Mankad MD
Associate Professor of Medicine, Mayo Clinic College of Medicine, Director, Transesophageal Echocardiography, Co-Director, Education, Echocardiography, Mayo Clinic, Rochester, MN, USA

Johannes F. E. Mann MD
Professor of Medicine, Friedrich Alexander University of Erlangen, Head, Department of Nephrology and Hypertension, Schwabing General Hospital, Ludwig Maximilians University, Munich, Germany

Ali J. Marian MD
Professor of Molecular Medicine and Internal Medicine (Cardiology), Director, Center for Cardiovascular Genetics, Institute of Molecular Medicine, The University of Texas Health Science Center, Houston, TX, USA

J. Antonio Marin-Neto MD, PhD, FACC
Full Professor of Medicine and Director, Cardiology Division, Department of Internal Medicine, Medical School of Ribeirão Preto, University of São Paulo, Ribeirão Preto, Brazil

Barry J. Maron MD
Director, Hypertrophic Cardiomyopathy Center, Minneapolis Heart Institute Foundation, Minneapolis, MN, USA

Bongani M. Mayosi DPhil, FCP(SA)
Professor of Medicine, Groote Schuur Hospital and University of Cape Town, Cape Town, South Africa

Catherine McGorrian MB, BCh, BAO, MRCPI
Clinical Fellow, Department of Medicine, McMaster University, Hamilton, Ontario, Canada

Martin McKee MD, DSc, FRCP, FRCPI, FFPH, FMedSci, CBE
Professor, European Centre on Health of Societies in Transition, London School of Hygiene and Tropical Medicine, London, UK

John J.V. McMurray MD
Professor of Medical Cardiology, BHF Glasgow Cardiovascular Research Centre, University of Glasgow, Glasgow, Scotland, UK

Prem Mony MD
CIHR Canada-HOPE Scholar, Centre for Global Health Research, St. Michael's Hospital, University of Toronto, Toronto, Ontario, Canada

James Moore
Bill and Melinda Gates Foundation, New Delhi, India

Carlos A. Morillo MD, FRCPC, FACC, FHRS, FESC
Professor, Department of Medicine, Director Arrhythmia & Pacing Service, McMaster University, Hamilton, Ontario, Canada

Katherine M. Morrison MD, FRCPC
Associate Professor, Department of Pediatrics, McMaster University, Hamilton, Ontario, Canada

Arashk Motiei MD
Fellow in Cardiovascular Diseases, Mayo School of Graduate Medical Education, Mayo Clinic College of Medicine, Rochester, MN, USA

Joseph B. Muhlestein MD, FACC
Professor of Medicine, University of Utah; Director, Cardiology Research, Intermountain Medical Center, Murray, UT, USA

Gerald V. Naccarelli MD
Bernard Trabin Chair in Cardiology; Professor of Medicine; Chief, Division of Cardiology, Penn State College of Medicine, Penn State Hershey Heart and Vascualr Institute, Hershey, PA, USA

Brahmajee K. Nallamothu MD, MPH, FACC
Associate Professor of Internal Medicine, Interventional Cardiology, Division of Cardiovascular Medicine, Department of Internal Medicine, University of Michigan Health System, Ann Arbor, MI, USA

Andrea Natale MD, FACC, FHRS
Executive Medical Director, Texas Cardiac Arrhythmias Institute at St. David's Medical Center, Austin, TX; Consulting Professor, Division of Cardiology, Stanford University, Palo Alto, CA; Clinical Associate Professor of Medicine, Case Western Reserve University, Cleveland, OH, USA

Pablo B. Nery MD
Assistant Professor of Medicine, University of Ottawa, Staff Cardiac Electrophysiologist, University of Ottawa Heart Institute, Ottawa, Ontario, Canada

Oyere K. Onuma MD
Mayo Clinic College of Medicine, Rochester, MN, USA

Raj S. Padwal MD, MSc, FRCPC
Associate Professor, Division of General Internal Medicine, University of Alberta, Edmonton, Alberta, Canada

Erica D. Penny-Peterson MD
Assistant Professor of Medicine, Cardiology and Cardiac Electrophysiology, Milton S. Hershey Medical Centre, Hershey, PA, USA

Marc A. Pfeffer MD, PhD
Department of Medicine, Harvard Medical School and Brigham and Women's Hospital, Boston, MA, USA

Andrew Pipe CM, MD
Professor, Faculty of Medicine, University of Ottawa; Chief, Division of Prevention and Rehabilitation, University of Ottawa Heart Institute, Ottawa, Ontario, Canada

Jeffrey L. Probstfield MD
Director, Clinical Trials Service Unit, Professor of Medicine (Cardiology), University of Washington School of Medicine, Seattle, WA, USA

Bruce M. Psaty MD, PhD
Professor, Medicine and Epidemiology, Cardiovascular Health Research Unit, University of Washington, Seattle, WA, USA

Zubin Punthakee MD
Department of Medicine, McMaster University and Hamilton Health Sciences, Hamilton, Ontario, Canada

Shahbudin H. Rahimtoola MB, FRCP, MACP, MACC, DSc(Hon)
Distinguished Professor, University of Southern California, George C. Griffith Professor of Cardiology, Professor of Medicine, Keck School of Medicine at University of Southern California, Los Angeles, CA, USA

Anis Rassi Jr MD, PhD, FACC, FACP, FAHA
Scientific Director, Anis Rassi Hospital, Goiânia, Brazil

K. Srinath Reddy MD
Department of Cardiology, All India Institute of Medical Sciences, New Delhi, India

Charanjit S. Rihal MD
Consultant, Division of Cardiovascular Diseases, Mayo Clinic Rochester; Professor of Medicine, Mayo Clinic College of Medicine, Rochester, MN, USA

Robert Roberts MD, FRCPC, MACC
President and CEO, Professor of Medicine and Director, Ruddy Canadian Cardiovascular Genetics Centre, University of Ottawa Heart Institute, Ottawa, Ontario, Canada

Paul J. Rocchiccioli MD
BHF Glasgow Cardiovascular Research Centre, University of Glasgow, Glasgow, Scotland, UK

Dan M.L. Roden MD
Professor of Medicine and Pharmacology, Director, Oates Institute, Assistant Vice-Chancellor for Personalized Medicine, Vanderbilt University School of Medicine, Nashville, TN, USA

Annika Rosengren MD
Professor of Medicine, Department of Medicine, Sahlgrenska University Hospital/ Ostra, Göteborg, Sweden

Scott Sakaguchi MD
Associate Professor of Medicine, Cardiac Arrhythmia Center, University of Minnesota Medical School, Minneapolis, MN, USA

Zainab Samad MD
Fellow, Division of Cardiology, Department of Internal Medicine, Duke University Medical Center, Durham, NC, USA

Pedro L. Sánchez MD, PhD
Head of Section, Department of Cardiology, Associate Professor; Hospital General Universitario Gregorio Marañón, School of Medicine, Complutense University, Madrid, Spain

Irina Savelieva MD
Department of Cardiology, Division of Cardiac and Vascular Science, St George's University of London, London, UK

Ernesto L. Schiffrin MD, PhD, FRSC, FRCPC, FACP
Physician-in-Chief and Chair, Department of Medicine, Sir Mortimer B. Davis-Jewish General Hospital, McGill University, Montreal, Quebec, Canada

André Schmidt MD, PhD
Assistant Professor, Cardiology Division, Medical School of Ribeirão Preto, University of São Paulo, Ribeirão Preto, Brazil

Jon-David R. Schwalm BSc, MD, FRCPC
Chief Cardiology Resident, McMaster University, Hamilton General Hospital Site, Hamilton, Ontario, Canada

Arya M. Sharma MD, PhD, FRCPC
Professor of Medicine, Chair for Obesity Management & Research, University of Alberta, Edmonton, Alberta, Canada

Ashfaq Shuaib MD, FRCPC, FAHA
Professor of Medicine and Neurology; Director, Stroke Program, University of Alberta, Edmonton, Alberta, Canada

Marcus Vinicius Simões MD
Medical School of Ribeirão Preto, University of São Paulo, Ribeirão Preto, Brazil

Samuel C. Siu MD, SM
Gunton Professor and Chair of Cardiology, Schulich School of Medicine and Dentistry, University of Western Ontario, London, Ontario, Canada

Elsayed Z. Soliman MD, MSc, MS
Associate Director, Epidemiological Cardiology Research Center (EPICARE), Assistant Professor, Department of Epidemiology and Prevention, Wake Forest University School of Medicine, Winston-Salem, NC, USA

Ray W. Squires PhD
Professor of Medicine, Mayo Clinic College of Medicine, Rochester, MN, USA

Garrick C. Stewart MD
Clinical Fellow, Division of Cardiovascular Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA

Jack C.J. Sun MD, MSc
Division of Cardiac Surgery, McMaster University, Hamilton, Ontario, Canada

Thoralf M. Sundt III MD
Consultant, Division of Cardiovascular Surgery, Professor of Surgery, Mayo Clinic, Rochester, MN, USA

Karl Swedberg MD, PhD
Head, Department of Emergency and Cardiovascular Medicine, Professor of Medicine, Sahlgrenska Academy, University of Gothenburg, Sahlgrenska University Hospital/ Östra, Göteborg, Sweden

Faisal S. Syed MD
Department of Cardiology, University of Newcastle-upon-Tyne, Newcastle, UK

Koon K. Teo MB, PhD, FRCPC, FRCPI
Professor of Medicine, Division of Cardiology, Department of Medicine, Population Health Research Institute, McMaster University, Hamilton, Ontario, Canada

Pierre Theroux CM, MD, FACC
Professor of Medicine, Montreal Heart Institute, University of Montreal, Quebec, Canada

Peter L. Thompson MD, FRACP, FACP, FACC, MBA
Clinical Professor, Cardiologist and Director of Research, Sir Charles Gairdner Hospital, Clinical Professor of Medicine and Population Health, University of Western Australia, Perth, Australia

William D. Toff MD, FESC
Department of Cardiovascular Sciences, University of Leicester, Leicester, UK

Thomas T. Tsai MD, MSc
Interventional Cardiology Fellow, Cardiovascular Center, University of Michigan Hospitals, Ann Arbor, MI, USA

Jack V. Tu MD, PhD
Institute for Clinical Evaluative Sciences, University of Toronto & Schulich Heart Centre, Sunnybrook Health Sciences Centre, Toronto, Canada

Zoltan G. Turi MD
Professor of Medicine, Robert Wood Johnson Medical School, Director, Structural Heart Disease Program, Cooper University Hospital, Camden, NJ, USA

Ameeth Vedre MD
Cardiovascular Center, University of Michigan, Ann Arbor, MI, USA

Rachel M. Wald MD, FRCPC
Staff Cardiologist, University Health Network and Hospital for Sick Children, Assistant Professor, Department of Pediatrics, University of Toronto, Toronto, Canada

Albert L. Waldo MD
Department of Medicine, Case Western Reserve, University School of Medicine, Division of Cardiovascular Medicine, University Hospitals Case Medical Center, Cleveland, OH, USA

Andrew Wang MD
Associate Professor of Medicine; Director, Cardiovascular Disease Fellowship Program, Duke University Medical Center, Durham, NC, USA

Deirdre Ward MRCPI
Director, Centre for Cardiovascular Risk in Younger Persons, Institute of Cardiovascular Science, Trinity College Dublin, Dublin, Republic of Ireland

John G. Webb MD, FRCPC, FACC
McLeod Professor of Valvular Heart Disease Intervention, Director, Interventional Cardiology and Cardiac Catheterization, St. Paul's Hospital, Vancouver, BC, USA

William S. Weintraub MD
Christiana Care Health System, Center for Heart & Vascular Health, Newark, Delaware, USA

Robert C. Welsh MD, FRCPC
Associate Professor; Director, Cardiac Catheterization and Interventional Cardiology; University of Alberta & Mazankowski Alberta Heart Institute, Edmonton, Alberta, Canada

David A. Wood MSc, FRCP, FRCPE, FFPHM, FESC
Garfield Weston Professor of Cardiovascular Medicine at the National Heart and Lung Institute, Imperial College London, UK

David A. Wood MD FRCPC
Interventional Cardiology, Director, Undergraduate Cardiovascular Medical Education, Clinical Assistant Professor, University of British Columbia, Vancouver, BC, Canada

Salim Yusuf DPhil, FRCPC, FRSC
Heart and Stroke Foundation of Ontario Research Chair, Professor of Medicine, McMaster University; Director, Population Health Research Institute, McMaster University, Hamilton Health Sciences; Vice President Research, Hamilton Health Sciences, Hamilton, Ontario, Canada

Witold Zatonski MD, PhD
Director of the Cancer Epidemiology and Prevention Division, The M. Sklodowska-Curie Memorial Cancer Center and Institute of Oncology, Warsaw, Poland

Preface to the third edition

'I had' said he 'come to an entirely erroneous conclusion which shows, my dear Watson, how dangerous it always is to reason from insufficient data'.

Sir Arthur Conan Doyle

Sherlock Holmes not only sought sufficient data, he scrutinized them with critical appraisal – two necessary prerequisites for an effective evidence based strategy. And so it is that clinical decision-making has come to rely more and more on best external evidence derived from well-executed large-scale clinical trials.

This is a big book. However, it can be used to best advantage in two ways: as a reference tome to gain in-depth understanding of a wide array of cardiovascular disorders, and as a source where clinicians can find and apply the best evidence to guide their management of specific cardiovascular conditions.

In 1964 over 50% of clinical research publications were devoted to clinical physiology experiments. There were no papers on clinical trials that year. The emphasis then was less on treatment and more on exploring mechanisms of disease. This changed in the 1980s so that by 2004 more than 20% of clinical research articles contained reports from large-scale clinical trials compared to only 3% that were laboratory based. This shift in emphasis from bench-to-bedside-to-community led to a startling paradox in which irrefutable evidence for the effectiveness of certain therapies not only assisted practising clinicians and their patients but begged the scientific question – "*How* and *why* does the therapeutic intervention work?" A clarion call for a community-to-bench paradigm.

In the preface to the second edition we stated, prophetically, that "Evidence-based medicine is a work in progress – a rapidly changing field – which cannot rest on its laurels, but must constantly be updated as newer and more effective treatments emerge". Although the very nature of book publication hardly competes with the instant gratification of "late breaking" trials presented at meetings or on-line, nevertheless the expert contributors of this compendium have successfully provided a clear and comprehensive overview of best evidence for the diagnosis and management of most cardiovascular disorders.

As with previous editions we continue to subscribe to the dictum that clinical decision-making ought to be an amalgam of best external evidence combined with clinical expertise and awareness of patients' needs and preferences. Although evidence-based guidelines are derived from clinical trial results, the reader should bear in mind that guidelines are disease (not patient) specific. In this context caution is urged whenever attempts are made to equate guidelines with standards of care. Not only are there multiple co-morbidities in over 60% of elderly patients but there are multiple co-medications as well. If one parses many of the studies outlined in this book one often finds that the effectiveness of a given therapy is proportional to disease severity and overall risk, whereas the harm of the intervention is often risk independent.

It is also recognized that clinical trials, irrespective of their strengths, need to be interpreted in the context of large registry databases that might reflect clinical practice on a wider scale. Trials have their strengths and limitations, as do registry studies, and both should be considered as complementary and not exclusive to each other.

This edition, like those before it, is comprised of four sections. Part I addresses some key concepts related to both evidence-based cardiology and critical appraisal. Part II is devoted to prevention and preventive strategies. Part III comprises several sections encompassing the management of specific cardiovascular disorders, and Part IV is a section on clinical applications describing how external evidence

is used in individual case studies. There are several new features including major vascular complications in susceptible patients undergoing non-cardiac surgery; evidence-based cardiology as applied to employment fitness in specific occupations such as transportation and aviation; ablation therapy for atrial fibrillation; arrhythmias due to monogenic disorders; different forms of cardiomyopathy including Chagas' disease and adult congenital heart disease.

Classification of recommendations and levels of evidence

Classification of recommendations and levels of evidence used in *Evidence-Based Cardiology* are as follows:

Classification of recommendations

Class I: Evidence and/or general agreement that a given procedure or treatment is beneficial, useful and effective.

Class II: Conflicting evidence and/or a divergence of opinion about the usefulness/efficacy of a procedure or treatment.

Class IIa: Weight of evidence/opinion is in favor of usefulness/efficacy.

Class IIb: Usefulness/efficacy is less well established by evidence/opinion.

Class III: Evidence and/or general agreement that a given procedure or treatment is not useful/effective and in some cases may be harmful.

Levels of evidence

Level A: Well-conducted, large and reliable RCTs (one or more) or their overview with clear results.

Level B: RCTs (one or more) or their overview with significant limitations.

Level C:

1) High quality and persuasive cohort studies, case control studies or case series.

2) Lower quality evidence from non-randomized studies including opinions of experts.

These **classes of recommendations** are identical to those used by the ACC/AHA/ESC in their Guidelines documents, and the **levels of evidence** are very similar. Comprehensive approaches are used, which incorporate many different types of evidence (e.g. RCTs, non-RCTs, epidemiologic studies and laboratory data), and examine the architecture of the information for consistency, coherence and clarity. Classes of recommendation and levels of evidence appear in blue type either within the text (e.g. **Class I, Level A**) or within a table in the chapter. The system is applicable only to preventive or therapeutic interventions. It is not applicable to many other types of data such as descriptive, genetic or physiologic.

List of abbreviations

Abbreviations commonly used in this book

AADs	antiarrhythmic drugs
ABI	Ankle Brachial Index
ACC	American College of Cardiology
ACD	absolute claudication distance
ACE	angiotensin-converting enzyme
ACS	acute coronary syndrome
ADA	adenine deaminase
ADMA	asymmetric dimethylarginin
AF	atrial fibrillation
AHA	American Heart Association
AIS	acute ischemic stroke
ALI	Acute limb ischemia
AMI	acute myocardial infarction
AMR	antibody-mediated rejection; acute mitral regurgitation
AR	aortic regurgitation
ARB	angiotensin receptor blockers
ARF	acute rheumatic fever
ARR	absolute risk reduction
ARVC	arrhythmogenic right ventricular cardiomyopathy
ARVD	arrhythmogenic right ventricular dysplasia
AS	aortic stenosis
ASA	acetylsalicylic acid
ASD	atrial septal defect
ASMR	age-standardized mortality rates
ATP	adenosine triphosphate
AVA	aortic valve area
AVB	atrioventricular block
AVR	aortic valve replacement
AVSD	atrioventricular septal defect
AVV	atrioventricular valve
BAV	bicuspid aortic valve
BNP	brain natriuretic peptide
BUN	blood urea nitrogen
CABG	coronary artery bypass graft
CAD	coronary artery disease
CAV	cardiac allograft vasculopathy
CBF	cerebral/coronary blood flow
CCB	calcium channel blocker
CCC	Chagas' cardiomyopathy
CCMR	chronic compensated mitral regurgitation
CDMR	chronic decompensated mitral regurgitation
CETP	cholesteryl ester transfer protein
CHD	coronary heart disease
CHF	congestive heart failure
CK	creatine kinase
CKD	chronic kidney disease
CLI	critical limb ischemia
CMR	cardiac magnetic resonance
CMV	cytomegalovirus
COPD	chronic obstructive pulmonary disease
CPVT	catecholaminergic polymorphic ventricular tachycardia
Cr	Creatinine
CRP	C-reactive protein
CSS	carotid sinus syndrome
CTA	computed tomographic angiography
CTEPH	chronic thromboembolic pulmonary hypertension
CTI	cavotricuspid isthmus
CTPA	computed tomographic pulmonary angiography
CVD	cardiovascular disease
CVRF	cardiovascular risk factors
DAD	delayed afterdepolarizations
DALYs	disability-adjusted life-years
DCM	dilated cardiomyopathy
DBP	diastolic blood pressure
DSA	digital subtraction angiography
EAD	early afterdepolarizations
EBV	Epstein–Barr virus
ECMV	encephalomyocarditis virus
EF	ejection fraction
EKG	electrocardiogram
EMB	endomyocardial biopsy

EPS	electrophysiologic testing	NCD	non-communicable diseases
ESC	European Society of Cardiology	NNT	number needed to treat
ESR	erythrocyte sedimentation rate	NRT	nicotine replacement therapy
FISH	fluorescence *in situ* hybridization	NSAIDs	non-steroidal anti-inflammatory drugs
GAS	group A streptococcal	NSVT	non-sustained ventricular tachycardia
GFR	glomerular filtration rate	NVAF	non-valvular atrial fibrillation
GSD	glycogen storage disease	OAC	oral anticoagulants
HAART	highly active antiretroviral therapy	OLAT	organized left atrial tachyarrhythmia
HCM	hypertrophic cardiomyopathy	OR	odds ratio
HCt	haematocrit	PAD	peripheral arterial disease
HDL	high-density lipoprotein	PAH	pulmonary arterial hypertension
HFSA	Heart Failure Society of America	PAP	pulmonary artery pressures
HIC	high-income countries	PARs	population-attributable risks
HIT	heparin-induced thrombocytopenia	PAU	penetrating atherosclerotic ulcer
HIV	human immunodeficiency virus	PBAV	percutaneous balloon aortic valvuloplasty
HRQoL	health-related quality of life	PBMV	percutaneous balloon mitral valvuloplasty
IART	intra-atrial re-entrant tachycardia	PCA	percutaneous angioplasty
ICD	implantable cardioverter-defibrillator; initial claudication distance	PCI	percutaneous coronary intervention
		PDA	patent ductus arteriosus
ICH	intracerebral hemorrhage	PDGF	platelet-derived growth factor
IE	infective endocarditis	PFO	patent foramen ovale
IFG	impaired fasting glucose	POTS	postural orthostatic tachycardia syndrome
IGT	impaired glucose tolerance	PPA	plexogenic pulmonary arteriopathy
ILR	implantable loop recorder	PR	pulmonary regurgitation
IMH	intramural hematoma	PS	pulmonary stenosis
INR	international normalized ratio	PSVT	paroxysmal supraventricular tachycardia
ISHLT	International Society for Heart and Lung Transplantation	PTLD	post-transplant lymphoproliferative disorder
		PUFA	polyunsaturated fatty acids
IV	intravenous	PV	pulmonary valve
IVUS	intravascular ultrasound	PVAR	paravalvular aortic regurgitation
LCSD	left cardiac sympathetic denervation	PVE	prosthetic valve endocarditis
LDH	lactate dehydrogenase	PVI	pulmonary vein isolation
LDL	low-density lipoprotein	PVR	pulmonary vascular resistance
LMIC	low- and middle-income countries	PVS	pulmonary valve stenosis
LMWH	low molecular weight heparin	PVT	prosthetic valve thrombosis
LoB	line of block	QALYs	quality-adjusted life-years
LR	likelihood ratio	QoL	quality of life
LSCA	left subclavian artery	RAS	renin-angiotensin system

Introduction

In 1836 Elisha Bartlett, the editor of the *American Journal of Medical Sciences*, heralded a study as "one of the most important medical works of the present century, marking the start of a new era in science."[1] What evoked such praise and suggested a paradigm shift was Dr Pierre Louis' systematic collection and numerical presentation of data on blood letting. Louis adopted a Baconian approach of collecting vast amounts of data on a large number of patients (by the standards of the early 1800s), which allowed him to systematically evaluate the efficacy of blood letting. Louis argued that large numbers of patients and enumeration were necessary to equalize differences between treatment groups since "by so doing, the errors (which are inevitable), being the same in two groups of patients subjected to different treatment, mutually compensate each other, and they may be disregarded without sensibly affecting the exactness of the results."[2] Louis subsequently went on to state: "a therapeutic agent cannot be employed with any discrimination or probability of success in a given case, unless its general efficacy, in analogous cases, has been previously ascertained" and thus, "without the aid of statistics nothing like real medicine is possible."[3]

The prevailing concept of illness, at the time, was that the sick were contaminated, whether by some toxin or contagion, or an excess of one humor or another. This understanding of illness contained within it the idea that these states were improved by opening a vein and letting the sickness run out. Louis' finding that blood letting hastened the death of the ill was a bombshell. George Washington had 2.4 liters of blood drained from him in the 15 hours prior to his death; he had been suffering from a fever, sore throat, and respiratory difficulties for 24 hours.[4] Some have suggested that Washington was murdered.[5–7]

While this is a relatively recent example, the plea for comparative evaluation is mentioned as early as the Old Testament. Throughout history there have been repeated exhortations to quantify medical or health problems and to compare outcomes in patient groups managed differently, with the goal of setting state policy or assisting individual physicians.

In this chapter we will consider what evidence-based medicine is and then discuss an approach to evidence-based decision making. We will use a clinical case to highlight the components of this approach which include: clinical state and circumstances, patient preferences and actions, research evidence, and clinical expertise. At the end of the chapter we will review the application of these components of evidence-based decision making as they apply to our patient and provide a decision aid that clinicians can use in such a case. This chapter is an overview of core concepts and other chapters in this book (e.g. clinical trials and meta-analysis) provide more in-depth coverage of specific topics.

What is evidence-based medicine?

Although the foundations for evidence-based medicine were laid over several centuries, an explicit philosophy with its attendant concepts, definitions, and models has been largely developed as a formal doctrine only during the last few decades. Evidence-based medicine is about solving clinical problems. Initially, the focus of evidence-based medicine was largely on finding the best objective quantifiable research evidence relevant to the particular problem, and applying that evidence in resolving the particular issue.[8] This early focus de-emphasized "intuition,

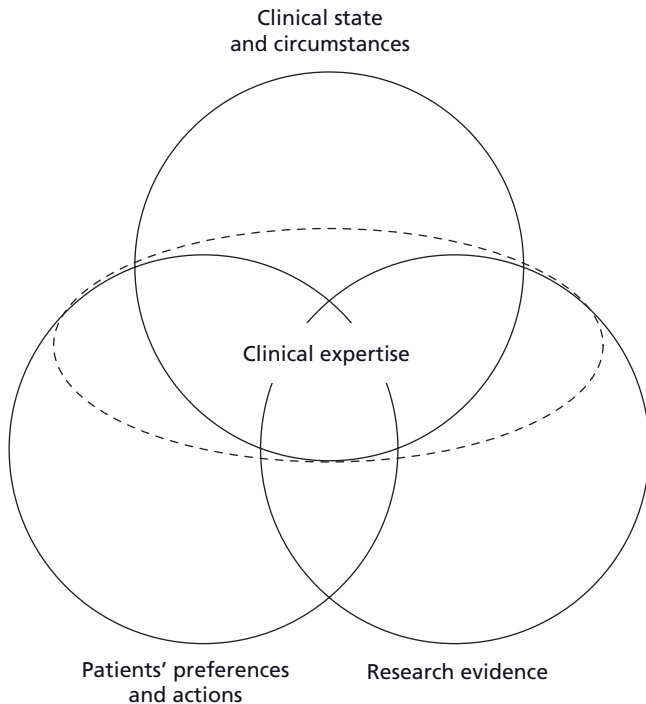

Figure 1.1 Current model of evidence-based clinical decision making.

Approach to evidence-based clinical decision making

Clinical scenario

A family physician refers a patient who has just moved cities to live with his daughter. The physician is requesting our input on the appropriateness of antithrombotic therapy. The patient is an 80-year-old male with a history of hypertension who 10 months ago, on routine exam, was diagnosed with atrial fibrillation. The patient suffered a major gastrointestinal bleed, requiring hospitalization, urgent endoscopy, and a transfusion 1 month prior to his diagnosis of atrial fibrillation. At the time of his bleed, the patient on endoscopy was diagnosed with a duodenal ulcer and *Helicobacter pylori*. The patient has been free of any gastrointestinal symptoms since his bleed 11 months ago and he received appropriate antibiotic and acid suppression therapy. Within 2 weeks of the patient's diagnosis of atrial fibrillation he underwent a transesophageal echocardiogram in his former city of residence and this demonstrated normal valvular and left ventricular function and a left atrium measurement of 6.5 cm without evidence of thrombus. An attempt at cardioversion was unsuccessful. The patient is very worried about having a stroke as his wife was left dependent on him for 2 years prior to her death, following a major stroke. The referring physician, who recently had a patient who suffered a serious gastrointestinal bleed while on warfarin, is very concerned about the risk of bleeding given this patient's age and history of gastrointestinal bleeding.

unsystematic clinical experience, and pathophysiologic rationale as sufficient grounds for clinical decision making" and stressed "the examination of evidence from clinical research."[9] Subsequent versions of evidence-based decision making have emphasized that research evidence alone is rarely sufficient to make a clinical decision.[10] Research evidence by itself seldom tells us what to do in individual situations, but rather it provides useful information that allows us to make more informed decisions. Clinicians must always view evidence in the context of the individual patient and then weigh the potential benefits versus the risks, costs, and inconveniences of each action. Ideally the patient's values and preferences affect these issues[10]

An initial description of evidence-based medicine from an editorial in 1996 provided the following definition: "Evidence-based medicine is the conscientious and judicious use of current best evidence from clinical care research in the management of individual patients."[10] The editorial also included the caveat that the definition of evidence-based medicine will evolve as new types of information emerge and therefore will be continuously refined. The concepts of evidence-based medicine have evolved considerably and the current model is outlined in Figure 1.1.[8] In the next section we use this model of evidence-based clinical decision making to help resolve a common clinical scenario.

Model for evidence-based clinical decisions

Figure 1.1 depicts a model for evidence-based clinical decisions,[8] which has more recently been redefined as "the integration of best research evidence with clinical expertise and patient values."[11] This model represents a desirable approach to how clinical decisions should be made. However, we acknowledge that, at present, many clinical decisions are not made this way. For instance, at present, clinicians' individual preferences (as distinct from clinical expertise) often play a large role in their actions, leading to large "practice variations" in managing similar cases. For example, when faced with critically ill patients with identical circumstances, different clinicians may, according to their preferences, institute aggressive life-prolonging interventions or withdraw life support.[12] Our model acknowledges that patients' preferences should be considered first and foremost, rather than clinicians' preferences, whenever it is possible and appropriate to do so (i.e. the patient wants to be involved in the decision making and they have the capacity to understand the outcomes and their consequences when explained by their physician). Although this model may look static, clinical decision making commonly requires an iterative approach whereby decisions are re-evaluated to ensure that they are still appropriate as evolv-

ing information comes to light. Integrating clinical state and circumstances, patient preferences and actions, and research evidence requires judgment and clinical expertise, thus constituting an overarching element. We will describe each of the components of the model, and the role of clinical expertise in integrating them.

Clinical state and circumstances

A patient's clinical state and circumstances often play a dominant role in clinical decisions. Clinical trials provide us with results reflective of the average patient within the treatment groups of the trial. Rarely is a patient in clinical practice the same as the average patient from a clinical trial. Individual patients have unique characteristics that typically put them at lower or higher risk of the outcome or treatment side effect than the average patient in the trial. As such, optimal clinical decisions should be individualized to the patient's clinical state. If a patient is at very high risk of a future vascular event but at low risk of any complication from a drug (e.g. a patient with a low-density lipoprotein value of 8.0 mmol/L post myocardial infarction and no contraindication to statin therapy), or conversely at low risk of the outcome and high risk of a treatment's complications (e.g. a 40-year-old man with atrial fibrillation without any associated stroke risk factors who has experienced a major gastrointestinal bleed 2 weeks ago), the clinical state of the patient may dominate the clinical decision-making process.

It is notable that the circles of clinical state and circumstances and research evidence overlap. Frequently research evidence can inform us about the influence of the clinical state and circumstances. Considering our patient, the pooled data from five randomized controlled trials (RCTs) evaluating the efficacy of warfarin in patients with non-valvular atrial fibrillation (NVAF) demonstrated an average annual stroke rate of 4.5% and major bleeding rate of 1% in patients not receiving antithrombotic therapy.[13] The investigators who combined the five RCTs used the control patient data to develop a clinical prediction tool to estimate the annual risk of stroke. Independent risk factors that predicted stroke in control patients were increasing age, a history of hypertension, diabetes, and prior stroke or transient ischemic attack (TIA).[13] These trials likely exclude patients with a history of bleeding 11 months prior to enrollment and as a result we would not want to rely upon these trials to estimate our patient's risk of severe bleeding; however, we believe, and research suggests,[14] that the estimate of stroke from the clinical prediction tool (which takes into account age) is relevant to our patient even though he is older than the average patient in the trials. Using this model, our patient's annual risk of stroke is predicted to be about 8%, which is higher than that of the average control patient in the five RCTs whose annual stroke rate was 4.5%.[13]

A clinical prediction tool has also been developed for predicting the risk of major bleeding (defined as the loss of 2 units of blood within 7 days or life-threatening bleeding) while taking warfarin therapy.[15] Independent risk factors that predict major bleeding in patients taking warfarin include age >65, history of stroke, history of gastrointestinal bleeding, recent myocardial infarction, anemia, renal failure, and diabetes (note that many of the factors that predict a higher risk of stroke also increase the risk of bleeding). Our patient's annual risk of major bleeding of 8% also differs from that of the average patient receiving warfarin in the five RCTs whose annual risk of major bleeding was 1.3%. We are unaware of any clinical prediction tool for predicting major bleeding while taking aspirin and the atrial fibrillation trials had inadequate power to estimate this risk. The results of the meta-analysis by the antithrombotic trialists' collaboration suggest that aspirin increases the risk of major bleeding from 1% to at least 1.3%.[16] This likely is an underestimation in our patient who is older than the average patient who participated in the atrial fibrillation trials, and in this setting of suboptimal information we estimate our patient's annual risk of major bleeding is approximately 2% with aspirin therapy.

The clinical circumstances we find ourselves in (e.g. our ability to administer and monitor a treatment) may be very different from that of an RCT. For example, the patient may not be able to obtain frequent tests of the intensity of anticoagulation. However, for a patient with the same clinical characteristics, we can frequently optimize clinical circumstances to decrease the risk of an outcome or treatment side effect. For example, we can decrease the risk of bleeding due to warfarin therapy by more intensive monitoring to ensure that the international normalized ratio (INR) is maintained in the range of 2–3. Thus, an "evidence-based" decision about anticoagulation for a patient with atrial fibrillation is not only determined by the demonstrated efficacy of anticoagulation and its potential adverse effects,[17] but will vary based on the patient's clinical state and according to individual clinical circumstances.

Patients' preferences and actions

Patients may have no views or, alternatively, unshakable views on their treatment options, depending on their condition, personal values and experiences, degree of aversion to risk, healthcare insurance and resources, family, willingness to take medicines, accurate or misleading information at hand, and so on.[8] Accordingly, individuals with very similar clinical states and circumstances may choose very different courses of action despite being presented with the same information about the benefits, risks, inconveniences, and costs of an intervention.

For our patient with NVAF, research evidence informs us about the differing preferences of patients and their

physicians for antithrombotic therapy in atrial fibrillation when they weigh the competing risks of stroke and bleeding.[18] In this study,[18] participants (i.e. both physicians and patients) reviewed flipcharts describing in detail the acute and long-term consequences of a major and minor stroke and a major bleeding event. Participants were instructed that the likelihood of a minor or major stroke was equal. The participants then underwent a probability trade-off technique which determined the minimum number of strokes participants needed to be prevented before they felt antithrombotic therapy was justified (this value was determined for both warfarin and aspirin), given the associated increased risk of bleeding, costs and inconveniences. The same technique was also used to determine the maximum number of excess bleeds the participant considered acceptable with antithrombotic therapy (determined both for warfarin and aspirin), given the benefits in terms of stroke reduction with this therapy. This study demonstrates significant variability between physicians and patients in their weighing of the potential outcomes associated with atrial fibrillation and its treatment. Patients required less stroke reduction and were more tolerant of the risk of bleeding than physicians. For example, on average, patients were willing to accept the risk of 17 extra major bleeding events in 100 patients over a 2-year period if warfarin prevented eight strokes among these 100 patients. Physicians, however, were only willing to accept 10 major bleeding events for the same level of benefit. Furthermore, physicians varied significantly among themselves in how much bleeding risk they thought was acceptable for a given stroke reduction associated with an antithrombotic agent. Hence different physicians would make very different recommendations to the same patient with identical risks of bleeding and stroke. This underscores the importance of having patient values and preferences drive clinical decision making. It is the patient who is at risk of the outcome and hence, when willing and able, they should be the one to weigh the potential benefits versus the risks, costs, and inconveniences.

There is debate regarding the optimal way to elicit and incorporate patient preferences into clinical decision making. One method is to discuss the potential benefits and risks with a patient and then qualitatively incorporate your impression of the patient's preferences into the clinical decision. Alternatively, at least two quantitative approaches exist: decision analytic modeling and probability trade-off technique. In a decision analytic model, a standard gamble, time trade-off or visual analog scale technique is used to determine the utility (patient value/preference) for the various outcomes. This information is then fed into a decision tree that includes the probabilities of the outcomes for all clinical decisions being considered. Using the decision tree, calculations are undertaken to determine what course of action optimally fits the patient's prefer-

ences. Probability trade-off technique presents patients with the probabilities for the various interventions being considered and then asks them to make a decision based on this information. This allows a direct and quantitative incorporation of the patient's preferences. The only study we are aware of that has directly compared these two quantitative approaches demonstrated that over twice as many patients stated they would base their preferences on the results of the probability trade-off as opposed to the decision analysis.[19]

Regardless of what their preferences may be, patients' actions may differ from both their preferences and their clinicians' advice.[20] For example, a patient may prefer to lose weight, quit smoking and take their medications as prescribed, but their actions may fall short of achieving any of these objectives. Alternatively, they may follow the treatment as prescribed, even if they resent its imposition, adverse effects, and costs. Unfortunately, clinicians' estimates of their patients' adherence to prescribed treatments have no better than chance accuracy.[21] Thus, physicians' decisions for care will better meet the model's specifications if they are able to assess whether their patients will follow, or are following, the agreed-upon decision.[21]

We recognize that at present formal incorporation of patients' preferences is rarely done in clinical practice. This may be related to lack of training of physicians in these approaches, a reluctance to tread unfamiliar ground, and also in many circumstances the lack of accurate quantitative information on risk and benefits as well as clinical risk prediction tools. However, this is likely to change as clinical models can be derived from large databases and hand-held computers can be utilized to quantitate risks and benefits at the bedside.

Research evidence

We support a very broad definition of research evidence, namely "any empirical observation about the apparent relation between events."[22] In keeping with this definition research evidence includes everything from the unsystematic observation of a single physician to a systematic review of large RCTs. Not all evidence is created equal and hence there exists a hierarchy of evidence that varies depending on whether one is addressing a diagnostic, prognostic or therapeutic decision. We will focus on the hierarchy of evidence for therapeutic decisions (Box 1.1).

All evidence has value and clinicians should give appropriate consideration to the best evidence available in the hierarchy, even if it is not at the top of the hierarchy. Therefore, the unsystematic observations of colleagues should not be dismissed when no higher level evidence exists. Indeed, unsystematic observations can lead to many important insights and experienced clinicians usually develop a respect for the insights of their astute colleagues.

However, it is equally important to recognize that unsystematic observations commonly are limited by the small number of observations, variability in outcomes, lack of objectivity, and the difficulties in integrating (e.g. taking

---

BOX 1.1 Hierarchy of evidence for treatment decisions*

Coherence of evidence from multiple sources
Systematic review of several well-designed, large randomized controlled trials
Single large randomized controlled trial
Systematic review of several well-designed small randomized controlled trials
Single small randomized controlled trial
Systematic review of several well-designed observational studies
Single observational study
Physiologic studies
Unsystematic observation from a physician
Animal study

This hierarchy is not meant to represent a rigid structure. At times a single observation may be very powerful (e.g. defibrillation for ventricular fibrillation) or observational studies may provide unequivocal evidence (e.g. smoking cessation and decreased risk of lung cancer). However, in most cases where treatment effects are likely moderate, outcomes variable or the clinical course unpredictable, clinicians may find the hierarchy proposed useful.

---

into account the natural history of a disorder, placebo effect, and a patient's desire to please) and drawing inferences from observations.[23] Clinicians should also realize that even for the highly cited animal studies demonstrating a beneficial treatment effect and published in a leading scientific journal, only a minority will be confirmed in human trials.[24]

All evidence has limitations. Although the majority of advances in medicine are initially uncovered through individual observations, physiologic studies, observational studies or randomized controlled trials evaluating surrogate endpoints, there have also been several extremely misleading findings that have, at times, resulted in harm. It is important to remember that contradictory results across studies on the hierarchy of evidence table are not isolated to one or two instances (Table 1.1).

Perhaps the most powerful example is the story of antiarrhythmic therapy. Despite encouraging evidence that encainide and flecainide could prevent premature ventricular beats after a myocardial infarction, a large RCT demonstrated a higher mortality rate with these drugs compared to placebo, such that these drugs resulted in an extra death for every 20 patients treated with encainide or flecainide.[39] It is estimated that more Americans were killed by these drugs than died in the Vietnam War.[40]

Ideally we would have evidence from all levels of the hierarchy and the evidence would be coherent across all levels. This would represent the most persuasive evidence.

Table 1.1 Some examples of contradictory results across studies at various positions in the hierarchy of evidence

Results from lower level evidence	Results from higher level evidence
Milrinone demonstrated improvement in left ventricular function during exercise.[25]	A large RCT[26] and meta-analysis of several RCTs[27] demonstrated a 28% relative increase in mortality with milrinone compared to placebo.
An observational study of extracranial to intracranial bypass surgery suggested a "dramatic improvement in the symptomatology of virtually all patients" undergoing the procedure.[28]	A large RCT demonstrated a 14% relative increase in the risk of fatal and non-fatal stroke in patients undergoing this procedure compared to medical management.[29]
A meta-analysis of 16 cohort studies and three cross-sectional angiographic studies (including studies of women with known coronary artery disease) demonstrated a relative risk of 0.5 (95% CI 0.44–0.57) for coronary artery disease among women taking estrogen.[30]	A moderate size secondary prevention RCT did not demonstrate any reduction in coronary heart disease events but did demonstrate an increase in thromboembolic events in patients receiving estrogen.[31] A primary prevention RCT (Women's Health Initiative) of 16,608 women demonstrated that hormone replacement therapy increases the risk of coronary artery disease (hazard ratio (HR) 1.29), stroke (HR 1.41), pulmonary emboli (HR 2.13), and breast cancer (HR 1.26).[32]
A secondary analysis of an RCT suggested that lower doses of ASA were associated with a higher risk of perioperative stroke and death in patients undergoing carotid endarterectomy.[33]	A large prospective RCT showed a higher risk of perioperative stroke, myocardial infarction, or death with high-dose ASA.[33]
A physiologic study demonstrated beta-blockers result in a decline in ejection fraction and increases in end-diastolic volume in patients with prior myocardial infarction.[34]	A meta-analysis of 18 RCTs[35] and three large trials (CIBIS-2,[36] MERIT-HF,[37] and COPERNICUS[38]) in patients with heart failure found a 32% relative risk reduction in death in patients receiving beta-blockers.

However, this rarely happens as even RCTs by chance may frequently demonstrate contradictory findings, especially when they are small. Therefore, physicians should always aim for the highest level of evidence for clinical decision making. Clinicians can still make strong inferences particularly when there is evidence from a systematic review of several well-designed large RCTs or simply a large single pragmatic RCT. The RCT is such a powerful tool because randomization is our only means to reduce bias in treatment comparisons by controling for unknown prognostic factors.[41] Therefore, RCTs have the potential to provide the most valid (i.e. likelihood that the trial results are unbiased) estimates of treatment effect.[42] Furthermore, large RCTs with broad eligibility criteria enhance the generalizability of their findings.

A common error in interpreting evidence relates to the confidence clinicians should have in a study based upon statistical significance despite its size and number of events. Consider two hypothetical RCTs that are both evaluating the effect of a new investigational drug versus placebo on patient mortality in patients at risk of a myocardial infarction. Both of these trials use identical methodology (e.g. blinding, complete patient follow-up, intention-to-treat principle). The first trial randomizes 100 patients to receive investigational drug A and 100 patients to receive placebo, and fewer patients assigned the investigational drug die (1 versus 9 patients, $P = 0.02$). The second trial randomizes 4000 patients to receive investigational drug B and 4000 patients to receive placebo, and fewer patients assigned the investigational drug die (200 versus 250 patients, $P = 0.02$). Given that both trials used the same methodology and achieved the same level of statistical significance, some would assume we should view both results with similar confidence. This, however, is not the case.

Although the P values in our hypothetical trials suggest that the results have the same probability of representing a true finding, we propose that there is a substantial difference in the fragility of the demonstrated P values. In the first trial if we were to add two events to the treatment group the P value would become 0.13 whereas adding two events to the treatment group in the second trial would have no meaningful impact on the P value which would remain 0.02. When one considers that there are at least nine independent risk factors associated with myocardial infarction,[43] the prevalence of these factors in patients suffering a myocardial infarction varies from 18% to 65%, and many of these risk factors have substantially larger associations with myocardial infarction (e.g. odds ratio 2.87 for current smoker versus never) than the moderate effects that are plausible in interventional trials, it is not difficult to understand how the effect seen in our first hypothetical trial could have easily occurred due to an imbalance in risk factors, whereas the size of our second trial substantially minimizes the likelihood of a meaningful imbalance in prognostic factors that could explain the result of our second trial.

The number of participants and events that represents the transition from a small trial to a large trial is a matter of debate and ongoing investigation. It is important to recognize that the number of both participants and events is relevant. Some have argued that cardiovascular trials with event rates of 10% require at a minimum several thousand participants and at least 350 events and ideally 650 events to provide convincing evidence of a moderate size treatment effect (i.e. a relative risk reduction of 20–30%).[44] Indeed, if the true effect of size is a 15% relative risk reduction, studies with over 1000 outcome events may be required. In the case of a more prevalent outcome or the rare case of a true large treatment effect, fewer participants and events are required. We encourage clinicians when assessing evidence to not simply assume that a P value <0.05 represents a true finding but to consider the sample size, number of events, and the fragility of the P value and to exercise caution when making clinical decisions based upon data from small trials. Research demonstrates that highly cited studies in leading medical journals are not uncommonly contradicted (16%) or demonstrated to have exaggerated treatment effects (16%) in subsequent studies, and the only identified factor explaining this outcome is that the initial trial had a small sample size.[45]

Another issue clinicians have to consider regarding research evidence is the applicability to their current patient. If a patient fulfills most of the eligibility criteria from a trial then most physicians would view the evidence as applicable to their patient, assuming the trial is high quality. If a patient does not fulfill most of the eligibility criteria, we recommend that physicians ask themselves if there is a strong biologic reason to believe their patient would respond quite differently to the intervention from the patients who participated in the trial. As stated above, it is likely that most of the atrial fibrillation trials excluded patients who had a history of gastrointestinal bleeding within 11 months of randomization. Given this, we think the results from the atrial fibrillation trials regarding bleeding risk are not applicable to our patient, and this is why we used a clinical model based upon a study that included patients with a prior history of gastrointestinal bleeding to estimate our patient's risk of severe bleeding with warfarin. However, we do not have a strong biologic rationale to suspect that the stroke benefit demonstrated in the trials is not applicable to our patient, and research suggests that despite his age we can expect a similar benefit.[14]

Considering our case of the patient with NVAF, the highest level of evidence comes from a systematic review of all the RCTs that have evaluated antithrombotic therapy in patients with atrial fibrillation.[17] This systematic review included six warfarin versus placebo RCTs that included a total of 2900 patients and 186 strokes, and six aspirin versus placebo RCTs that included a total of 3337 patients and 376 strokes, and demonstrated that warfarin reduced the rela-

tive risk of stroke (ischemic and hemorrhagic) by 62%, and aspirin by 22%.[17]

Considering the risk of bleeding associated with warfarin therapy, there is an RCT of 325 patients with 25 major bleeding events that demonstrates a 50% decrease in the risk of bleeding if a patient is willing to undergo education, training, and self-monitoring of prothrombin time.[46]

Clinical expertise

Evidence-based decision making requires clinical expertise to establish and balance the patient's clinical state and circumstances, preferences and actions, and the best research evidence. Before a therapeutic decision can be considered, clinical expertise is required to get the diagnosis and prognosis right. As shown above, clinical prediction tools can be extremely helpful in determining a patient's prognosis but they are unlikely to eliminate the need for sound clinical judgment acquired through clinical experience.

Sizing up the clinical circumstances has never been more challenging, as commonly there exist several potential interventions, some of which require technical expertise for their effective and safe delivery. Getting the evidence right requires the skill to identify, evaluate, and apply the evidence appropriately. Communicating with patients has always been considered important. This takes on greater importance, given that there is a growing desire on the part of patients to be involved in decisions relating to their health.[47] Expertise is required to provide patients with the information they need, to elicit their preferences and to incorporate their preferences into the decision.

Currently there is no consensus on how this information should be presented to patients and how their preferences should be incorporated. However, research suggests that information should not be presented to patients in relative terms (e.g. warfarin will decrease your risk of stroke by 62%) because patients assume their baseline risk is 100% even when they are instructed it is not.[48] A recent systematic review of RCTs compared decision aids (i.e. interventions designed to help people make specific choices among options by providing information on the options and outcomes relevant to the patient's health) to traditional ways of involving/informing patients in decision making and demonstrated that decision aids, compared with usual care, improved average knowledge scores of patients for the options and outcomes by 20% (95% CI 13–25), reduced decisional conflict scores (i.e. patients felt more certain, informed, and clear about values in their decision), and increased patient participation in decision making.[49] Where available, decision aids provide a potential means to facilitate information presentation, incorporation of preferences, and participation in the decision making process.

The varying roles of the components of evidence-based clinical decisions

Depending on the circumstances, any of the circles in the new model could dominate. Varying the size of the circles to reflect their actual contribution to the clinical decision could visually portray this concept. Sometimes the clinical state or circumstance dominates the clinical decision. For example, a patient who is at very high risk of an outcome and low risk of a complication may have their clinical state dominate the decision-making process. A patient living in a remote area may not have access to anticoagulation monitoring and this would likely dominate the decision-making process. Patients' preferences can be so strong that they act as the driving factor in the decision-making process. For example, some patients will not take blood products regardless of the clinical situation. Research evidence can be the main factor in decision making when the benefit of an intervention is moderate to large in size and the risk of treatment small, as with ACE inhibitors in coronary artery disease or heart failure, or cholesterol lowering with statins. Finally, clinical expertise can dominate especially when it is related to technical capabilities.

Approach to decision making

We advocate a shared decision-making process between the physician and patient with both as active partners.[47] There is evidence to support better health outcomes when shared decision making occurs.[50] Considering a therapeutic decision, the physician must incorporate the clinical state and circumstances into the relevant evidence to help inform the patient and then elicit the patient's values regarding the potential benefits, risks, costs, and inconveniences associated with the intervention. If a patient chooses not to take an effective therapy that the physician believes is in the patient's best interest then the physician's role is to ensure that the patient's choice represents a difference in values (e.g. monetary concerns) as opposed to a misunderstanding about the probable benefits, risks, inconveniences, and costs. Regardless of a patient's wishes (e.g. CABG surgery in the setting of extensive coronary artery disease without graftable distal vessels, non-therapeutic use of narcotics) no physician is required to provide an intervention that they feel is unethical, illegal or not in the patient's best interest. Although more patients want shared decision making, some may choose to take a passive role in the decision-making process.[47] For example, a patient may ask the physician "If it were you or your loved one what would you do?" This question permits the physician to present an evidence-based background, the uniqueness of the clinical state and circumstances, and the doctor's explicit values associated with their recommendation. If a physician does

this they will provide the patient with a helpful understanding of their recommendation, and if a patient disagrees they can then express their perspective. Finally, after making a decision it is important to ensure that the patient understands that even the best evidence-based decision does not guarantee the patient that they will not suffer a negative outcome.

Application to our patient

For our patient the evidence would suggest an annual 8% risk of stroke and 1% risk of major bleeding without any antithrombotic therapy. With warfarin therapy we would expect the annual risk of stroke to decrease to 3% and the risk of major bleeding to increase to 8%. This risk of major bleeding could potentially be reduced to 4% if the patient was willing to undergo self-monitoring of their prothrombin time and an education program as discussed above; however, it is important to acknowledge that our confidence in this intervention is not strong as the results are based upon one small trial with few events.[46] With aspirin therapy we would expect the annual risk of stroke to decrease to 6% and the risk of major bleeding to increase to 2%.

As discussed above, there is no consensus on how to present this information to our patient or incorporate his preferences. The patient expresses that he would like to participate in the decision-making process and you then share with him a decision aid for patients with atrial fibrillation that describes atrial fibrillation (Table 1.2), a major and minor stroke (Table 1.3), a severe bleed (Table 1.4), and

Table 1.2 Atrial fibrillation: the most common disorder of the heartbeat	
Risk	Chances of developing atrial fibrillation increase with age and it occurs in approximately 10% of all people above the age of 75
Physical Symptoms	Irregular and usually rapid beating of the heart, sensed as a fluttering in the chest. Some patients feel no symptoms and are unaware that they have atrial fibrillation
Complications	Stroke • Atrial fibrillation increases the risk of a clot developing in the heart. This clot can be swept up towards the brain, causing a stroke • The chance of developing a stroke with atrial fibrillation increases with either age greater than 65 years, high blood pressure, diabetes, heart failure, or a history of strokes or "mini-strokes" • The risk of developing a stroke with atrial fibrillation varies, depending on how many of these risk factors you have
Treatment	• There are medications that thin the blood, which help to prevent clots and therefore stroke • Because the blood is thinned there is an increased risk of bleeding

Table 1.3 Strokes can be minor or major in severity. If you have a stroke as a result of atrial fibrillation, your chance of having a minor or major stroke are equal

	Minor stroke	**Major stroke**
Physical symptoms	You suddenly cannot move or feel one arm and one leg	You suddenly are unable to move one arm and one leg You cannot swallow
Mental symptoms	You are unable to fully understand what is being said to you You have difficulty expressing yourself	You are unable to understand what is being said You are unable to speak
Pain	You feel no physical pain	You feel no physical pain
Recovery	You are admitted to hospital Your weakness, numbness and problem with understanding improve, but you still feel weak or numb in one arm and one leg You are able to do almost all of the activities you did before the stroke You can function independently You leave the hospital after 1 week	You are admitted to hospital You cannot dress The nurses feed you You cannot walk After 1 month of physiotherapy you are able to wiggle your toes and lift your arm off the bed You remain this way for the rest of your life
Further risk	You have an increased risk of having more strokes	Another illness will probably cause your death

Table 1.4 Severe bleeding while taking warfarin or ASA: an example of a stomach bleed

Physical	You feel unwell for 2 days, then suddenly you vomit blood
Treatment	You are admitted to hospital
	You stop taking warfarin or ASA
	A doctor puts a tube down your throat to see where you are bleeding from
	You receive sedation to ease the discomfort of the test
	You do not need an operation
	You receive blood transfusions to replace the blood you lost
Recovery	You stay in hospital for 1 week
	You feel well at the end of your hospital stay
	You need to take pills for the next 6 months to prevent further bleeding
	After that you are back to normal

Bleeding from the stomach is the most common type of serious bleeding while taking warfarin or ASA; however, rarely other serious forms of bleeding can occur, such as bleeding within the head after a fall.

Warfarin or ASA can also cause minor bleeding, including bruising and nose bleeds.

Taking warfarin can mean costs and inconvenience to yourself and family. For example: need for blood tests; parking/transportation; cost of warfarin.

Taking ASA can mean costs to yourself.

For example: cost of ASA.

Without any blood thinning medication
Chance of stroke over next 2 years
is ____ out of 100
Chance of severe bleeding over next 2 years
is ____ out of 100

ASA
Chance of stroke over next 2 years
is ____ out of 100
Chance of severe bleeding over next 2 years
is ____ out of 100

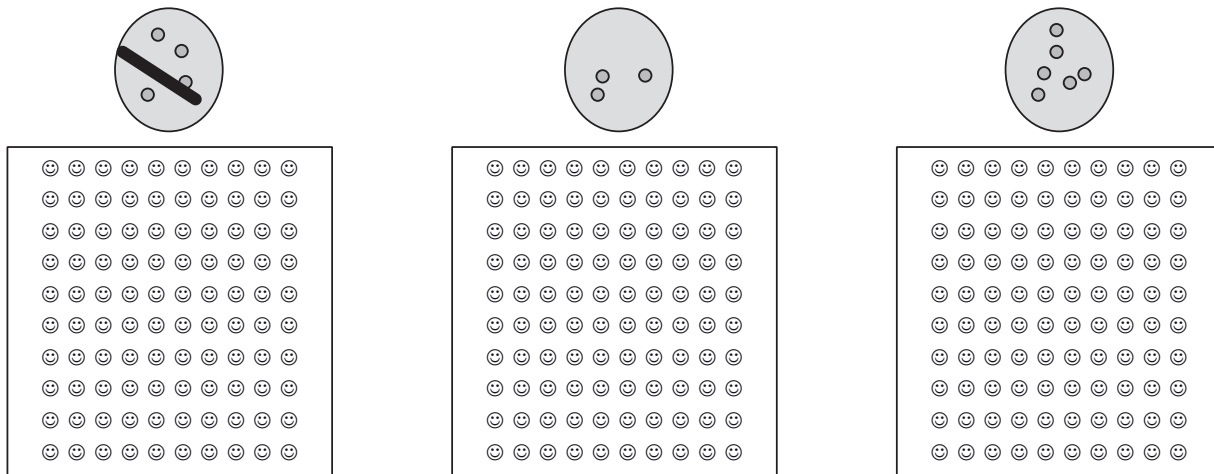
Warfarin
Chance of stroke over next 2 years
is ____ out of 100
Chance of severe bleeding over next 2 years
is ____ out of 100


Figure 1.2 Patient decision aid.

a probability trade-off for no treatment, aspirin, and warfarin therapy (Fig. 1.2), which you individualize for him, filling in the specific numbers and coloring the faces relevant to his care. The description of major and minor stroke and a severe bleed are slight modifications of the descriptions developed and tested by Man-Son-Hing and colleagues.[51] After careful consideration of this information, our patient decides he wants to take warfarin therapy. He recognizes his increased risk of bleeding but places sub-stantially more weight on avoiding a stroke than a severe bleed.

Once this evidence-based clinical decision is reached, our job is not over. The patient will need monitoring to ensure he is able to follow through on his clinical decision. One advantage of the decision aid provided (including his individualized probability trade-off) is that the patient can take the information home and does not have to rely on his memory to recall the facts discussed during your meeting.

Limitations of the evidence-based clinical decision model

This model does not consider the important roles that society, governments or healthcare organizations can play in decision making. We purposely restricted ourselves to decisions made by patients and their healthcare providers to allow a focused exploration of the issues involved in their immediate decision-making process. However, a healthcare organization may pre-empt these decisions. For example, not funding primary percutaneous transluminal coronary angioplasty in acute myocardial infarction can have an impact on health outcomes and will impose a clinical decision on all patients and physicians by eliminating this option. Alternatively, the system may fund preferentially, and at a higher level, a theoretically more attractive but more expensive and in reality no more effective therapy (e.g. dual-chamber pacemaker compared to single-chamber pacemaker for bradyarrhythmia) and this can distort the information presentation to patients, recommendations, and decisions made by physicians and healthcare providers. Physicians will have to factor in such issues when considering their patient's clinical circumstances.

Conclusion

The foundations for evidence-based medicine were established over the centuries but the specific philosophies, concepts, definitions, and models have essentially evolved over the past few decades. Evidence-based medicine is about solving clinical problems. Evidence-based decision making depends upon utilizing clinical expertise to integrate information about a patient's clinical setting and circumstances with the best research evidence while incorporating the patient's preferences and actions. Although there have been substantial advances throughout the last few decades, if evidence-based decision making is to achieve its full potential there is a need for further research to inform both the evidence base and the process of decision making. This chapter has provided an introduction to the concepts of evidence-based decision making, and subsequent chapters expand on the points we have discussed, describing different aspects of evaluating evidence and applying them.

2 Obtaining incremental information from diagnostic tests

Raymond J Gibbons
Mayo Clinic, Rochester, MN, USA

Consider the following case history. A 75-year-old male presents with a history of exertional chest pain. The patient describes substernal chest pain that he perceives as a "pressure sensation" occurring when he walks too fast, uphill or in the cold. It is relieved by rest within a few minutes. On two recent occasions, he tried a friend's nitroglycerin tablets and obtained even more rapid relief of his symptoms. His symptoms have never occurred at rest. The patient has a history of diabetes mellitus, hypertension and hypercholesterolemia. He smokes one pack of cigarettes a day. Several male family members died of coronary artery disease before the age of 60. The patient underwent carotid artery surgery a year ago for treatment of transient ischemic attacks.

On the basis of his age, gender, chest pain description, and risk factors, this patient is highly likely to have significant obstructive coronary artery disease (CAD). The added, or incremental, value of any stress test for the diagnosis of the presence of disease in such a situation is very small. Out of 100 patients with this presentation, perhaps only one or two will not have obstructive CAD. The potential contribution of stress testing is therefore restricted to only these one or two patients.

This example demonstrates the importance of the concept of incremental value for diagnostic tests. In the current era of healthcare reform, it is no longer sufficient that a test simply provide "more information". The more appropriate current questions are:
- is it likely to influence clinical decision making?
- at what cost?
- will more informed decisions lead to better outcomes?

The demonstration of the incremental value of diagnostic tests requires rigorous methodology. The principles of the required methodology should be credited primarily to Dr George Diamond and his colleagues at Cedar Sinai Medical Center in Los Angeles.[1–3] First and foremost, such an analysis should reflect clinical decision making. Since clinical assessment is performed before any diagnostic tests, and usually at lower cost, parameters available from this assessment should be considered separately without any information from subsequent testing. The analysis should preferably focus on hard, demonstrable endpoints such as significant obstructive CAD, severe (three-vessel or left main) coronary artery disease, myocardial infarction or death. Although alternative endpoints, such as functional impairment, unstable angina, and the need for revascularization, are often included to increase statistical power, such endpoints have major limitations with respect to reversibility, subjectivity, and definite impact on patient outcome.

The analysis should create appropriate models that include all available important variables. An experienced clinician always takes the patient's age, gender, and history into account in making his or her clinical decision regarding patient management, even when testing results are available. These important clinical parameters must therefore be included in any final model that reflects the clinical decision-making process. The analysis must demonstrate that the additional information is statistically significant in an appropriate patient population. Analyses that demonstrate additional information in older, "sicker" inpatient populations should not be casually extrapolated to younger, "less sick" outpatients in whom testing is customarily performed. Finally, the test must provide information that is clinically significant and cost effective. In very large patient samples, differences that have little, if any, clinical significance for individual patient management may emerge as statistically significant. The potential impact on patient management in *some* patients must compare favorably with the incremental cost of the test in *all* the patients who must be tested.

This chapter will attempt to elucidate this methodology using the published data with respect to the diagnosis of significant obstructive CAD, non-invasive screening for

severe CAD, and patient outcome. All of these examples are drawn from the arena of ischemic heart disease, because this entity dominates clinical practice in cardiology, and the published literature is voluminous and extensive. However, the same principles apply to other disease entities, both cardiac and non-cardiac.

Clinical assessment

As outlined above, the initial step in any analysis designed to demonstrate incremental value is the consideration of all the information available prior to performance of the test. This will always include the results of the history and physical examination, and may sometimes include the results of other tests already performed. This section focuses on the information available from clinical assessment.

Diagnosis of coronary artery disease

As demonstrated by the earlier example, clinicians often encounter patients with chest pain and suspected CAD. The ability of clinical assessment to predict the likelihood of significant obstructive CAD has been demonstrated in numerous studies. The likelihood of significant disease based on clinical assessment is appropriately labeled the "pretest probability", in statistical terms.

Age, gender, and the patient's chest pain description are the most important clinical parameters for estimating the likelihood of CAD.[4] Older patients, men, and patients with chest pain that is typical, or classic, for angina pectoris are more likely to have coronary disease. Although multiple different systems have been used to classify chest pain, the simplest and easiest was proposed by Diamond.[5] He suggested a classification based on three elements – substernal location, precipitation by exertion, and relief by rest or nitroglycerin. If all three elements are present, the chest

pain is classified as "typical angina". If two elements are present, the chest pain is classified as "atypical angina". If only one or none is present, the chest pain is classified as "non-anginal chest pain".

Table 2.1 shows published estimates of pretest probability on the basis of age, gender, and chest pain description.[4] It is obvious that there is a very wide range of pretest probability, ranging from 1% for a 35-year-old woman with non-anginal chest pain to 94% for a 65-year-old man with typical angina. Note that a 50-year-old man with atypical angina has about a 50% probability of disease.

A more comprehensive attempt to consider all clinical characteristics, including risk factors for atherosclerosis, was published from the Duke University Medical Center databank.[6] In addition to the three parameters previously discussed, this analysis found that evidence for previous infarction, smoking, hyperlipidemia, ST and T wave changes on the resting electrocardiogram (ECG), and diabetes were all highly significant predictors of the presence of coronary artery disease. Figure 2.1 shows a published nomogram for men that incorporates all of these parameters. Careful inspection of this figure demonstrates that the impact of clinical parameters other than age, gender, and chest pain is variable. ECG and historical evidence of previous infarction have a major impact, diabetes and ECG ST-T changes have a modest impact, and lipids and smoking have a minimal impact. For example, a 50-year-old male with atypical angina has a 46% pretest probability of disease in the absence of smoking, hyperlipidemia or diabetes, a 48% pretest probability in the presence of both smoking and hyperlipidemia, and a 65% pretest probability if he has diabetes as well. In the presence of ECG Q-waves and a history of MI, his pretest probability exceeds 90%.

Recent evidence, particularly from the NHLBI-sponsored Women's Ischemic Syndrome Evaluation (WISE) Study,[7,8] has suggested that this traditional approach significantly underestimates the presence of obstructive CAD in women,

Table 2.1 Pretest probability of coronary artery disease

Age (years)	Pretest probability (%)							
	Asymptomatic		Non-anginal chest pain		Atypical angina		Typical angina	
	F	M	F	M	F	M	F	M
30–39	<1	2	1	5	4	22	26	70
40–49	1	6	3	14	13	46	55	87
50–59	4	9	8	22	32	59	79	92
60–69	8	11	19	28	54	67	91	94

From Diamond and Forrester.[4] Reprinted by permission of the *New England Journal of Medicine,* and Diamond GA.

History – ECG
Point score

Angina – Typical – 26
        Atypical – 10
        Non-angina – 0

Previous MI
        History only – 11
        ECG Q waves – 12
        Both – 30

ECG ST-T Changes – 6
Diabetes mellitus – 7

Directions for use

Step 1: Calculate the history ECG score and
        locate point on left scale

Step 2: Using the appropriate age scale extrapolate
        to the reading line for age (right scale)

Step 3: Place a ruler between the
        point score and age (moved
        to the reading line)

Step 4: Read off the probability of
        significant CAD on the
        center scale
Figure 2.1 Nomogram for predicting the probability of significant coronary artery disease (CAD) in men. ECG, electrocardiogram; MI, myocardial infarction. (After Pryor *et al.*[6]) Example: a 50-year-old, white male with atypical angina and diabetes mellitus, but no ECG ST changes, previous MI, smoking or hyperlipidemia. Point score on left scale = 10 + 7 = 17. Appropriate reading line on right labeled "no smoking or lipids". Connect age 50 on this reading line to point score of 17 with a straight edge. This intersects the middle line at 60, indicating that this is the percentage probability of significant CAD.

particularly younger women. Moreover, many women without obstructive disease continue to have symptoms and a poor quality of life.[9–11] Many of these have evidence of microvascular dysfunction.[12] There is a growing interest in the development of gender-specific tools for the assessment of ischemic heart disease in women, but the evidence is not yet robust enough to support the widespread use of a new approach.

Non-invasive screening for severe coronary artery disease

Not surprisingly, clinical parameters are also very important in estimating the likelihood of severe (three-vessel or left main) CAD.[13] The same parameters that are most important for predicting the presence of disease – age, gender, and chest pain description – remain important. In addition, diabetes mellitus and history or ECG evidence of myocardial infarction are also very important. The simplest approach to estimating the likelihood of severe disease was published by Hubbard *et al*.[14] They assigned one point each for: male gender; typical angina; history and ECG evidence of myocardial infarction; diabetes; and insulin use. Thus, the point score had a minimum value of 0 and a maximum value of 5. Figure 2.2 shows a nomogram for the probability of severe CAD based on age and this point score. It is quickly apparent that age is an extremely important parameter for predicting severe disease.

A more comprehensive analysis on a larger number of patients was published from the Duke University Medical Center databank.[15] In addition to the five parameters already mentioned, these workers found that the duration of chest pain symptoms, other risk factors (blood pressure, hyperlipidemia, and smoking), a carotid bruit, and chest pain frequency were also important determinants of the likelihood of severe CAD. However, the magnitude of their additional effect was modest.

Prediction of patient outcome

The ability of clinical assessment to predict patient outcome has been demonstrated in numerous previous studies. The largest and most important of these came from the Duke
Figure 2.2 Nomogram showing the probability of severe (three-vessel or left main) coronary artery disease based on a five-point score. One point is awarded for each of the following variables – male gender, typical angina, history, and electrocardiographic evidence of MI, diabetes, and use of insulin. Each curve shows the probability of severe coronary disease as a function of age. (From Hubbard *et al*,[14] with permission.)

University databank[16] and the Coronary Artery Surgical Study Registry.[17] Many of the same parameters that predict the presence of disease and the presence of severe disease are also associated with adverse patient outcome. Age, gender, chest pain description, and previous myocardial infarction all have independent value in predicting patient outcome. In addition, history and physical examination evidence for congestive heart failure, history and physical examination evidence of vascular disease, unstable chest pain characteristics, and other ECG findings, such as ST and T-wave changes, left bundle branch block, and intra-ventricular conduction delay, all have prognostic value. It is not generally appreciated how well clinical parameters perform in this regard. The Duke group reported that 37% of the patients undergoing stress testing at their institution had a predicted average annual mortality of 1% or less over the next three years, on the basis of clinical assessment.[17]

Several studies have shown that a normal resting ECG, and the absence of a history of prior infarction, predict a normal ejection fraction with 90% confidence,[18,19] and therefore a favorable prognosis.[20–22]

Approaches to the assessment of incremental value

Once the information available from clinical assessment (and other tests already performed) has been considered, there are a variety of conceptual and statistical approaches that can be employed to assess the incremental value of the test in question. This section will present examples of three such approaches.

Diagnosis of CAD

The application of multiple different stress tests for the diagnosis of coronary artery disease has been extensively studied. The most common approach used in this setting to demonstrate the incremental value of a new test employs Bayes' theorem.[23] This theorem indicates that the likelihood of disease following testing (post-test probability) can be calculated from the test characteristics (sensitivity and specificity) and the pretest probability. This calculated post-test probability is often plotted graphically as a function of pretest probability (Fig. 2.3).

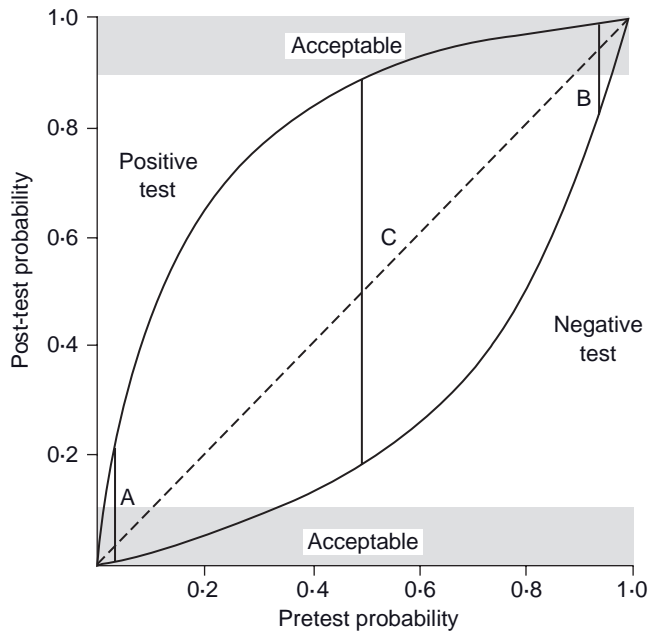
In Figure 2.3, the pretest probability is shown on the *x*-axis and the post-test probability is shown on the *y*-axis. The dotted line represents the line of identity. The vertical distance from this line to the upper solid curve represents the increase in the probability of disease as a result of a positive test. In analogous fashion, the vertical distance from this dotted line to the lower solid curve represents the decrease in probability as a result of a negative test. The solid vertical lines describe three different clinical situations.


Figure 2.3 Relationship between pretest probability and post-test probability. The solid curves for positive and negative tests are plotted for a test with 80% sensitivity and a 90% specificity. Post-test probabilities that are acceptable for diagnosis (90% and 10%) are shown in the shaded zones. Line A represents a patient with a very low pretest probability; line B, a patient with a high pretest probability; line C, a patient with an intermediate probability. (Modified from Berman DS, Garcia EV, Maddahi J. Thallium-201 scintigraphy in the detection and evaluation of coronary artery disease. In: Berman DS, Mason DT, eds. *Clinical Nuclear Cardiology*. New York: Grune and Stratton, 1981, with permission.)

Line A represents a patient with a very low pretest probability, such as a 40-year-old woman with non-anginal pain. A negative test changes probability very little. A positive test increases probability somewhat, but the post-test probability remains well under 50%, and the test is most likely a "false positive".

Line B represents a patient with a high pretest probability of disease, such as a 65-year-old man with typical angina. A positive test will increase the probability only slightly. A negative test will decrease the probability of disease somewhat, but the post-test probability remains substantially greater than 50%, so that the test is most likely a "false negative".

The final situation (line C) represents a patient with an intermediate probability of disease, such as a 50-year-old male with atypical angina. A positive test in such a patient would increase the probability of disease substantially to near 90%. On the other hand, a negative test would decrease the probability of disease substantially to approximately 18%.

Thus, it is evident that the incremental value of diagnostic testing is greater in patients with an intermediate probability of disease, a principle that is broadly recognized.[23] However, it is also recognized that this kind of analysis has

a number of limitations. The single curves for positive and negative tests do not take into account the degree of test abnormality. The test results are therefore better displayed for a whole range of values for a parameter that helps distinguish normal from abnormal. The best known example of this would be the magnitude of ST segment depression on treadmill exercise testing.[24] In addition, multiple other parameters are reported during a treadmill exercise test, which help to distinguish severely abnormal tests from only mildly abnormal tests.[25] Ideally, all of these parameters would be incorporated into a single "score" and a series of curves would be plotted.

Next, construction of such curves relies on the premise that the sensitivity of tests will be identical for any population of patients with disease regardless of disease prevalence. This assumption is usually invalid. As demonstrated in the previous section, those parameters which help to identify the presence of disease also help to identify the presence of severe disease. In general, the sensitivity of most tests is greater in patients with more severe disease. It is therefore quickly evident that sensitivity would be expected to vary with the prevalence of disease. This point has been demonstrated by several investigators[26] and provides justification for the use of logistic regression analysis for diagnostic purposes.[27] Despite these limitations, Bayesian analysis serves as a useful framework for understanding the potential incremental value of diagnostic tests.

Post-test referral bias, also known as work-up bias or verification bias, occurs whenever the results of the test in question influence the subsequent performance of the "reference" test (sometimes referred to as the "gold standard"). This bias has been recognized for more than 20 years.[28] An early survey of the literature on exercise testing showed that only two of 33 studies avoided this bias.[29] The recognition of the importance of this phenomenon was emphasized in a landmark paper in 1983, which described the "declining specificity" of radionuclide angiography as a result of this bias.[30] Almost 20 years ago, a monograph from the Institute of Medicine emphasized this well-established concept.[31] The key question to ascertain whether postreferral bias is present is "did the results of the test being evaluated influence the decision to perform reference standard?".[32]

Although this bias potentially occurs for any diagnostic test, it is particularly important for non-invasive diagnostic tests for CAD. Patients with positive non-invasive tests are often referred to coronary angiography (the "reference" test). In contrast, patients with negative tests are often sent home without coronary angiography. The effects of this preferential referral to coronary angiography are to markedly decrease the observed specificity of the test in question and modestly increase its sensitivity.

The clearest solution to the problem of post-test referral bias is to avoid it completely by studying patients in whom the decision to proceed with the "reference" test is made

before the performance of the diagnostic test in question.[31] For the diagnosis of CAD, this standard is incredibly difficult and rarely achieved. A more feasible alternative is the mathematical correction of sensitivity and specificity for post-test referral bias using one of two published formulae and information about all of the patients who were studied using the diagnostic test in question and did not proceed with coronary angiography.[33,34] There are a number of published studies demonstrating the effect of these corrections on the observed test performance for exercise electrocardiographic testing,[35] exercise echocardiography,[36] and exercise single photon computed tomography (SPECT) perfusion imaging.[37] Correction for referral bias markedly increases the specificity and modestly decreases the sensitivity of these tests. As a result, the predictive value of a positive test is improved, but the predictive value of a negative test decreases. It is generally difficult to confirm the validity of these corrections. However, a carefully designed prospective study of exercise echocardiography in women performed as part of the WISE study reported sensitivity and specificity values that were very close to those reported after correction for referral bias.[38]

Post-test referral bias has numerous important implications for the interpretation of the diagnostic literature.[38] Many of the reported sensitivity and specificity values are very likely to be erroneous.[38] Widespread misconceptions exist regarding gender differences in test performance. The post-test probability of CAD is higher for either a positive or negative test than that which would be calculated from Bayes' theorem using the reported values of sensitivity and specificity.[37]

Non-invasive screening for severe CAD

The incremental value of testing for the diagnosis of severe CAD has been studied using both Bayesian analysis and logistic regression analysis. When the latter analysis is conducted properly, all the previously discussed clinical parameters that are associated with severe coronary disease are incorporated into a model that is used to predict the probability of severe CAD. The output of such a model is a probability that ranges between 0 and 1. It is critically important that these candidate variables be "forced" into the model, even if they are statistically insignificant in the population under study. Most study populations are too small to have adequate power to detect the true significance of these variables, which has been demonstrated in very large subsets. For example, age should always be forced into such models, even if it does not appear to be significant in the particular population in question, because there is abundant evidence that it should always be considered (and indeed usually is by clinicians).

Using this approach, a second model should then be constructed which includes all the clinical parameters, as well

as pertinent new parameters from the test in question. If these parameters have statistical significance independent of the clinical parameters, the test has incremental value. This approach is demonstrated in Table 2.2, which shows the improvement in the logistic regression model for severe CAD reported by Christian *et al*,[22] when the exercise test was added to clinical parameters, and when thallium imaging parameters were added to clinical and exercise parameters. Note that age and sex are both included in the clinical and exercise model (as well as the clinical, exercise and thallium-201 model). Magnitude of ST depression and (peak heart rate times peak systolic blood pressure) both added significantly to the clinical variables in the clinical and exercise model. An alternative approach is to construct the receiver operating characteristic (ROC) curves, which display sensitivity and specificity as a function of the predicted probability of severe disease (the output of a logistic regression model). The area under the ROC curve can then be compared between the model that incorporates clinical parameters and the model that incorporates clinical parameters and the new test parameters. Methods are available for determining the statistical significance of changes in the area under these two ROC curves.[39] An example of this approach is shown in Figure 2.4, taken from Christian *et al*.[22] The clinical significance of these differences in the models (assessed by either x^2 analysis or ROC curves) is discussed later.

Prediction of patient outcome

The demonstration of incremental prognostic value for diagnostic tests is obviously extremely important for clinical decision making. It requires strict adherence to the rigorous standards that were outlined previously. In general, very few of the published studies demonstrating prognostic value of diagnostic tests meet the strict criteria necessary to demonstrate *incremental* prognostic value for these tests. The statistical model most often used for this purpose is a linear proportional hazards, or Cox, model.[40] When strictly applied, all the previous information available to the clinician, from either clinical assessment or previous testing, should be incorporated into a linear proportional hazards model that predicts time to an event. Once again, parameters that have been clearly demonstrated in larger populations to be significant must be "forced" into such models to make sure that their contribution is not neglected. The events in question should preferably be hard endpoints such as death and myocardial infarction. As previously mentioned, unstable angina and the need for revascularization are alternative endpoints that are often included to enhance statistical power, but these have major limitations.

One of the earliest examples of a rigorously constructed analysis demonstrating incremental prognostic value of cardiac imaging was published by Pollock *et al*.[41] They tested the association between various combinations of

Table 2.2 Logistic regression multivariate analysis: prediction of three-vessel or left main (coronary artery) disease

Model	Direction	Odds ratio (95% CI)	P value
Clinical			
Diabetes mellitus	Present	2.0 (1.3–3.1)	0.001

variables and time to death or myocardial infarction, in a linear proportional hazards model using the x^2 statistic. Clinical and exercise variables were significantly better than clinical variables alone. Similarly, a model that added thallium redistribution to clinical and exercise variables was significantly better than the combination of clinical and exercise variables.

A subsequent rigorous analysis was reported by Christian et al[22] in patients with a normal resting electrocardiogram. Using a similar approach, these investigators reported that a model adding thallium variables to clinical and exercise variables did not add significantly to the model using clinical and exercise variables. In contrast, Kwok et al[42] performed a similar analysis on patients with non-specific ST-T abnormalities on their resting ECG. Exercise thallium variables added significantly to clinical and exercise variables in predicting patient outcome. The findings of Kwok et al may explain the positive findings reported by Pollock et al, as Pollock et al included many patients with abnormal resting ECGs in their study.

Pollock et al, Christian et al, and Kwok et al studied patients who were symptomatic with chest pain, and developed clinical models incorporating symptoms for their specific populations. In contrast, studies of asymptomatic populations should preferably use the Framingham risk score as a beginning clinical model, since it was developed and validated over decades in a population-based study.

Novel biomarkers such as high-sensitive C-reactive protein and brain natriuretic peptide identify asymptomatic individuals who are at increased risk for adverse outcomes such as death and myocardial infarction. However, when they were carefully assessed for their incremental value compared to the Framingham risk score, they added little (Fig. 2.5)[43] as measured by the concordance statistic.

In contrast, severe coronary calcification by computed tomographic (CT) scanning appears to add significantly to the Framingham risk score (Fig. 2.6), as reported by Greenland et al.[44] In particular, CT calcification may help identify

Figure 2.5 Receiver operator characteristic (ROC) curves showing sensitivity and specificity of Framingham risk score without novel biomarkers (dotted curve) and with addition of five novel biomarkers (solid curve) for five-year mortality. Although these curves were statistically different, the C (concordance) statistic increased only modestly from 0.80 to 0.82 with the addition of biomarkers. (From Wang et al,[43] with permission.)

Figure 2.6 Rate of coronary death or non-fatal myocardial infarction (MI) over seven years in asymptomatic patients grouped by their coronary artery calcium score (CACS) and their Framingham risk score (expressed on the predicted rate of death or MI over 10 years). (From Greenland et al,[44] with permission.)

patients with intermediate-risk Framingham scores who merit more intensive risk factor modification, although the ability of such an approach to improve patient outcomes has not yet been demonstrated.

Clinical significance and cost effectiveness

Even when statistically significant incremental value has been demonstrated for a diagnostic test using appropriate rigorous methodology, the clinical significance of the findings must be equally rigorously examined. The two fundamental issues that should be addressed are the actual impact of this incremental value on clinical decision making and, where possible, cost effectiveness. The available published data on diagnostic testing in coronary disease that will be presented here use only rudimentary concepts with respect to decision analysis. Formal cost analysis also requires understanding of a much greater body of published knowledge, which will not be presented here. The elementary examples presented here will only demonstrate the principle.

Diagnosis of CAD

The clinical significance of diagnostic testing can best be understood in terms of decision-making thresholds.[45] From the standpoint of diagnosis, a test will be useful primarily if it moves a significant number of patients from an "uncertain" pretest probability to an "acceptably certain" post-test probability. The exact criteria, or threshold, to be used in these classifications are clearly a matter of judgment; many investigators have chosen post-test probabilities of less than 10% and greater than 90% as criteria for definitive diagnosis.[36] Thus, non-invasive testing will be useful for diagnosis if it moves a reasonable number of patients into the shaded zone shown in Figure 2.3.

Although treadmill testing has clear incremental value for diagnosis, particularly in patients with intermediate pretest probability, as discussed earlier, its ability to move patients across such thresholds of probability appears to be very limited. Goldman et al[46] examined the ability of treadmill exercise variables to classify 329 patients with CAD. Their results are summarized in Table 2.3. The pretest model was very powerful, as it classified 84% of the patients correctly. Table 2.3 shows the number of additional patients classified correctly for given thresholds of probability. For example, if 10% was considered an acceptable threshold to "rule out" CAD, eight of 324 patients were moved across this threshold but only six were moved correctly. Similarly, for a 90% threshold to "rule in" CAD, 53 patients were moved across this threshold but only 33 were moved across

Table 2.3 Effect of treadmill exercise test results in moving patients across various diagnostic thresholds

Threshold probability	Patients moved across (n)	Correctly moved	Incorrectly moved	Net increase in diagnoses (correct/ incorrect)
0.10	8	6	2	4
0.90	53	33	20	13
Either 0.10 or 0.90	61	39	22	17 (5%)

Figure 2.7 Percentage of patients classified with a given probability of coronary disease before and after exercise radionuclide angiography. The prospective study group of 76 patients excluded males of 40 years or older with typical angina. (From Gibbons et al,[47] with permission.)

Figure 2.8 Correct (C), incorrect (I), and uncertain (U) classification of patients with three-vessel or left main coronary artery disease by the use of logistic regression multivariate models. Low, intermediate, and high probability defined using: clinical variables only; clinical and exercise variables; clinical, exercise, and thallium-201 variables. (From Christian et al,[22] with permission.)

correctly. As a result, the net total number of patients who were correctly moved into the diagnostic zone in Figure 2.3 was only 17, or 5% of the patient population. Thus, the clinical significance of the incremental value provided by the treadmill test appears to be very limited.

Similar rigorous analyses have been published for radionuclide angiography.[47] The results of one of these are displayed in Figure 2.7. The study group excluded men with typical angina over the age of 40 in order to eliminate most patients with a high pretest probability. Logistic regression models developed on a retrospective population were applied prospectively to a group of 76 patients. As demonstrated in Figure 2.7, eight (11%) of the 76 patients could be classified with 90% certainty on the basis of clinical variables alone. Following radionuclide angiography, 24 patients (32%) could be classified directly. Thus, the incremental value of exercise radionuclide angiography in moving patients across clinically meaningful decision thresholds appeared to be much greater than for the treadmill exercise test, as 21% of the patients were correctly classified by the radionuclide angiogram.

Similar findings have been reported for planar thallium imaging.[48,49] Unfortunately, no rigorous analyses are available for SPECT imaging using either thallium or sestamibi or both, primarily because post-test selection bias has greatly limited the feasibility of such studies in the current era.

Non-invasive screening for severe CAD

The same threshold approach has been applied to the non-invasive identification of severe CAD. Here the ability of tests to move patients across somewhat different thresholds of probability, as assessed by logistic regression models, has been tested. Christian et al[22] defined a low-probability group for severe CAD as <0.15, a high-risk group as >0.35, and an intermediate group as 0.15–0.35. These thresholds were chosen to correspond to earlier work from Duke University reporting on the utility of the early positive treadmill test.[50] Figure 2.8 shows the results that were obtained using this approach. Using clinical parameters alone, 189 patients (46% of the study group) were correctly classified as low or high probability. Thirty-seven patients (9%) were incorrectly classified as low or high probability. The remaining 185 patients (45% of the study group) had an intermediate probability, and were therefore in an uncertain category. The addition of exercise parameters correctly classified an additional 37 patients at the expense of 13 additional incorrect classifications, for a net of 24 additional correct classifications (6% of the study group). The addition of thallium parameters led to 12 additional correct classifications and two fewer incorrect classifications, for a net increase of 14 correct classifications (3% of the study group). These workers then used Medicare reimbursement figures to calculate the cost per additional

correct classification. For exercise testing, the cost per additional correct patient classification was $1524. For thallium scintigraphy, the cost was $20 550 per additional correct classification.

Thus, this analysis demonstrated that the clinical impact was modest, and the cost was high, when thallium imaging was used in patients with a normal resting ECG to try to identify patients with severe CAD non-invasively. Although thallium scintigraphy clearly had statistically significant incremental value, it did not appear to be cost effective for this purpose.

Prediction of patient outcome

The issues of clinical significance and cost effectiveness are particularly pertinent to the application of diagnostic tests for the prediction of the patient outcome. These applications often involve relatively low-risk patient groups with few subsequent events. Tests applied to the entire population may identify a subset of patients who are at considerably increased risk compared to the remainder of the population.[51,52] These results will be highly statistically significant and generate very impressive P values and risk ratios. However, it must be recognized that the absolute rate of events often remains quite low in the patient subset at "increased" risk. Furthermore, the cost of this identification is often prohibitive when viewed on a per event or per patient basis.

This concept was nicely demonstrated in a study by Berman *et al*[53] on symptomatic patients with a low clinical likelihood of CAD studied by SPECT sestamibi. During 20 months of follow-up, only patients with an abnormal sestamibi study suffered death or myocardial infarction. This difference was statistically highly significant ($P = 0.007$). However, this increment in prognostic value was clearly not cost effective, as noted by the authors. Although the cost analysis by the authors was quite detailed, the cost ineffectiveness of this approach is readily apparent with very simple analysis. The 107 patients in the abnormal group suffered only three events during 20 months of follow-up. In order to identify the abnormal group, testing was required in 548 patients. Using a Medicare reimbursement figure of $700 per test,[22] more than $383 000 of testing would be required to identify the abnormal cohort. The cost of testing alone would therefore exceed $127 000 per possible event prevented. This simple analysis ignores the additional costs that would accrue from the subsequent cardiac catheterizations and coronary revascularizations that would be necessary in the high-risk group in order to attempt to prevent the three events. (There is obviously no certainty that the three events could actually be prevented by revascularization.)

Attempts to screen asymptomatic individuals to prevent subsequent CAD events are well intentioned but have similar limitations. "Targeting" individuals at "greater" risk will improve but not eliminate the problem. For example, Greenland *et al* demonstrated the incremental prognostic value of CT calcification in asymptomatic individuals with intermediate-risk Framingham scores.[44] However, they had to test 640 individuals to identify a subset of 118 with a calcium score of >300, who suffered 16 cardiac events (including an estimated 3 deaths) over seven *years* of follow-up. At $250 per CT scan, the cost of testing alone (without cardiac catheterization or revascularization) would exceed $10,000 per possible event prevented, and $50,000 per possible death prevented.

As a general principle, it should be recognized that non-invasive testing for the assessment of prognosis is far less cost effective in subsets of patients at intrinsically low risk.

Conclusion

Clinicians should recognize that an evidence-based approach to the evaluation of the incremental value of diagnostic tests is not simple or straightforward. Unfortunately, it is far easier for both clinicians and investigators to use simple, less rigorous, approaches that appear to demonstrate important incremental value for each new diagnostic test. Although convenient, such approaches lead to incorrect conclusions and generally overestimate the added value of each new testing modality. The examples presented in this chapter should provide a framework for thinking clinicians to more carefully evaluate new publications on new diagnostic tests. However difficult these analyses may be, and however disappointing the results, the escalating costs of healthcare demand an approach of rigorous methodology and thoughtful analysis to make certain that the *incremental* value of a diagnostic test is not only statistically significant, but clinically significant and cost effective.

Clinical trials and meta-analysis

Jonathan R Emberson and Colin Baigent
Clinical Trial Service Unit, Oxford, UK

Introduction

Although large effects on survival arising from certain treatments may occasionally be obvious from simple observation (as, for example, when cardioversion for ventricular fibrillation avoids otherwise certain death), the vast majority of interventions have only moderate effects on major outcomes and hence are impossible to evaluate without careful study. Unfortunately, enthusiasm for the biologic foundations of a particular therapeutic approach often leads to exaggerated hopes for the effects of treatment on major clinical outcomes. These hopes may be based on dramatic laboratory measures of efficacy or on the types of surrogate outcome that are commonly studied before drugs go into Phase III or IV studies; for example, a drug may almost completely prevent experimental ischemia progressing to infarction or practically abolish experimental thrombosis. However, these large effects on surrogate endpoints very rarely translate into large effects on major clinical outcomes; the overwhelming message from over three decades of clinical trials in cardiology is that the net effects of most treatments are typically moderate in size. This chapter explains why large-scale randomized evidence, either in a single "mega-trial" or in a meta-analysis of similar trials, is generally an absolute requirement if such moderate effects on major outcomes are to be characterized reliably.

It is important to appreciate that progress in cardiologic practice, and in the prevention of cardiovascular disease, has been and remains dependent on the availability of large-scale randomized trials and of appropriately large-scale meta-analyses of such trials. In the management and prevention of acute myocardial infarction (MI), for example, these methods have helped to demonstrate that fibrinolytic

therapy,[1–4] aspirin,[2,4,5] blood pressure-lowering treatments,[6] and statins[7,8] all produce net benefits which, although individually moderate in size, have together produced a substantial improvement in the prognosis of acute MI. Similarly, the demonstration that angiotensin-converting enzyme (ACE) inhibitors and beta-blockers produce moderate reductions in the risk of death, cardiovascular disease and rates of hospitalization for worsening heart failure[9,10] has improved the outcome of patients with chronic heart failure.

Clinical trials: minimizing biases and random errors

Any clinical study whose main objective is to assess moderate treatment effects must ensure that any biases and any random errors that are inherent in its design are both substantially smaller than the effect to be measured.[11] Biases in the assessment of treatment can be produced by differences between randomized arms in factors other than the treatment under consideration. Observational (that is, non-randomized) studies, in which the outcome is compared between individuals who received the treatment of interest and those who did not, can be subject to large biases.[12] Avoidance of biases can only be guaranteed by proper randomized allocation of treatment, blinded outcome assessment and appropriate statistical analysis, with no unduly data-dependent emphasis on specific subsets of the overall evidence (Box 3.1).[11,13]

Avoidance of moderate biases

Proper randomization to prevent foreknowledge of treatment allocation

The fundamental reason for random allocation of treatment in clinical trials is to maximize the likelihood that each type of patient will have been allocated in similar proportions to the different treatment strategies being investigated.[14] A key requirement is that treatment allocation should be con-

cealed at the point of randomization since, if the next treatment allocation can be deduced by those entering patients, decisions about whether to enter a patient may be affected and, as a result, those allocated one treatment might differ systematically from those allocated another.[15] For example, in the Captopril Prevention Project (CAPPP) trial,[16] envelopes containing the antihypertensive treatment allocation could be opened before patients were irreversibly entered into the study. Highly significant differences in pre-entry blood pressure between the treatment groups, which were too large to have been due to chance, may well have been the result of this design weakness.[17] Proper randomization therefore requires that trial procedures are organized in a way that ensures that the decision to enter a patient is made irreversibly and without knowledge of the trial treatment to which a patient will be allocated. Once randomized, it is also generally desirable to "blind" both the patient and their doctor (whenever feasible) to the allocated treatment, for reasons discussed below.

Blinding of treatment allocation and of outcome assessment

While randomization should ensure a valid, i.e. unbiased, assessment of the effectiveness of a study drug, substantial bias can still be introduced if there is the potential for subjective judgment in the reporting, evaluation or data processing of clinical events (particularly when such judgments are made with knowledge, or suspected knowledge, of the treatment allocation) or if patients or their doctors are

themselves aware of the treatment to which they have been randomized (since their subsequent healthcare and health behaviors may differ systematically from the comparison group in a way that influences clinical outcomes). Patients (and their doctors) should therefore be blinded to the randomized treatment wherever possible and, critically, study outcomes should be evaluated by people who are *unaware of the allocated treatment*.

Of course, some drugs may produce characteristic side effects which cannot effectively be hidden from a doctor or, indeed, from a well-informed patient. In some types of trials it may be impossible to blind a patient to the treatment received (e.g. surgical intervention trials). Moreover, even when blinding of patients and doctors is theoretically possible, in some circumstances it could act as a barrier to the practical feasibility of the study through the introduction of unnecessary complications and cost (for instance, in a trial where the doses of different study drugs need to be adjusted during the follow-up period). To overcome such problems, PROBE[18] (Prospective Randomized Open-label Blinded Endpoint) study designs are increasingly being employed (e.g. in the Anglo-Scandinavian Cardiac Outcomes Trial (ASCOT)[19] and the Incremental Decrease in Endpoints through Aggressive Lipid lowering (IDEAL) study[20]). The key feature of a PROBE design is that patients are aware of the study medication to which they have been randomized, as are their doctors. (It is important to note that, while patients and their doctors are unblinded to treatment allocation in a PROBE trial, it remains critically important that randomization procedures prevent foreknowledge of the next treatment to be allocated, and that outcome assessors are blinded to study allocation.) A potential for bias exists, however, if knowledge of a patient's study medication results in any differential reporting of study outcomes by study staff or differential use of concomitant drugs. This can be largely mitigated by the use of clearly defined and verifiable outcomes, blinded outcome adjudication and various means of evaluation of all or a random subset of patients to assess whether events have been missed, and whether any "missingness" is differential. The potential advantages of PROBE designs include their reduced cost and their similarity to standard clinical practice. However, it is important that these benefits are not achieved at the expense of moderate biases in estimates of treatment effects.

Intention-to-treat analyses

Even when studies have been properly randomized and blinded, moderate biases can still be introduced by inappropriate analysis or interpretation. This can happen, for example, if patients are excluded after randomization, particularly when the prognosis of the excluded patients in one treatment group differs from that in the other (such as might occur, for example, if non-compliant participants

were excluded after randomization). This point is well illustrated by the Coronary Drug Project,[21] which compared clofibrate versus placebo among around 5000 patients with a history of coronary heart disease. In this study, patients who took at least 80% of their allocated clofibrate ("good compliers") had substantially lower five-year mortality than "poor compliers", who did not (15.0% vs 24.6% respectively; $P = 0.0001$). However, there was a similar difference in outcome between good and poor compliers in the placebo group (15.1% vs 28.3%; $P < 0.00001$), suggesting that good and poor compliers were prognostically different even after allowing for any benefits of actually taking clofibrate.[21] Under the null hypothesis of no treatment effect, the least biased assessment of the treatment effect is that which compares all those allocated to one treatment versus all those allocated to the other (that is, an "intention-to-treat" analysis), irrespective of what treatment they actually received.[22]

Because some degree of non-compliance with allocated treatments may be unavoidable in randomized trials, intention-to-treat analyses will tend to underestimate the effects produced by full compliance. However, "on treatment" (or "per protocol") analyses, which estimate treatment effects through analyses of compliant patients, are potentially biased; it is more appropriate to calculate an "adjustment" based on the level of compliance and then to apply this to the estimate of the treatment effect provided by the intention-to-treat comparison.[23] For example, in a meta-analysis of the randomized trials of prolonged use of antiplatelet therapy among patients with occlusive vascular disease, the average compliance one year after treatment allocation seemed to be around 80%.[24] Application of this estimate of compliance to the proportional reduction of about 30% in non-fatal MI and stroke estimated from intention-to-treat analyses of these trials suggests that full compliance with antiplatelet therapy might produce reductions in risk of about 35–40%.

Inappropriate use and interpretation of subgroup analyses

In the medical literature a particularly important source of bias is unduly data-dependent emphasis on selected trials or on particular subgroups of patients. Such emphasis is often entirely inadvertent, arising from a perfectly reasonable desire to understand the randomized trial results in terms of who to treat, which treatments to prefer or disease mechanisms. However, whatever its origins, selective emphasis on particular parts of the evidence can often lead to seriously misleading conclusions. This is because the identification of categories of patients for whom treatment is particularly effective (or ineffective) requires surprisingly large quantities of data. Even if the real sizes of the treatment effects do vary substantially among subgroups of patients, subgroup analyses are so statistically

insensitive that they may well fail to demonstrate these differences. On the other hand, if the real proportional risk reductions are about the same for everybody, subgroup analyses can vary so widely just by the play of chance that the results in selected subgroups may be exaggerated. Indeed, it can be shown that if an overall treatment effect is conventionally statistically significant at the 5% level (i.e. $P = 0.05$), and patients are randomly split into two equal-sized groups, then there is a 1 in 3 chance that there will be a statistically significant treatment effect in one group and a non-significant effect in the other.[25] Thus, even when significant "interactions" are found, they may be a poor guide to the sizes (and even the directions) of any genuine differences, owing more to chance than to reality.

However, even if true differences in the effect of a treatment do exist between different groups of patients, then under certain circumstances, the overall treatment effect can still provide a better estimator of the effect in any given subgroup than the estimate actually derived from that subgroup (the mathematical theory of James-Stein estimators provides formal mathematical support for this).[26] The logical basis for placing emphasis on overall trial results is that, when there is definite and consistent evidence of benefit (and negligible hazard) in all categories of patients that have been studied extensively (such as for statins in the prevention of major vascular events)[8], then although the relative benefit in another (relatively unstudied) category might not be exactly the same, it is unlikely to be vastly different and, in particular, is extremely unlikely to be zero. Nonetheless, "exploratory" data-derived subgroup analyses are still widely reported in medical journals and at scientific meetings, with potential adverse consequences for medical care.

An example of how subgroup analyses have resulted in inappropriate management of patients is provided by the early trials of aspirin for the secondary prevention of stroke. Here, emphasis on the results in men led to a situation where, for almost 20 years, the US Food and Drug Administration approved the use of aspirin only for men; subsequent evidence shows this to have been a mistake, with aspirin reducing the risk of vascular events among high-risk people by about one quarter irrespective of sex.[24] A further example is provided by the large Italian GISSI-1 trial comparing streptokinase versus control after acute MI. The overall results favored streptokinase but subgroup analyses suggested that streptokinase was beneficial only in patients without prior MI. Fortunately, the GISSI investigators were circumspect about this finding[3] and their caution turned out to have been wise, as a subsequent overview of all the large fibrinolytic trials showed that the proportional benefits were similar, irrespective of a history of MI.[1] Many thousands of patients with a previous history of MI might well have been denied fibrinolytic therapy, however, if the apparent pattern of the results in the GISSI-1 subgroups had been believed.

Avoidance of moderate random errors

Trials may produce false-negative results

Whereas the avoidance of moderate biases requires careful attention to both the randomization process and the analysis and interpretation of the available trial evidence, the avoidance of moderate random errors requires large studies. When making inferences about the likely true effect of a drug based on observations in a clinical trial, there are two types of error that can be made. A type I error occurs if a trial reaches a false-positive result, i.e. when it appears that a beneficial treatment effect has been demonstrated but the drug is actually ineffective. The second, type II, error occurs when a trial achieves a false-negative result, i.e. when the estimated effect of a beneficial treatment fails to reach statistical significance. A critical part of the design of any clinical study is a decision about how small these type I (α) and type II (β) error rates need to be. Together with an estimate of the minimum size of the effect one wishes to detect, these error rates determine the number of events required in a trial. The smaller the desired type I and type II error rates for a trial, the more patients that trial will need to recruit to be able to demonstrate any true treatment effects. Conversely, for a fixed sample size, the "power" (which is the *a priori* probability, $1 - \beta$, of avoiding a false negative) of a trial to detect "meaningful" treatment effects reduces rapidly if the true magnitude of a treatment effect has been overestimated at the design stage. For example, as illustrated in Figure 3.1, in a trial of 10 000 participants in which one-fifth

of the control group has the primary endpoint, the power (at a type I error rate of 1%) to detect a true relative risk reduction of 20% would be excellent (>99%), but the power to detect a true reduction of 10% would be less than 1 in 2.

The power of a trial to identify a true treatment effect is greatly reduced if the true relative risk reduction is smaller than anticipated. However, it is also reduced if the study outcome occurs in a smaller than expected proportion of those randomized. Trials of major outcomes therefore need to accumulate large numbers of primary endpoints before the results can be guaranteed to be statistically (and hence medically) convincing. For example, the early trials of intravenous fibrinolytic therapy for acute myocardial infarction were individually too small to provide reliable evidence about any moderate effects of this treatment on mortality, although several did identify an increased risk of serious bleeding. As a result, fibrinolytic therapy was not used routinely until the GISSI-1[3] and ISIS-2[2] "mega-trials" provided such definite evidence of benefit that treatment patterns changed rapidly.[27] It is worth noting, however, that GISSI-1 and ISIS-2 each included more than 10 000 patients and 1000 deaths but had they only been one-tenth as large, the observed reduction in mortality would not have been conventionally significant and would therefore have had much less influence on medical practice.

When a clinical trial fails to demonstrate a statistically significant difference between two treatment groups, either there is not a true difference or, if there is, the trial was too small to detect it. In some circumstances, however, an appropriate objective may be the demonstration that two or more treatments are equally effective, in which case the statistical framework for the trial analysis is quite different from that required when the aim is to demonstrate treatment differences. The underlying model assumptions in such an "equivalence" study are essentially a reversal of those used in a conventional study design: the null hypothesis, rather than being one of no true difference between treatments, is that a small true difference Δ of size at least δ, say, exists between treatments (i.e. $|\Delta| \geq \delta$ where $\delta > 0$) and the aim is to accumulate evidence against this hypothesis. Hence, if the null hypothesis is rejected, the implication is that $|\Delta| < \delta$, i.e. the effects of each treatment differ by no more than the small amount δ. Similarly, in a non-inferiority trial, where the object is to demonstrate that a new drug is at least as good as an existing one, the null hypothesis would be expressed as $\Delta \leq -\delta$ (assuming that positive values of Δ are taken to mean that the new drug is better than the old one). Rejection of this hypothesis would imply that $\Delta > -\delta$; that is, the new drug has either similar or superior effects to the old one. Appropriate selection of the null hypothesis for a given clinical question plays a critical role not only in determining the sample size needed, but also in dictating how the results should be interpreted. Unfortunately, there are numerous examples

Figure 3.1 Power to detect different relative risk reductions in a trial of 10 000 patients (5000 active vs 5000 control), an outcome rate of 20% in the control group and a type I error rate of 0.01.

of trials that were designed to test for a difference between two drugs, but were subsequently interpreted under a different null hypothesis.

Effect of non-compliance on study power

Even in a situation where a trial is designed to have sufficient statistical power to address its primary hypothesis, study power can quickly be eroded through higher than expected levels of non-compliance. This is because the sample size needed to achieve a given power is inversely proportional to the *square* of the difference, between treatment groups, in the proportions taking study treatment or a non-study equivalent. For example, suppose a trial of 10 000 patients was originally designed so that it had 80% power, at a type I error rate of 5%, to address its primary hypothesis, but that the sample size calculations assumed full compliance among all trial participants. Then suppose that during the trial 20% of those allocated active treatment stop taking it ("drop outs") and 10% of those allocated control start taking the active treatment, or non-study equivalent, instead ("drop ins"). In these circumstances, the actual sample size that would have been needed to maintain study power is 20 000 patients (since $10\,000/[1 - 0.2 - 0.1]^2 \approx 20\,000$). It is therefore crucial that strenuous efforts are made to maintain compliance during a trial. In the Clopidogrel in Unstable angina to prevent Recurrent Events (CURE) trial,[28] for instance, many patients having a percutaneous coronary intervention were treated with open-label clopidogrel during the procedure and so discontinued allocated treatment; these patients were encouraged to restart afterwards in order to maximize the likelihood of the trial reaching a clear result for its primary outcome of cardiovascular death, non-fatal myocardial infarction or stroke.

Need for large-scale randomized trials

If the aim is to detect a moderate difference in a major clinical outcome then randomization is essential to avoid moderate biases and large numbers of events are required to avoid moderate random errors. The only study design that can be guaranteed to detect such differences, therefore, is a large-scale randomized trial. Trials of the effects of treatments on major outcomes can only be made large if they are kept as simple as possible. In particular, as many as possible of the main barriers to rapid recruitment need to be removed. An important way in which trial design can facilitate this is to limit the amount of information that is recorded. For example, data recorded at baseline can often be restricted to important clinical details, including at most only a few major prognostic factors and only a few variables that are thought likely to influence substantially the benefits or hazards of treatment. Similarly, the information recorded at follow-up need not be extensive and can be limited to those major outcomes that such studies have been designed to assess, and to approximate measures of compliance.

(Other outcomes that are of interest but which do not need to be studied on such a large scale may be best assessed in separate smaller studies or in subsets of these large studies when this is practicable.) Likewise, complicated eligibility criteria and inappropriately detailed consent procedures,[29] both of which consume time and resources unnecessarily, can prevent the recruitment of large numbers of patients. Furthermore, if trials are complex they are likely to involve a high cost per patient, which again tends to limit their size. Either way, complexity is rarely a virtue in trials designed to assess major outcomes, whereas simplicity can sometimes lead to the rapid randomization of very large numbers of patients, and to results that change clinical practice within very short periods of time.[2,27]

Large-scale randomized trials are costly, but their value for money can be greatly enhanced by randomizing patients twice or more to different types of treatments. Such "factorial designs" can assess more than one study hypothesis at little additional cost, and there are numerous examples illustrating the efficiency of this design for improving clinical care. For instance, in the MRC/BHF Heart Protection Study, 20 536 patients at high risk of vascular disease were randomized both to daily simvastatin or matching placebo and to antioxidant therapy or matching placebo (so that one-quarter of the patients received both simvastatin and antioxidant therapy, one quarter received simvastatin only, one quarter received antioxidant therapy only, and one-quarter received neither).[7,30] This "2 × 2" factorial design allowed the Heart Protection Study to assess the separate effects of simvastatin and antioxidant therapy on the risk of death from any cause (with each comparison involving about 10 000 patients allocated to active drug versus 10 000 allocated placebo). Factorial designs also provide the ideal setting for testing whether the size of the effect of one treatment depends on whether another is given (i.e. whether there are any "interactions" between treatments), though surprisingly large numbers of patients are needed for this purpose. A common concern over the use of factorial designs is the potential for adverse drug interactions, potentially affecting patient safety, compliance or study power. However, a review of factorial trials published between 2000 and 2002 found that treatment interactions were rare – in only two out of 31 tests for interaction (from 26 trials) were "significant" interactions detected.[31]

The "uncertainty principle"

For ethical reasons, randomization is appropriate if, and only if, both the doctor and the patient feel substantially uncertain as to which trial treatment is best. The "uncertainty principle" maximizes the potential for recruitment within this ethical constraint (see Box 3.2). In addition, if many hospitals are collaborating in a trial then wholehearted use of the uncertainty principle encourages clinically appropriate heterogeneity in the resulting trial

BOX 3.2 The uncertainty principle

A patient can be entered if, and only if, the responsible physician is substantially uncertain as to which of the trial treatments would be most appropriate for that particular patient. A patient should not be entered if the responsible physician or the patient is, for any medical or non-medical reason, reasonably certain that one of the treatments that might be allocated would be inappropriate for this particular individual (in comparison either with no treatment or with some other treatment that could be offered to the patient in or outside the trial).[32]

population which, in large trials, may add substantially to the practical value of the results. Among the early trials of fibrinolytic therapy, for example, most of the studies had restrictive entry criteria that precluded the randomization of elderly patients, and so those trials contributed nothing of direct relevance to the important clinical question of whether treatment was useful in older patients. Other trials that did not impose an upper age limit, however, did include some elderly patients and were therefore able to show that age alone is not a contraindication to fibrinolytic therapy.[1]

Thus, homogeneity of those randomized may be a serious defect in clinical trial design, whereas heterogeneity may be a scientific strength; after all, trials do need to be relevant to a very heterogeneous collection of future patients. Therefore, adoption of the "uncertainty principle" not only ensures ethicality and clinically useful heterogeneity, but is also easily understood and remembered by busy collaborating clinicians, thereby helping to encourage the randomization of large numbers of patients.

Interim analyses, stopping rules and the DMC

Trials can only be made large if they have proper oversight. Trial management committees, trial steering committees and data monitoring committees all have important roles to play in the successful running of a large trial. For instance, if sufficient evidence accumulates during a trial that one treatment is clearly better than the other, and that the results would be expected to have a substantial impact on clinical practice, the trial may need to be stopped or modified. Such oversight is typically the responsibility of the trial's Data Monitoring Committee (DMC; also sometimes called the Data and Safety Monitoring Board – DSMB), upon review of unblinded "interim" analyses. The DMC balances the welfare of the patients in the trial against the welfare of future patients, whose care may be affected by the results of the trial. If a trial is stopped early, the estimate of the treatment effect will be less precise and, as a consequence, might fail to have a major influence on future clinical practice. (On average, it will also be biased, overestimating the effect of treatment that would have been observed had the trial been allowed to run its course.[33])

Hence, a key question that the DMC should consider prior to recommending the termination of a trial is whether the current evidence is likely to lead to a material change in clinical practice. If the answer is no, then sufficient uncertainty probably remains for the trial to be allowed to continue. However, as the number of planned interim analyses increases, so does the overall type I error rate. If, for example, one employs the conventional $p < 0.05$ "threshold" value at which to reject the null hypothesis, the actual false-positive rate is 8% for two analyses (i.e. one interim analysis and one final analysis), almost 15% for five analyses and nearly 20% for 10 analyses.[34]

Various "stopping rules" have therefore been proposed to help maintain the overall type I error rate of a trial when multiple interim analyses are planned.[35] The O'Brien–Fleming rule, for instance, increases the stringency of the nominal significance level for rejecting the null hypothesis at each interim analysis, thereby offering an opportunity for early termination only when initial results are extreme, while essentially maintaining the type I error rate of the predetermined final analysis.[36] Similarly, an approach proposed by Haybittle[37], and later supported by Peto *et al*[22], recommends termination of a trial at an interim analysis only if the evidence against the null hypothesis is very strong (e.g. $P < 0.001$), so that the overall type I error rate after the final analysis (should the trial continue that far) is essentially unaffected.

Large-scale meta-analysis

Because meta-analyses are appearing in medical journals with increasing frequency it is useful to be able to judge the reliability of such reviews and, in particular, the extent to which confounding, biases or random errors could lead to misleading conclusions. (In randomized trials, "confounding" exists when a comparison of a treatment with a control group involves the routine co-administration in one group, but not the other, of another intervention that might affect the outcome.) To avoid any possibility of confounding, and to avoid any uncertainty about which trials to consider, meta-analyses should generally include only unconfounded properly randomized trials. The main problems that then remain are those of biases and random errors.

Small-scale meta-analyses may be unreliable

Two types of bias could affect the reliability of a meta-analysis: those that occur within individual trials and those that relate to the selection of trials. More empirical research into the numerous biases that can occur within randomized trials would be valuable. However, it is clear from existing studies that, for example, inadequate concealment of treatment allocation and inadequate blinding do quite often result in exaggerated estimates of treatment effect,[38,39] and

that the inappropriate postrandomization exclusion of particular patients is common.[40] Including such trials in a meta-analysis would most likely manifest as an increase in heterogeneity of treatment effect between the studies (possibly in addition to a systematic bias). Such "methodological" defects can have unpredictable consequences for a particular trial, however, and no generalization about the size, or even direction, of the resultant bias is possible.

Publication bias

A particular problem in performing a meta-analysis involves the process of identifying all relevant trials. Unfortunately, the subset of trials that is eventually published (and hence which is conventionally available) is often a biased sample of the trials that have been done. Trials are more likely to be submitted for publication if their results are strikingly positive than if they are negative or null.[41–44] Such "publication bias" can, along with other sources of bias, produce surprisingly impressive-looking evidence of effectiveness for treatments that are actually useless.[45] The particular circumstances in which publication bias has contributed to producing misleading estimates of treatment are difficult to identify, and it is still more difficult to generalize about the exact size of any bias when it does occur. The problem with incomplete ascertainment is likely to be particularly acute within small meta-analyses that contain no more than a few hundred major outcomes and which consist mainly of small published trials. This is because results from trials with only a limited number of endpoints are subject to large random errors, and such trials are therefore particularly likely to generate implausibly large effect estimates. If publication bias then results in emphasis on the more promising of these small trial results, the remaining summary odds ratios are likely to be unreliable.[46]

One example where publication bias might have influenced interpretation of treatment effects is in the trials of magnesium among people who have had a myocardial infarction (Fig. 3.2). In the early 1990s there was considerable optimism that infusions of magnesium might limit the damage arising from blockage of the coronary artery. Eight small trials,[47–54] including a total of only about 1500 patients, had in aggregate found a statistically significant, but implausibly large, benefit (42/754 deaths among those allocated magnesium versus 86/740 among the controls, $2P < 0.001$), leading some to argue that magnesium should be widely used without the need for further randomized evidence. Nevertheless, two subsequent trials, one (LIMIT-2)[55] involving 2300 patients and the other (ISIS-4)[56] involving 58 000 patients, were set up to assess the possible effects of magnesium much more reliably. The first, published in 1992, yielded a moderately promising reduction in mortality risk of about one quarter.[55] However, a few years later, the much larger ISIS-4 trial yielded a completely unpromising result,[56] so that the overall evidence by that time (including four more small trials identified after LIMIT-2)[57–60] based on ~60 000 randomized patients was non-significantly adverse (Fig. 3.2). However, some cardiologists still remained hopeful that magnesium might prove to be effective among specific subgroups, such as older patients who could be treated within a few hours of reperfusion therapy or those not eligible for reperfusion therapy. Accordingly, the MAGIC trial subsequently randomized 6200 such patients to magnesium versus placebo but, in 2002, reported that there was no evidence of any benefit to such patients.[61]

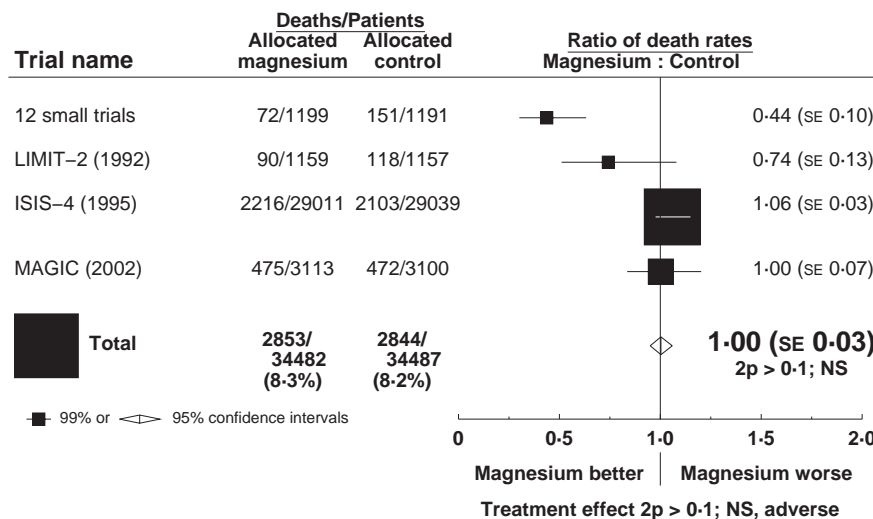
The lesson to be learned here is that, unless the particular circumstances of a small-scale meta-analysis suggest that publication bias is unlikely, it may be best to treat such results as no more than "hypothesis generating". On the


Figure 3.2 Magnesium in acute myocardial infarction: one-month mortality.

other hand, a thoroughly conducted meta-analysis that in aggregate contains sufficient numbers of major outcomes to constitute "large-scale" randomized evidence[1,8,24] is unlikely to be materially affected by publication bias and, provided there are no serious uncontrolled biases (see above) within the individual component trials, is likely to be fairly trustworthy – although, even then, inappropriate subgroup analyses may generate mistaken conclusions. A further lesson to be learned is that in the absence of large-scale randomized evidence, formal statistical tests for publication bias, for instance those based on detecting asymmetry in plots of trial effect size against associated standard errors, can be severely underpowered[62] and therefore misleadingly reassuring. For instance, based on the 12 small magnesium trials prior to LIMIT-2, ISIS-4 and MAGIC, Egger's test for funnel plot asymmetry[63] gives a *P*-value of 0.24 (i.e. no evidence of publication bias). Only when all the trials are considered together does the evidence for publication bias become clear (*P* = 0.0001).

"Fixed-effect" versus "random-effect" methods

Two general approaches exist for combining the results from different trials in a meta-analysis: "fixed-effect" and "random-effect" methods. In a fixed-effect method, a weighted average of the like-with-like comparisons within each trial is calculated (with bigger trials having proportionally more weight than smaller trials). Consequently, the resulting effect estimate is not directly influenced by any heterogeneity among the true effects of treatment in different trials. This terminology is, however, unsatisfactory, for it misleadingly suggests that any heterogeneity between the true effects of treatment in different trials is assumed to be zero, whereas no such unjustified assumptions are involved.[64] A better terminology for the fixed-effect method, therefore, might be "assumption free". Random-effect methods, on the other hand, estimate the heterogeneity in treatment effects across trials and incorporate this variability into the estimate of the overall result. However, this approach relies on the assumption that the different trial designs were randomly selected from some underlying set of possibilities (i.e. it assumes representativeness) which, in most cases, is extremely unlikely to be true. Indeed, in certain circumstances, such "assumed representativeness" methods can lead to small, potentially seriously biased studies gaining an inappropriately large statistical weight at the expense of larger, more reliable studies, which can lead to importantly wrong answers: applied to the 15 separate magnesium trials in Figure 3.2, a standard "random-effects" meta-analysis yields a summary odds ratio of 0.67 (95% CI 0.52–0.85; 2*P* < 0.001), suggesting, quite incorrectly, that magnesium reduces mortality by about one-third.

Use of meta-regression to investigate heterogeneity

It is not uncommon for clinical trials of a particular drug to give rise to somewhat different estimates of treatment effect (indeed, one would expect them to give slightly different estimates because of sampling variation). However, if these differences are substantially larger than would be expected by chance alone (i.e. when there is statistically significant heterogeneity between the trial results), it may be possible to identify reasons for the differences.[65] In particular, "meta-regression" can be used to relate the primary results of each trial to underlying features of the trial population, in the same way that standard regression techniques relate observations made on individuals to potential "explanatory variables".[66] Say, for instance, that the effectiveness of a drug depends on the dose used, the duration of treatment, and the age of the patient, and that all of these factors differed, on average, between a series of reported trials. Essentially, meta-regression would allow one to look at the trial results "adjusted" for these differences, to see if the apparently disparate results can be explained by them, and to allow estimation of any residual heterogeneity.

For example, in the Cholesterol Treatment Trialists' collaboration of 14 randomized controlled trials of statin therapy, the relative reduction in the risk of vascular events in the different trials was found to be linearly related to the LDL cholesterol reduction achieved in the trials (i.e. the difference in mean follow-up LDL cholesterol levels observed between those patients allocated a statin and those allocated placebo).[8] As a consequence, substantial statistical heterogeneity (χ^2 = 37.4 on 13 degrees of freedom, *P* = 0.0004) between the effects on major vascular events in each of the 14 trials was observed (since the trials in which a big lipid difference between the treatment groups was observed tended to find larger proportional reductions in major vascular events than the trials in which smaller lipid differences were observed). However, by standardizing the trial results to correspond to a common 1 mmol/L difference in LDL cholesterol between the two treatment groups, the between-trial statistical heterogeneity was greatly reduced (χ^2 = 10.1, *P* = 0.70) and was no longer statistically significant.[8]

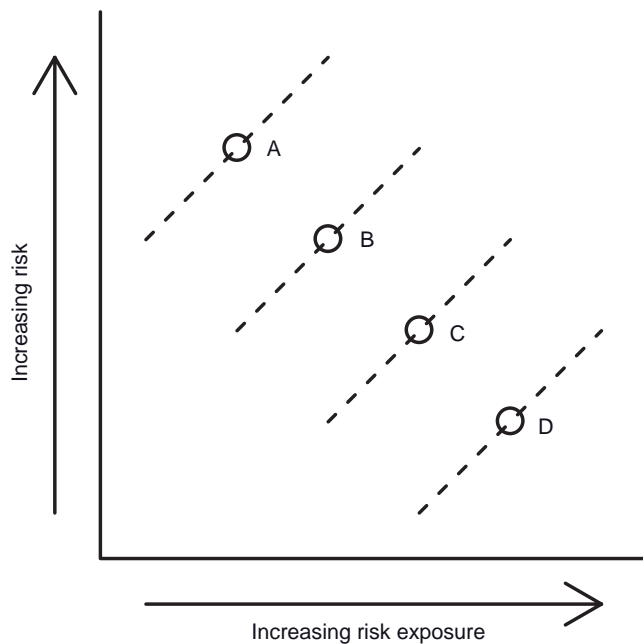
However, it is important to note that while meta-regression techniques can sometimes lead to an improved understanding of the reasons for apparent differences in trial results, they are susceptible to ecologic bias (also known as aggregation bias),[67] which is the bias that can be introduced through examination of associations at the "study" rather than at the "individual" level. Figure 3.3, for example, shows a hypothetic example in which, for each of four different studies A–D, the true relationship between a particular risk exposure and the incidence of disease is positive and linear. However, when average levels of the


Figure 3.3 Hypothetical example of the potential effects of ecologic bias. The circles represent average risk exposure levels and average disease incidence rates observed in four hypothetical studies A–D. At the "study level" (i.e. drawing a line through the four circles) there is a clear inverse association between exposure to the risk factor and disease risk. However, this masks the fact that, within each study, the opposite is observed. The "ecological bias" (which, in this case, must have arisen because of large differences between the studies in at least one important risk factor) has, therefore, totally reversed the direction of the true risk–relationship.

risk exposure for each study are plotted against average disease incidence rates, the relationship is apparently inverse. The cause of this bias would typically be other differences between the studies that importantly modify individual risk (i.e. the bias could be due to confounding). It is therefore important that, when ecologic analyses are performed, estimates are standardized for potential confounders wherever possible. Nonetheless, such statistical adjustments might only be able to partially remove these effects. The only way to guarantee avoiding ecologic bias is to obtain information on individual participants.

Individual patient data meta-analyses

Meta-analyses based on individual patient data (IPD) rather than aggregate patient data (i.e. from summary information presented in publications) are generally thought of as the "gold standard" of meta-analysis.[68] While it may be more costly and time consuming to perform an IPD meta-analysis, it offers several clear advantages. Data can be checked centrally and the quality of the randomization and follow-up procedures assessed. Furthermore, it may be possible to use common definitions and outcomes

in all the studies, and analytical methods can be standardized. In particular, the availability of IPD permits the use of detailed "time-to-event" analyses for estimation of the effects of treatment on patient survival. The collection of detailed information in a really large meta-analysis that includes several thousand major outcomes, such as death[1] or cancer recurrence,[69,70] also makes it feasible to identify particular groups of individuals in whom the benefits or hazards of treatment are especially great. (Where it has been possible to establish co-operation between trialists before any of the trial results are known, having just a few prespecified subgroup hypotheses can provide some protection against unduly data-dependent emphasis on particular results in an IPD meta-analysis.[71]) In some conditions (such as breast cancer[69]) IPD meta-analyses can also be updated over time to take account of continued follow-up of patients beyond "in-trial" treatment periods, allowing for reliable estimation of long-term treatment effects many years after the individual trials have ended. Collaboration with trialists from across the world may also lead to a more global and balanced interpretation of the results.

Can observational studies substitute for large-scale randomized trials/meta-analyses?

As the resources will never be sufficient to allow large, simple trials to address all the questions of clinical interest, there have been suggestions that observational studies might be able to provide reliable estimates of the effects of particular treatments. Non-randomized studies do not necessarily provide inaccurate estimates of the effects of treatments, but the point is that they cannot be *guaranteed* to produce reliable estimates because of biases that are inherent in their design. Even when treated and control groups appear similar in key prognostic factors, non-randomized studies can still give seriously misleading results, leading to over- or underestimations of treatment effects which can be large enough to lead studies to falsely conclude significant findings of benefit or harm.[72] It may well be difficult or impossible to avoid such biases or to adjust for their effects.[73] A review of different statistical methods for adjusting estimated treatment differences in non-randomized studies (e.g. using standardization, regression or propensity score methods) found that adequate correction was only possible when selection depended on a single factor (moreover, in some situations, adjusted results were *more* biased than unadjusted results).[72] When non-randomized studies suggest that certain treatments have surprisingly large effects, such findings are often refuted when those treatments are assessed in large randomized trials.[74] For example, the claims of hazards with digoxin in heart failure,[75] based on non-randomized evidence, were not

confirmed by the very large randomized DIG (Digitalis Investigation Group) trial.[76] Even if non-randomized comparisons happen to get the right answer then nobody will really know that they have done so.

However, there are several scenarios in which a randomized controlled trial may be unnecessary, inappropriate, impossible or inadequate.[77] Rare adverse effects with extreme relative risks can often be recognized reliably by careful clinical observation or by other non-randomized methods, and such relative risks are sometime best quantified in case–control or cohort studies (as for the greatly increased risk of rhabdomyolysis from taking cerivastatin with the fibrate drug gemfibrizol).[78,79] Non-randomized observational studies are also unavoidable when there are substantial ethical or legal obstacles to performing a randomized controlled trial or when the outcome of interest is in the distant future (for example, the long-term consequences of oral contraceptives may not manifest for decades), making it difficult to perform a trial. However, when the primary aim is to assess moderate treatment effects (whether beneficial or adverse) on major outcomes within a reasonable time frame, non-randomized studies are of limited practical value.

Conclusion

Many interventions in cardiology practice produce only moderate effects on major outcomes such as death or serious disability. However, even a moderate effect of treatment, if demonstrated clearly enough for that treatment to be widely adopted, can prevent disabling events or death in substantial numbers of people. Moreover, if, as in the treatment of acute myocardial infarction, more than one moderately effective treatment can eventually be identified, the combination of two or three improvements individually moderate in outcome may collectively result in substantial health gains. In some instances sufficient information is already available from large-scale randomized trials – or, better still, from meta-analyses of those trials – to allow the balance of risk and benefit of particular treatments to be defined for particular patients. But many important questions have still not been answered reliably, and there remains a need for many more large "streamlined" mega-trials, and meta-analyses of such trials, to help resolve some of the outstanding clinical uncertainties in the management of cardiovascular disease.

4 Understanding concepts related to health economics

Mark A Hlatky
Stanford University School of Medicine, Stanford, CA, USA

Introduction

Economics is concerned with how to allocate scarce resources among alternative uses efficiently and effectively. It is a fundamental principle of economics that resources are limited relative to human wants, and that those resources have alternative uses.[1] Consequently, when people say that the cost of healthcare has grown too high, they mean that the quantity of resources flowing toward medical care has grown to the point where additional funds cannot be spent on other things that society values, such as education, public safety, environmental protection, public works, pensions for the retired or disabled, or assistance to the poor. The fact that most people put a very high value on health does not mean that they are willing to provide limitless resources to medical care. Indeed, the goal of improving health and longevity may also be served by non-medical expenditures on programs such as nutritional supplements, a safe and clean water supply, police and fire protection or safety improvements to roads.

The cost of medical care has been rising steadily for the past 40 years in all developed countries[2] but it has only been in the past decade that the level of expenditure has become so large as to cause alarm among policy makers, payers, and the general public (Table 4.1). The steady expansion of healthcare has now begun to meet substantial resistance in the large industrial countries, and new policies and payment mechanisms have been introduced to contain the rising cost of medical care. As a consequence, physicians must now consider cost as they design programs to prevent, diagnose, and treat disease. Cardiovascular diseases consume a large share of healthcare resources (Table 4.2), so cardiovascular specialists must be particularly knowledgeable about health economics.

This chapter will attempt to outline the major principles of health economics relevant to cardiovascular medicine. First, some general concepts of health economics will be presented. Second, methods to identify and compare the costs of cardiovascular interventions will be described. Finally, the principles of cost-effectiveness analysis will be discussed.

General concepts

Various societies have adopted different systems to pay for healthcare and these systems reflect societal values and the historical experience within each country. The United Kingdom has a national health service, Canada has national health insurance, France and Germany have public/private financing for healthcare, and the United States has a perplexing and evolving patchwork of public and private health insurance systems. These are very different systems for financing healthcare and yet each is faced with the same issues of how to allocate the limited resources available to best provide healthcare. Each country is also facing the same steady rise of healthcare costs, despite the wide differences in the ways they finance healthcare.

Provision of cardiovascular services requires resources in all societies, irrespective of the method of financing or delivering healthcare. Coronary bypass surgery, for example, is very resource intensive, requiring cardiac surgeons, a cardiac anesthesiologist or anesthetist, a perfusionist, several nurses, and considerable quantities of specialized supplies and equipment. Postoperative care also requires skilled nurses and physicians, with support from specialized supplies, equipment, and facilities. Each health professional involved in cardiac surgery spends the scarce resource of time to care for the patient – time that could be put to other valuable uses, such as care for other patients. The drugs used, the disposable supplies, the operating room equipment, even the hospital building, all cost money. All of these are true costs to the system, even if the coronary bypass operation is performed "for free" – that is, without

Figure 4.1 General relationship between increasing healthcare resources (horizontal axis) and health outcomes (vertical axis). At point A, outcomes are improving rapidly with increased resources and treatment is cost effective. At point B, outcomes are still improving with increased resources, but at a rate that is not cost effective. At point C, increased resources are no longer improving outcome (that is, "flat of the curve"), and at point D increased resources actually lead to worse outcomes, through iatrogenic complications and overtreatment.

an acute myocardial infarction, for example, survival would be improved as more resources are applied, such as pre-hospital transportation, electrocardiographic monitoring, access to defibrillation, and a competent team to deliver coronary care. Outcomes might be further improved by reperfusion therapy, but with a greater increment in survival from using a cheaper, basic approach (streptokinase, for example) relative to no therapy than from more expensive alternatives (such as tissue plasminogen activator or primary angioplasty). The extra benefit from adding even more aggressive care will be smaller still, and at some point the patient may be harmed by overly aggressive care. Helping physicians to define the optimal point on this curve (Fig. 4.1) is one of the goals of economic analysis.

Determination of costs

The cost of producing a particular healthcare service can be defined in a variety of ways. The cost of performing a coronary angiogram can be used as a specific example that will illustrate the various aspects of cost and how the cost might be measured.

Performing a coronary angiogram requires a variety of resources, including radiographic equipment, trained personnel (including an angiographer and technical assistants), and specialized supplies such as catheters, radiographic contrast, and sterile drapes. The equipment needed is very expensive to purchase and the healthcare facility where it is installed may require special modifications to insure proper radiation shielding and adequate electrical power. The capital cost for a coronary angiography laboratory will be

charge to the patient. The scene in the operating room, the postoperative recovery areas, and the hospital wards is much the same in the United Kingdom, Canada, France, Germany, and the United States despite the different ways in which these societies pay for medical care. The resources used in the care of patients and the increasing sophistication of that care drive healthcare costs up in each of these countries, irrespective of the way in which such care is paid for.

Another basic concept of economics is the so-called "law of diminishing returns". This concept is illustrated in Figure 4.1, in which the quantity of resources used in healthcare is plotted on the horizontal axis and the resulting health benefits on the vertical axis. In the case of the patient with

considerable, perhaps $2–3 million, depending on the type of equipment purchased. The laboratory will have a physical lifespan of perhaps 7–10 years, although technologic innovations may lead to replacement of the equipment before the end of its physical lifespan. The cost of building an angiography suite represents a large *fixed cost* for coronary angiography, a cost that is roughly the same whether the laboratory performs 200 or 2000 angiograms per year. The cost per case is lower in the high-volume laboratory, however, because the fixed equipment costs can be spread over more cases. Thus, if the equipment costs $2.5 million and has a useful life of 10 years, the prorated share of fixed costs for each patient in the low-volume laboratory performing 200 cases per year is:

$$\text{Fixed costs/case} = \frac{\$2\,500\,000}{(200 \text{ cases/yr})(10 \text{ years})} = \$1250/\text{case}$$

whereas in the high-volume laboratory (2000 cases per year) the prorated share of fixed costs per case would be:

$$\text{Fixed costs/case} = \frac{\$2\,500\,000}{(2000 \text{ cases/yr})(10 \text{ years})} = \$125/\text{case}$$

Procedures that have high fixed costs will be performed with greater economic efficiency in centers that have sufficient volume to spread those fixed costs over a larger number of individual patients. (There may be additional advantages to larger procedure volumes as well, since the technical proficiency is higher and clinical outcomes of many procedures are usually better when performed in higher volume clinical centers.[3–5]) Procedures with lower fixed costs will have a smaller effect of volume on costs.

In contrast to the fixed equipment costs, the cost of supplies consumed in performing coronary angiography varies directly with the volume of cases performed, and the supply cost per case will be fairly constant irrespective of the volume of cases performed (apart from the small effect of discounts available to large-volume purchasers). The cost of laboratory staff falls in between these two extremes, in that the hours worked in the catheterization laboratory by technical staff can be varied somewhat according to the volume of cases performed, but some staff effort is required regardless of patient volumes, such as supervisors.

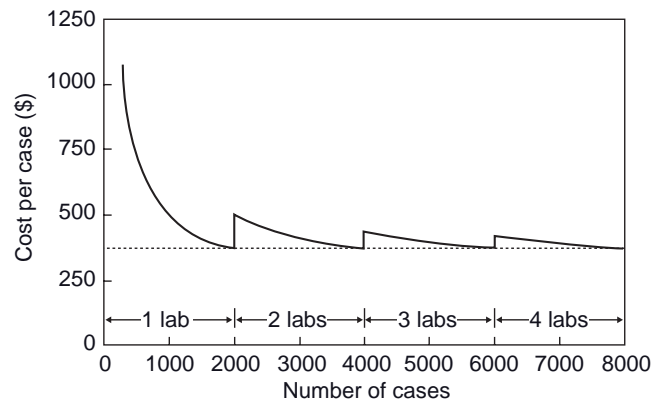
Hospital overhead is also a real cost but one that is less directly linked to any one medical service or procedure. Hospitals must pay for admitting offices, the medical records department, central administration, the laundry service, the cafeteria, housekeeping and utilities, to name just a few areas. These costs cannot be tied easily to the coronary angiography procedure in the same way as the cost of the catheters or radiographic contrast. Most facilities assign a share of these costs to patient care services according to a formula such as the step-down method. Discussion of specific methods to allocate hospital overhead is beyond the scope of this chapter but can be found in several articles and books.[6,7]


Figure 4.2 Cost per case for coronary angiography as a function of clinical volume. Assumes fixed costs per laboratory of $250000 per year, and marginal (that is, variable) costs of $250 per case. When volume reaches 2000 cases per year in a laboratory, the model assumes an additional laboratory will be built. The dotted line indicates the "long run average" cost per case of $375.

The overall effect of procedure volume on the cost per case is illustrated in Figure 4.2. In general, the cost per case declines as more cases are performed, up to the limit of the facility's capacity (for example, 2000 cases). If volume increases further, more facilities must be built, increasing the cost per case, as more fixed costs are spread over a few more patients. Figure 4.2 also illustrates the distinction between concepts of "marginal cost" and long run "average cost". The marginal cost is the added cost of doing one more case. In an already equipped and staffed coronary angiography laboratory, the marginal cost of performing one more procedure is just the cost of the disposable supplies consumed in the case: the catheters, radiographic contrast, and other sterile supplies. In the example of Figure 4.2, the marginal cost is $250 per case. The marginal cost is lower than the average cost per case ($375 per case), which also includes a prorated share of the salaries of the laboratory staff, depreciation of the laboratory equipment costs, and the facility's overhead costs.

It is important to distinguish "cost per case" from "total health system costs". The example above suggests that it is more economically efficient to perform 2000 procedures per year in one center (total cost $750000/year) than it is to perform 500 procedures per year in each of four centers (total cost $1500000/year). Of course, if the four centers each performed 2000 procedures per year instead of 500 procedures, the total cost to the health care system would be higher overall ($3000000/year) even though the cost per case would have been reduced (from $750/case to $375/case).

Estimation of costs

The cost of providing a specific service, such as coronary bypass surgery, can be established in several alternative ways. In principle, one valid way to measure cost would

be to identify a competitive market for medical service, and note the charge (price) for coronary bypass surgery in that market. While competitive market pricing might work well for commodities such as consumer electronic devices or farm products, it is not well suited to medical care, where there are few competitive markets. An alternative method is to take note of the charges for a service and apply correction factors to estimate cost more accurately. A third method to estimate costs is to examine in detail the resources used to provide a service, and apply price weights to the resources used.[8]

Most health economic studies currently use this third method to measure the costs of care. The price weights are taken from standardized reimbursement schedules (for hospital or outpatient services) or average prices (for drugs and supplies) paid in the community. A consistent set of price weights should be used, taking all the prices from the US Medicare system, for instance, or all from the US private insurance market.

International perspectives

With the advent of large multicenter clinical trials that enroll patients from several countries, interest has developed in cost comparisons between countries for the same service. Cost estimation as part of large randomized trials will enhance clinical decision making, as the randomized design is the strongest way to compare all outcomes of therapeutic alternatives, including cost. Extension of cost comparisons across national borders introduces a number of technical and conceptual issues that deserve discussion.

Different countries measure cost in their respective national currencies, so that readers in another country need to convert between units (for example, UK pounds or euros to US dollars). These conversions can be done using currency exchange rates or the closely related purchasing power parity factors. The differences between countries in units of measurement are fairly simple to address.

A more thorny issue in international comparisons is differences in the relative prices of the resources used to provide a service and differences in resource profiles used to provide a service. Thus, if the cost of service j is defined as:

$$Cost_j = \sum (Quantity)_{ij} \times (Price)_{ij}$$

then cost may differ among countries due to differences in the quantity of resources used to provide a service, price differentials for the same resources, or both. A specific example will help illustrate these concepts (Table 4.3). Care of a patient with acute myocardial infarction given thrombolysis includes the cost of the drug, the cost of basic hospital care, and the cost of additional tests and treatments in the convalescent phase. Table 4.3 presents hypothetical

Table 4.3 Effect of differences in medical prices on costs of alternative treatments

	Country 1		Country 2	
	Tx A	Tx B	Tx A	Tx B
Drug ($)	2000	200	1500	150
Nursing hours	50	54	50	54
Nursing wages ($)	30	30	35	35
Total ($)	3500	1820	3250	2040
Cost savings ($)	1680		1210	
Cost ratio B/A	52%	63%		

Tx, treatment

Table 4.4 Effect of differences in resource utilization on costs of alternative treatments

	Country 1		Country 2	
	Tx A	Tx B	Tx A	Tx B
Drug/nursing ($)	3500	1820	3250	2040
Coronary angiography	40%	60%	10%	15%
Angio cost ($)	1000	1000	1000	1000
Total ($)	3900	2420	3350	2190
Cost savings ($)	1480		1160	
Cost ratio (B/A)	62%	65%		

Tx, treatment

costs of basic care in two countries, with monetary values expressed in dollar units for simplicity. The costs of drugs in Country 1 are higher than in Country 2, where drug prices are strictly regulated. The time spent by the hospital staff to care for the patient are quite similar in Country 1 and Country 2 (50 hours per patient for Treatment A and 54 for Treatment B, a difference due to lower complication rates with Treatment A). The average hourly compensation for hospital staff is, however, higher in Country 2, so that total personnel costs are higher as well. Thus, both cost savings and the relative costs of Treatment A and B are different in these two healthcare systems, due to different prices for the same resources used to care for a myocardial infarct patient.

There may also be differences in the level of resource use between countries, especially for discretionary procedures such as coronary angiography. Suppose that the use of Treatment A cuts the use of coronary angiography by one-third, partially offsetting the higher cost of the drug. If, however, the baseline rates of angiography are different between countries, the cost implications of reducing angiography by one-third in each country will be quite different (Table 4.4). A reduction by one-third in the high rate of

angiography in Country 1 (from 60% to 40%) provides a $200 cost offset per patient, whereas a reduction by one-third in the low rate of angiography in Country 2 (from 20% to 15%) provides only a $50 cost offset per patient.

International comparisons of the cost of therapies can thus be affected by (a) differences in resource use patterns that reflect differences in practice style and the organization of medical care, and (b) differences between countries in the prices attached to specific resources, such as health-care wages, drugs, and supplies. Data from cost studies can be most readily applied in different practice environments if the study provides information on both resource consumption patterns and price weights attached to the specific resources used, as well as a summary cost measure. This detail is needed for readers to understand the applicability of the cost findings to their own practice settings.

Cost-effectiveness analysis

The cost of providing a particular medical service can be measured, but determination of whether the service provides good value for the money spent is a more difficult judgment. Cost-effectiveness analysis is a method of weighing the cost of a service in light of the health effects it confers in an attempt to facilitate the ultimate value judgment about whether the service is "worth" the cost.

Cost-effectiveness analysis is one of several alternative analytic methods, each with its own strengths and limitations.[6] If two alternative therapies are either known to yield identical results or can be shown to be clinically equivalent, they can be compared on the basis of cost alone. This form of analysis, which is termed "cost-minimization analysis", is particularly appropriate for commodities such as drugs, supplies, and equipment that can be expected to yield equivalent results when applied clinically. In such situations, the relative costs of the alternatives become the predominant consideration.

Many alternative therapies are known to differ both in clinical outcomes and in cost. In this situation, both the difference in cost and the difference in effectiveness of the therapeutic alternatives must be measured and weighed against each other. When the effectiveness on intervention is measured in clinical terms (for example, lives saved, years of life added), the analysis is termed "cost effectiveness". If the clinical measures of effectiveness are translated into monetary units, the term "cost–benefit analysis" is applied. Cost–benefit analysis has been used to guide public policy in areas outside medicine, such as in the construction of transportation systems or whether to remove or reduce environmental exposures. Cost–benefit analysis measures the effects of programs in monetary terms, so that net cost (in dollars) can be compared with net benefits (in dollars). Since there is great reluctance on the part of physicians and health policy makers to assign a dollar value to saving a life or improving a patient's function, cost-effectiveness analysis rather than cost–benefit analysis has been applied predominantly to medical problems.

Cost-effectiveness analysis was first applied to medical programs only 30 years ago[9,10] and has since been widely used.[11–13] The principles of cost-effectiveness analysis for medical programs have been examined in detail by a task force convened by the United States Public Health Service.[14–16] A group of experts attempted to establish consensus on a number of methodologic issues, with the goal of standardizing the technical aspects of cost-effectiveness analysis among studies, thereby enhancing their comparability. The principles articulated by this group are reasonable and should guide this important field in its next 20 years.

A basic principle of cost-effectiveness analysis is that the analysis should compare alternative programs and not look at any single program in isolation. Thus, a drug to treat life-threatening arrhythmias might be compared with placebo, or an implantable cardioverter defibrillator might be compared with a drug. In essence, cost-effectiveness analysis must always answer the question "cost effective compared with what?".

Another principle is that the costs included in cost-effectiveness analysis should be comprehensive. The cost of a specific therapy should include the cost of the intervention itself (for example, thrombolytic therapy for acute myocardial infarction) and the costs of any complications the therapy induced (for example, bleeding), less any cost savings due to reduction of complications (such as heart failure). The need for other concomitant therapy should also be included, which is particularly important when assessing the cost effectiveness of screening programs or diagnostic testing strategies. The length of follow-up should be sufficient to include all relevant costs and benefits – such as readmissions to the hospital due to treatment failures. Non-monetary costs directly related to the medical intervention should also be included, such as the cost of home care by the patient's family, since omission of these costs would bias assessments toward programs that rely on unpaid work by family members or volunteers. Other costs not directly related to the intervention, however, such as the patient's lost wages or pension costs, are omitted by convention from the measured costs in a cost-effectiveness analysis.

Another important issue in cost-effectiveness analysis is the perspective taken by the analysis. There is general agreement that the analysis should include all relevant costs, regardless of who pays them. This principle is known as "taking the societal perspective" and it assures a complete accounting of costs in the analysis. A hospital, for instance, may not care about the out-of-pocket costs paid directly by the patient but these are real costs and should be considered in the analysis.

Medical costs may accrue over long periods of time, especially in preventive programs or the treatment of chronic disease. Time scales of more than a year or so bring up two related but distinct issues – inflation and discounting. The nominal value of any currency changes over time; a dollar in 1998 had more purchasing power than a dollar in 2008. Studies conducted over long time periods will need to correct for the changing value of currencies, typically by application of the Consumer Price Index (or the GDP deflator). Application of the Consumer Price Index removes the effect of inflation but does not address the separate issue of time preference for money. Even in a country free of inflation, citizens would prefer to receive $100 today than a promise they will be paid $100 in a year. One might have to promise to pay more money in a year, say $103, to compensate for the delay. The same is true in health programs: we would prefer to be paid today instead of in the future, and we would also prefer to pay our obligations in the future rather than today. Use of a discount rate provides a way to correct for the lower value of future costs relative to current costs. The technical experts' consensus is that future costs should be discounted at a rate equivalent to the interest paid on safe investments such as government bonds in an inflation-free environment, or about 3% per year. The effect of alternative discount rates between 0% and 5–10% per year should also be checked to document the sensitivity of the analysis to future costs.

In summary, a cost-effectiveness analysis should include all medical costs, including those of complications of therapy and adverse effects prevented. The study should be of sufficient duration to measure all relevant costs and benefits of the treatment. All costs and benefits should be included, regardless of who bears or receives them. In studies covering more than a year or so, corrections should be made for inflation, and 3% per year discount rate should be applied to follow-up costs.

Measuring effectiveness

The effectiveness of an intervention in practice can be measured in a variety of ways, with different outcome measures most appropriate for specific applications. Physiologic endpoints are often used in clinical trials, with the result of therapy assessed by a laboratory measure such as millimeters of mercury for blood pressure or episodes of non-sustained ventricular tachycardia on an electrocardiographic monitor. Laboratory measures are useful in judging the physiologic effects of therapy and its mechanism of action, but these surrogate markers may not predict the ultimate effect of therapy on mortality and morbidity, as vividly illustrated by the results of the Cardiac Arrhythmia Suppression Trial.[16] Physiologic endpoints are also tied closely to one specific disease, making comparisons against other benchmark therapies difficult. The patient and public are most concerned with the effect of therapy on survival and on their ability to function – that is, upon the length and quality of life. A common denominator measure of effectiveness is thus the life-years of expected survival or quality-adjusted life-years (QALYs). This measure is relevant to patients and to the public and can be applied to virtually any therapy.

Mortality is a common endpoint in clinical trials and leads directly to the measure of life-years of survival. The mean life expectancy of a cohort of patients is equal to the area under a standard survival curve. The difference in life expectancy between two therapies is therefore equal to the difference in the areas under their respective survival curves. Since many clinical studies do not follow patient cohorts long enough to observe complete survival times for all patients, some assumptions and modeling of long-term survival may be needed to estimate the full survival benefit of therapy for a cost-effectiveness analysis.[17]

Improvement in quality of life is often as important to patients as reducing mortality, and it is often the main goal of therapies, such as the relief of disabling angina or improvement in exercise tolerance. A quality of life measure can be translated into a scale that ranges from a low of 0.0 (the worst possible health state, usually taken as death) to 1.0 (perfect health). This quality of life measure is multiplied by the length of time a patient spends in the health state to yield a QALY. Thus:

$$QALY = \sum Q_i \times t_i$$

where QALY = the quality-adjusted life-years, Q_i = the quality factor for follow-up period "i" and t_i = the length of time spent in period "i". This equation shows that the effectiveness of a treatment, as measured in QALYs, can be improved by enhancing either the patient's quality of life (Q_i) or the patient's length of life (t_i), or both.

Calculation of cost effectiveness

After the costs of therapy and the medical effectiveness of therapy have been assessed, cost effectiveness (CE) can be calculated as:

$$CE\ ratio = \frac{Cost_2 - Cost_1}{QALY_2 - QALY_1}$$

where $Cost_1$ and $Cost_2$ represent the costs of program 1 and program 2, respectively, and $QALY_1$ and $QALY_2$ represent the effectiveness of programs 1 and 2, respectively.

There are several implications of using this formula. First, cost-effectiveness ratios that are positive (that is, >0) result if and only if one alternative has both higher cost and greater effectiveness – that is, $Cost_2 > Cost_1$ and $QALY_2 > QALY_1$ (or the reverse: $Cost_2 < Cost_1$ and

$QALY_2 < QALY_1$). Cost-effectiveness ratios of less than zero are not generally important for decision making, since they arise only when one alternative has both lower costs and greater clinical effectiveness than the other; for example, $Cost_2 > Cost_1$ and $QALY_2 < QALY_1$. In this case, program 1 is superior in all respects: it has better outcomes and lower cost than program 2 and thus is said to "dominate" the alternative. The decision of which program to recommend is therefore simple.

Most commonly, one of two therapeutic alternatives has higher costs and greater effectiveness, and use of the formula yields a cost-effectiveness ratio greater than zero. One treatment may have a cost-effectiveness ratio of $5000 per year of life saved and another might have a ratio of $75 000 per year of life saved. Since it is problematic to assign a dollar value to life, interpretation of these ratios is best made by consideration of benchmarks – other generally accepted therapies that serve as a rough gauge to an "acceptable" cost-effectiveness ratio. Renal dialysis is a form of therapy that most people would consider expensive, and yet dialysis is an intervention that the USA and most other industrialized countries provide as a life-saving therapy. The end-stage renal disease program in the USA costs about $50 000 a year per patient and if this therapy were withdrawn, the patient would die. Thus, renal dialysis has a cost-effectiveness ratio of $50 000 per year of life saved (or if one considers the reduced quality of life for a dialysis patient, perhaps $75 000 per quality-adjusted year of life saved). Therapies with cost-effectiveness ratios considerably more favorable than renal dialysis (that is, <$20 000) would be considered very cost effective, whereas therapies with cost effective ratios much higher (say >$125 000) would be considered too expensive.

Different societies may come to different conclusions about the level of cost effectiveness they consider good value. Wealthy countries with high per capita incomes are more willing to pay for expensive therapies than are poor countries. For instance, the percentage of gross domestic product and per capita health spending in Eastern Europe is much less than in Western Europe or North America, and these countries have not chosen to provide expensive services such as bypass surgery as readily or as frequently. The World Health Organization has suggested three times GDP per capita as a rough guide for the cost-effectiveness threshold.

A therapy that is cost effective is not necessarily affordable in the setting of limited resources. In particular, the aggregate effect of a new therapy on healthcare expenditures depends on both the number of patients treated and the incremental cost per patient. Expensive treatments for common diseases may raise costs by billions of dollars (e.g. coronary stents, implantable defibrillators). Decisions to adopt new technologies will consider the aggregate budgetary impact, not just the cost-effectiveness ratio.

Decisions about funding programs might be more equitable and rational when guided by the relative cost effectiveness of programs. When studies use similar methods to measure cost and effectiveness, cost-effectiveness ratios can be compared to rank the economic attractiveness of alternatives. Tables comparing various treatments, such as Table 4.5, have been termed "league tables" because of

Table 4.5 Cost effectiveness of selected cardiovascular therapies

Strategy	Patient group	Cost effectiveness[a]
Statin	Post-MI	Saves dollars and lives
	Men 45–54	
	Chol ≥250	
ACE inhibitor	CHF	Saves dollars and lives
	EF <35%	
Radiofrequency ablation	WPW, post cardiac arrest	Saves dollars and lives
Physician counseling	Smoking	$1300
Beta-blocker	Post-MI	$3600
	High-risk	
CABG	Left main CAD	$9200
	Severe angina	
Beta-blocker	Post-MI	$20 200
	Low-risk	
Statin	Primary prevention	$20 200
	Men 55–64	
	Chol >300	
	Three risk factors	
tPA vs SK	Acute MI	$32 800
ICD	Sustained VT	$35 000
CABG	Two-vessel CAD	$42 500
	Angina	
Statin	Primary prevention	$78 300
	Men 55–64	
	Chol >300	
	No other risk factors	
PCI	Mild angina (COURAGE)	$168 000[18]
CABG	Single-vessel CAD	$1 142 000
	Mild angina	
Statin	Primary prevention	$2 024 800
	35–44 year old women	
	Chol >300	
	No other risk factors

their similarity to the athletic league standings published in newspapers. Given the uncertainty inherent in measuring cost and effectiveness of medical interventions, and the methodologic variations among studies, only relatively large differences in cost-effectiveness ratios should be considered significant. Thus, a program with a cost-effectiveness ratio of $5000 per life year added is much better than one with a ratio of $30 000. Programs with ratios of $25 000 and $30 000 are so close that no firm conclusion about the relative values should be drawn.

A league table of cost-effectiveness ratios may help guide policy decisions about which therapies to provide within a health care system, but other factors also affect such decisions. The total budgetary impact of a therapy is the product of the number of treated patients and the net cost per patient. Two therapies with similar cost-effectiveness ratios may have quite different impacts on the health care budget, which policy-makers must consider as well. Furthermore, cost-effectiveness concerns economic efficiency, but policymakers also have to consider the distribution of resources and ensure fairness. They may decide to cover the only available therapy for a certain disease, even though it has a less favorable cost-effectiveness ratio than a second-line treatment for a different disease.

Patient selection and cost effectiveness

Drugs and procedures in medicine are applied to different patient groups for different clinical indications. The medical effectiveness of therapies varies considerably according to patient selection. Cholesterol-lowering therapy, for instance, will extend the life expectancy of a patient with multiple cardiac risk factors more than it will for a patient with the same cholesterol level and no other cardiac risk factors. Coronary bypass surgery provides greater life extension to a patient with left main coronary artery obstruction than it does to a patient with single vessel disease.[18] The cost-effectiveness ratio for these therapies will therefore vary among patient subgroups due to the impact of patient characteristics on the clinical effectiveness of therapy, which forms the denominator of the cost-effectiveness ratio. Similarly, the cost of a particular therapy may also vary according to patient characteristics, since the therapy itself may be more or less expensive according to different patient subgroups, or the likelihood of costly complications may be higher or lower in different groups of patients.

The clinical effectiveness of a therapy is generally the most important factor determining cost effectiveness. The reasons for this importance are (a) that clinical effectiveness of a therapy generally varies more among patients than does the cost of therapy, and (b) the value of the cost-effectiveness ratio is more sensitive to changes in the denominator (effectiveness) than to changes in the numera-

tor (cost). In the last analysis, a therapy must be clinically effective before it can be cost effective. Cost-effectiveness analysis relies more on the assessment of medical effectiveness than it does on determination of cost.

Diagnostic tests and cost effectiveness

Cost-effectiveness analysis has been applied primarily to assess specific therapies or therapeutic strategies, for which it is natural to measure effectiveness in terms of patient outcome. The principles of cost effectiveness can be extended to analyze screening tests and diagnostic strategies as well, but some additional factors must also be considered.

Therapies are expected to improve patient outcome *directly*, by intervening in the pathophysiology of disease processes. In contrast, a diagnostic test is expected to provide the physician with information about the patient, which in turn is expected to improve management and thereby *indirectly* improve patient outcome. The value of a test is therefore linked closely with patient selection for therapy, and the value of testing may well change as new therapies are developed or alternative tests become available.

The information provided by a test may be used in different decisions, and the test may be more or less useful in these different settings. An exercise electrocardiogram, for example, can be used as a diagnostic test for coronary disease, a prognostic test for patients with recent myocardial infarction, a monitoring test to assess the effect of anti-ischemic therapy or even as a way to establish target heart rates for an exercise training program. The efficacy and cost effectiveness of applying the exercise electrocardiogram will be different for these varied uses of the information provided by the test. The value of the test will depend on the indication for which it is used, much as the value of a beta-blocker will vary whether it is used to treat hypertension or as secondary prevention after a myocardial infarction.

The same test (for example, the exercise ECG) applied for the same purpose (such as diagnosis of coronary disease) will provide more information in some groups of patients than in others. As discussed elsewhere in this book, a diagnostic test provides more value if used when the pretest probability of disease is intermediate than when it is either very high or very low. The test has the most value when the result is likely to change the estimated probability of disease such that clinical management is changed. Tests that never change patient management cannot change patient outcome, which is the "bottom line" in assessing cost effectiveness.

Conclusion

Economic analysis is designed to assist decisions about the allocation of scarce resources. Physicians now must address

the cost implications of clinical decisions, and be aware of the effects on scarce resources. Economic efficiency is but one of many goals, however, and issues of fairness and humaneness are also central to medical care and must be considered as well.

5 Major vascular complications in patients undergoing non-cardiac surgery: magnitude of the problem, risk prediction, surveillance, and prevention

Philip J Devereaux,[1] Matthew Chan[2] and John Eikelboom[3]

[1] Departments of Clinical Epidemiology and Biostatistics and Medicine, McMaster University, Hamilton, Ontario, Canada
[2] Department of Anesthesia, The Chinese University of Hong Kong, Hong Kong, China
[3] Department of Medicine, McMaster University, Hamilton, Ontario, Canada

Magnitude of the problem

Throughout the last few decades, non-cardiac surgery has made substantial advances in treating diseases and improving patient quality of life, and as a result, the number of patients undergoing non-cardiac surgery is growing. A recent study used surgical data from 56 countries around the world to determine that globally there are over 230 million major surgical procedures undertaken annually.[1] The fact that cardiac and pediatric surgery only account for a minority of major surgical cases suggests that over 200 million adults undergo major non-cardiac surgery annually.

Non-cardiac surgery is associated with an increased risk of major vascular complications (i.e. vascular death, non-fatal myocardial infarction, non-fatal cardiac arrest, and non-fatal stroke). A recent review found only one study, by Lee and colleagues,[2] that evaluated the incidence of major perioperative vascular complications in a prospective cohort that fulfilled the following criteria: more than 300 patients, the patients were relatively unselected (i.e. not restricted to patients referred to internal medicine or to patients with or at high risk of coronary artery disease), not restricted to a specific type of surgery (e.g. orthopedics), and required patients to have at least one measurement of a cardiac biomarker or enzyme after surgery.[3] This study suggests that major perioperative vascular events occur in 1.4% (95% confidence interval (CI) 1.0–1.8%) of adults undergoing elective non-cardiac surgery. Conservative estimates suggest that at least half of the 200 million adults

undergoing non-cardiac surgery are in an at-risk age group.[4] These data together with the data from the Lee study suggests that worldwide, 1–1.8 million adults suffer a major perioperative vascular complication annually.

There is concern, however, that this is a substantial underestimation of the actual incidence. The recent Peri-Operative ISchemic Evaluation (POISE) trial included 8351 patients from 190 hospitals in 23 countries in a randomized controlled trial comparing the effects of a beta-blocker relative to placebo among patients undergoing non-cardiac surgery.[5] The incidence of major perioperative vascular complications in the POISE trial was more than three times higher than what was predicted by the Revised Cardiac Risk Index, which was developed from the study by Lee and colleagues. This suggests the possibility that the current incidence of major perioperative vascular complications is substantially higher than the estimate from the Lee study. Several limitations associated with the Lee study support this position. Lee *et al* did not include stroke as an outcome, and excluded patients undergoing emergency surgery.[2] Emergent cases represent about 10% of non-cardiac surgeries[6] and patients undergoing emergency surgery are at higher risk of major perioperative vascular events than patients undergoing elective surgery (odds ratio (OR) 2.6, 95% CI 1.2–5.6).[7] The data from Lee and colleagues are over 15 years old. Considering that patients with coronary artery disease are living longer and there has been a practice pattern shift towards advanced care for the elderly (including surgery), this suggests that older patients with high burdens of coronary artery disease are now surviving to develop other conditions that require an operation and these elderly patients are undergoing surgery.

These limitations support the finding in the POISE trial, and this suggests that the current worldwide incidence of adults suffering a major perioperative vascular

complication in the first 30 days after surgery is probably in the range of 3–5.4 million annually. This is in the range of the global incidence of new patients acquiring human immunodeficiency virus (HIV) annually,[8] and identifies major perioperative vascular complications as a similarly common and important public health problem.

Preoperative risk prediction

Need for preoperative risk prediction

Accurate estimation of perioperative vascular risk in patients undergoing non-cardiac surgery is important to guide perioperative management and to allow patients and physicians to make informed decisions about the appropriateness of surgery. The majority of non-cardiac surgeries are elective procedures. An accurate estimate of risk facilitates patient and physician decision making. For example, if an elderly female with multiple risk factors undergoing hip arthroplasty for osteo-arthritis was accurately informed that her risk of a major perioperative vascular event was 10–12%, she may decide to defer surgery for a year, living with suboptimal quality of life until after her granddaughter's wedding. Further, accurate perioperative cardiac risk prediction can inform management decisions (e.g. whether to delay or cancel surgery or type of anesthetic approach) and monitoring decisions (e.g. whether a patient should go to a telemetry unit after surgery).

Clinical risk prediction

Researchers have developed two types of clinical models – generic and Bayesian – to estimate perioperative cardiac risk in patients undergoing non-cardiac surgery. The generic risk models estimate a patient's risk of a perioperative cardiac event through determination of how many predictors of risk (e.g. history of coronary artery disease, diabetes, emergency surgery) an individual patient fulfills.

The Bayesian risk models modify the average cardiac event rate for a specific surgery or group of comparable surgeries (pretest probability) through use of a patient's individual index score (likelihood ratio), which is based upon how many predictors of risk (e.g. history of coronary artery disease, diabetes) an individual patient fulfills. The result provides an estimate of the patient's risk of a perioperative cardiac event (post-test probability).

Four clinical models developed to predict perioperative cardiac events fulfill the following criteria: assessed in >300 patients, validated at least within the original study, and not restricted to a specific type of non-cardiac surgery (e.g. vascular surgery).[2,7,9,10] Table 5.1 presents information on the studies that developed these clinical models and Table 5.2 presents their scoring systems. All studies had a small to moderate number of events and were underpowered to assess the independent effect of each variable given the number of variables assessed. These clinical models were designed to predict cardiac outcomes of varying importance, and no model included stroke. Table 5.3 presents the studies that have evaluated the predictors of stroke in patients undergoing non-cardiac surgery.[11–15] Although there are few studies and most observed few events, they do suggest overlap between the predictors of stroke and major cardiac events in patients undergoing non-cardiac surgery. The study with the most number of perioperative strokes (i.e. 61 strokes) suggests that perioperative stroke is a serious outcome (i.e. 18% died and 31% were care dependent at discharge).[15]

The Revised Cardiac Risk Index is the simplest of the models to use and is more predictive than the Original Cardiac Risk Index.[2,7] Of the two Bayesian models, the Veterans Affairs Model is simpler to use and the one study that compared these two models suggested the Veterans Affairs Model was as predictive as the Modified Cardiac Risk Index.[7] Although several studies have compared the predictive accuracy of the generic and Bayesian risk models,[2,7,9,16,17] only two have used pretest probabilities in the Bayesian models based upon contemporary data from the hospitals included in the studies.[7,9] The most recent of

≥26	78%					≥3	9%				

abn rhythm, rhythm other than sinus or premature atrial contractions on last preoperative electrocardiogram; APE, alveolar pulmonary edema; CCSC, Canadian Cardiovascular Society Class; CHF, congestive heart failure; Cr, creatinine; CVA, stroke or transient ischemic attack; IHD, ischemic heart disease; JVD, jugular vein distension; mo, months; poor status, PO₂ < 60, PCO₂ > 50 mmHg, K < 3.0, HCO3 < 20 meq/L, blood urea nitrogen >50, creatinine >3.0 mg/dL, abnormal serum glutamic oxalacetic transaminase, signs of chronic liver disease, or patient bedridden from non-cardiac causes; Pts, points; PVCs, premature ventricular contractions; U/A, unstable angina; vasc, vascular; VAS, valvular aortic stenosis; low-risk Sx, low-risk surgery (e.g. ophthalmology, maxillofacial, plastic, low-risk orthopedic, urologic, general surgery and non-thoracotomy thoracic procedures); Interm-risk Sx, intermediate risk surgery (e.g. neurosurgery, ENT surgery, major orthopedic surgery); high-risk Sx, high-risk surgery (e.g. intraperitoneal, intrathoracic, or aortic surgery); misc vasc Sx, miscellaneous vascular surgery (e.g. all lower extremity amputations, arteriovenous access procedures).

these two studies demonstrated superior prediction capabilities of the Bayesian risk models.[7]

Despite this finding, the current predictive accuracy of the Modified Cardiac Risk Index and the Veterans Affairs Model is uncertain because there is no high-quality study that has established contemporary complication rates for individual surgeries or groups of comparable surgeries, and it is unknown if contemporary complication rates at one institution are applicable to another institution. Further, it is unclear whether the Bayesian models would demonstrate superior prediction capabilities if the generic risk models included more specific surgeries or groups of comparable surgeries as risk factors, because it is likely that the type of surgery a patient undergoes influences the probability of a vascular complication.

The Vascular events In non-cardiac Surgery patIents cOhort evaluatioN (VISION) Study is a prospective cohort study of 40 000 patients undergoing non-cardiac surgery in several countries around the world (ClinicalTrials.gov, number NCT00512109). A primary objective of this study is to develop a current clinical risk estimation model for predicting major perioperative vascular complications. Until further studies like the VISION Study are complete, physicians need a practical clinical risk index. The Revised Cardiac Risk Index from the Lee study is the simplest to use in clinical practice, and several studies have validated the factors included in the index as independent predictors of major perioperative vascular complications.[18] The Revised Cardiac Risk Index consists of six equally weighted risk factors: high-risk surgery (intraperitoneal, intrathoracic

Table 5.3 Predictors of stroke in patients undergoing non-cardiac surgery

Study	Enrolment years	Design	Patient population	Events	Predictors of perioperative stroke
Larsen[11]	1981–1983	Single center prospective cohort study	2463 patients >40 years old who had elective or acute non-cardiac surgery; carotid surgery cases were excluded	3 TIAs and 6 strokes	Prior CVD, coronary artery disease, PVD, and hypertension predicted perioperative stroke and TIA in unadjusted analyses ($P < 0.001$, <0.001, <0.05, and <0.05, respectively)
Landercasper[12]	1981–1988	Single center retrospective cohort study	Patients who had general anesthesia were included, those who had cerebrovacular or neurosurgery were excluded; 173 of the 7690 patients had a prior history of stroke	5 strokes	Prior stroke predicted perioperative stroke in unadjusted analysis ($P < 0.001$)
Parikh[13]	NR	Single center case–control study	19 patients who suffered a perioperative stroke after general or vascular surgery and 19 controls matched for age and procedure operated on during the same time period; patients who had carotid endarterectomies were excluded	19 strokes	Prior hypertension, neurologic symptoms, abnormal cardiac rhythm predicted perioperative stroke in unadjusted analyses ($P = 0.02$, 0.02, and 0.04, respectively)
Rockman[14]	1988–1993	Singe center retrospective cohort study	Patients who had a carotid endarterectomy were included; those who had surgery for recurrent carotid stenosis and non-atherosclerotic disorders were excluded; 183 of the 606 patients had a prior history of stroke	13 strokes	Prior stroke predicted perioperative stroke in unadjusted analysis ($P = 0.01$)
Limberg[15]	1986–1996	Single center case–control study	61 patients who suffered an ischemic stroke after non-cardiac surgery and 122 randomly selected controls matched for age, sex, procedure, and year of surgery; patients who had heart, brain, vessel or neck surgery were excluded	61 strokes (ischemic)	AOR for prior CVD = 13 (95% CI 2.1–74); AOR for COPD = 9 (95% CI 2.5–31); AOR for PVD = 8 (95% CI 2.3–28); AOR for admission MAP = 1.04 (95% CI 1.01–1.07)

AOR, adjusted odds ratio; CVD, cerebrovascular disease; COPD, chronic obstructive pulmonary disease; PVD, peripheral vascular disease; MAP, mean arterial pressure; TIA, transient ischemic attack; NR, not reported; neurologic symptoms, optic migraine, transient ischemic attack, and stroke.

or suprainguinal vascular surgery), history of ischemic heart disease, history of congestive heart failure, history of cerebrovascular disease (i.e. stroke or transient ischemic attack), use of insulin therapy for diabetes, and a preoperative serum creatinine >175 μmol/L (>2.0 mg/dL). Table 5.4 presents data from the original study and demonstrates the percentage risk of patients suffering a major perioperative cardiac event (i.e. cardiac death, non-fatal myocardial infarction, and non-fatal cardiac arrest) and the corresponding 95% confidence intervals, based on the number of risk factors met. As stated above, the observed event rate in the recent large international POISE trial demonstrated an observed event rate that was three times higher than that predicted by the Revised Cardiac Risk Index. Therefore, physicians may want to double or triple the estimates from Table 5.4 until further data are available.

Non-invasive cardiac stress testing

Although clinical risk indices help to identify patients at risk of a major vascular complication, they underestimate risk in a substantial proportion of patients.[3,17] This likely occurs because for a prolonged period of time prior to undergoing surgery, many patients have limited mobility (e.g. patients with arthritis, peripheral vascular disease, cancer). Some of these patients have underlying cardiac disease but are not active enough to experience symptoms. Although it is likely that researchers will develop more accurate clinical risk indices, it is also likely that a substantial proportion of patients undergoing non-cardiac surgery (e.g. patients with limited mobility, diabetes) will require further evaluation beyond clinical symptoms to optimize their risk assessments.

To address this problem researchers have assessed the prognostic capabilities of non-invasive cardiac stress tests (e.g. stress echocardiography, nuclear scintigraphy imaging), prior to non-cardiac surgery.[3] A recent meta-analysis evaluating these two tests demonstrated that they have only moderate negative likelihood ratios (stress echocardiography 0.23 and stress perfusion imaging 0.44), and

Table 5.4 Perioperative cardiac risk estimation based upon predictors in the Revised Cardiac Risk Index

Number of risk factors	Percentage risk of patients suffering a major perioperative cardiac event	95% CI
0	0.4%	0.1–0.8%
1	1.0%	0.5–1.4%
2	2.4%	1.3–3.5%
>3	5.4%	2.8–7.9%

This table is reproduced with permission from Devereaux *et al.*[3]
Risk factors = high-risk surgery (intraperitoneal, intrathoracic or suprainguinal vascular surgery), history of ischemic heart disease (defined as a history of myocardial infarction, positive exercise test, current complaint of ischemic chest pain or nitrate use, or ECG with pathologic Q waves; patients with prior coronary bypass surgery or angioplasty were included only if they had such findings after their procedure), history of congestive heart failure (defined as a history of heart failure, pulmonary edema or paroxysmal nocturnal dyspnea; an S3 gallop or bilateral rales on physical examination, or a chest radiograph showing pulmonary vascular resistance), history of cerebrovascular disease (i.e. stroke or transient ischemic attack), use of insulin therapy for diabetes, and a preoperative serum creatinine >175 μmol/L (>2.0 mg/dL).
Major perioperative cardiac event = cardiac death, non-fatal myocardial infarction or non-fatal cardiac arrest; note that this table does not include postoperative cardiogenic pulmonary edema and complete heart block, which were included as outcomes in the Lee index.

more than a third of the patients who suffered a major perioperative cardiovascular event had a negative test result.[19] The studies that directly compared these tests suggested there was no difference between the two tests regarding their positive likelihood ratios. When either of these tests had a moderate-to-large defect it was associated with a positive likelihood ratio of 8; however, this test result was only present in a small proportion of patients (i.e. <15% of the patients undergoing one of these tests).

These data likely represent a best-case scenario for these tests because the results report the direct association between the non-invasive cardiac stress test and the risk of a major perioperative cardiovascular outcome. Because of the cost and time associated with these tests, the more relevant data are whether these non-invasive cardiac stress tests provide additional predictive value, beyond clinical variables, for the occurrence of major perioperative cardiovascular events. Most of the studies have not assessed whether these non-invasive cardiac stress tests provide independent prognostic information. The studies that have undertaken multivariable analysis are unreliable because they did not include all the known independent clinical variables or the analysis had too few events for the number of variables assessed.[20–24] The results and the limitations of these data leave considerable uncertainty as to the role of non-invasive cardiac stress testing prior to non-cardiac surgery.

Preoperative BNP and NT-proBNP measurement

Ventricular myocytes secrete brain natriuretic peptide (BNP), a prohormone, and its inactive cleavage product N-terminal fragment of the prohormone (NT-proBNP) into the blood in response to myocardial stretch and ischemia.[25,26] Plasma BNP and NT-proBNP are powerful predictors of death and major adverse cardiovascular events in patients with stable coronary artery disease, acute coronary syndromes, and congestive heart failure.[27–31] Table 5.5

Table 5.5 Adjusted association between pre-operative BNP/NT-proBNP level and perioperative cardiovascular event

Study and year of publication	Marker and threshold (pg/mL)	Outcome	No of events/no of patients in study	Adjusted OR (95% CI)
Dernellis 2006[32]	BNP (189)	Cardiac death, non-fatal MI, pulm. edema, VT	96/1590	34 (17–69)
Feringa 2006[33]	NT-proBNP (533)	Death, non-fatal MI	13/170	17 (3–106)
Cuthbertson 2007[34]	BNP (40)	Death, myocardial injury, arrhythmia†	12/204	7 (2–29)
Cuthbertson 2007[35]	BNP (170)	Cardiac death, myocardial injury	11/40	14 (2–98)
Cardinale 2007[36]	NT-proBNP (various*)	Atrial fibrillation	72/400	28 (13–59)
Yun 2008[37]	NT-proBNP (201)	Cardiac death, non-fatal MI, pulm. edema, non-fatal stroke	25/279	8 (2–27)

MI, myocardial infarction; pulm., pulmonary; VT, ventricular tachycardia; ACS, acute coronary syndrome.
* Authors employed six age- and sex-dependent thresholds;
† resulting in hemodynamic compromise or requiring intervention.

reports six studies that have evaluated the independent association between a preoperative BNP or NT-proBNP measurement and major perioperative cardiovascular events.[32–37] All studies suggest that an elevated preoperative BNP or NT-proBNP measurement is a strong independent predictor of a major perioperative cardiovascular event. Although there are limitations to these studies regarding the number of events, variations in the outcomes and thresholds evaluated, and the width of the confidence intervals, these results are encouraging. A large substudy (10 000 patients) of the VISION Study currently under way is evaluating the prognostic capabilities of preoperative NT-proBNP and will provide further insights into whether NT-proBNP, a relatively cheap and easily accessible test compared to the non-invasive cardiac stress tests, can enhance perioperative clinical risk predictions.

Perioperative myocardial infarctions

Considering the major perioperative vascular complications (i.e. vascular death, non-fatal myocardial infarction, non-fatal cardiac arrest, and non-fatal stroke) myocardial infarction is the most common event. For example, in the POISE trial 1.6% of patients suffered a vascular death, 0.7% suffered a stroke, 0.5% suffered a non-fatal cardiac arrest, and 5.0% suffered a myocardial infarction in the first 30 days.[5]

Pathophysiology of perioperative myocardial infarction

Rupture of atherosclerotic plaque with superimposed arterial thrombosis constitutes the underlying pathophysiology in the majority of *non-operative* myocardial infarctions.[38] Between 64% and 100% of patients with non-operative myocardial infarctions have coronary artery plaque fissuring[39,40] and 65–95% have an acute luminal thrombus.[40–44]

A commonly proposed mechanism of perioperative myocardial infarction relates to myocardial oxygen supply demand mismatch.[45] Fluid shifts, catecholamine surges, hypotension, anemia, pain, hypothermia, and hypoxia can occur during and after major non-cardiac surgery and transiently increase myocardial oxygen demand.[3] In coronary vessels with high-grade stenoses or occlusions, the supply response may be limited, resulting in supply/demand mismatch myocardial infarction. Consistent with this hypothesis, two small retrospective autopsy studies (<70 patients in total) that reported the coronary pathology of patients who suffered a fatal perioperative myocardial infarction revealed that two-thirds of patients had significant left main or three-vessel coronary artery disease.[46,47] Most of the patients did not exhibit plaque fissuring and only about one-third had an intracoronary thrombus. Although these data require cautious interpretation because the timing of the autopsies relative to the myocardial infarctions may have allowed resolution of intracoronary thrombus, these data suggest that a substantial proportion of fatal perioperative myocardial infarctions may be secondary to an increase in oxygen demand in the setting of a fixed coronary artery stenosis.

Although POISE does not provide direct evidence regarding the pathophysiology of perioperative myocardial infarction, some of the findings challenge the theory that perioperative myocardial infarction result from an increase in oxygen demand in the setting of fixed coronary artery stenoses.[5] In POISE, perioperative beta-blockers prevented myocardial infarctions (beta-blockers 4.2% v placebo 5.7%; hazard ratio (HR) 0.73; 95% CI 0.60–0.89; P = 0.0017) but increased clinically significant hypotension (systolic blood pressure less than 90 mmHg that someone intervened upon; beta-blockers 15.0% vs placebo 9.7%; HR 1.55; 95% CI 1.38–1.74; P < 0.0001). Clinically significant hypotension had the largest population-attributable risk for perioperative death and perioperative stroke but appeared to have minimal impact on the risk of perioperative myocardial infarction. Because myocardial oxygen supply is critically dependent on maintaining coronary blood flow during diastole, hypotension of sufficient severity to cause stroke and death would be expected to further compromise coronary perfusion in patients with pre-existing fixed coronary artery stenosis, thereby increasing the risk of perioperative myocardial infarction with beta-blockers rather than reducing the risk. Therefore, the POISE results suggest the possibility that other mechanisms beyond increased oxygen demand in the setting of a fixed coronary artery stenosis are involved in the pathogenesis of perioperative myocardial infarction.

An additional or alternative mechanism of perioperative myocardial infarction is that the acute stress of surgery and mechanical tissue injury induce a hypercoagulable state that increases the risk of coronary thrombus formation at the sites of a fissured plaque or low coronary flow. This mechanism might also explain the reduction in perioperative myocardial infarction seen with beta-blockers in POISE because sympathetic hyperactivity promotes hypercoagulability by upregulating coagulation and platelets and downregulating fibrinolysis, and this effect can be suppressed by beta-blocker therapy.[48–51]

Consistent with the thrombosis hypothesis, a small study of 21 patients who suffered a perioperative myocardial infarction who had undergone a coronary angiography prior to vascular surgery revealed that the majority of non-fatal perioperative myocardial infarctions occurred in arteries without high-grade stenoses, suggesting that these events may result from acute coronary artery thrombosis superimposed on fissured coronary artery plaques.[52] Further, evidence to support this hypothesis comes from

the Coronary Artery Revascularization Prophylaxis (CARP) trial[53] which randomized 510 patients undergoing elective vascular surgery, who had at least one coronary artery with a ≥70% stenosis that was suitable for revascularization, to receive coronary artery revascularization or no coronary artery revascularization before vascular surgery. This trial did not demonstrate a significant reduction in perioperative myocardial infarctions in the patients who first underwent coronary revascularization prior to their non-cardiac surgery. If hemodynamically significant stenoses are the major cause of perioperative myocardial infarctions, it is surprising that there was no reduction in the risk of a perioperative myocardial infarction despite coronary revascularization prior to non-cardiac surgery.

These limited and conflicting data regarding the pathophysiology of perioperative myocardial infarction highlight the need for large studies to provide insights. Such studies will inform the selection of appropriate preventive and management interventions to evaluate in subsequent large randomized controlled trials.

Diagnosing perioperative myocardial infarction

A recent review identified studies assessing patients undergoing non-cardiac surgery, that required patients to have at least one measurement of a cardiac biomarker or enzyme after surgery, and reported whether patients who suffered a perioperative myocardial infarction experienced cardiac symptoms.[54] This review identified three studies that included a total of 1309 patients, and 38 of these patients suffered a perioperative myocardial infarction.[55–57] Although the small sample size requires cautious interpretation, the findings were striking. Of the patients who suffered a perioperative myocardial infarction, only 14% experienced chest pain and only 53% had any potential sign or symptom that could have suggested a myocardial infarction.

These results are similar to the findings in the recent POISE trial, which also monitored cardiac biomarkers or enzymes in all patients for the first 3 days after surgery. Box 5.1 presents the definition used for myocardial infarction in the POISE trial, in which only 35% of the patients suffering a perioperative myocardial infarction had ischemic symptoms.[5] The fact that approximately 75% of these myocardial infarctions occurred within the first 48 hours after surgery helps to explain why so many patients may not have experienced ischemic symptoms (i.e. this is a period when the majority of patients receive high-dose analgesic medication to blunt surgical discomfort). These data suggest perioperative myocardial infarctions present differently from the majority of myocardial infarction in the emergency room and that perioperative myocardial infarctions are at high risk of going undetected if troponin measurements are not monitored for the first few days after surgery. The ongoing VISION Study will provide further

---

BOX 5.1 Diagnostic criteria for perioperative myocardial infarction in the POISE trial

The diagnosis of perioperative myocardial infarction required any one of the following

Criterion 1   A typical rise of troponin or a typical fall of an elevated troponin or a rapid rise and fall of CK-MB. Patients also had to have one of the following:
1. ischemic signs (e.g. chest, arm or jaw discomfort; shortness of breath)
2. development of pathologic Q waves in two contiguous leads on an ECG
3. ECG changes indicative of ischemia in at least two contiguous leads
4. coronary artery intervention (e.g. percutaneous coronary intervention)
5. new or presumed new cardiac wall motion abnormality on echocardiography or new or presumed new fixed defect on radionuclide imaging

Criterion 2   Pathologic findings of an acute myocardial infarction

ECG, electrocardiogram.

---

insights into this issue in a large unselected population of patients undergoing non-cardiac surgery who are having troponins monitored throughout the first 3 days after surgery.

Do perioperative myocardial infarctions matter and is surveillance justified?

A relevant question is whether a perioperative myocardial infarction alters prognosis to an extent that would justify routine monitoring for this event. In the POISE trial both asymptomatic and symptomatic perioperative myocardial infarctions were independent predictors of death at 30 days (OR 3.45; 95% CI 2.20–5.41 and OR 3.31; 95% CI 1.78–6.15, respectively). Smaller studies have also suggested that an elevation of a troponin measurement after surgery is an independent predictor of death in the first year after surgery.[58,59] These data suggest perioperative myocardial infarctions alter prognosis in an important way.

Another relevant question is whether detecting perioperative myocardial infarctions that would have otherwise gone unrecognized will allow physicians to improve patient outcomes. A present, there are no randomized controlled trials evaluating interventions among patients suffering a perioperative myocardial infarction. Therefore, it remains unproven that physicians detecting perioperative

myocardial infarction can improve patient outcomes, but there is a strong rationale to suspect that the detection of perioperative myocardial infarctions will enhance patient outcomes.

Between 10% and 20% of patients suffering a perioperative myocardial infarction will die prior to hospital discharge,[57,60] and it is logical to assume that early detection of a myocardial infarction will afford physicians the greatest opportunity to prevent death, as is the case in the non-operative setting. A number of strategies for managing detected perioperative myocardial infarctions are more likely to benefit than harm patients, including: (1) more frequent monitoring of vital signs to allow early detection and reversal of cardiovascular instability; (2) management in a telemetry monitored unit or cardiac care unit; (3) identifying and correcting potential contributing factors (e.g. hypoxia, anemia); (4) optimal intravascular volume management to minimize the risk of heart failure; and (5) a few therapies known to benefit patients suffering a non-operative myocardial infarction (e.g. acetyl-salicylic acid (ASA), angiotensin-converting enzyme (ACE) inhibitor).[61]

We believe that it is also reasonable to suspect that even patients who would survive to hospital discharge, despite having suffered an undetected perioperative myocardial infarction, can benefit from detection of their myocardial infarction. Approximately 10% of patients who suffer a perioperative myocardial infarction with or without signs or symptoms will suffer a major cardiac event within 1 year of hospital discharge after surgery.[57,62,63] Given that the majority of these patients have some degree of underlying coronary artery stenosis,[46,47,52] it would seem prudent to offer these patients long-term management with known beneficial secondary prophylaxis cardiac interventions (e.g. beta-blocker, HMG CoA reductase inhibitor (statin)), until definitive perioperative myocardial infarction randomized controlled trials are conducted.

Prevention of perioperative vascular complications

The plethora of triggers and activated mechanisms (e.g. pain, fasting, hypothermia, bleeding/anemia, platelet activation, hypercoagulability, inflammation, sympathetic activation)[3] that may result in a perioperative myocardial infarction suggests many potential prophylactic interventions. This multitude of triggers and mechanisms also suggests it is unrealistic to expect that any single intervention, which is likely to affect no more than a few triggers or mechanisms, will have a large effect. Realistic moderate-sized treatment effects can, however, have substantial impact in preventing major vascular complications among the 200 million adults globally who undergo non-cardiac surgery annually.

Beta-blockers

In the 1970s, physicians were encouraged to withhold beta-blockers prior to surgery out of concern that beta-blockers would inhibit compensatory cardiovascular responses when patients developed hypotension in the perioperative setting.[64] As research suggested that tachycardia was associated with increased myocardial oxygen demand and perioperative cardiovascular events this led to physicians (starting in the 1980s) to propose using perioperative beta-blockers as a means to prevent major perioperative cardiovascular complications.[65] Two small trials in the 1990s (total sample 312 patients) with methodologic limitations (unblinded, stopped early for unexpected large treatment effects, failure to follow intention-to-treat principle) suggested perioperative beta-blockers had a large treatment effect in preventing major cardiovascular events and death.[66,67] Based upon physiologic rationale and the results of these two trials, guideline committees recommended giving perioperative beta-blockers to patients undergoing non-cardiac surgery who were considered at risk for a major perioperative cardiovascular event.[68,69] In 2006 two moderate-sized trials (1417 patients in total), which did not suffer from the methodologic limitations of the early trials, reported no benefit with perioperative beta-blockers.[70,71] Despite these new data, guideline committees continued to recommend perioperative beta-blockers.[72]

Most recently, the POISE trial evaluated the effect of a perioperative beta-blocker versus placebo in 8351 patients recruited in 190 hospitals in 23 countries.[5] POISE included patients with or at risk of atherosclerotic disease who were undergoing non-cardiac surgery. The intervention was extended-release metoprolol succinate (metoprolol CR) or matching placebo. Patients had to have a systolic blood pressure (SBP) $\geq$100 mmHg and a heart rate $\geq$50 beats per minute (bpm) in order to receive the study drug. The dosing regimen in POISE was designed so that patients could get 200 mg of the study drug (i.e. metoprolol CR or matching placebo) during the first 24 hours.[73] Patients received 100 mg 2–4 hours prior to surgery and then another 100 mg 6 hours after surgery. Patients thereafter received 200 mg of the study drug daily for 30 days. If a patient's heart rate was below 45 bpm or their SBP < 100 mmHg, their study drug was withheld until their heart rate or SBP recovered and then they restarted the study drug at 100 mg orally once a day. Patients whose heart rate was 45–49 bpm and SBP >100 mmHg delayed taking the study drug for 12 hours until their hemodynamic measurements recovered.

In the POISE trial 99.8% of the patients completed the 30-day follow-up and all analyses were undertaken according to the intention-to-treat principle. Fewer patients in the metoprolol CR group (244, 5.8%) suffered the primary outcome (i.e. a composite of cardiovascular death, non-

fatal myocardial infarction, and non-fatal cardiac arrest) compared to the placebo group (290, 6.9%) (HR for the metoprolol group, 0.84; 95% CI 0.70–0.99; $P = 0.04$).[5] This beneficial effect resulted from a reduction in myocardial infarction (176, 4.2%, in the metoprolol group compared to 239, 5.7%, in the placebo group; HR 0.73; 95% CI 0.60–0.89; $P = 0.002$). In contrast to this beneficial effect there was an excess of deaths in the metoprolol CR group (129, 3.1%) compared to the placebo group (97, 2.3%) (HR 1.33; 95% CI 1.03–1.74; $P = 0.03$). Further, there were more strokes in the metoprolol group (41, 1.0%) than in the placebo group (19, 0.5%) (HR 2.17; 95% CI 1.26–3.74; $P = 0.005$).

To many, the excess of deaths and strokes was a surprise finding. These findings are, however, supported by a recently published meta-analysis of high-quality perioperative beta-blocker randomized controlled trials by Bangalore and colleagues.[74] This meta-analysis, which included the POISE data, demonstrated a higher death rate among patients assigned a beta-blocker (160, 2.8%) compared to control (127, 2.3%) (OR 1.27; 95% CI 1.01–1.61; I^2 27%), and a higher risk of non-fatal strokes among patients assigned a beta-blocker (38, 0.7%) compared to control (17, 0.3%) (OR 2.16; 95% CI 1.27–3.68; I^2 0%).[74]

Further analyses in the POISE trial offer insights into whether and how metoprolol CR may have resulted in an excess of deaths and strokes. More patients assigned metoprolol CR (625, 15.0%) compared to placebo (404, 9.7%) experienced clinically significant hypotension (i.e. a SBP < 90 mmHg that someone had to do something about) (HR 1.55; 95% CI 1.38–1.74; $P < 0.0001$). *Post hoc* multivariable analyses were undertaken and population-attributable risks (PARs) were reported, which represent the proportion of all outcomes attributable to the relevant risk factor if causality were proven. Clinically significant hypotension had the largest PAR (37.3%) for death and the largest intraoperative/postoperative PAR (14.7%) for stroke. These findings suggest that an important pathway through which perioperative metoprolol CR caused death and stroke might be clinically significant hypotension.

The finding of excess deaths related to shock with perioperative beta-blockers is similar to the signal seen in the world's largest non-operative beta-blocker trial (i.e. the COMMIT trial), which randomized 45 852 patients to metoprolol CR or placebo in acute myocardial infarction.[75] In the COMMIT trial there was no impact on 30-day mortality but there was a statistically significant increase in death due to shock with beta-blocker therapy.[75] The main difference between POISE and COMMIT was that clinically significant hypotension was more common in the perioperative setting in POISE than in the acute myocardial infarction setting in COMMIT, and this may explain why the overall balance of total mortality went up in POISE and was neutral in COMMIT.[5,75]

Questions raised after POISE

Some authors have suggested that the beta-blocker dose used in POISE was too high.[76] Would a lower dose of a perioperative beta-blocker provide the benefits seen in POISE without the demonstrated risks? POISE used metoprolol CR (a long-acting beta-blocker) and targeted a dose that represents 50% of the maximum daily therapeutic dose (MDTD). Considering the two small positive beta-blocker trials – that have a total sample that is 4% of POISE's sample size – upon which the guidelines primarily based their recommendations, the first of these trials used atenolol (a long-acting beta-blocker) and targeted a dose that represents 50% of the MDTD.[66] The second used bisoprolol (a long-acting beta-blocker) starting at a dose that represents 25% of the MDTD and allowed titration to 50% of the MDTD.[67] The next largest perioperative beta-blocker trial after POISE is the DIPOM trial, which randomized 921 patients.[70] DIPOM used metoprolol CR and targeted a dose that represents 25% of the MDTD. The 30-day data from DIPOM demonstrated a trend towards excess deaths and strokes with metoprolol CR despite using half the POISE dose. Consistent with these findings are the results of the recent perioperative beta-blocker meta-analysis by Bangalore and colleagues that demonstrated a consistent finding of excess deaths and strokes with various perioperative beta-blockers and dosing regimens.[74] Although it is possible that a different perioperative beta-blocker dosing regimen may provide the benefits seen in POISE while avoiding the risks, the current evidence suggests this is unlikely.

Some authors have suggested that there is a benefit to starting a beta-blocker earlier than the initiating time used in POISE.[76] Considering that POISE demonstrated that a beta-blocker resulted in a beneficial effect when starting just a few hours prior to surgery (e.g. reduction in risk of myocardial infarction), the relevant question is whether starting a beta-blocker weeks prior to surgery would make the drug safe. Although this is possible, the POISE results offer insights that suggest it is not probable. In POISE 9.7% of the patients in the placebo group developed clinically significant hypotension. Therefore, a titrated beta-blocker dose that appears effective preoperatively is unlikely to inform what dose of a beta-blocker is safe after surgery when clinically significant hypotension is common. Another relevant question relates to the practicality of seeing patients preoperatively, initiating a beta-blocker, and seeing them a few more times before surgery to titrate their beta-blocker. Given that worldwide there are likely 100 million at risk adults undergoing non-cardiac surgery annually and most preoperative clinics see patients very close to the time of surgery, the practicality of starting and titrating a beta-blocker before surgery is questionable.

Another relevant question is how physicians should manage patients undergoing non-cardiac surgery who are already taking a beta-blocker. POISE does not directly inform this question, because it excluded patients who were already taking a beta-blocker prior to surgery. Issues to consider include the following: the potential exacerbation of cardiac ischemia that may occur from stopping a beta-blocker acutely before a patient undergoes surgery; and the beta-blocker dose that is safe in the non-operative setting may still exacerbate clinically significant hypotension after surgery and result in the negative consequences demonstrated in POISE. Until a large, adequately powered trial is undertaken to directly inform this issue, physicians may want to consider halving the patient's beta-blocker dose around the time of surgery (i.e. starting on the morning of surgery and continuing for the first few days after surgery) and to only administer the beta-blocker if the patient's SBP is >115–120 mmHg. This suggestion tries to balance the concern about beta-blocker withdrawal ischemia and exacerbating clinically significant hypotension after surgery with a beta-blocker. This suggestion is not, however, informed from strong direct evidence, and therefore physicians will have to individualize the perioperative management of each patient who is on a beta-blocker until strong direct evidence becomes available.

Take-away message from POISE

POISE suggest that for every 1000 patients with a similar risk profile undergoing non-cardiac surgery, metoprolol CR would prevent 15 patients from suffering a myocardial infarction, three from undergoing cardiac revascularization, and seven from developing new clinically significant atrial fibrillation. POISE also suggests that metoprolol CR would result in an excess of eight deaths, five patients suffering a stroke, 53 experiencing clinically significant hypotension, and 42 experiencing clinically significant bradycardia. Patients who would place three times more value on avoiding a perioperative stroke (a majority of which resulted in death, incapacitation or a patient requiring help with everyday activities) compared to a perioperative myocardial infarction (a minority of which resulted in death or ischemic symptoms), or who are unwilling to accept a probable increase in mortality, would not want a perioperative beta-blocker.

POISE has another take-away message that goes beyond perioperative beta-blockers. Guidelines have recommended perioperative beta-blockers for over a decade. Even if only 10% of physicians acted on the guideline recommendations throughout the last decade (several studies suggest >30% of physicians prescribed a perioperative beta-blocker to the at-risk patients),[77–79] 100 million patients would have received a beta-blocker around the time of

surgery. If the results of POISE are widely applicable, throughout the last decade 800 000 patients would have died prematurely and 500 000 patients would have suffered a stroke because they were given a beta-blocker around the time of surgery. This highlights the risk in assuming a perioperative beta-blocker regimen has benefit without substantial harm, and the importance and need for large randomized trials in the surgical setting.

Alpha-2 agonists

Like beta-blockers, alpha-2 agonists attenuate the stress response but through a different mechanism. Alpha-2 agonists act on central and presynaptic receptors to inhibit the release of norepinephrine, causing an overall reduction in central sympathetic outflow.[80,81] A meta-analysis of alpha-2 agonists included 12 non-cardiac surgery randomized controlled trials that assessed three alpha-2 agonists (clonidine, dexmedetomidine, mivazerol).[82] The authors of this systematic review reported separately the results for patients who had vascular surgery and patients who had non-vascular non-cardiac surgery. The meta-analysis demonstrated a statistically significant reduction in both deaths (39 events; relative risk (RR) 0.47; 95% CI 0.25–0.90) and myocardial infarction (110 events; RR 0.66; 95% CI 0.46–0.94) with alpha-2 agonist therapy among the patients who underwent vascular surgery. The investigators found no effect on mortality (31 events; RR 1.09; 95% CI 0.52–2.09) and myocardial infarction (62 events; RR 1.25; 95% CI 0.83–2.21) among the patients who underwent non-vascular non-cardiac surgery. The six trials that reported hypotension did not support an increase with administration of an alpha-2 agonist around the time of non-cardiac surgery (RR 1.03; 95% CI 0.89–1.21; P for heterogeneity 0.22).

Clonidine is the most widely available alpha-2 agonist, and it has a number of effects that make it attractive as a potential agent to prevent major cardiovascular complications around the time of non-cardiac surgery. Perioperative clonidine results in documented sympatholysis,[83,84] anesthetic/sedative/ anxiolytic/analgesic effects,[85–87] and anti-shivering effects[88] and is able to reduce tissue necrosis factor (TNF)-alpha and myocardial oxygen uptake.[89,90] A meta-analysis of two small randomized control trials (total sample size 358 patients) and another small randomized controlled trial (sample size 190 patients), published since the systematic review, have demonstrated that perioperative administration of clonidine reduces the incidence of myocardial ischemia in patients undergoing non-cardiac surgery without significantly affecting hemodynamic stability.[84,91] This is in contrast to a meta-analysis of trials of perioperative beta-blockers that demonstrated a clear increase in hypotension requiring treatment across 10 non-cardiac surgery trials (RR 1.27; 95% CI 1.04–1.56; I^2 6%).[92] Although these results are encouraging, they warrant a

cautious interpretation. Confirmation of these results is required in a large, well-designed trial.

ASA

Immediately after non-cardiac surgery, patients experience a rise in circulating platelet release products.[93] Platelet surface catalyzing coagulation reactions facilitate thrombin generation and these events may promote thrombus formation and lead to arterial occlusion in the perioperative setting.[3] Acute withdrawal of chronic ASA results in a pro-thrombotic state (i.e. increased thromboxane A2 and decreased fibrinolysis).[94,95] Given these physiologic changes, ASA initiation or continuation for chronic users, which inhibits platelet aggregation, may prevent major perioperative vascular events.[96]

A systematic review of antiplatelet therapy versus placebo in patients undergoing infrainguinal bypass surgery identified 10 randomized controlled trials, of which six evaluated the effects of ASA.[97] There were 76 vascular events (i.e. vascular death, non-fatal myocardial infarction or non-fatal stroke) among the 893 patients randomized to antiplatelet therapy compared to 92 vascular events among the 872 patients randomized to placebo (OR 0.76; 95% CI 0.54–1.05).

In contrast to this encouraging evidence, the Pulmonary Embolism Prevention (PEP) trial suggested worse cardiac ischemic outcomes with ASA therapy in patients undergoing surgery for a hip fracture.[98] There were 105 cardiac ischemic events (i.e. death due to ischemic heart disease or non-fatal myocardial infarction) among the 6679 patients randomized to ASA compared to 79 cardiac ischemic events among the 6677 patients randomized to placebo (HR 1.33; 95% CI 1.00–1.78). More ASA patients (197) compared to placebo patients (1570 suffered a postoperative bleeding episode requiring a transfusion (relative risk increase (RRI) 24%; 95% CI 1–53%). In the PEP trial ASA therapy did, however, prevent pulmonary emboli (HR 0.43; 95% CI 0.18–0.60).

Given the clear evidence that ASA prevents cardiovascular events in the non-operative setting,[99] the conflicting randomized controlled trial evidence surrounding the impact of ASA on perioperative vascular events, and the likelihood of increased bleeding risk with perioperative ASA, there is a need for a large randomized controlled trial to determine the balance of benefits and risks of ASA in patients undergoing non-cardiac surgery. Until such a trial is completed, physicians will have to weigh the increased risk of bleeding against the potential but yet unproven vascular benefits.

Statins

Some authors have suggested the statins may prevent major perioperative vascular complications through plaque

stabilization and improved endothelial function.[100] A recent meta-analysis of 10 non-cardiac surgery observational studies demonstrated a reduction in the composite outcome of death and acute coronary syndrome among patients receiving a perioperative statin (OR 0.70; 95% CI 0.53–0.91); however, this benefit was only seen among the retrospective studies (OR 0.65; 95% CI 0.50–0.84) and was not demonstrated in the pooled estimate from the three prospective cohort studies (OR 0.91; 95% CI 0.65–1.27).[101] A recent large retrospective cohort study raised a safety concern related to perioperative statin use when it demonstrated an increased adjusted risk of delirium after non-cardiac surgery associated with statin use (OR 1.33; 95% CI 1.16–1.53).[102] The authors suggest this increased risk of delirium with statin use may have occurred as a result of altered cerebral blood flow autoregulation.[102,103]

Three randomized controlled trials have evaluated the effects of a perioperative statin among patients undergoing non-cardiac surgery, but two of these studies are only published in abstract form as of January 2009. The one full-text published trial randomized 50 patients to receive atorvastatin and 50 patients to receive placebo who were undergoing vascular surgery.[104] Patients started taking the study drug at least 2 weeks prior to vascular surgery and continued for a period of 45 days. Four patients in the atorvastatin group and 13 in the placebo group suffered the primary outcome (a composite of cardiac death, non-fatal myocardial infarction, ischemic stroke, and unstable angina) at 6 months after surgery (relative risk reduction 69%; 95% CI 18–89%). One of the trials reported in abstract form was an unblinded trial that randomized 1066 patients to fluvastatin XL 80 mg daily or control therapy starting a median of 34 days prior to non-cardiac surgery.[105] There was no effect on the primary outcome (a composite of cardiac death and myocardial infarction) at 30 days after surgery, with 3.2% of fluvastatin patients and 4.9% of control patients experiencing the primary outcome (HR 0.65; 95% CI 0.35–1.10). There were, however, only 43 primary events in this trial. The second trial, only available in abstract form, randomized 253 patients to fluvastatin XL 80 mg daily and 247 patients to placebo, a median of 34 days prior to vascular surgery.[106] Fewer patients in the fluvastatin group (27 patients, 10.9%) experienced the primary outcome (myocardial ischemia) compared to the placebo group (47 patients, 18.9%) (OR 0.56; 95% CI 0.35–0.89). The abstract also reports that fewer fluvastatin patients suffered the secondary outcome (a composite of cardiac death and non-fatal myocardial infarction) (OR 0.48; 95% CI 0.24–0.95); however, there were only 37 secondary events.

A meta-analysis evaluating the effect of early statin therapy in almost 18 000 patients suffering an acute coronary syndrome demonstrated no statistically significant effect on myocardial infarction until 24 months and no effect on cardiovascular death until 24 months.[107] These

results contrast the quick and large effects suggested in the small perioperative trials.

Given the limited nature of the current perioperative statin efficacy data, the contrasting non-operative data, and the potential safety concern, it is difficult to outline a firm perioperative statin recommendation. Until a large trial with a lot of events is undertaken, physicians will have to weigh the limited available data when deciding whether to prescribe a perioeprative statin.

Neuraxial blockade

Uncontrolled pain after surgery leads to stimulation of the sympathetic system and activation of coagulation cascade, which leads to an increase in heart rate, arterial pressure, myocardial oxygen demand, and hypercoagulability.[3] Effective epidural blockade provides superior analgesia and may therefore reduce perioperative vascular events.[108] A meta-analysis of 141 trials involving 9559 patients demonstrated a decrease in the incidence of death (total of 247 deaths) after surgery with neuraxial blockade (epidural and spinal anesthesia) (OR 0.70; 95% CI 0.54–0.90), and neuraxial blockade also demonstrated a significant reduction in vascular events (venous thrombotic events, myocardial infarctions), bleeding requiring a transfusion, and pneumonia.[109] A subsequent meta-analysis of 11 trials that included 1173 patients evaluated the effects of postoperative epidural analgesia and demonstrated a trend towards a lower rate of perioperative myocardial infarction (total of 44 myocardial infarctions) with epidural analgesia (OR 0.56; 95% CI 0.30–1.03).[110]

Since the publication of these meta-analyses, two moderate-sized randomized controlled trials have been published. Despite better postoperative pain relief, the Multicenter Australian Study of Epidural Anesthesia (MASTER) trial found no effect of epidural anesthesia and analgesia on death (5.2% versus 4.3% in the treatment and control group, respectively) and cardiovascular events (25.7% versus 24.0% in the treatment and control group, respectively) among the 915 participants who underwent major abdominal surgery.[108] Similarly, the Veterans Affairs Co-operative Study (VACS, n = 1021) failed to observe a benefit with epidural anesthesia/analgesia (death occurred in 20 versus 17 patients and myocardial infarction in 44 versus 57 patients assigned to the treatment and control groups, respectively).[111] The lack of significant findings in these two trials may simply relate to their limited power. But these are the two largest trials and relatively free of biases.

Cardiac revascularization

The Coronary Artery Revascularization Prophylaxis (CARP) trial evaluated the management strategy of preoperative coronary artery revascularization prior to non-cardiac surgery.[53] Patients undergoing elective vascular surgery for an abdominal aortic aneurysm or severe claudication were recommended for coronary angiography. Patients were eligible if they had at least one coronary artery with a ≥70% stenosis that was suitable for revascularization; 33% of the patients who participated in the trial had three-vessel coronary artery disease. The trial excluded patients with unstable angina, left main coronary artery stenosis ≥50%, a left ventricular ejection fraction <20% or severe aortic stenosis.

It randomized 258 patients to receive coronary artery revascularization before vascular surgery and 252 patients to receive *no* coronary artery revascularization before vascular surgery, and patients were followed for a mean of 2.7 years. Among the patients assigned to coronary artery revascularization, 38% underwent CABG surgery, 55% underwent PCI, and 7% did not receive coronary revascularization. The primary outcome of total mortality during the long-term follow-up demonstrated 70 deaths in the revascularization group and 67 in the no revascularization group (RR 0.98; 95% CI 0.70–1.37).

A recent pilot trial randomized 101 patients undergoing major vascular surgery who demonstrated extensive cardiac ischemia on their preoperative cardiac stress test.[112] Coronary angiography in the patients assigned to coronary revascularization prior to non-cardiac surgery demonstrated three-vessel coronary disease in 67% of the patients. The primary outcome (a composite of death and myocardial infarction) at 30 days after the index surgical procedure occurred in 21 patients (43%) assigned to receive coronary revascularization prior to their vascular surgery and in 17 (33%) assigned to receive *no* coronary artery revascularization before their vascular surgery (HR 1.4; 95% CI 0.73–2.8).

Although these two trials do not exclude the possibility of a reduction in risk from preoperative coronary artery revascularization prior to non-cardiac surgery, they do not support any benefit from this invasive, time-consuming, and costly intervention.

Conclusion

Non-cardiac surgery is common, and annually several million patients will suffer a major vascular complication in the first 30 days after surgery. Clinical risk factors such as coronary artery disease and cerebrovascular disease can help to identify patients at risk of a major perioperative vascular complication. A preoperative NT-proBNP measurement may substantially enhance perioperative vascular risk prediction and troponin measurements for the first few days after surgery hold great promise as a surveillance strategy to allow physicians to avoid missing the majority of perioperative myocardial infarctions. The results of the POISE trial, which demonstrated that a perioperative beta-

blocker prevented myocardial infarctions but at a cost of excess strokes and deaths, highlight why large perioperative trials are necessary. There is encouraging evidence that several interventions (e.g. clonidine) may prevent major perioperative vascular complications; however, there is an urgent need for large trials to evaluate these interventions. Current evidence does not support a management strategy of coronary artery revascularization prior to non-cardiac surgery.

6 Implementing evidence-based medicine in cardiology

Brahmajee K Nallamothu,[1] Thomas T Tsai[1] and Jack V Tu[2]
[1]University of Michigan, Ann Arbor, MI, USA
[2]Schulich Heart Program, Sunnybrook Health Sciences Center, Toronto, Canada

Introduction

Remarkable advancements have been made over the last several decades in our understanding of the basic mechanisms and treatments related to cardiovascular diseases. This has led to dramatic improvements in public health. Between 1960 and 2000, for example, overall life expectancy for newborns in the United States increased by nearly seven years with approximately 70% of these gains in survival resulting specifically from lower rates of cardiovascular death.[1] For coronary artery disease (CAD) alone, age-adjusted mortality fell by more than 50% during the past two decades.[2] Similar patterns of improvements in survival have also been noted for patients with heart failure, despite an overall rising prevalence of this condition due to aging populations.[3,4]

Importantly, many of these benefits have been attributed to the discovery of evidence-based therapies in cardiology. Aspirin, beta-blockers, angiotensin-converting enzyme (ACE) inhibitors and statins can reduce the risk of death after acute myocardial infarction (AMI) by 20–35%.[5,6] The timely use of acute reperfusion therapy in ST elevation myocardial infarction lowers mortality by an additional 25%.[7] In heart failure, ACE inhibitors, angiotensin receptor blockers (ARB) and aldosterone blockers have all been linked to significant improvements in quality of life as well as lower rates of hospital admissions and mortality in patients with impaired left ventricular (LV) systolic function.[8] Similar advances have been noted in atrial fibrillation with anticoagulation therapy,[9] acute stroke management with fibrinolytic therapy,[10] and in the primary and secondary prevention of cardiovascular events using aspirin, statins and lifestyle modifications like smoking cessation counseling.[11]

Development of new therapies has been the traditional role of large national biomedical enterprises like the National Institutes of Health (NIH), as well as the pharmaceutical and device industries. Over the last several decades, this framework has been enormously successful in expanding the "evidence" behind much of what we know. However, it has clearly fallen short in its ability to guide these same scientific breakthroughs into routine clinical practice. Despite established data supporting their use, long-term adherence rates to evidence-based therapies such as aspirin, beta-blockers and statins in patients with CAD remain low in community-based practices across the United States, at between 45% and 70%.[12] For heart failure, long-term adherence rates for ACE inhibitors may be as low as 20%.[12] In fact, some estimates suggest that it takes on average 17 years for new therapies to be adopted into widespread clinical practice.[13] Simply increasing the use of existing evidence-based therapies in cardiology would have profound implications for the healthcare system and enhance the public health as much as new discoveries.

Practice gaps, knowledge translation and quality improvement science

The practice gaps between "what we know" and "what we do" have been well documented and widely recognized by policy makers and providers, although the reasons for them are less certain.[14] Moreover, these practice gaps are not limited to any single country or healthcare system but have been shown in a variety of regions and settings.[15] Strategies to address these challenges were introduced years ago but gained much more momentum during the 1990s, evolving from approaches that relied on the passive diffusion of knowledge to recent efforts to incorporate information technology and systems engineering into a transformation of the healthcare delivery system. Yet despite these advances, substantial practice gaps remain in medicine and these have been difficult to overcome. In its

landmark report in 2001, the Institute of Medicine (IOM) referred to these practice gaps as the "quality chasm" and called for renewed efforts to develop better systematic approaches for bringing evidence to the bedside.[16]

Accordingly, this chapter focuses on strategies for improving the implementation of evidence-based cardiology based on research in knowledge translation. Knowledge translation has been described variably but a frequently cited definition is the one proposed by the Canadian Institutes of Health Research:

> "Knowledge translation is a dynamic and iterative process that includes synthesis, dissemination, exchange and ethically sound application of knowledge to improve the health of [populations], provide more effective health services and products and strengthen the health care system."[17]

Furthermore, the scientific investigation of specific methods to promote the use of research findings in clinical practice may be considered "quality improvement" science or research.[18] In different settings, similar concepts have been labeled as "knowledge transfer research" and "implementation science or research". In this chapter, we most frequently use the terms "knowledge translation" and "quality improvement science".

In the following sections, we discuss (1) the overall scope of the problem in practice gaps, (2) possible barriers identified in translating evidence to clinical practice, and (3) specific approaches that have been studied in quality improvement science to overcome these barriers. Many of the issues raised here are universal to medicine but we try to focus on examples in cardiology while still highlighting broader themes. We end the chapter by briefly discussing unique challenges faced in quality improvement science, including the growing tension between the immediate desire to improve quality and the rigor required for objectively studying its improvement.

Practice gaps: scope of the problem

Evidence-based medicine has been described as "the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients".[19] The application of evidence-based medicine therefore is necessarily dependent upon the existence of a mature base of knowledge that can inform providers of what treatments are appropriate (and inappropriate) in specific clinical settings. Despite the fact that persistent voids continue to remain in some key clinical areas within cardiology, no specialized field of medicine is as well developed or evidence-based. This makes cardiology ideally suited in many ways for providers to optimize their

use of evidence-based approaches. Yet even in areas of cardiology with a clear base of evidence, like acute myocardial infarction (AMI), heart failure, atrial fibrillation and hypertension, the practice gaps between "what we know" and "what we do" remain large and extend across the entire spectrum of care from inpatient to outpatient settings (Table 6.1).

Hospital setting

Practice gaps in the inpatient setting have been demonstrated for a number of disease processes in cardiology. For

Table 6.1 Recent examples of practice gaps in cardiovascular disease

Condition	Example
Coronary artery disease	*Beta-blocker use:* • Hospital data from 2004 indicate that mean performance at US hospitals for beta-blockers at admission remains at 85% (Jha *et al* 2005[86]) • Outpatient data from 1998 to 2000 indicate that 45% of patients with prior myocardial infarction remain on long-term beta-blockers (McGlynn *et al* 2003[12])
Heart failure	*ACE inhibitor use:* • Inpatient data from 2002 to 2003 found that median rates of compliance with ACE inhibitors in hospitalized patients with heart failure and left ventricular systolic dysfunction are suboptimal at 72% (Fonarow *et al* 2005[25]) • Outpatient data suggest that only 60–65% of Medicare patients with heart failure and left ventricular systolic dysfunction who are discharged on ACE inhibitors remain on these agents 90 days after their hospitalization (Butler *et al* 2004[87])
Atrial fibrillation	*Anticoagulation:* • Among 5333 inpatients and outpatients with atrial fibrillation enrolled in 35 countries in the Euro Heart Survey between 2003 and 2004, 67% of eligible patients and 49% of ineligible patients were prescribed oral anticoagulation therapy (Nieuwlaat *et al* 2005[29])
Hypertension	*Blood pressure management:* • NHANES data from 1999 to 2000 suggest that only 31% of patients with hypertension in the US had blood pressures under adequate control. Furthermore, 31% were not even aware of their disease (Wang and Wang 2004[88]) • REACH Registry data found 55% of patients with a history of atherothrombosis and hypertension to have elevated blood pressures noted at their clinic visit (Bhatt *et al* 2006[31])

example, acute reperfusion therapy with either fibrinolytic therapy or primary percutaneous coronary intervention (PCI) in ST elevation myocardial infarction reduces mortality and morbidity. While the use of acute reperfusion therapy has improved over recent years, recent data suggest that worldwide, as many as a third of eligible patients still do not receive it even at centers capable of delivering both treatments.[20] Furthermore, the overall effectiveness of acute reperfusion therapy is highly dependent upon its timely delivery, but both fibrinolytic therapy and primary PCI are often administered after long delays. Data from just a few years ago suggest that fewer than 50% of patients in the United States were treated with primary PCI within 90 minutes or fibrinolytic therapy within 30 minutes.[21] Similar practice gaps have been noted in other countries, including those in the developing world. In India, for example, evidence-based therapies like acute reperfusion therapy, beta-blockers, ACE inhibitors (or ARBs) and statins are used in between 50% and 60% of hospitalized patients with acute coronary syndromes.[22]

Others have documented wide regional variation in the appropriate use of cardiac catheterization and PCI after AMI (including data that suggest both under- and overutilization).[23,24] In a recent analysis of nearly 45 000 patients, investigators noted that regions of the United States with a higher intensity of invasive procedure utilization performed cardiac catheterization at increased rates in both appropriate (i.e. for an ACC/AHA Class I indication) and inappropriate (i.e. for an ACC/AHA Class III indication) situations.[24] In addition, the use of invasive procedures was inversely correlated to the baseline risk of the patient assessed by their Global Registry of Acute Coronary Events (GRACE) risk score.

Similar patterns of practice gaps in the inpatient setting (including recent trends toward improvement) have also been demonstrated in heart failure and atrial fibrillation.[25,26] For example, the initial Euro Heart Surveys found rates of ACE inhibitor and beta-blocker use of 61.8% and 36.9%, respectively, among hospitalized patients with heart failure,[27] although these numbers have improved somewhat in more recent surveys.[28] Among inpatients and outpatients patients with atrial fibrillation enrolled at 182 hospitals in 35 countries in the Euro Heart Survey, roughly two-thirds of eligible patients were prescribed oral anticoagulation therapy.[29] Furthermore, oral anticoagulation therapy was not targeted at those patients who were the highest risk for stroke but instead depended upon nonclinical factors such as the availability of outpatient laboratory monitoring.[30]

Outpatient setting

In 2003, McGlynn *et al* published a landmark study demonstrating that just over 50% of patients received "recom-

mended" care for a variety of healthcare conditions in the outpatient setting, using a complex survey design of 12 metropolitan areas of the United States between 1998 and 2000.[12] Recommended care in this study primarily focused on processes of care that were defined using the RAND-UCLA modified Delphi method to specific identify quality indicators through expert panels. Although rates of compliance with recommended care were generally higher for CAD (68%) and heart failure (64%) than other disease-specific conditions, critical practice gaps were still noted. For example, only 45% and 61% of patients with myocardial infarction received beta-blockers and aspirin, respectively, despite the absence of clear contraindications and strong evidence of long-term benefit with both. Rates of recommended care associated with atrial fibrillation were even less and dropped below 25%. Furthermore, the investigators noted broad differences in practice gaps based on the "mechanism" required for performing recommended care, regardless of the healthcare condition. Care that was related to direct encounters with providers or medications had the highest proportion of compliance at approximately 70%, whereas counseling or education was performed in fewer than 20% of cases (Table 6.2).

Similar findings were also noted in the international REACH registry, which enrolled nearly 68 000 patients 45 years or older with evidence of atherosclerotic disease from 5473 physician practices across 44 countries.[31] Physician practices in this registry included a broad mix of clinical practices such as primary care providers and specialists; urban, rural and suburban environments; and office-based and hospital-based settings. Importantly, this study noted suboptimal adherence rates with statins (69%) and antiplatelet agents (79%) in these patients, as well as evidence for undertreatment of hypertension, with 50% of patients found to have elevated baseline blood pressures above 140/90 mmHg.

Disparities and the risk-treatment paradox

Key patterns have emerged from these studies with important clinical and policy implications. First, practice gaps that have been documented in clinical practice have consistently been largest among vulnerable populations, including the elderly, minority patients and women. These appear to be particularly evident for expensive and resource-intensive procedures, such as coronary revascularization and implantable cardioverter defibrillators (ICDs).[32–34] The extent to which these practice gaps are due to biological factors, reduced access to care, or systematic biases in the delivery of care to vulnerable populations is unclear. A similar association between practice gaps and socioeconomic status has also been recognized, including examples from developing countries. In the CREATE

Table 6.2 Adherence to outpatient quality indicators by mechanism in a random sample of US adults from 12 metropolitan areas (from McGlynn et al 2003[12])

Indicator area	No. of indicators	No. of participants eligible	Total no. of times indicator eligibility was met	Percentage of recommended care received (95% CI)*
Encounter or other intervention	30	2843	4,329	73.4 (71.5–75.3)
Medication	95	2964	8,389	68.6 (67.0–70.3)
Immunization	8	6700	9,748	65.7 (64.3–67.0)
Physical examination	67	6217	19,428	62.9 (61.8–64.0)
Laboratory testing or radiography	131	5352	18,605	61.7 (60.4–63.0)
Surgery	21	244	312	56.9 (51.3–62.5)
History	64	6711	36,032	43.4 (42.4–44.3)
Counseling or education	23	2838	3,806	18.3 (16.7–20.0)

*CI denotes confidence interval. All pairwise differences were statistically significant at $P < 0.001$ except those between medication and encounter or other intervention ($P = 0.02$), physical examination and immunization ($P = 0.001$), surgery and immunization ($P = 0.004$), and surgery and physical examination ($P = 0.05$). The difference between surgery and laboratory testing or radiography was not significant ($P = 0.39$).

registry, for example, 30-day mortality was significantly higher in poor hospitalized patients with acute coronary syndromes when compared with rich patients in 50 cities across India. Importantly, this mortality difference was largely explained by differences in rates of evidence-based therapy use. Studies such as the CREATE registry have provided invaluable insights by focusing on low- and middle-income countries where 80% of the global burden of cardiovascular disease exists. In general, there remains a paucity of data from these countries on practice gaps and additional work is urgently needed to improve our understanding of clinical practice patterns in these regions.

Second, there is evidence supporting a "risk-treatment" paradox for many evidence-based therapies. That is, those patients who may stand to benefit the most from a therapy paradoxically are the least likely to receive it. Among nearly 1500 patients in the EFFECT cohort with heart failure and LV systolic dysfunction, ACE inhibitor, ARB and beta-blocker use were inversely associated with the severity of the patient's condition and their predicted risk of death in the upcoming year.[35] After accounting for potential contraindications to therapy, low-risk patients were more likely to receive ACE inhibitors or ARBs (adjusted hazard ratio (HR), 1.6) and beta-blockers (adjusted HR, 1.8) than high-risk patients (both $I < 0.001$). Similarly, another population-based study from Ontario found statin use to be significantly lower among high-risk patients with established CAD or diabetes mellitus.[36] Interestingly, recent data suggest that much of the risk-treatment paradox may be explained by clinical factors not typically captured in administrative data, including functional limitations and depressive symptoms.[37]

Barriers to knowledge translation

A number of common barriers to implementing evidence-based medicine in clinical practice have been identified. We focus here primarily on barriers related to provider-level (e.g. physician and hospital) and system-level factors. While we recognize the importance of patient-level factors in the use of evidence-based therapies, it is beyond the scope of this discussion. One simple conceptual model for understanding these barriers suggests that incorporating new therapies into clinical practice proceeds from changes in *knowledge* to *attitudes* to *behavior* (Fig. 6.1).[38,39] This model mirrors other approaches that emphasized the progression from awareness to acceptance to adoption among providers,[40] but slightly differs by noting that each step is potentially independent of others in the process. For example, behavior can be changed through incentives at the organizational-level without necessarily improving knowledge or attitudes among providers.

Knowledge

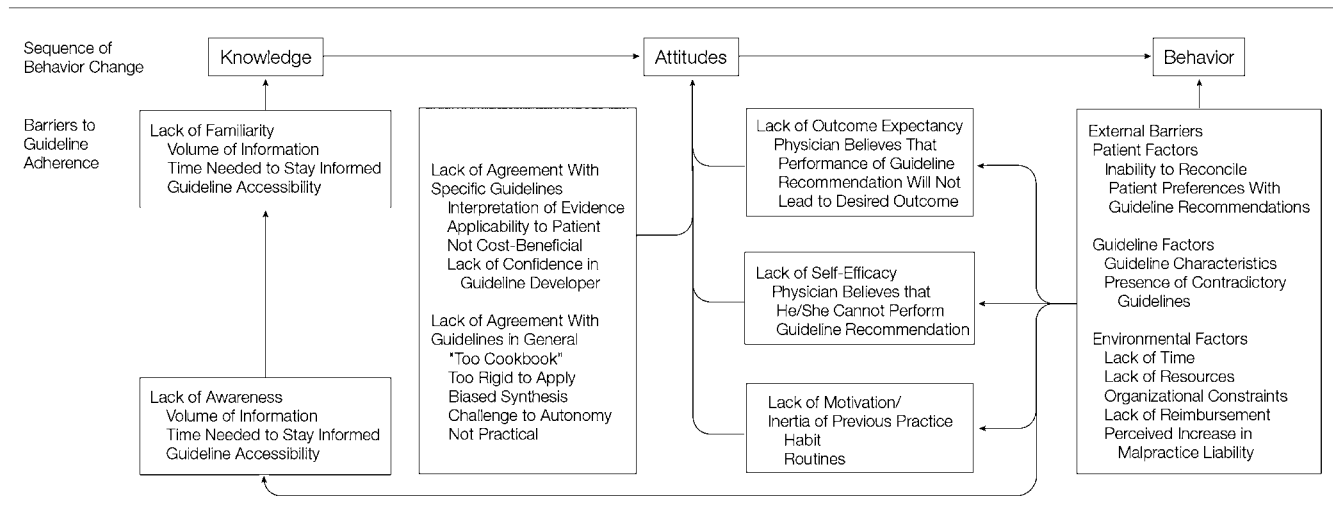
Improving knowledge relies on providing new information to clinicians primarily through increasing their awareness of the published literature. The enormous size and complexity of contemporary biomedical research make this a particularly challenging barrier to implementing evidence-based medicine. For example, in 2006 the top 10 clinical cardiovascular journals alone published 4065 articles, averaging 78 articles per week. It is clearly impossible for busy providers in clinical practice today to stay on top of the latest developments even in a specialized field like cardiol-


Figure 6.1 Barriers to use of guidelines and evidence-based medicine. (From Cabana *et al*,[38] with permission.)

ogy. An understanding of this barrier has led to the development of guidelines and evidence-based summaries to synthesize the published literature by professional organizations and other groups. In fact, it is one of the key motivations for writing this textbook.

Attitudes

Even when providers become familiar with the available evidence, recommendations may be incomplete or confusing. This can lead to barriers to changing the attitudes of providers (i.e. their acceptance of new evidence). For example, summary clinical guidelines and consensus statements from expert panels may be large, unmanageable or poorly developed.[41] Conflicting recommendations also can arise if different (and sometimes competitive) organizations produce separate guidelines for the same disease process. Finally, attitudes can limit acceptance when providers feel that recommendations inadequately reflect the nuances of clinical practice, making them less applicable to their patients or their healthcare system.

Behavior

Barriers to the adoption of behavior can still exist even when providers have moved beyond awareness and acceptance of evidence. Adoption of behaviors can be particularly challenging since it requires that changes occur in the actual performance of a task at the provider or organizational level. For providers, barriers to adoption can vary from factors as ordinary as the influence of habit and routine to more complex issues that reflect lack of time or resources.[42] Organizational-level factors that impact on behavior include reimbursement or payment structures for

providing care as well as the availability of or access to specialized services and medications.

Finally, it is important to recognize that patients can also indirectly influence the adoption of new recommendations by providers. A perceived lack of adherence to lifestyle recommendations by patients has been described as a frequent reason by providers for inconsistent recommendations about smoking cessation.[43] This also can be problematic in cases where patients often have set expectations for receiving a particular service. For example, providers may be reluctant not to pursue cardiac catheterization in an active individual with a low-risk stress test who believes it is necessary based on personal experiences (e.g. "My father had it done!").

Multiple barriers

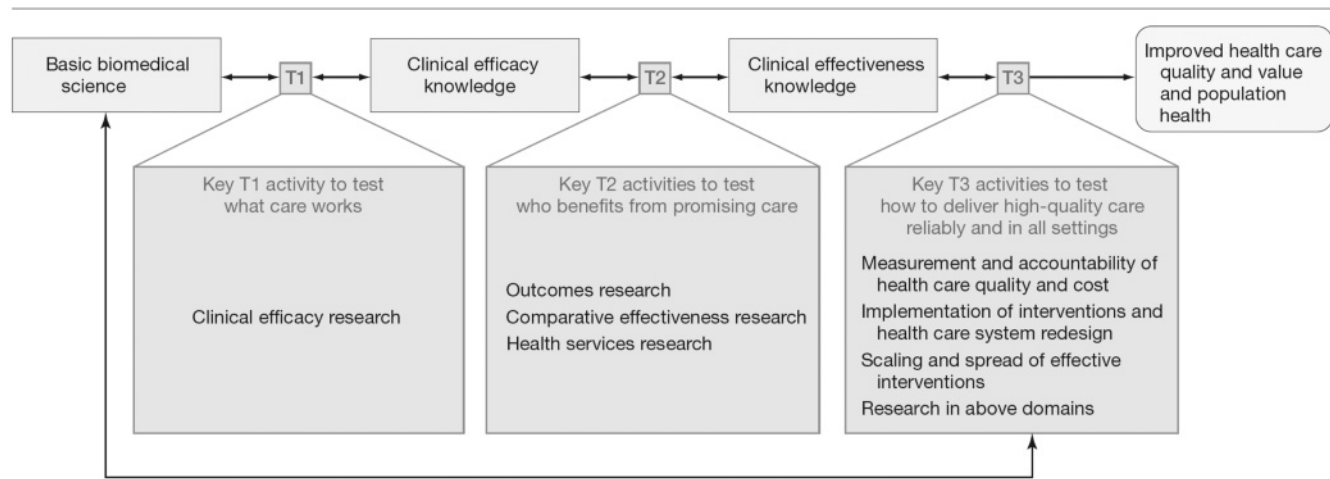
It is rare for a single barrier to be responsible for the limited use of an evidence-based therapy. Instead multiple barriers often contribute to poor implementation, and barriers identified in one clinical environment may be less relevant for other areas or settings. For example, high out-of-pocket drug costs may be a pertinent barrier to statin use in patients with CAD, while limited availability of a high-quality program may be an important barrier for cardiac rehabilitation. In patients interested in smoking cessation, drug costs for nicotine replacement therapy and the availability of counseling programs could play important roles. Similarly, in urban areas barriers to timely access for primary PCI could be accomplished by redesigning emergency medical services to integrate new technologies like prehospital electrocardiography (ECG).[44] However, large geographic distances between hospitals with and without cardiac catheterization laboratories would limit

the applicability of this approach in rural healthcare systems.[45]

Important socioeconomic factors can also affect patterns of adoption for evidence-based therapies, especially depending upon the structure of the healthcare delivery system into which these therapies are introduced. For example, an important reason why behavior modifications such as smoking cessation, nutritional counseling and cardiac rehabilitation may be difficult to implement is that most physicians are not traditionally trained in the skills required for these activities and reimbursement is disproportionately low for them. In contrast, physicians have a greater proclivity for performing diagnostic tests and therapeutic procedures since these are what they are often trained to do best and because their reimbursement is more aligned with these services. This has a potentially perverse effect on a healthcare system by encouraging overuse of expensive procedures (even when marginally effective) and underuse of useful simple diagnostic and therapeutic approaches (even when evidence-based and cost effective).[46]

An important limitation of existing literature in quality improvement science is that interventions are often developed without researchers first rigorously studying what local barriers may be contributing to insufficient knowledge translation. Furthermore, even when intervention-based studies report the presence of local barriers, descriptions frequently lack adequate detail. In a large review of studies examining barriers to guideline use among physicians, Cabana and colleagues found that just half of all intervention-based studies reported more than one category of barriers in their results.[38] Without a better appreciation of what barriers may have been present at baseline, it is impossible for readers to judge whether the findings associated with an intervention would be applicable in their own clinical practices.

Strategies for quality improvement

There have been a number of studies exploring different strategies for overcoming barriers to the implementation of evidence-based medicine in cardiology and improving quality. These strategies have evolved significantly over the years from simple educational interventions (i.e. one-time dissemination of educational materials) targeted at improving provider knowledge to complex and multifaceted approaches designed to leverage information and systems-based technologies (i.e. computerized order entry and reminders). On the "road map" for moving basic research into clinical practice, Dougherty and Conway have distinguished research in quality improvement science from other translational research and identified it as the third translational step (i.e. "T3") (Fig. 6.2).[47] While the first two translational steps focus primarily on moving evidence from basic science research to clinical efficacy (i.e. "T1") and clinical effectiveness (i.e. "T2"), T3 research should be focused on understanding how evidence-based medicine can be reliably delivered to broad populations of patients across different healthcare settings.


T indicates translation. T1, T2, and T3 represent the 3 major translational steps in the proposed framework to transform the health care system. The activities in each translational step test the discoveries of prior research activities in progressively broader settings to advance discoveries originating in basic science research through clinical research and eventually to widespread implementation through transformation of health care delivery. Double-headed arrows represent the essential need for feedback loops between and across the parts of the transformation framework.

Figure 6.2 The three translational steps on the roadmap from evidence into clinical practice. (From Dougherty and Conway,[47] with permission.)

Evolution of strategies

According to David Naylor, strategies aimed at knowledge translation have developed in four phases over the years, evolving as our understanding of barriers improved.[48] The first group of strategies initially relied exclusively on "passive diffusion" of evidence-based medicine into clinical practice (i.e. "Just publish it").[48] In this scenario, providers were largely responsible for accessing, reviewing and then incorporating new evidence by themselves. During this time period, proponents believed that the key to quality improvement was to educate providers to be efficient consumers of evidence-based medicine. Given the growing size and complexity of the medical literature, however, it soon became obvious that it was impossible for most providers to remain abreast of current developments, even within a narrow field, without help. This led to the second group of strategies aimed at developing guidelines and consensus statements to synthesize the literature for providers (i.e. an "active diffusion" of information exemplified by the documents that are now routinely produced by the American College of Cardiology (ACC) and American Heart Association (AHA)).[48]

However, simply producing guidelines does not always change clinical practice in a reliable manner. The third group of strategies, which arose from this understanding, represents what Naylor refers to as the "Era of Industrialization".[48] Strategies during this time reflected a growing interest in applying quality improvement tools from other industries to measuring, evaluating and then managing provider behavior. Rather than specific interventions, these strategies frequently emphasized incremental process-of-care improvements and were exemplified by the concepts of continuous quality improvement (CQI) and total quality management (TQM) adopted by the manufacturing industry during the 1980s.[49] Moving beyond a framework of CQI/TQM, the most recent group of strategies has focused on incorporating advances in information technology and systems engineering to completely redesign clinical pathways.[48] These strategies are exemplified by computerized ordering and reminder systems, as well as the development of clinical information tools to aid in informed decision making between patients and providers.

A general framework for categorizing strategies

One useful framework for categorizing strategies aimed at improving the implementation of evidence-based medicine is by the level of care within the healthcare system that the strategy is targeting. The Cochrane Collaboration's Effective Practice and Organization of Care (EPOC) group has used this type of framework to identify four categories of quality improvement interventions: *provider-level*, *organiza-tional-level*, *financial-level*, and *regulatory-level* interventions.[50] Provider-level (i.e. professional) interventions include those aimed at continuing medical education, audit and data feedback. Organizational-level interventions are those aimed at the systems level that might include the incorporation of physician extenders or nursing in case management programs. Financial-level interventions are aimed at using economic incentives to influence clinical practice. Regulatory-level interventions include strategies such as public reporting of processes of care or outcomes, changes in medical liability or regionalization of specialized services. Specific examples from each of these categories that have been frequently discussed in the literature are presented in greater detail in Table 6.3.[51]

Education

Interventions aimed at improving provider awareness of guidelines or evidence-based recommendations are among the most studied in the published literature. Specific approaches include workshops or conferences targeted at large groups of providers, distribution of printed or electronic material to inform providers of new developments through mass media, and "academic detailing" that uses a trained individual to target and inform a particular provider (or group) about an explicit recommendation. Local opinion leaders are often utilized in these approaches. These types of interventions are frequently used in cardiology when guidelines have been updated or new therapies are discovered.

Reminder systems

Another common area of focus for interventions is the use of reminder systems that target providers. Paper-based or electronic reminder systems have been utilized to prompt providers to recognize patient-specific information during an encounter. When electronic, these reminder systems can also be supplemented with decision support tools to guide providers toward appropriate referrals or medication adjustments when indicated. These types of interventions have been used successfully during outpatient visits for notifying providers of cardiovascular risk assessment and helping with decisions about initiating statins.[52]

Audit and data feedback

The use of audit and feedback systems has been well studied at both the provider and organizational levels. This type of intervention frequently presents data to individual clinicians, groups of clinicians, a hospital or even a larger healthcare system. Data that are typically reported include summaries of the proportion of eligible patients within their practice or institution that receive a treatment or other

Table 6.3 Common examples of quality improvement interventions (from Shojania and Grimshaw 2005[18])

Strategy definition and examples	Effectiveness
Provider education – examples: • Conferences or printed educational materials detailing current recommendations for management of a particular condition • Educational outreach visits to providers' offices, usually targeting more specific aspects of care, such as appropriate medication choices for a target condition	• Generally ineffective if judged on the basis of improving patient outcomes • If judged in terms of increasing provider knowledge, can be effective
Provider reminder systems and decision support (systems for prompting health professionals to recall information relevant to a specific patient or clinical encounter; when accompanied by a recommendation such systems are classified as clinical decision support) – examples: • Sheet on front of chart alerting provider to date of the patient's most recent mammogram and its result • Computer-generated suggestion to intensify diabetes medications based on most recent HbA1c values	• Reminders often effective if well integrated with workflow • Decision support sometimes effective, but less so for the more complex situations in which it would be most desirable
Audit and feedback (summary of clinical performance for an individual provider or clinic, transmitted back to the provider) – example: • Reports to providers or provider groups summarizing percentages of their eligible patients who have achieved a target outcome (cholesterol below a certain value) or received a target process of care (counseling about smoking cessation), accompanied by recommended targets	• Small to modest (at best) benefits for various forms of audit and feedback (such as report cards, benchmarking) • Variations in format may explain some of the observed variations in effectiveness, in addition to providers' attitudes toward the accuracy or credibility of the reports
Patient education – examples: • Individual or group sessions with nurse educator for patients with diabetes • Medication education from a pharmacist for patients with heart failure	• Modest to large effects for some conditions and patient populations
Organizational change – example: • Changes in the structure or organization of the healthcare team or setting designed to improve processes or outcomes of care	• Mostly positive results for case management and disease management programs • Mixed results for total quality management and continuous quality improvement
Financial incentives, regulation, and policy – examples: • Financial bonuses for achieving target level of compliance with targeted processes of care • Change from fee-for-service to salaried or capitated reimbursement systems	• Some evidence for achieving target goals, but also for concerning decreases in access and conflicts of interest in physician–patient relationships

recommendation relative to national or local peer providers. The National Cardiovascular Data Registry (NCDR) sponsored by the American College of Cardiology provides this type of benchmarking information routinely to hospitals on established quality indicators. Regional examples of audit and data feedback have shown substantial quality improvements in PCI and coronary artery bypass grafting (CABG). For example, use of quarterly data feedback to clinicians and hospitals in a statewide PCI registry was associated with improved clinical outcomes and reduced practice variation in quality indicators related to vascular complications, contrast-related nephropathy and stroke.[53]

Disease and case management programs

These types of programs include any structured system designed for co-ordinating the diagnosis, treatment or ongoing management of a patient through a person or team in collaboration with the primary provider. Many of these programs have been studies in heart failure and have suggested benefits in reducing resource utilization and improving quality of life.[54] However, the heterogeneous nature of heart failure and case management programs often makes it difficult to tease out what (if any) aspects of these types of interventions are most responsible for their effectiveness and their potential generalizability to other clinical set-

tings. This has led to tremendous challenges with implementing disease and case management programs in clinical practice.[55]

Financial and regulatory interventions

Financial interventions aim to improve the use of evidence-based medicine in clinical practice by modifying reimbursement systems for providers. The goal of these types of interventions is to reward behavior by providers and organizations that promotes quality and efficiency of care. Examples include changes from fee-for-service to capitated reimbursement systems as well as pay-for-performance programs. Pay-for-performance programs have drawn recent attention since these efforts attempt to tie evidence of improvement in quality indicators to increased reimbursement for services. Regulatory interventions include public reporting of outcomes and process-of-care measures. In some states like New York and California, public reporting has already been well established for several years for CABG.[56] This is also true in the United Kingdom where the Healthcare Commission now provides a national system with information on outcomes after CABG for hospitals and surgeons.[57] In addition, the Centers for Medicare & Medicaid Services (CMS) now publicly report process-of-care measures for quality indicators in acute myocardial infarction, heart failure and other disease processes across hospitals.[58]

Overall effectiveness of strategies

Several themes have emerged from studies examining strategies for improving the use of evidence-based medicine, many of which have been summarized in a series of systematic reviews and meta-analyses. In 1995, two systematic reviews were published that analyzed available data on strategies aimed at improving guideline use by providers, primarily through education-based interventions.[59,60] Both reviews found that no strategy consistently appeared to produce large or sustained benefits (i.e. no "magic bullet", according to the title of one article). Both systematic reviews also suggested that the most effective approaches were "active" and "multifaceted". Multifaceted refers to the simultaneous use of multiple strategies as an intervention (i.e. reminder systems combined with auditing and data feedback). In contrast, passive and simple strategies had little or no effect on changing behavior (i.e. a one-time dissemination of paper-based educational materials).

However, effects of more complex interventions applied at the provider level have not always been consistent. Audit and data feedback, for example, appeared to have a limited impact unless they were repetitively applied or coupled with other strategies. A more recent systematic review – actually a systematic review of 41 systematic reviews on interventions to change provider behavior – suggested that even those strategies that were determined to be effective have a largely modest impact on increasing the use of evidence-based medicine.[61] In this analysis, the median absolute improvements in recommended care varied from 6% to 14% across different types of interventions and there was great heterogeneity both across and within any specific intervention. Clinical reminders showed the greatest variation, with 14 cluster-randomized trials showing reported median effects of this intervention varying from -1.0% to 34.0%. This is not entirely unexpected. By necessity, strategies are tested in variable environments and sometimes across different providers or disease processes, making it likely that there would be inconsistent effects under these different circumstances. Finally, unlike the two prior systematic reviews, this latest study did not find significant improvements associated with the use of active and multifaceted interventions relative to other interventions.

The evidence base for organizational-, financial- and regulatory-level interventions has also shown mixed results. Case management programs in heart failure have been studied extensively but the impact of their utilization on clinical outcomes has shown large variation. In one recent meta-analysis, there were wide differences in the pre- and postdischarge components that were included. These varied from telephone follow-up to clinic follow-up to home visits. Duration of programs, time commitments and costs also differed. Not surprisingly, the effect of case management programs also varied, with studies suggesting anywhere from an approximately 50% relative risk reduction in repeat hospitalizations to no effect.[62] This heterogeneity was significant and has been implicated as a potential reason why case management programs may be underutilized in heart failure.[63]

Data exist that suggest that compensation systems for providers can impact on the use of evidence-based therapies. A market-level analysis of 56 medical groups affiliated with 15 integrated healthcare systems in the United States in 2001 found that compensation incentives and managed care pressures influenced the use of clinical guidelines, critical pathways and case or disease management programs by physicians.[64] A more recent example of financial-level interventions being pushed forward as a strategy for encouraging the adoption of evidence-based medicine is pay-for-performance programs introduced in the United States. While these programs all link changes in process of care and outcome measures to reimbursement, they vary substantially on where to apply the level of financial incentive and its size. In a recent systematic review of empirical studies that examined the relationship between financial incentives and quantitative measures of quality improvement, Petersen *et al* found that six studies focused on

physician-level incentives, seven focused on provider groups, and two on healthcare system levels.[65] The majority of these studies did suggest improvements in process-of-care measures, most of which were targeted toward preventive services.

However, there was some evidence that unintended consequences also occurred, including adverse selection of patients (i.e. the avoidance of more severely ill patients) and less provider attention to aspects of care that are not subject to incentives. Furthermore, a recent analysis of the voluntary CRUSADE registry found no evidence that instituting a pay-for-performance program that was tied to bonus payments by CMS improved the use of evidence-based therapies in AMI using a composite measure.[66] Among the 54 hospitals within the pay-for-performance program, higher rates of improvement were noted relative to 446 control hospitals for two individual measures: aspirin use at discharge (odds ratio (OR), 1.31; 95% confidence interval (CI), 1.18–1.46) and smoking cessation counseling (OR, 1.50; 95% CI, 1.29–1.73). These mixed data, lack of suitable targets for measurement, and potential concerns about unintended consequences have pushed some to advocate for pay-for-participation programs, especially to improve quality for procedures.[67]

Regulatory-level interventions are being used more extensively even within loosely organized healthcare systems like those in the United States. As with other types of interventions, the data supporting regulatory-level interventions are mixed and heterogeneous. For example, public reporting of outcomes for hospitals and clinicians is a commonly used regulatory strategy although there are few empirical data supporting its use. In 2000, Marshall *et al* reviewed seven reporting systems in the United States (including the New York CABG reporting program) and found little evidence that consumers or physicians used (or trusted) the data, although hospitals appeared more responsive to it.[68] A more recent updated systematic review on the topic found increasing support that public reporting stimulates quality improvement efforts at the hospital level, but otherwise concluded that data on the impact of these programs remain scant.[69] As with pay-for-performance programs, however, there are challenges with selecting appropriate metrics to report and for public reporting to potentially lead to unintended consequences with the adverse selection of patients. A recent analysis of two large statewide PCI registries by Moscucci *et al* found that public reporting may have led clinicians to avoid PCI in higher-risk patients in New York as compared with Michigan.[70]

Similarly, the use of certificate-of-need (CON) programs as a regulatory-level intervention to improve quality has shown mixed results with potential improvements in utilization balanced by concerns of restricting access to specialists and specialized cardiovascular procedures. A recent study using data from the Medicare program suggested that mortality rates after CABG among beneficiaries were lower in states with certificate-of-need regulations, potentially due to the concentration of these procedures at higher-volume hospitals.[71] Furthermore, a separate analysis in the Medicare population suggested that although certificate-of-need regulations decrease the overall use of these procedures, these effects are negligible in those with strong clinical indications such as high-risk patients after AMI that require cardiac catheterization.[72]

Finally, expanding healthcare insurance and drug coverage to more individuals may also dramatically impact on the use of evidence-based therapies given that out-of-pocket spending is a significant barrier to utilization for patients. In one analysis based on a computer-based simulation model, expanding full coverage of medication benefits to insured patients after AMI would result in 1.1 fewer deaths and 13.1 fewer recurrent AMIs while saving insurers nearly $6000 in costs per patient.[73] However, the challenge of regulatory-level interventions like expanded drug coverage is that their likelihood of success depends strongly upon the political, social and cultural settings of a healthcare system.

Future directions

Improving the use of evidence-based medicine in cardiology remains an important but challenging goal for healthcare systems around the world. Three areas that will need to be addressed in the future relate to (1) the growing tension between the immediate need for quality improvement efforts and the time required to perform quality improvement science, (2) the development of stable funding sources and infrastructure for T3 translational research dedicated to moving evidence-based medicine generated at academic medical centers into clinical practice in the community, and (3) the creation of formal educational pathways for both individual and institutional providers that are dedicated to implementing quality improvement within their local environments.

Balancing quality improvement efforts and quality improvement science

Methodological approaches for assessing strategies for improving the use of evidence-based medicine have undergone substantial transformation as patient safety and quality improvement efforts have become increasingly emphasized over the last decade. Early study designs focused on case reports, case series and pre/post study designs. The primary goal of investigators was to rapidly report experiences with innovative strategies to allow for quick dissemination. However, more recent efforts have emphasized the need for a strong theoretical framework in

designing interventions and implementing them within rigorous study designs where their impact can be accurately assessed. As stated eloquently by Shojania and Grimshaw in a recent review on this topic: "Strategies for implementing evidence-based medicine require an evidence base of their own".[18]

A recent article by Auerbach and colleagues has comprehensively summarized the arguments for and against rapid dissemination of interventions in quality improvement without an adequate scientific base of knowledge (Table 6.4).[74] Numerous examples exist where shortcomings in study designs have suggested large benefits for interventions that were subsequently overturned after more rigorous evaluations. For example, the recent AFFECT trial was a cluster randomized controlled trial that examined the effectiveness of hospital report cards generated by administrative data on process of care and outcome measures in AMI among 76 Canadian hospitals.[75] While the use of hospital report cards had been reported as successful in a number of observational studies, this carefully conducted study found no evidence supporting this approach. Rather than being seen as a 'negative' trial, the AFFECT trial provides important information on the limitations of report cards for benchmarking, which is critically important given the widespread dissemination of this type of intervention. A similar challenge has been raised in recent debates regarding the Institute for Healthcare Improvement's "100,000 Lives Campaign". This national campaign was clearly successful at galvanizing interest in patient safety at more than 3000 participating hospitals across the United States, but its true impact on outcomes remains controversial.[76,77]

In fact, Ting and colleagues[78] have argued that quality improvement science may benefit from following the same stepwise paradigm that has guided the development of scientific breakthroughs for the last several decades. Based on this framework, strategies in quality improvement should progress from preclinical, Phase I and II trials focused on feasibility at single centers toward larger and more definitive Phase III and IV trials that address broader implementation (e.g. the AFFECT trial).[79] This type of approach has been described in the United Kingdom Medical Research Council's research phases for complex interventions (e.g. case management programs for heart failure or strategies for increasing uptake of guidelines by clinicians) (Fig. 6.3).[79] Early research phases in this

Table 6.4 Arguments for and against the rapid dissemination of interventions in quality improvement (from Auerbach *et al* 2007[74])

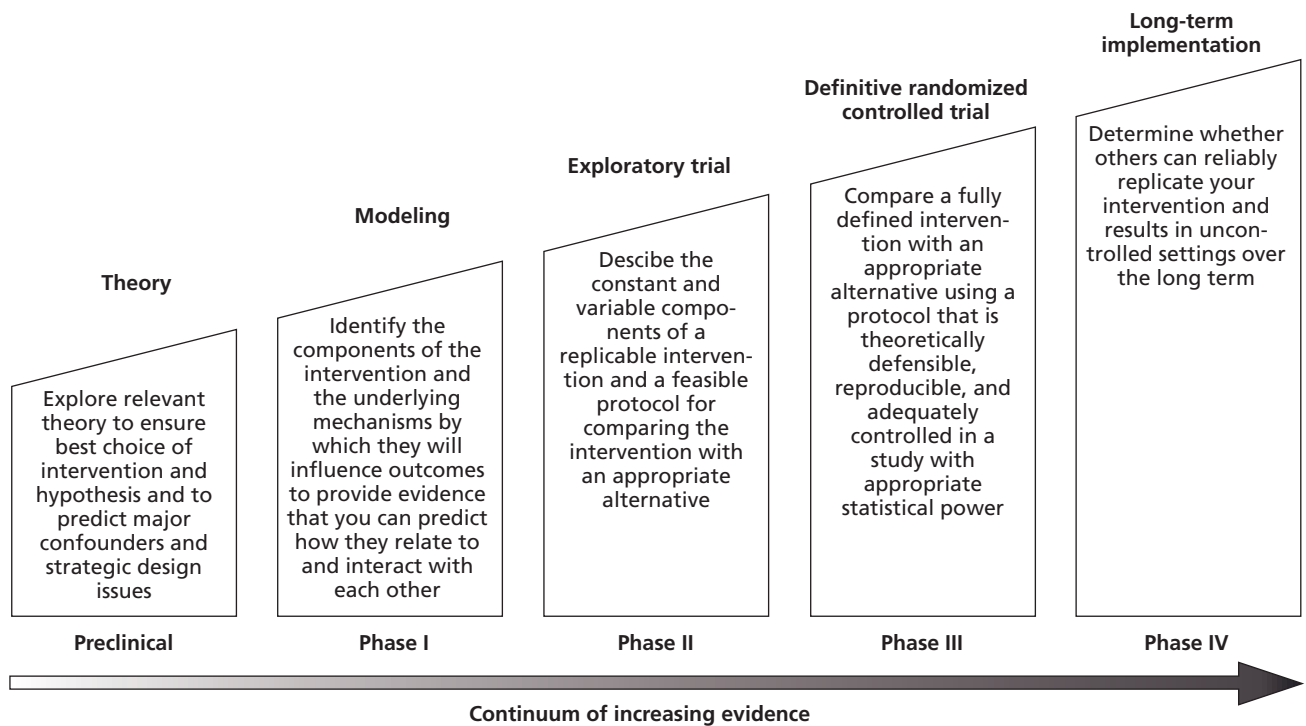
| Argument	Why proceeding quickly is critical	Why evaluation is critical
We cannot wait – the need to improve the quality of care is urgent	Thousands of patients are injured or killed each year by medical errors	The need to improved the treatment of many diseases is equally urgent, yet we demand rigorous evidence that a therapy works before recommending it widely
Any effort to improve quality is better than the current state of affairs	On balance, the harms of quality improvement are likely to be far less than those of the status quo	Knowledge of the harms and opportunity costs of quality improvement is important for an understanding of the net benefit to patients and healthcare systems, which is often small
Emulating successful organizations can speed effective improvement	Emulation and collaboration provide an efficient means of disseminating potentially effective solutions	Emulation and collaboration can incorrectly promote or even overlook interventions that have not worked
The effectiveness of some quality improvement strategies is obvious	Insistence on evidence may lead us to underuse interventions that are obviously effective	Even though many quality improvement practices have a simple rationale, they may be less effective than expected and can be difficult to implement fully
Innovation can be catalyzed by dissemination of strategies that have promise but are unproven	Preliminary data provide an important opportunity to speed innovation and improve care rapidly	Flawed, biased or incomplete data may lead to adoption of interventions that are ineffective or harmful
The framework of evidence-based medicine does not apply to quality improvement	The nature of quality improvement exempts it from the usual strategies of assessment	Given the complexity of quality and safety problems, the complexity of their causes, and how little we understand them, we should use rigorous study designs to evaluate them
Developing evidence in quality improvement is too costly	The resources and expertise required to evaluate quality and safety interventions rigorously make trails impractical, particularly when the field is moving so quickly	As compared with the large opportunity costs incurred by wide implementation of ineffective quality and safety strategies, investments in better evaluation would be small


Figure 6.3 Sequential research phases for developing evidence in complex interventions. (From Campbell *et al*,[79] with permission.)

framework focus on establishing the 'efficacy' of quality improvement interventions in at least one setting and are designed using traditional methodologies from industrial quality improvement, the social sciences, cognitive psychology, human factors engineering, and organizational theory. All of these disciplines represent the 'basic sciences' of quality improvement. Later research phases examine the generalizability and long-term implementation of interventions aimed at quality improvement in larger and more diverse settings.

Funding and infrastructure for quality improvement science

The challenges associated with knowledge translation and quality improvement science are not unique to a particular healthcare system or country. Funding agencies worldwide that are involved in the biomedical and health sciences have a direct interest in ensuring that scientific breakthroughs are translated into clinical practice in their own local communities. For this to happen though, these agencies have recognized that they must play a more active and integral role in knowledge translation. Specific activities that these groups may use to ensure this include (1) requiring all grant proposals in clinical research to describe plans for knowledge translation and to use this as a criterion for funding and/or (2) explicitly increasing funding opportunities for research that is focused on developing new strate-

gies in quality improvement science. Funding agencies can also be instrumental in early dissemination by promoting findings through traditional (i.e. journals) and non-traditional (television) media sources. In a recent qualitative survey of 33 funding agencies across the world, knowledge translation was directly or indirectly referred to in 23 mission statements but relatively new to all these groups.[80] Moreover, funding agencies appeared to have widely differing views of what knowledge translation even meant, their requirements of researchers to participate in it, and how engaged the funding agencies should be in this process overall.[80]

One potential solution that has been widely discussed for expanding the infrastructure for quality improvement science is the development of practice-based research networks. The simple concept behind practice-based research networks is that our traditional notions of research need to move outside traditional academic environments into those clinical practice settings where the great majority of care is routinely delivered. There unfortunately is little infrastructure at this time for conducting research in these typically non-academic and outpatient environments. For these reasons, there has been great interest in providing resources to expand their development, particularly in the United States. Westfall and colleagues have pointed out how the NIH Roadmap supports practice-based research networks as part of its plan to re-engineer clinical research within the framework of the Clinical and Translational

Science Awards (CTSAs).[81] Of course, practice-based research networks do not only provide an infrastructure for examining interventions. They also have the advantage of supporting observational study designs to understand where practice gaps really exist in real-world settings.

Improving provider education in strategies for quality improvement

Optimizing the use of evidence-based medicine requires that individual and institutional providers will have the necessary skills to evaluate their own performance and to design tailored solutions that meet the needs of their local clinical practice. These issues become critical given that skills and knowledge may decline with the number of years physicians are out in practice.[82] Providers therefore must be life-long learners and continually improve their own knowledge base and training in quality improvement, but these areas have not been a traditional focus of training. In the past, formal training in quality improvement was uncommon during medical school or even postgraduate training. This has changed remarkably in recent years, though. Accreditation of postgraduate training programs in the United States is now tied to competency in systems-based practice and practice-based learning.[83] Even for physicians who have completed training and are actively in practice, recertification depends upon demonstrating knowledge in self-evaluation of practice performance.[84]

It is encouraging that a recent review of 39 studies on the effectiveness of teaching quality improvement to clinicians suggested that most appeared to apply established adult learning principles such as self-directed learning and reflection.[85] However, educational outcomes showed more consistent improvements than clinical outcomes which were rarely reported. Furthermore, while the majority of studies described providing teaching content to implement and evaluate local systems for changes, few taught about the larger healthcare system or patients' perspectives about the system. Further research is clearly needed to develop better methods for training providers in these skills as efforts to improve knowledge translation and quality improvement science expand in coming years.

Conclusion

Substantial developments have been made over the last several decades in our understanding of the role of evidence-based medicine in cardiology. However, while there has been an improved understanding of the basic mechanisms and treatments related to cardiovascular diseases, we have clearly fallen short in our ability to guide scientific breakthroughs into routine clinical practice. The practice gaps between "what we know" and "what we do" continue

to challenge policy makers and providers. Strategies to address these practice gaps through more effective knowledge translation continue to gain momentum, transforming from earlier approaches that relied on the passive diffusion of knowledge to recent efforts to incorporate information technology and systems engineering into a transformation of the healthcare delivery system. These strategies frequently utilize complex interventions that can be aimed at multiple levels of the healthcare delivery system. As these strategies move forward, there remain important challenges in the need to improve the evidence base for quality improvement science, to create stable funding and infrastructure for these efforts, and to improve provider education in this area.

7 The application of evidence-based medicine to employment fitness standards: the transportation industries with special reference to aviation

Michael Joy

Postgraduate Medical School, Surrey University, Guildford, Surrey, UK

Introduction

Medical standards are applicable to a number of occupational groups. Some of these are voluntary codes of practice, some statutory. The police and armed forces are examples, as is the offshore oil industry. Employers have a duty of care to protect employees from harm as well as guarding against medical conditions which may have a detrimental effect on performance in the workplace. Likewise, employees have an obligation to indicate any medical condition which might erode ability in the discharge of duty.

Medical standards exist for all transport modalities including roads, railways, shipping and in the air to protect both the individual as well as third parties. The development of these standards was initially empiric rather than evidence based. This no longer applies to aviation, and to some extent to road transport, both of which have based their fitness requirements on risk of event. As it is impossible in one short chapter to review the evidence base for the breadth of cardiologic standards across the workplace, it is intended to consider road and, more specifically air transport as examples of the application of evidence-based medicine (EBM) to achieve the twin goals of safety and good practice.

Passenger transportation does not have to be completely safe and the controling legislation does not require it to be so. It has to be "safe enough." It is self-evident that the good conduct of a means of transport requires it to be fit for purpose. Design, construction, maintenance and operation should be sound and reliable. This implies the need for regulation. The concept of safety criticality suggests that the consequences of failure of any aspect of the enve-

lope need to be identified, minimized and tolerable in the operational environment. Sometimes systems are duplicated (redundant) but not always if a sufficiently low target failure rate can be achieved without. How, then, can these targets be identified and met?

People operate motor cars, railway trains and aircraft and may fail due to health or other considerations. This event rate, like the vehicles they operate, can be to some extent predetermined. Age makes a contribution. Decrement in human function or performance may be associated with sudden catastrophic failure or subtle, with gradual loss of efficiency. The safe operation of a system of transportation involves a level of medical fitness of those responsible for the lives of others.

The regulatory process

Operational standards (including medical standards) in civil aviation are agreed by international statute[1] and are implemented by national agencies (e.g.. the Civil Aviation Authority (CAA) in the UK). There may be additional supranational oversight (e.g.. the European Aviation Safety Agency (EASA)). There are also agreed European standards for the regulation of driving, including medical standards.[2,3] Medical fitness to fly and to drive has been swept up into the legal frameworks of the Western world, and elsewhere. Some medical conditions are inconsistent with driving or flying status and an adverse decision may terminate employment. Some cardiologic conditions such as coronary artery disease, on account of their large outcome databases, lend themselves to risk modeling. Others such as atrial fibrillation, due to symptomatic capriciousness, are more difficult. And there are orphans such as the long QT syndrome where risk stratification is based on slender outcome data, but where decisions still have to be taken. Third-party safety takes precedence but best practice is paramount to avoid the adoption of clinical courses of

action solely for the purpose of the preservation of employment. The need for good governance in the decision-making process requires no further emphasis.

Modes of transport and regulation

Regulation got off to an early start and in 2500 years BC the Cretans required maintenance and loading inspection of their ships, a practice which was revived in Europe in the Middle Ages. It was not until 1894 in the UK that the load line on a ship was made law in an attempt to reduce the number of vessels and crews lost from overloading. In 1930 international agreement was achieved. In Europe, the development of the European Union led to a harmonization process for all land (and air) based activities. This was to include competition, taxation (inevitably), safety and technical requirements, track rules and signaling, where appropriate. The endpoint was to be interoperability of road and rail across the continent. Currently 1.2 million lives are lost in road transport accidents each year, with some 0.5 billion injuries, worldwide. Although observational data are scarce, medical incapacitation accounts for only 0.1% of road traffic accidents of which some 25% may be attributed to cardiologic causes.[4] Historically, but with certain exceptions, the railways have had the best safety record on land.

The aviation environment

Aviation also has an impressive safety record and is tightly regulated. In 2006, 2.1 billion passengers were carried in some 35 million scheduled and non-scheduled flying hours for the loss of 863 passengers. The average sector length is now 2 hours. This has doubled in the last 30 years. Aviation is the only system of mass transportation that is regulated by international statute. All contracting states have treaty status with the International Civil Aviation Organization (ICAO), a safety directorate of the United Nations Organization. All are bound to maintain the standards in Annex 1 to the Convention on International Civil Aviation (ICAO Annex 1).[1] The Standards and Recommended Practices (SARPs) are promulgated in Annexes to the Convention and are regularly updated. The Standards are safety directed and obligatory. Recommended Practices are not so binding.

The ICAO cardiologic Standard is enshrined in eight brief paragraphs but may be interpreted by "accredited medical conclusion" to permit ongoing licensing provided flight safety will not be jeopardized. ICAO also publishes guidance material. In Europe and elsewhere, an operational multi-crew limitation (OML) may be imposed to prevent a pilot from flying on single-crew operations if the risk of medical (cardiologic) event is perceived as too high.

The Joint Airworthiness Authorities framework in Europe was set up in 1970, later becoming the Joint Aviation Authorities (JAA). The medical standards in the Joint Aviation Requirements FCL part 3 Medical[5] related guidance material were the first comprehensive approach, worldwide, to provide a written protocol. The cardiologic standards originated from four cardiologic workshops[6–9] specifically tasked to the interface with aviation. These have been amplified in the UK by a series of algorithms showing pathways of problem management which guide medical fitness and certification. This material has been adopted outside Europe but has no regulatory status elsewhere. The EASA[10] is the legally based successor to the JAA. Within the curtilage of this chapter, the terms *certificate* and *license* (to fly) are used synonymously whilst *fitness* indicates fitness to fly. The class 1 certificate relates to professional aircrew and the class 2 certificate to private pilots These are regulatory terms and should not be confused with classes of recommendations and levels of evidence as used in this book.

Aviation accident experience due to medical cause

Eighty percent of fatal aircraft accidents are attributable to "human factors." One-third of airline pilots admit to some level of incapacitation whilst on duty at some time during their career,[11] most commonly due to gastroenteritis. Significant medical cause incapacitation is rare, mainly because such events are rare in the population of pilot age (<65 years for professional pilots). Subtle incapacitation (see above) leading to error may be as important as complete incapacitation. It can be caused by illness, fatigue or the effects of medication. Routine medical scrutiny, which includes resting electrocardiography, identifies a few of those at increased risk of cardiologic mishap, allowing intervention, e.g. hypertension, diabetes. Alternatively, problems may present spontaneously, e.g. myocardial infarction, stroke. Notwithstanding, the UK license loss from cardiovascular cause remains low at <0.1%/thousand professional license holders per annum.

There were 29 airline accidents, worldwide, attributable to medical incapacitation during the years 1946–1985. There were five fatal accidents attributed to acute coronary events during the years 1961–1968.[12–14] In 1972 the HS Trident G-ARPI (known as Papa India) crashed 150 seconds into its flight when it stalled due to premature retraction of a leading edge lift device. This fatal error was attributed in part to incapacitation of the captain by an acute coronary event. One hundred and eighteen people died.[15]

In the aftermath of the Papa India disaster a number of initiatives were taken nationally and internationally. The ICAO required regular incapacitation training of multi-

crew pilots; flight deck voice recorders were also mandated. Some well-travelled cardiologists were so shaken by the event that the American College of Cardiology[16] and the Royal College of Physicians of London[17] called for increased cardiologic scrutiny of pilots. This was to include exercise electrocardiography. But middle-aged otherwise fit males have a low probability of fatal/non-fatal coronary event and this recommendation was not evidence based in safety terms, nor justifiable in (Bayesian) terms of conditional probability. Had exercise electrocardiography been adopted it would have led to many more pilots being investigated for disease they did not have (false-positive responders) than those who did (true-positive responders). And, as an investigation for coronary artery disease, exercise electrocardiography is only 60–70% sensitive in the asymptomatic middle-aged male.

The Papa India disaster is the worst UK aviation accident to date. The pilot population at the time was relatively old and there was no crew training for recognition of incapacitation of a colleague. Following the accident, pilots were subsequently reviewed more rigorously but inconsistently as there were no agreed protocols of review. Since 1974, improved crew training, better cockpit resource management, better safety systems and better aircraft design have all contributed to the exceptional safety levels which are now being achieved in multi-crew (more than one pilot) airline operations. There have been almost no accidents/incidents attributable to pilot incapacitation in the 2/3 billion hours flown since, in spite of deaths and incapacitations which have continued to occur whilst aircrew are on their duty period.

Evidence-based medicine and workshops in aviation cardiology

Pre-empting Sackett *et al*[18] by nearly two decades, it was evident that there was a need for an authoritative overview of the evidence base on the presentation, natural history, outcome and impact of intervention on the common, and sometimes not so common, cardiologic conditions to make regulatory decisions more scientific, objective and fair. This led to the four workshops in aviation cardiology which took place between 1982 and 1998.[6–9] They followed the same pattern. Twenty-five cardiologists and epidemiologists who were leaders in their field, together with directly relevant specialists, were tasked to produce position papers on chosen topics. This resulted in one of the most comprehensive statements available on cardiologic problems and aircrew certification available at the time, or since.

Devereaux *et al*[19] produced a Venn diagrammatic model for the evolution of evidence-based clinical decisions. The key elements include research evidence, patient preferences and actions, the clinical state and circumstances, with

clinical expertise being in the command or "overarching" position. In the regulatory environment an extra dimension is introduced. Transport safety is concerned with the probability of an incapacitating event in the operator but the decision to grant medical fitness is a binary one. The subject is either fit or unfit for the task with the exception of a detente where there is an OML. There are, therefore, potential conflicts between patient choice and the boundaries of regulation.

The regulator is not the pilot's physician and must play no part in clinical management. Certain clinical choices may deny subsequent fitness – the use of a mechanical valve in the management of aortic stenosis in a pilot, for example. The clinical indication for warfarin in this context is associated with fitness denial at present in Europe on account of the summative risk of bleeding from the treatment and the risk accruing from the underlying pathology. Thus although the thromboembolic rate of the tissue and mechanical valves in the aortic position is comparable, the risk of bleeding in the patient with an anticoagulated mechanical valve is significantly higher,[20] exceeding the target event rate (see below). The choice of a tissue valve may, however, be agreed between the patient and his/her cardiologist in spite of its long-term poorer performance[20] without pre-emption towards regaining flying status. This represents operation of the fourth dimension in Devereaux's Venn diagram. The decision to replace the valve will have been a clinical one,[21] assuming that the pilot with aortic stenosis was asymptomatic. Provided the UK CAA algorithm (Fig. 7.1), for example, can be subsequently navigated successfully, a favorable fitness statement should be possible.

The "1% rule" and best evidence

Although the workshop proceedings were to become manuals of regularly updated informal guidance material, their ground-breaking contribution was the evolution of what was to become known as the "1% rule." Credit is due to Tunstall-Pedoe[22,23] who related the chance of "failure" of a pilot in medical terms to the risk of failure of any major system in the aircraft. It is derived as follows: the industry target fatal accident rate for large jet aircraft is 1 in 10 million flying hours. Not more than 1 in 10 of such events should be due to a major system failure (i.e. the pilot) and not more than 1 in 10 of those due to failure of a subsystem (i.e. medical incapacity). This makes for an objective of 1 fatal accident in 1000 million hours from all-cause medical incapacitation.

This target will be met provided the all-cause crew medical failure rate does not exceed 1%/annum – the approximate cardiovascular mortality of a 66-year-old male in North West Europe. This is argued as follows: there

NOTES:

1) May require OML (Class 1) or OSL (Class 2) whilst under investigation.

2) By a cardiologist acceptable to the Aeromedical Section (AMS). Systolic function should be normal (EF >60%) and Aortic valve calcification should be minimal.

3) The cardiology report will be reviewed by the AMS. It may be necessary to see the investigations in which case the actual tracings/films/videos will be requested. In difficult cases a secondary review panel of cardiologists will be convened.

4) The principal measurement to determine medical certification of pilots with aortic stenosis is aortic valve area during echocardiography. Suggested certificatory assessment, based on European Society of Cardiology Guidelines.

VALVE AREA	MEAN AORTIC GRADIENT (Echo-Normal flow conditions)	SEVERITY	CERTIFICATION
>1.5 cm^2	0–30 mm Hg	Mild	Unrestricted Class 1/2
1–1.5 cm^2	30–50 mm Hg	Moderate	Class 1 OML / Unrestricted Class 2
<1 cm^2	>50 mm Hg	Severe	Unfit all classes

Indexing valve area to Body Surface Area (BSA) can be useful in cases of unusually large or small BSA (Moderate 0.6–0.9 cm^2/m^2; Severe <0.6cm^2/m^2)

However, other factors will need to be considered in each case, including

Left ventricular hypertrophy
Reduced left ventricular diastolic function
Reduced left ventricular ejection fraction
Aortic regurgitation
Pull back pressure gradients measured during catheter studies are 10–15 mm Hg lower than echocardiographically measured peak pressures

5) Follow up at the discretion of the AMS - at least annual echocardiography if mean pressure gradient 30 mm Hg or more

Results acceptable to the AMS (note 3)

Figure 7.1 Algorithm for certification to fly following the diagnosis of aortic stenosis. The cut-off points relate to the hierarchy of increasing risk assumed by reduction in valve area, and the prognostic implications of the presence of valvular calcification, left ventricular hypertrophy and the presence or absence of reduced left ventricular ejection fraction (**Class I**). Note that in the regulatory process, the terms "Class 1" and "Class 2" refer to the level of fitness assessment for professional and private aircrew respectively.

are 10 000 hours in a year (actually 8760 hours). If incapacitation occurs at 1% each year, the risk in any one hour will be 1 in $100 \times 10\,000 - 1$ in 1 million. But there are two crew members and only 10% of the flight is critical (take off, climb out, approach and landing) and with adequate training (based on simulator data) only 1 in 100 such incidents will lead to an accident.

Thus the medical incapacitation *of one of the two crew members* should not lead to an accident more often than 1 in 1 million 1 in 10×1 in 100, i.e. 1 in 1000 million hours. This coincides with the industry target for an unpredicted total loss which experience has shown to be realistic and appropriate. The chance of both pilots suffering medical incapacitation in the same hour will be the square of the individual risk (1 in 1 million $\times$ 1 in million $- 1 \times 10^{12}$) which is extremely remote. The carriage of two pilots should, therefore, guarantee safety in all but the most adverse cir-

cumstances. In contrast, the single-pilot operation is uniquely vulnerable.[24,25]

In modeling the 1% rule, total cardiovascular mortality and coronary artery mortality were used as these are the most easily defined endpoints in the expression of cardiovascular risk. Co-morbid, non-lethal events, including stroke and unstable angina, will be 2–3 times as common but in the regulatory environment, screening by self-declaration following event will have removed some of this risk. Thus a 1% mortality in the general population is equivalent to a 1% event rate in the regulatory environment.[23]

Further development of the rule by Mitchell and Evans[26] has suggested that the target event rate could be relaxed to 2% *for multi-crew operations* without appreciable increase in risk to flight safety. This they based on a number of factors including reduced relative flight criticality brought about by longer flight duration and better equipment.

Furthermore, since the late 1970s, cardiovascular mortality in the UK has fallen 46%[27,28] in the under-65 year age group but in actuarial terms this risk reduction is "lost" in 3–4 years.[29,30] In other words a subject's "cardiologic age" at somatic age 64 years, now, is the equivalent of what it used to be at age 60, 25 years ago. Partly as a result of this, the age of professional pilot retirement from passenger-carrying operations has been increased from 60 to 65 years.

The impressive safety achievement in multi-crew operation is impossible in single-crew operations where the whole flight is critical in the context of pilot "failure" from any cause, including medical. In this environment the fatal accident rate due to failure by the single crew member will always be significantly worse than the medical incapacitation rate. The chance of being killed as a passenger in a single-pilot machine from any cause is likely to be one or two orders of magnitude ([mult]10–100) greater than in the multi-crew operation.

The foregoing arguments are predicated on the aviation environment but the principles are applicable elsewhere. In road and rail transportation, with a single crew operator, there may be sufficient warning of illness to permit safe conduct of a machine to a standstill. In rail transport the "dead man's handle" safety device is designed to stop the vehicle in the event of incapacitation of the driver. It is not universally fitted.

The 1% rule was evolved to define an appropriate cut-off point for denying multi-crew operational fitness to a pilot; it is not a yardstick for judging single crew fitness. In the context of coronary artery surgery, for example, if the predicted risk of event is <1%/annum, the pilot may be fit for multi-crew, but not single-crew operation. With the geometric increase in risk of occult coronary artery disease with age, it is not easy to determine placement of the risk cursor with its all-or-nothing impact on certification to fly. Doubling cardiovascular risk at age 60 years will be associated with a substantial increase in absolute risk when compared with age 40 years.[30]

Specific cardiologic issues in aircrew

Fitness to fly has evolved significantly over the years in tandem with the diagnostic, pharmacologic and interventional progress that has been made in medicine. The boundaries of fitness are under constant review as challenges to stretch the envelope in regulatory terms are made. The interface between regulation and cardiology is as broad as the specialty itself and for this reason only two of the most common cardiologic conditions will be considered in more detail – coronary artery disease and atrial fibrillation, whilst a third, rare, condition will also be examined. A fuller treatment of the subject is available.[31]

Figure 7.2 Survival probability curves of American Airline male pilots and an age- and sex-matched sample of the general population. (Reproduced with permission from the United States Federal Aviation Administration.[32])

Health maintenance

Of all occupational groups, aircrew are in one of the most favorable positions for health maintenance. Required as they are to pass regular medical examinations in order to maintain fitness (and thereby employment), it would be surprising if, as an occupational group, professional pilots did not enjoy a long retirement. Experience has shown this to be the case (Fig. 7.2). In the American Airlines study,[32] the median survival of pilots achieving age 60 in a sample of 2209 pilots and flight engineers was to age 83.8 years whilst that of age-matched white males was 78.2 years. This study is the only significantly robust one available although a number of other reports have suggested a similar effect. One from the UK contained limited data[33] and a similar one from Japan suggested increased longevity although the study was not sufficiently highly powered to estimate the survival benefit.[34]

Prevention of cardiovascular disease

If regular medical scrutiny is to be beneficial, the outcome must be acted upon, if indicated. There is abundant evidence that increased cardiovascular risk in terms of morbidity and mortality is present when one or more of the cardinal vascular risk factors is present. These include hypertension, increased total cholesterol, diabetes, smoking, obesity, sedentary lifestyle and the sometimes overlooked but increasingly powerful risk input of age. The European Health Charter[35,36] advocates the development and implementation of comprehensive health strategies and policies (**Class I**). This is to some extent enshrined in the new EASA requirements.[37]

A comprehensive review of the evidence and strategy for cardiovascular disease prevention is available[36] but in spite of this, it is not uncommon for a pilot in middle years to present with the signs of established hypertension, for example, when previously recorded levels have been within the normal range. There are a number of possible

explanations including lack of awareness of, or a willingness to ignore, the importance and value of intervention in the preservation of cardiovascular health.

Coronary artery disease

Loss of license to fly from cardiovascular cause remains significant in the Western world in spite of the impressive fall in cardiovascular mortality. Neuropsychiatric problems are similarly important. The two most common cardiologic problem areas are coronary artery disease and the arrhythmias. Coronary artery disease, on account of its stealth, capricious presentation (often without diagnostic prodromal symptoms) and its ability to cause complete or subtle incapacitation, is important, notably in the single-crew operational environment. Increased chance of its presence can be calculated from risk algorithms but it remains what Rose has called the "prevention paradox" in that only three-fifths of subsequent events will occur in those in the top quintile of vascular risk. Purging high-risk asymptomatic individuals from the workforce has been attempted in the past, elsewhere, but was abandoned. In Europe, further investigation, particularly of single-crew operators, with exercise electrocardiography may be carried out and is routine at age 65 and 4 yearly thereafter. Although a pilot can be counselled on strategies of risk reduction, denial of fitness cannot be predicated on risk alone in the absence of evidence of disease although this has been attempted in certain states. It is possible to restrict such pilots to multi-crew operation but this appears difficult to apply consistently.

Coronary artery disease, unlike certain other cardiovascular disorders (such as thoracic aortic aneurysm), is not specifically disbarred under the European (EASA) rules. NPA 200817c: MED. B.005. (b)1 states "Applicants shall not possess any cardiovascular disorder which is likely to interfere with the safe exercise of the privileges of the applicable licence(s)."[37] The regulator, post hoc, is not as concerned with the first presentation of coronary disease as with its subsequent stability. In general terms the best-risk applicant will be asymptomatic, not receiving antianginal therapy, have no coronary obstruction >50% in any vessel unattended by percutaneous coronary intervention (PCI) or graft surgery, unless subtending a completed myocardial infarction (>30% in the proximal left anterior descending and left main stem vessels). Left ventricular function shall be good (ejection fraction >50%, however measured). Furthermore, the predicted risk of co-morbid MACE (major adverse cardiac event) has to be not more than that encompassing a mortality of the order of 1% per annum – see above. Finally, intervention against vascular risk factors present shall have been taken. This is a pretty tall order and some might question how durable the guiding principle of the 1% rule (recently relaxed to 2% per annum[26]) is in the

context of multiple stent implantation, in spite of concomitant pharmacologic intervention with statins and angiotensin-converting enzyme inhibitors (ACEI) for both their effect on outcome and their pleiotropic effect on plaque stability.[38,39]

Coronary artery disease lends itself to the mathematic modeling of risk on account of the massive amount of outcome data available. In the early days of recertification following coronary surgery, the validity of the step was underscored by Chaitman et al[40] who compared the survival of best-risk post coronary surgical patients with the profile of the pilot population who had undergone full revascularization, and who had normal or near normal left ventricular function, with a Framingham peer group. The surgical patients fared significantly better over a 5-year period. Under the circumstances it was both equitable and safe to allow fitness to fly (**Class I, Level C1**).

The postsurgical MACE rate is reassuringly flat 6 months later. The subsequent trajectory following stenting is less favorable than after coronary surgery.[41–45] The post-stent 12-month outcome in the recently published OLYMPIA data[42] using the Taxus stent "in the real world environment" was 4.5% for cardiac death, myocardial infarction and re-intervention alone. This is above what is tolerable in the aviation environment although some of the candidates in this study would have been excluded on the basis of age or co-existing pathology.

Figure 7.3 shows the rate of revascularization (for recurrent symptoms) following first intervention in the study of Hannan et al.[43] After the implantation of a drug-eluting stent in this comparative study of coronary artery surgery versus coronary stenting (PCI) for multi-vessel coronary artery disease, the 18-month repeat PCI rate was 28.4% versus 5.1% following coronary surgery (CABG) (*P*<0.001) although only one-quarter of interventions were for target vessel revascularization. This implies incomplete revascularization first time round, itself a reason for the denial of fitness status. It will also be noted that after the 6-month regulatory required waiting period, the revascularization rate has slowed but these data do not include other

Figure 7.3 Revascularization following coronary artery surgery (CABG) and drug-eluting stenting (PCI). (Reproduced with permission from Hannan et al.[43])

MACE events. A similar increased need for reintervention following revascularization with a coronary stent when compared with bypass surgery was also noted by Serruys' group.[44,45]

Case history 1

The subject, JK, was a 57-year-old Air Traffic Control Officer (ATCO) who developed midsternal discomfort on first effort in cold weather. When guiding aircraft on the approach to London Heathrow airport at times of high traffic density he experienced similar symptoms and sought medical advice. He was normotensive (132/82) but there was a family history of coronary artery disease. He had smoked one pack of cigarettes a day until aged 40 and had a total cholesterol of 7.3 mmol/L. Exercise performance was limited by chest pain with diagnostic electrocardiographic change at 6 minutes 45 seconds of the Bruce treadmill protocol whilst subsequent coronary angiography confirmed the presence of proximal three-vessel coronary artery disease. Although the evidence is not recent, three controlled trials have shown the benefit of surgical revascularization in this context, versus medication, and the excellent outcome and low event rate in "best-risk" subjects[40,46] (**Level A**).

JK underwent quadruple bypass grafting including insertion of the left internal mammary artery into the anterior descending coronary artery. Six months later he was returned to duty having competed 11 minutes of the Bruce protocol without abnormality and having reduced his total cholesterol to 4.1 mmol/L with a statin.

Comment

Would a percutaneous intervention (coronary angioplasty/stenting) have been appropriate if technically feasible? At the preintervention conference it was agreed by the attending cardiologists that the percutaneous (PCI) approach was technically feasible. Inspection of the data, however, suggests that it is difficult to show a benefit both in survival terms as well as for MACE-free survival in this context.[47] In the COURAGE trial[47] which included 2287 subjects, the event rate for patients in the medically treated group was the same as in the angioplasty group over a mean of 4.6 years (the majority of the stents were bare metal). Composite death, myocardial infarction and stroke, together with hospitalization for acute coronary syndrome, was 20.0% in the PCI group and 19.5% in the medically treated group. Additionally, in the PCI group 21.1% had undergone further revascularization over the 4.6-year period (**Level A**). Such rates comfortably exceed the target event rate of 1–2% mortality with associated co-morbid events.

The event rate following stenting makes it less desirable than coronary artery surgery and there seems little reason to revise the earlier view of Webb-Peploe[48] that the procedure should be restricted in the aviation context to the reduction of not more than two lesions which should exclude the proximal left anterior descending and left main vessels (**Class I, Level A**).

Case history 2

The subject, DF, was a 53-year-old Airline Transport Pilot License (ATPL) holder who experienced indigestion-like symptoms whilst on a stopover in Hong Kong. He was asymptomatic on the return flight on which he acted as pilot in command. He sought medical advice when the symptoms recurred 2 weeks later. He was found to have borderline hypertension (156/88) and a total cholesterol of 6.4 mmol/L. He was a non-smoker and non-diabetic. He completed 8.1 minutes of the Bruce exercise protocol before being stopped by chest pain and diagnostic ST-T changes. Coronary angiography demonstrated proximal near obstruction of the right main vessel with non-flow limiting disease (30% stenosis) in the proximal left anterior descending coronary artery. The circumflex system showed early disease only.

As he was symptomatic, the right coronary artery was stented, the hypertension treated with an ACEI and the elevated cholesterol with a statin, both of which have been suggested to have a beneficial pleiotropic effect on atheromatous plaque stability.[38,39] Following a normal pharmacologic stress thallium myocardial perfusion scan (MPI) and an echocardiogram indicating well-preserved left ventricular function, he was assessed fit for multi-crew operation only, subject to annual review with exercise electrocardiography. Although there is no evidence of outcome benefit, either for coronary artery bypass grafting or coronary stenting in this clinical situation, the presence of symptoms and exercise-induced myocardial ischemia justifies the interventional approach, in addition to medication (**Class I, Level C2**). Six months later he was asymptomatic and had undergone a pharmacologic stress thallium MPI.[49,50] He was assessed fit for multi-crew operation subject to annual follow-up with exercise electrocardiography.

Comment

The current UK CAA algorithm for recertification to fly in the context of known coronary artery disease is shown in Figure 7.4 (**Class I**).

Atrial fibrillation

Atrial fibrillation is the most common sustained rhythm disturbance. In the Renfrew/Paisley study, its incidence was 0.4/1000 person-years in subjects aged 45–49 years rising to nearly 2.0/1000 person-years in subjects aged 60–64 years.[51] Twenty-five percent of males >40 years will develop the arrhythmia during their lifetime. Whereas the Renfrew population will not reflect the pilot population, it mirrors the Framingham experience[52] in terms of age-skewed prevalence. In Framingham the prevalence of atrial fibrillation appears to be increasing and was associated

**JAA Class 1/2 certification - Coronary artery disease**

Coronary artery disease including:
   Myocardial infarct
   Coronary artery surgery
   Angioplasty/stenting

Grounded of
6 months

Cardiology review (note 1)
   Symptoms/treatment/risk factors (note 2)
   An angiogram shall be available (note 3)
Shall require:
      Exercise ECG (note 4)
      Echocardiogram (note 5)
      Myocardial perfusion scan (angioplasty/stent only - note 6)
May require:
      24-hour ECG (note 7)

Results acceptable
to the AMS (note 8)

Operational assessment (note 9):
   Class 1 OML (Operational Multi-Crew)
   Class 2 unrestricted
   Class 2 OSL (Safety pilot)

   Follow-up at AMS discretion (note 10)

UK Civil Aviation Authority 04/05
Aviation House
Gatwick Airport South
West Sussex RH6 0YR
UK

NOTES:

1) By a cardiologist acceptable to the Aeromedical Section (AMS).

2) No angina or antianginal medication. Risk factors shall be assessed and reduced to an appropriate level. All applicants should be on acceptable secondary prevention treatment.

3) Angiogram - obtained around the time of, or during, the ischaemic myocardial event. There shall be no stenosis more than 50% in any major untreated vessel, in any vein/artery graft or at the site of an angioplasty/stent, except in a vessel supplying an infarct. More than two stenoses between 30% and 50% within the vascular tree should not be acceptable. The whole coronary vascular tree shall be assessed (particular attention should be paid to multiple stenoses and/or multiple revascularisations). An untreated stenosis greater than 30% in the left main or the proximal left anterior descending coronary artery should not be acceptable.

4) Exercise ECG - should be symptom imited to a minimum of Bruce stage 4 or equivalent, with no evidence of myocardial ischaemia or significant rhythm disturbance.

5) Echocardiogram - myocardial function shall be assessed and show no important abnormality of wall motion and a LV ejection fraction of 50% or more.

6) Myocardial perfusion scan - showing no evidence of reversible ischaemia shall be required at least 6 months after angioplasty/stenting, but not after other events (myocardial infarction or bypass grafting) unless there is doubt about myocardial perfusion.

7) 24 hour ECG - may be necessary to assess the risk of any significant rhythm disturbance.

8) The cardiology report will be reviewed by the AMS. It may be necessary to see the investigations, in which case the actual tracings/films/videos will be requested. Further investigations may be required. In difficult cases a secondary review panel will be convened.

9) Class 1 recertification will require a multi-crew limitaion (OML). Unrestricted Class 2 certification is possible having completed all the above investigations. Class 2 safety pilol (OSL) recertification is possible having completed a satisfactory exercise ECG test (as in note 4).

10) Periodic follow/-up (at least annually for the first 5 years) shell include a specialist cardiology review, cardiovascular risk assessment and an acceptable exercise ECG (as in note 4 above). In all cases coronary angiography and/or myocardial perfusion scanning shall be considered at any time if symptoms, signs or non-invasive tests indicate cardiac ischaemia. In all cases of coronary artery vein bypass grafting (except Class 2 OSL) a myocardial perfusion scan shall be performed 5 years after the procedure (if not done before).

Figure 7.4 Algorithm for certification to fly following the diagnosis of coronary artery disease. Important issues are full revascularization and preservation of left ventricular function which powerfully predicts outcome.

with a fivefold increased risk of stroke overall. This and heart failure contributed to the excess mortality observed. In the Euro Heart survey of atrial fibrillation,[53] the mean age of the population was higher than the pilot population (65 +/− 14 years) and two-thirds had hypertension, one-third ischemic heart disease. It also complicated valvular heart disease (rheumatic mitral valve disease increases the risk of cerebral thromboembolism 10-fold), primary muscle disease as well as metabolic and other disorders. In about 25% of the population <65 years the arrhythmia may be "lone" and not associated with any demonstrable abnormality at presentation although genetic predisposition is attracting increasing attention.

Atrial fibrillation may be seen as an isolated self-limiting event in a normal subject following vomiting or alcoholic excess, for example. It may be conveniently divided into isolated (single episode sometimes with provocative cir-

cumstance), paroxysmal (self-terminating), persistent (persisting >1 week and until cardioversion) and permanent (immutable) forms. It may be completely asymptomatic, occasionally symptomatic and/or intolerable. It may cause distraction (subtle incapacitation) or syncope (complete incapacitation). It may be suppressed completely, partially or not at all by medication which may or may not give side effects. The potential for side effects (tremor and persistence of vision) of the class 1C antiarrhythmic agents (e.g. propafenone, flecainide) disbars them as a rule in the aviation but not road transport environment. Finally it is associated with an increased risk of cerebral thromboembolism, the incidence of which increases sharply with age, if hypertension, diabetes, heart failure or structural abnormality is present, or if previous thromboembolism has occurred. Even in the absence of stroke, atrial fibrillation is associated with memory impairment, cognitive dysfunc-

tion and hippocampal atrophy.[54,55] Against this unpromising background the regulator has to develop some ground rules.

The requirements for flying status following the diagnosis of atrial fibrillation are similar to those for other cardiovascular conditions. The applicant shall be free of symptoms under all circumstances and the predicted event rate shall not exceed that of the co-morbid event rate reflected by an annual cardiovascular mortality of 1%. Freedom from symptoms can only be determined at consultation but further insight may be obtained by exercise electrocardiography. The diagnosis *per se* does not disbar certification to fly but if other pathology co-exists it is likely to deny fitness in view of the increasing risk of thromboembolic stroke. The long-term outcome is not different whether the subject maintains sinus rhythm with the use of (permitted) therapeutic agents or remains in atrial fibrillation with rate control.[56,57]

The assessment of risk of cerebral thromboembolism and mitigation of the risk of stroke is a central component of the management of atrial fibrillation. The choice of an antiplatelet agent versus anticoagulation with warfarin has been well researched.[58,59] In European aviation, at present, warfarin and similar products such as phenindione are prohibited due to lack of reliability and risk of hemorrhage. In one review, the annual risk of bleeding in subjects receiving warfarin was identified as 0.6% (fatal), 3.0% (major) and 9.6% (minor), about five times the rate expected without warfarin.[60] The risk appears to be highest at the start of treatment, the first month bearing 10 times the risk of that a year later. Significant co-morbidity and age increase the risk whilst tight control of the INR between 2.0 and 3.0 reduces it. Warfarin reduced the thromboembolic risk in non-valvular atrial fibrillation by two-thirds[61] although the risk of cerebrovascular hemorrhage was doubled to 0.46%/annum. In the regulatory environment this risk has to be added to the uncovered stroke risk as well as to associated co-morbidity. A recent overview reports a relative risk reduction of 60% for all stroke (ischemic plus hemorrhagic).[62]

Aspirin is not contraindicated in fliers and its use reduced the risk of stroke by 21% in three trials[63] (**Level A**). The CHADS2 risk graticule was created by assigning one point each for the presence of congestive heart failure, hypertension, age >75 years and diabetes mellitus whilst two points were given for a history of stroke or transient ischemic attack.[64] It has proved superior to other models in the prediction of low and high risk of stroke. The crude annual stroke risk, on no treatment, for CHADS2 grade 0 is 1.2% and 2.8% for CHADS2 grade 1. Assuming the use of aspirin, lowest risk non-valvular atrial fibrillation, whether paroxysmal, persistent or permanent, is acceptable in aviation subject to the ability to fulfill the algorithm in Figure 7.5 (**Class I, Level A**).

Case history 3

The pilot was a normotensive 37-year-old Senior First Officer with no significant past medical history. He was receiving no medication and his alcohol intake was 10 units (8 g)/week. He presented with asymptomatic well-controlled atrial fibrillation at routine examination. His cardiovascular system was otherwise normal. He completed 13 minutes of the Bruce exercise protocol, achieving a maximum instantaneous heart rate of 230 beats/minute. His echocardiogram was normal and ambulatory monitoring revealed no significant other rhythm disturbance. There was no RR interval >3.0 s. As his atrial fibrillation was paroxysmal, he was asymptomatic and his thromboembolic risk judged to be acceptable (i.e. CHADS2 score 0), he was returned to flying. He was treated with aspirin and an OML was imposed to deny single-pilot operating privileges on smaller aircraft. He remained in paroxysmal atrial fibrillation for 4 years but for the last 7 has been in this rhythm permanently. Apart from atrial fibrillation, his resting and exercise electrocardiograms, and echocardiogram have remained normal.

Regulatory orphans and the long QT syndrome

As has been seen above, regulatory medical decision making evolves as the science of medicine moves forward. It must remain ethical and be fully justifiable.[65] The great majority of applicants will have no health issues and satisfy the requirements laid down. Most cardiologic problems are to some extent age related and have sufficient data in the literature for safe and fair fitness recommendations. Certain conditions such as the ion channelopathies are associated with an increased risk of ventricular tachycardia (torsades de pointes), syncope and sudden death (SCD) and are sufficiently newly described for the outcome database to be inadequate for fully informed judgment. In this circumstance either the pilot has to be made unfit (the easy option) or a best evidence view taken which relies to some extent on knowledge of the operational safeguards which exist.

Case history 4

The pilot was a 38-year-old asymptomatic normotensive airline captain who had previously undergone routine electrocardiography without comment having been passed. When he changed his employer, a computer-read recording correctly identified a prolonged QTcB (480 ms) – male normal </= 440 ms (see ECG 1, Fig. 7.6a). He underwent exercise electrocardiography which demonstrated non-sustained slow ventricular tachycardia on recovery (see ECG 2, Fig. 7.6b). A subsequent echocardiogram and magnetic resonance imaging were normal. Two repeat exercise electrocardiograms following treatment with a beta-blocking agent were normal. His 24-hour Holter recording, off treatment, showed no atrial or ventricular ectopic activity. The configuration of the ST segments and T waves, notably in V5 and V6, suggested the long QT2(a) variant.[66]

NOTES:

1) By a cardiologist acceptable to the Aeromedical Section (CAA approved cardiologist - Class 1, local cardiologist - Class 2).

   Blood tests - Thyroid function normal. Alcohol as a cause of AF should be excluded with a minimum of LFTs (to include GGT) dnd MCV.

   Exercise ECG - Bruce protocol and maximal effort or symptom limited. At least 9 minutes with no significant abnormality of rhythm or conduction, nor evidence of myocardial ischaemia. (See UK CAA exercise ECG protocol).

   24 hr ECG - More than one may be required The following criteria should be met.
   If in sinus rhythm (ie single original episode of AF) - No episodes of AF and no pauses >2.5 secs whilst awake.
   Established AF - RR interval >300 msecs and <3.5 secs (ie no very rapid rates or long pauses). Ventricular arrhythmia should not exceed an aberrant beal count >2% of total, with no complex forms
   Paroxysmal AF - As above plus the longest pause on recapture of sinus rhythm should not exceed 2.5 sec whilst awake.

   Echocardiogram - Shell show no significant selective chamber enlargement or significant structural or functional abnormality, and a LVEF of 50% or more.

   Further tests - may include repeat 24 hour ECG recordings, electrophysiological studies,cardiac MRI, myocardial perfusion scanning and/or coronary angiography.

2) The cardiology report(s) will be reviewed by the AMS. It may be necessary to see the investigations, in which case the actual tracings/films/videos will be requested. In difficult cases a secondary review panel of cardiologists may be convened.

   Acceptable treatment includes sotalol or other beta-blocking drugs, verapamil and digitalis. Exceptionally flecainide or propafenone may be uesd (Class 1 - permanent OML restriction). Amiodarone is unacceptable for Class 1, but may be acceptable for Class 2 (maximum dose 200 mg daily, night flying will require an AMS ophthalmological review). Anticoagulation is not acceptable

3) Only Class 2 pilots with a documented recurrence free period from a single episode of AF are likely to obtain unrestricted certification at this time. Initial follow-up cardiology review should be 6 monthly to include a minimum of 24 hour ECG monitoring.

4) Likely to be 2 years for Class 1 and 1 year for Class 2. A single original episode of AF with no recurrence will allow unrestricted Class 1/2 certification. Other cases will require individual assessment. It is unlikely that a pilot over ege 65 with other than a single episode of AF will gain an unrestricted certificate (Class 1 or 2).

5) Subsequent follow-up at the discretion of the AMS.

Figure 7.5 Algorithm for certification to fly following the diagnosis of atrial fibrillation. Only subjects with "lone" atrial fibrillation (no structural abnormality of the heart, no history of hypertension or diabetes and no metabolic cause) can be considered and then only if asymptomatic. The disturbance may be paroxysmal, persistent or permanent (see text). These are updated from time to time and reference needs to be made to the CAA website (Class I).

Comment

Over 300 mutations on seven genes (LQT1–7) have been described. Transmitted as autosomal dominant genes, all involve fast and slow activating delayed potassium repolarizing currents with the exception of the LQT3 which involves the SCN5A sodium encoding gene shared by the Brugada syndrome.[67] All are characterized by risk of ventricular tachycardia, syncope, cardiac arrest and sudden death. Data are incomplete and although the highest event rate seems to occur before adulthood,[68,69] the natural history of the condition remains to be fully characterized, particularly in later years. A recent review of some 18 500 UK Class certificate holders over a 10-year period revealed exactly 100 males in whom the QTcB exceeded the upper limit of normal (440 ms). All were asymptomatic and in only five the QTcB excoeded 480 ms. All were, and have remained, asymptomatic. All except one, an ATCO, retained their licenses, most with an OML endorsement.[70]

There are differences in presentation, LQT1 tending to occur with exercise, LQT2 with sudden arousal such as noise, and LQT3 at rest. There are also differences in response to treatment as the LQT2 variant may obtain less benefit from beta-blockade.[71] Ventricular tachycardia and aborted sudden death justify an implantable defibrillator. Excessive prolongation of the QTc (>500 ms) predicts events in LQT1 and 2 but not LQT3[68] and the locus of the mutation is also predictive.[71] The overall event rate is higher in LQT1 and 2 but the lethality of an event is higher in LQT3.[68,72] In due time, it is likely that genomic profiling of the individual will enable risk profiling with more confidence.

On an *ad hominem* basis, the regulatory issue is to balance the safety advantage of maintaining the flying status of a 10 000 hour pilot with the risk of an adverse cardiac event.
Figure 7.6 (a) The resting electrocardiogram of a 38-year-old airline captain with the LQT2 pattern and a QTcB of 480 ms. (b) Same patient: immediate postexercise non-sustained ventricular tachycardia.

Any prodromal event would deny certification, as would any subsequent event. Priori *et al*[68] suggested that the incidence of first cardiac arrest/sudden death <40 years in LQT2(a), before therapy. is 0.46%/year although the risk is not linear and data beyond 40 years are scant. This may be expressed as risk/hour – 0.00525% and for any arbitrary 6 minutes of flight criticality (i.e. during take off and landing),[26] 0.000525%. In the general population the annual incidence of sudden death in the age range 20–75 years is 0.1%/annum – 0.0011%/hour[73] but this will be age skewed and whatever additional burden the LQT proband carries, he/she will bear a cumulative additional age-related risk from coronary artery disease, for example. This additional increase in relative risk is not acceptable for an operational situation where the sole co-pilot could be inexperienced.

However, in certain long-haul operations, a third (sometimes a fourth) pilot is carried which would all but abolish the operational risk but for a very limited period. The regulatory authority was advised to consider the possibility of a limitation to heavy crew operation only, with an upper age cut-off, in the absence of further evidence of any event, of 60 years (**Class I, Level C2**).

Conclusion

The interface between evidence-based medicine and the regulatory environment reflects some of the most interesting and challenging problems in cardiology. Before regulation was based on scientific principles, fitness determination

was arbitrary with implications both for safety and for the prosperity and well-being of the professional groups involved. Progress in cardiology should be matched by improved and enlightened attitudes to certification.

Note

Some of the material in this chapter relates to legally based requirements for medical fitness in the transportation industries. The statements and opinions are those of the author and have no regulatory standing. Those requiring further guidance should consult the relevant authority. The UK CAA algorithms (reproduced with permission) are regularly updated and are available at the web address provided at the end of the chapter.

Prevention of cardiovascular diseases

Salim Yusuf and John A Cairns, Editors

8 Global perspective on cardiovascular disease

K Srinath Reddy

All India Institute of Medical Sciences, New Dehli, India

Introduction

In the second half of the 20th century, cardiovascular diseases (CVD) became the dominant cause of global mortality and a major contributor to disease-related disability. At the beginning of the 21st century, this pattern has become even more pervasive as the CVD epidemic accelerates in many developing regions of the world, even as it retains its primacy as the leading public health problem in the developed regions.[1–9]

An estimated 17.5 million people died from cardiovascular diseases in 2005, representing 30% of all global deaths. Of these deaths, an estimated 7.6 million were due to coronary heart disease and 5.7 million were due to stroke. Over 80% of cardiovascular deaths took place in low- and middle-income countries and occurred equally in men and women.[1] The low- and middle-income countries contributed 83.8% of all CVD deaths and 88.5% of disability-adjusted life-years (DALY) loss attributed to CVD that year.

Around 9 million stroke cases were reported to occur in 2004. Large geographic differences exist in the burden of stroke as well as its case fatality rates globally. There is an increasing trend in the incidence of stroke in developing countries as opposed to the decreasing or stabilizing trend in developed countries. While coronary heart disease (CHD) was the dominant form of CVD in the developed countries, Latin America and India, stroke was the leading cause of cardiovascular deaths in sub-Saharan Africa and China. Epidemiologic studies in developing countries provide evidence that stroke mortality rates tend to be higher than coronary heart disease rates, and may be considerably higher than in developed countries.[1,2] In 2004, low- and middle-income countries contributed to 86.7% of global deaths due to cerebrovascular diseases. Hypertension and diabetes are more widely prevalent in stroke patients in developing countries as compared to developed countries.[3]

The rise and recent decline of the CVD epidemic in the developed countries have been well documented.[9–12] The identification of major risk factors through population-based studies and effective control strategies combining community education and targeted management of high-risk individuals have together contributed to the fall in CVD mortality rates (inclusive of coronary and stroke deaths) that has been observed in almost all industrialized countries. It has been estimated that, during the period 1965–90, CVD-related mortality fell by 50% or so in Australia, Canada, France and the United States and by 60% in Japan.[8] Other parts of Western Europe reported more modest declines (20–25%).[9] The decline in stroke mortality has been more marked compared to the decline in coronary mortality. In the United States, the decline in stroke mortality commenced nearly two decades earlier than the decline in coronary mortality and maintained a sharper rate of decline.[11] During the period 1979–89, the age-adjusted mortality from stroke declined, in that country, by about one-third while the corresponding decline in coronary mortality was 22%.[11] In Canada, Japan, Switzerland and the United States, stroke mortality has declined by more than 50% in men and women aged 65–74 years since the 1970s.[12] In Japan, where stroke mortality outweighs coronary mortality, the impressive overall decline in CVD mortality is principally contributed by the former.

However, recent trends in some of the developed countries have provoked some concern. A flattening of age-adjusted mortality rates for major cardiovascular diseases in the USA has been reported since 1990, with an especially well-documented absence of a decline in stroke mortality since that year. This has been accompanied by an increase in mortality from congestive heart failure. Lack of decline in incidence of CHD and stroke, fall in the rate of decrease in cardiovascular risk factor levels and rising levels of obesity since 1990 have all been incriminated as factors

responsible for such a plateau effect on CVD mortality rates in USA over the past decade.[13]

Within Europe, there is a considerable variation in cardiovascular and all-cause mortality on both a national and a regional level. Mortality from both CHD and CVD has continuously been decreasing in most Western European countries over the last three decades. In most Central and Eastern European countries, on the other hand, cardiovascular mortality increased during the 1970s and 1980s and started to decline or stabilize in the early to mid-1990s. Despite the recent decrease, rates are considerably higher in most Central and Eastern European countries. With regard to cerebrovascular mortality rates, a different pattern is observed. Cerebrovascular mortality is reduced in the center of Western Europe, with the lowest national mortality rates in Switzerland, France, Norway, Spain, The Netherlands and Italy. Countries and regions with higher mortality rates surround this circle of reduced mortality such as the Central and East European Countries as well as some Mediterranean countries including Greece, Portugal and certain regions of Southern Spain and Italy.[14]

CHD, previously considered rare in sub-Saharan Africa, now ranks eighth among the leading causes of death in men and women. A wide variety of studies from Ethiopia, Ghana, Kenya, Nigeria, Tanzania and Zaire suggest that the incidence and prevalence of CVD is increasing, especially in urban and semi-urban areas.[15] This is the result of adverse behavioral and lifestyle changes associated with urbanization and epidemiologic transition.

Developing countries like China and India have experienced an epidemiologic transition in a much shorter time than many countries. Mortality analysis of China shows that deaths due to chronic diseases have increased as a proportion of all deaths, from 41.7% in 1973 to 74.1% in 2005, with CVD being a major contributor. China already has 177 million adults with hypertension.[16] An increasingly larger number are at risk of cardiovascular diseases because of smoking, dietary changes and reduced physical activity. In India, too, cardiovascular disease is now the leading cause of death, accounting for 29% of all deaths in 2005. The risk factors are also on the rise, as evidenced by a number of community surveys in different regions of the country. India is presently home to 40 million persons with diabetes and 118 million hypertensive individuals. These are projected to increase even further by 2025.[17]

Rheumatic heart disease (RHD) continues to be a burden in developing countries, although there is an overall decline in the incidence and deaths resulting from RHD. Of 12 million people currently affected by rheumatic fever and RHD, two-thirds are children between 5 and 15 years of age. There are around 300 000 deaths each year with 2 million people requiring repeated hospitalization and 1 million likely to require surgery in the next 5–20 years.[18]

Early age of CVD deaths in developing countries

Although the present high burden of CVD deaths is itself a reason for attention, a greater cause of concern is the early age of CVD deaths in developing countries compared to developed countries. Globally, more than 38% of CVD deaths occurred below the age of 70 years in 2002. Deaths from cardiovascular diseases in people younger than 70 years accounted for 21% of all deaths.[19] Age-specific CVD mortality rates for those between 35 and 64 years have increased many-fold between 1984 and 2002 in less developed countries. This kind of concentration of CVD deaths among people of working age (35–64 years) is not seen in industrialized nations. In India, China, Russia and Brazil, 30–40% of the CVD deaths occur in people of working age. The Philippines has over 50% of its CVD deaths in this age group, 8–10 times higher than the Western experience.[20]

South Asians have a greater prevalence of coronary risk factors than the rest of the world, and coronary artery disease often manifests at an early age.[21] Asians tend to have slimmer body build than Westerners, with less muscle mass and connective tissue than stockier subjects.[22] Further, Asian populations have a different fat distribution pattern from the Western population and are more prone to central obesity, even at low BMI levels.[23] Such considerations raise the possibility that the risks associated with adiposity at lower levels of BMI are greater in Asian population.

Epidemiologic transition and the evolution of the CVD epidemic

What is the "transition"?

The health status and dominant disease profile of human societies have been historically linked to the level of their economic development and social organization at any given stage. The shift from nutritional deficiencies and infectious diseases, as the major causes of death and disability, to degenerative disorders (chronic diseases like CVD, cancer, diabetes) has marked the economic ascent of nations as they industrialized. This shift has been called the epidemiologic transition.

The economic and social changes that propel this transition are related to a rise in per capita income, greater investments in public sanitation, housing and healthcare, assured availability of adequate nutrition and technologic advances in medical care. Life expectancy rises as causes of childhood and early adult mortality decline. This, in turn, leads to a decline in fertility. The age profile of the population changes from a pyramidal distribution dominated by the young to a columnar structure where adults and the elderly progressively expand their numbers. This has been

described as the demographic transition. Since the disease profile is also linked to the age profile of the population, the health transition encompasses the effects of the epidemiologic and demographic transitions.

CVD profile at different stages of the epidemiologic transition

The model of epidemiologic transition originally described by Omran,[24] with three phases (the age of pestilence and famine, the age of receding pandemics;,the age of degenerative and man-made diseases), was later modified to include a fourth phase (the age of delayed degenerative diseases).[25] Life expectancy progressively increases from around 30 years in the first phase to over 70 years in the fourth phase. The shift to a dominant chronic disease profile occurs in the third phase. As the average life expectancy exceeds 50–55 years, the proportionate mortality due to CVD begins to exceed that of infectious diseases.[26]

The transition not only occurs between the broad disease categories but also within them. The disease profile within CVD alters at each phase of the epidemiologic transition. In the first phase (the age of pestilence and famine), CVD accounts for 5–10% of deaths.[26] The major causes of CVD are, however, related to infectious and nutritional deficiencies. Thus, RHD and cardiomyopathies (e.g. Chagas' disease) are the main CVD in this phase. Even as countries emerge from this phase, the residual burden of chronic valvular heart disease and congestive heart failure often remains for some period. These effects are still evident in sub-Saharan Africa and parts of South America and South Asia.[26]

In the second phase (the age of receding pandemics), the decline in infectious disease which accompanies socioeconomic development ushers in changes in diet. As the subsistence nutrition changes to more complete diets, the salt content of the food increases. Hypertension and its sequelae (hypertensive heart disease and hemorrhagic stroke) now affect the population whose average age also has risen with increased life expectancy. Some residual burden of RHD and cardiomyopathies is also evident. These non-atherosclerotic diseases contribute to 10–35% of deaths. This pattern currently prevails in parts of Africa, North Asia, and South America.[26]

In the third phase (the age of degenerative and man-made disease), accelerated economic development and increased per capita incomes promote lifestyle changes in diet, physical activity, stress, and addictions. A diet rich in calories, saturated fat and salt is accompanied by reduced physical activity through increased use of mechanized transport and sedentary leisure time pursuits. The metabolic mismatch leads to obesity, increased blood lipids, diabetes, and elevated blood pressure. Tobacco consumption, especially cigarette smoking, starts as a pleasurable

pastime and turns into a severe addiction. These factors result in the onset of clinically manifest atherosclerotic vascular disease (CHD, atherosclerotic stroke, and peripheral vascular disease) at around 55 years of age. Such patterns first occur in the upper socio-economic classes who have disposable income to expend on rich diets, tobacco and transport vehicles. Several countries in South America and Asia currently manifest this pattern. As the epidemic advances further and involves all social strata, with homogenization of risk behaviors and risk factors across the population, the death toll of CVD rises to range between 35% and 65% of all deaths. This scenario is currently observed in Eastern Europe.

In the fourth phase (the phase of delayed degenerative disease), a number of changes occur in the society to modify risk behaviors and reduce risk factor levels in the population. Health research augments the knowledge of CVD risk factors. The desire to reduce the adverse impact of CVD on individuals as well as on society steers the community as well as the policymakers to apply this knowledge for disease prevention and health promotion. Community awareness through education, as well as its ability to exercise healthy choices through supportive regulatory measures, empowers its members to adopt healthier lifestyles. Saturated fat and salt consumption declines and leisuretime physical activity and exercise programs are avidly pursued. With concerns over the effects of active and passive smoking, tobacco consumption falls. Simultaneously, medical research makes available new technologies which are very effective in saving lives, modifying the course of disease, and reducing the levels of risk factors. All of these changes, in unison, delay the onset of disease, lower the age-standardized mortality rates and reduce the disability. The contribution of CVD to total mortality falls to 50% or below. These patterns are now established in most of North America, Western Europe, and New Zealand.[26]

Recent developments in some countries of Eastern Europe, with sharp declines in life expectancy and other health indices, led to a fifth phase of health transition being postulated.[7] In this stage of "social upheaval and health regression", the CVD spectrum too may witness a reversal with CHD and stroke occurring at younger ages, resulting in a fall in life expectancy, as in Russia. Further transition may also occur in the future, due to health impacts of global climate change and environmental degradation which can profoundly influence both infectious diseases and chronic diseases.

Variations in the transition

There are, however, variations on this theme. Even within Europe, for example, there is still a clear north-east to south-west gradient in mortality from CHD. With regard to the east–west gradient, dietary fat intake appears to play

a major role. In Eastern Europe, higher consumption of saturated fat was reported during the 1980s and early 1990s. In Poland, changes in the dietary fat intake during the 1990s, leading to a more favorable ratio of polyunsaturated to saturated fat, were associated with a drop in mortality from CHD by approximately one-quarter. The attribution of single risk factors to regional variation may also vary depending on geographic location of the area of interest. For example, regional differences between Israel, Germany and Greece were found to be associated particularly with differences in blood pressure levels.[14]

The results of the Sino-MONICA study (1987–93) in China have shown large differences in the occurrence of coronary and stroke events, with higher rates in northern provinces and lower rates in southern provinces. This geographic difference in CVD mortality and incidence reflects underlying differentials in risk factor profiles (like hypertension and cholesterol levels).[27,28] Prevalence of CHD in the Japanese population remains lower than that in the US and other Western populations. However, lifestyle changes in recent decades have been accompanied by the increasing prevalence of hypercholesterolemia and diabetes, and recent data indicate an increase in prevalence of CHD.[29] The prevalence of lipid risk factors in younger Japanese people is now similar to that in the US.

The question of "arrested epidemiologic transition" is also raised with respect to some of the developing countries. If poverty continues to be a major problem for them, will they experience the CVD epidemic in its full fury or will the pre-transitional diseases of nutrition and infection continue to occupy the center stage? Even now, there is evidence that the social gradient has begun to reverse for risk factor levels and even for morbidity measures in some populations in the developing world.[5] Unless economic development is greatly stunted in some countries, it is likely that the model of epidemiologic transition will be applicable to most of the developing world.

The transition to the atherothrombotic phase of the epidemic may be preceded by a sharp fall in the burden of hemorrhagic strokes. The recent decline in CVD mortality reported from South Korea reflects such a fall in the contribution from hemorrhagic strokes, while thrombotic stroke and coronary heart disease burdens have just begun to rise.[30] The model of "health transition", while very useful, is not immutable and is likely to vary according to both levels of development and the nature of public health responses to social transition.

The model of health transition should also not lead to complacency regarding the high absolute burdens and early deaths in the developing countries. For example, even in a country in "early transition" like Tanzania, the stroke mortality rates in the age group of 15–59 years in rural and urban areas are 2–4 times higher than those in UK, in a similar age group.[31]

Early and late adopters

The pace of epidemiologic transition will vary both among countries and within countries. Usually lifestyle changes towards risk-prone behaviors occur first in the higher socio-economic groups and urban communities for whom the innovations of modernity are more easily accessible and affordable. As these innovations diffuse and become routinely available at prices amenable to mass consumption, the poorer sections and rural communities also join the CVD bandwagon. Soon the awareness of CVD risks as well as the economic independence to make healthy lifestyle choices in relation to diet and leisure time exercise (along with the greater ability to access healthcare) moves the "early adopters" in the affluent and urban strata into a reduced risk zone. The burden of CVD then is largely concentrated in the lower socio-economic groups and rural populations who continue to practice high-risk behaviors and display elevated risk factor levels.[24] These "late adopter" groups also will slowly alter their behaviors, lower their levels of risk and reduce their burden of CVD, as healthcare responses to the CVD epidemic become universally effective. The progressive reversal of CVD risk factors with increasing levels of urbanization is now evident in India.[32]

This is the evolutionary profile of the CVD epidemic, as evident from the analysis of mature epidemics in industrial nations and the advancing epidemics in the developing countries. Differences within countries and between countries, suggested by cross-sectional views at any point in this evolution, should not obscure the longitudinal perspective of an evolving epidemic in which most countries will traverse similar paths, albeit at different times determined by their pace of development. Global shifts in CVD risk factors and their reflection in global CVD trends indicate that all countries and communities have far more in common in terms of disease causation than the differences which demarcate them. The challenge of epidemiologic transition is not whether it will happen in the developing countries, but whether we can apply the available knowledge to telescope the transition and abbreviate phase three of the model in these countries.

Projections

The Global Burden of Diseases study estimates that annual mortality from non-communicable diseases will rise from an estimated 28.1 million deaths in 1990 to 49.7 million in 2020.[7] CVD, which accounts for a large proportion of these, will rise as a result of the accelerating epidemic in the developing countries. CHD will continue to be the leading cause of death in the world and, in terms of DALY lost, will rise from its fifth position in 1990 to top the DALY table in

Table 8.1 Global % change in CHD and stroke mortality 1990–2020

	CHD		Stroke	
	Men	**Women**	**Men**	**Women**
Developed countries	48	29	56	28
Developing countries	137	127	124	107
World	100	80	106	78

Adapted from Murray and Lopez.[4]

Table 8.2 Contribution of cardiovascular disease to DALY loss (percentage of total)

Region	**1990**	**2020**
World	10.85%	14.7%
Developed countries	25.7%	22.0%
Developing countries	8.9%	13.8%

Adapted from Murray and Lopez.[4]

Table 8.3 Millions of projected deaths and DALYs for all chronic diseases as a proportion of deaths and DALYs for all causes in 23 selected low- and middle-income countries for 2005, 2010 and 2030

	2005	**2015**	**2030**
Deaths (all ages)	23.1 (61%)	27.2 (66%)	34.3 (71%)
Deaths in people younger than 70 years	11.2 (46%)	12.4 (50%)	13.7 (53%)
DALYs	496 (50%)	538 (55%)	597 (59%)

Adapted from Abegunde *et al.*[19]

2020.[7] Men as well as women in the developing countries will experience the largest rise in CHD and stroke mortality rates across the world (Table 8.1).

The profile of DALY loss attributable to CVD in 1990 in various regions of the world and the projected estimates for 2020 (Table 8.2) also indicate a large rise.[4] Among the developed countries, the sharp decline in the industrial nations is partly offset by the rise in the former socialist countries.

Deaths attributable to tobacco, a risk factor for CVD and other chronic diseases, are projected to rise from 3.0 million in 1990 to 8.4 million in 2020. The largest increases will be in India, China and other developing countries in Asia, where tobacco-attributable deaths will rise from 1.1 million to 4.2 million in 2020.[33]

These projections have been updated on the basis of substantial improvements in data availability and methods for dealing with incomplete and biased data (Table 8.3). According to the revised model, age-specific death rates for most chronic diseases are projected to decrease slightly at rates of around 0.5–1.0% per year in low- and middle-income countries. This is with the exceptions of lung cancer and chronic obstructive pulmonary disease (which are increasing because of the tobacco epidemic) and diabetes mellitus (which is increasing because of projected increases in the prevalence of overweight and obesity). Adverse trends for some risk factors like overweight and physical inactivity were probably more than offset in the selected countries by improved control of other risk factors like high blood pressure, high blood cholesterol and tobacco smoking and improved access to effective treatment interventions. Total deaths from cardiovascular diseases and diabetes are projected to rise to 14.3 million in 2015 and 17.3 million in 2030 in 23 selected low- and middle-income countries.[19] Just under half of these deaths will occur in people younger than 70 years compared to 27% in high-income countries.

Mechanisms which propel a cardiovascular disease epidemic in developing countries

Demographic changes due to the epidemiologic transition

A major public health challenge, identified by recent analyses of global health trends, is the projected rise in both proportional and absolute CVD mortality rates in the developing countries over the next quarter century. The reasons for this anticipated acceleration of the epidemic are many.[5] In the second half of the 20th century, most developing countries experienced a major surge in life expectancy. This was principally as a result of a decline in deaths occurring in infancy, childhood and adolescence and was related to more effective public health responses to perinatal, infectious and nutritional deficiency disorders and to improved economic indicators like per capita income and social indicators like female literacy in some areas. These demographic shifts have augmented the ranks of middle-aged and older adults. The increasing longevity provides longer periods of exposure to the risk factors of CVD, resulting in greater probability of clinically manifest CVD events. The concomitant decline of infectious and nutritional disorders (competing causes of death) further enhances the proportional burden due to CVD and other chronic lifestyle-related diseases.

The ratio of deaths due to pre-transitional diseases (related to infections and malnutrition) to those caused by post-transitional diseases (like CVD and cancer) varies

among regions and between countries, depending on factors like the level of economic development and literacy as well as availability and access to healthcare. The direction of change towards a rising relative contribution of post-transitional diseases is, however, common to and consistent among the developing countries.[34] The experience of urban China, where the proportion of CVD deaths rose from 12.1% in 1957 to 35.8% in 1990, illustrates this phenomenon.[35]

Population expansion and aging

The aging of all populations heightens the importance of CVD both in people of working age and in those who are beyond working age. The world population is expected to rise from 5.71 billion in 1995 to 8.29 billion in 2025. By 2020, the median age of the population in much of the developing world will begin to approach that of the West. By 2040, the total number of people more than 65 years old in more developed countries will be only one-third of the number in less developed countries.[20]

While all the countries have experienced and will continue to experience a significant increase in population aged 65 and over, a difference is noted in "young" countries (those with a higher proportion of people aged less than 65 years). It will first produce a bulge of people of working age. Although overall dependency will fall, combined with changes in the demographic profile, this will result in a large number of adults potentially vulnerable to CVD. By 2020, the number of persons aged 65 years or above is projected to reach more than 690 million globally, with 460 million in the developing countries.[36] In India, for example, the population is expected to rise from 683.2 million in 1981 to somewhere between 1253.8 and 1480.5 million in 2021. Simultaneously, the proportion of adults aged 35 years or above will rise from 28.4% of the population to 42.4%.[37]

Increased standard of living leading to deleterious health behaviors

A third reason to arouse concern is that, if population levels of CVD risk factors rise as a consequence of adverse lifestyle changes accompanying industrialization and urbanization, the rates of CVD mortality and morbidity could rise even higher than the rates predicted solely by demographic changes. Both the degree as well as the duration of exposure to CVD risk factors would increase as a result of higher risk factor levels coupled with a longer life expectancy. Increase in body weight (adjusted for height), blood pressure and cholesterol levels in Chinese population samples aged 35–64 years, between the two phases of the Sino-MONICA study (1984–86, 1988–89) and the substantially higher levels of most CVD risk factors in urban popu-

lation groups compared to rural population groups in India, provide evidence of such trends.[35] The increasing use of tobacco in a number of developing countries will also translate into higher mortality rates of CVD, lung cancer and other tobacco-related diseases, while undesirable alterations in diet and physical activity are also impacting adversely on cardiovascular health.

In developing countries, risk factors often increase with rising incomes (hypertension and obesity). partly attributable to changing diet, that has more fats, salt and calories, and partly to increasing body weight and less exercise among the affluent.[20] The global availability of cheap vegetable oils and fats has resulted in greatly increased fat consumption among low-income countries in recent years.[38] The transition now occurs at lower levels of the gross national product than previously and is further accelerated by rapid urbanization. In China, for example, the proportion of upper-income persons who were consuming a relatively high-fat diet (>30% of daily energy intake) rose from 22.8% to 66.6% between 1989 and 1993. The lower and middle income groups also showed a rise (from 19% to 36.4% in the former and from 19.1% to 51.0% in the latter).[30] The Asian diet, traditionally high in carbohydrates and low in fat, has shown an overall decline in the proportion of energy from complex carbohydrates along with an increase in the proportion of fat.[38] The globalization of food production and marketing is also contributing to the increasing consumption of energy-dense foods that are poor in dietary fiber and several micronutrients.[39]

The rising tobacco consumption patterns in most developing countries contrast sharply with the overall decline in the industrial nations.[40] Recent projections from the World Health Organization suggest that by the year 2020 tobacco will become the largest single cause of death, accounting for 12.3% of global deaths.[33] India, China and countries in the Middle Eastern crescent will by then have tobacco contributing to more than 12% of all deaths. It is estimated from a recently conducted study in India that by 2010, the annual number of deaths from smoking will be about 1 million, 70% of which will occur in the middle age group. Also 20% of excess mortality among those resulting from cardiovascular diseases could be attributed to smoking alone.[41] Reports also indicate that the greatest increase in tobacco use between 1998 and 2005 occurred in persons between the ages of 15 and 24 years.[42]

Thrifty gene

A "programming" effect of factors promoting selective survival may also determine individual responses to environmental challenges and, thereby, the population differences in CVD. The "thrifty gene" has been postulated to be a factor in promoting selective survival, over generations, of persons who encountered an adverse environment of

limited nutritional resources.[43] While this may have proved advantageous in surviving the rigours of a spartan environment over thousands of years, the relatively recent and rapid changes in environment may have resulted in a metabolic mismatch. Thus a salt-sensitive person whose forefathers thrived despite a limited supply of salt now reacts to a salt-enriched diet with high blood pressure. It has also been hypothesized that populations subjected to food scarcity have undergone selection of a gene which increases the efficiency of fat storage through an oversecretion of insulin in response to a meal. While this favors survival in a situation of low caloric availability, a current excess of caloric intake may lead to obesity, hyperinsulinemia, diabetes, and atherosclerosis. Similarly, an insulin-resistant individual whose ancestors may have survived because a lack of insulin sensitivity in the skeletal muscle ensured adequate blood glucose levels for the brain in daunting conditions of limited calorie intake and demanding physical challenges may now respond to a high-calorie diet and a sedentary lifestyle with varying degrees of glucose intolerance and hyperinsulinemia. While such mechanisms seem plausible, their contribution to the acceleration of the CVD epidemic in the developing countries remains speculative.

Maternal–fetal exposures as a cause of midlife CVD

A recently reported association which, if adequately validated by the tests of causation, may have special relevance to the developing countries is the inverse relationship between birth size and CVD in later life.[44–50] The "fetal origins hypothesis" states that adverse intrauterine influences like poor maternal nutrition lead to impaired fetal growth, resulting in low birth weight, short birth length, and a small head circumference. These adverse influences are postulated to also "program" the fetus to develop adaptive metabolic and physiologic responses which facilitate survival. These responses, however, may lead to disordered responses to environmental challenges as the child grows, with an increased risk of glucose intolerance, hypertension and dyslipidemia in later life, with adult CVD as a consequence. While an increasing body of global evidence for the hypothesis has been provided by observational studies, it awaits further evaluation for a causal role. The association of small birth size and "rebound adiposity" in early childhood, with adult-onset diabetes in an Indian cohort, lends credibility to the role that early life influences play in programmed susceptibility to adult metabolic and vascular diseases but the interaction with later environmental influences needs to be better studied.[51] If it does emerge as an important risk factor for CVD, the populations of developing countries will be at an especially enhanced risk because of the vast numbers of poorly nourished infants who have been born in the past several decades. The steady improvement in child survival will lead to a higher proportion of such infants surviving to adult life when their hypothesized susceptibility to vascular disease may manifest itself.

Ethnic diversity

Although ethnic diversity in CVD rates, risk factor levels and risk factor interactions are evident from population studies, the extent to which genetic factors contribute is unclear. It is only after demographic profiles, environmental factors and possible programming factors are ascertained and adjusted for that differences in gene frequency or expression can be invoked as a probable explanation for interpopulation differences in CVD.[52] The extent to which chronic diseases, including CVD, occur within and amongst different populations is determined by genetic–environmental interaction which occurs in a wide and variable array, ranging from the essentially genetic to the predominantly environmental. This is perhaps best illustrated by the knowledge gained from studies in migrant groups, where environmental changes due to altered lifestyles are superimposed over genetic influences. These "natural experiments" have been of great value in enhancing the understanding of why CVD rates differ amongst ethnic groups. The classic Ni-Hon-San study of Japanese migrants revealed how blood cholesterol levels and CHD rates rose from Japan to Honolulu and further still to San Francisco, as Japanese communities in the three areas were compared.[53] Similarly, the Tokelau islanders who migrated to New Zealand had a higher risk of diabetes and were more obese compared to non-migrants.[54] The Boston- Irish Diet Heart Study, a study of the effects of Irish migration to USA, used sib comparison methodology and highlighted the role of key dietary factors attributable to relatively high burden of CHD.[55]

The experience gleaned from the study of South Asians, Chinese and Pima Indians further elucidates the complexities of ethnic variations in CHD.[56–58] The comparison of Afro-Caribbeans, South Asians and Europeans in UK brought out the sharp differences in central obesity, glucose intolerance, hyperinsulinemia and related dyslipidemia between the three groups despite similar profiles of blood pressure, body mass index and total plasma cholesterol.[59] Migrant studies have demonstrated a 1.1–3.8 CHD mortality ratio among migrants from the Indian subcontinent when compared to local populations.[60–62] However, urban–rural comparisons within India,[37] as well as migrant Indian comparison with their non-migrant siblings,[63] reveal large differences in these conventional risk factors. Thus, where the environment is common but gene pools differ, the non-conventional risk factors appear to be explanatory of risk variance, while when the same gene pool is confronted

with different environments, the conventional risk factors stand out as being of major importance.

The extent to which ethnic diversity in response to CVD risk factors influences the course of the CVD epidemic in different developing countries remains to be studied. However, the experience of some of the migrant groups (e.g. South Asians) portends severe epidemics in the home countries as they advance in their transition.

Strategies to deal with the coronary epidemic

Risk factor

Decades of research, embracing evidence from observational epidemiology and clinical trials, have demonstrated that CHD is multifactorial in causation. The term "risk factor" was first used in the context of CHD.[64] A risk factor must fulfill the criteria of causality: strength of association (high relative risk or odds ratio), consistency of association (over many studies), temporal relationship (cause preceding the effect), dose–response relationship (the greater the exposure, the higher the risk), biologic plausibility, experimental evidence and, very importantly, evidence from human studies. Several such risk factors have been identified, ranging from the established "major" factors like smoking, elevated blood cholesterol and hypertension (conventional risk factors) to the recently investigated factors like homocysteine, lipoprotein A, apolipoprotein B, triglycerides, non-esterified fatty acids and C-reactive protein.

A major case–control study, involving 52 countries, has identified nine easily measured risk factors (smoking, lipids, hypertension, diabetes, obesity, diet, physical activity, alcohol consumption and psychosocial factors) that account for 90% of the risk of acute myocardial infarction (AMI). The INTERHEART study found that these risk factors are the same in almost every geographic region and every racial/ethnic group worldwide and are consistent in men and women. The strongest risk predictor was the apoB/apoA1 ratio (a more reliable marker of cholesterol risk), followed by current smoking. These two risk factors together predict 66.4% of all AMIs, worldwide. Five factors (smoking, lipids, hypertension, diabetes and abdominal obesity) accounted for 80% of the population-attributable risk. This landmark study provides the scientific basis for current intervention options even in countries where classic cohort studies have not been conducted to identify coronary risk factors.[65]

"Clinical" vs "prevention" norms

The need for making "clinical" decisions related to the management of these risk factors led to definition of thresh-

old levels of risk and practice guidelines based on those. These "clinical norms" erroneously came to be identified, by health professionals as well as the community, to also represent the prevention norms. The former are defined by evidence of benefit exceeding risk when an intervention reduces a risk factor below a particular level (the net benefit being demonstrated in clinical trials specifically designed for that purpose). The latter, however, are usually identified from observational studies (long-term longitudinal prospective studies of large cohorts) and denote the optimal values of the risk factor at which the risk of developing disease is minimal.

The targeting of individuals is promoted by the "clinical" approach of healthcare providers who seek to identify persons at "high risk" of disease or its outcomes for intensive investigation and intervention. Thus thresholds are defined to categorize persons with "high cholesterol" or "high blood pressure" and implement individualized control strategies. Attention and action above this threshold often contrast with indifference and inertia below it.

As trial evidence is gathered, the clinical norms may progressively move towards the prevention norms, as in the case of cholesterol or hypertension where the thresholds for intervention have been lowered dramatically in the last decade. They may, however, remain higher than the prevention norms, since clinical trials may be conducted at a stage in the natural history where the risks of prior exposure may not be completely reversible and also because the intervention may itself be associated with some adverse effects. Thus the benefits of lowering a risk factor may appear less than those that may occur by preventing its rise in the first place.

The continuum of risk

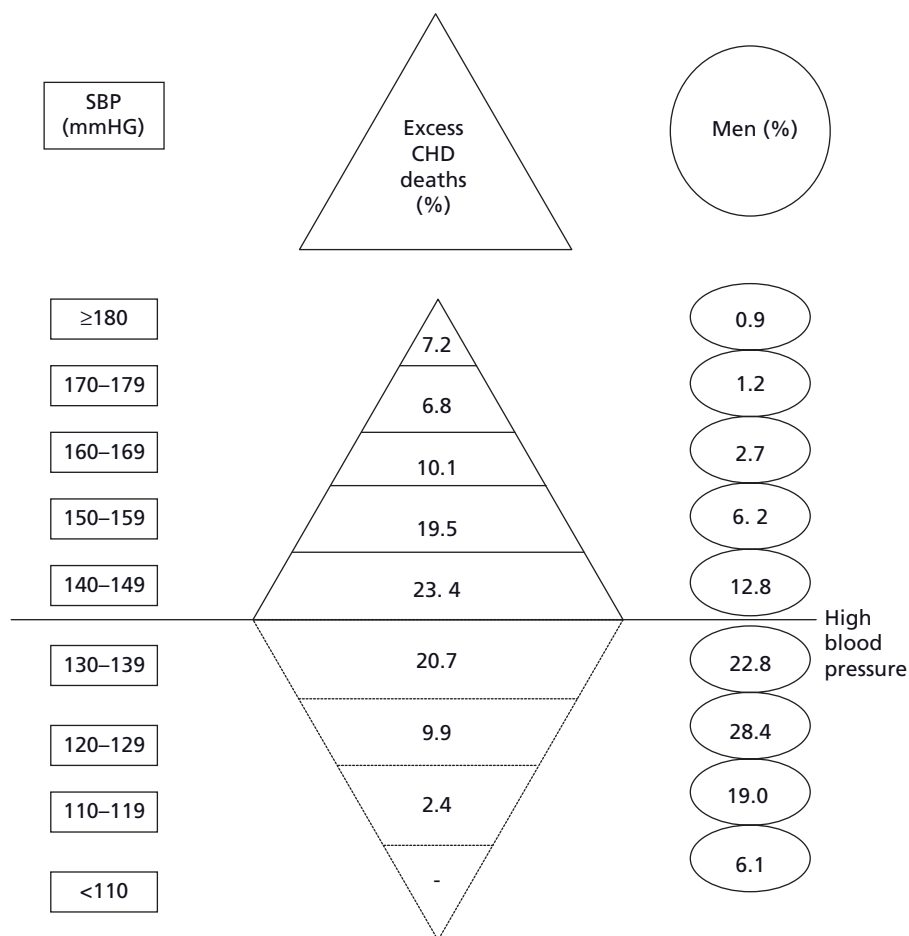
It is clear that even though lifestyle disorders afflict some individuals, they arise from causes that are widespread in the population as a whole. Risk factors like cholesterol and blood pressure operate in a continuum of progressively increasing risk rather than through an all-or-none relationship suggested by cut-off values. For example, a systolic blood pressure (SBP) in the range 130–139 mmHg carries a higher risk than values in the range 120–129 mmHg for both heart attacks and strokes. While a SBP of 180 mmHg carries a much higher risk for an individual than 140 mmHg, the number of persons in any population who have SBP values in the range 130–139 mmHg is higher than those with values of 180 mmHg or higher. The Multiple Risk Factor Intervention Trial's (MRFIT) cohort study in the United States revealed that of all heart attacks which are attributable to SBP, 7.2% arise from the 0.9% segment of the population which represents the 180+ mmHg range, while 20.7% of all such heart attacks occur in the 22.8% segment of the population which has pressures in the range 130–139 mmHg[66] (Fig. 8.1). Similarly, 57% of all excess deaths


Figure 8.1 The risk pyramid for blood pressure and coronary heart disease (CHD): baseline SBP and CHD death rates for men screened in MRFIT. (Adapted with permission from Stamler et al.[66])

attributable to diastolic blood pressure occur in the range 80–95 mmHg compared to only 15% which occur in the high range of 105–130 mmHg.

This dichotomy is also clearly seen in the Framingham Study on coronary risk factors.[66] People with a blood cholesterol level of 300 mg/dL run 3–5 times the risk of CHD as do people at a cholesterol level of 200 mg/dL. At cholesterol levels over 300 mg/dL, 90 out of 100 people developed the disease in the next 16–30 years of follow-up in Framingham. At cholesterol levels under 200 mg/dL, the rate was 20 out of 100 during the same period. However, more than twice as many people developed CHD with cholesterol levels under 200 mg% all their lives as did those with cholesterol levels over 300 mg%. This is because a 20% fraction of a 45% segment of the population is a much larger number than a 90% fraction of a 3–5% segment of the population.[67]

Thus, for most causal factors, there is a "risk pyramid". Those at the top of the pyramid are at the highest individual risk of disease but those at the lower levels of the pyramid account for the largest number of cases in the community because they constitute the largest segment of the population. Any approach which targets only those at the highest risk produces limited gains for the community, despite conferring definite benefits to the individuals in that category.

The concept that "sick individuals arise from sick populations" was propounded and proved by Geoffrey Rose.[68,69] He demonstrated that risk factor "distributions" throughout the population are predictive of disease burden in that community. The mean (average) levels of a risk factor across different populations correlate with the proportions of high-risk individuals in those populations, whatever the cut-off value is. Thus, as the average blood pressure value rises amongst populations, the proportion of hypertensive individuals also rises. In each population, there are groups who represent the extremes of the risk profile (very low risk versus very high risk). However, the proportion at "high risk" would be determined by the average value of that risk factor in the population. This in turn is dependent on the dominant behaviors that characterize the society at each stage of its development.

While Rose highlighted the importance of shifting the distribution at the level of any country's population, the

principle is also relevant to the global population as a whole. With the developing countries acquiring higher levels of risk, the global distributions of blood pressure and cholesterol are shifting rightwards. Even if preventive measures succeed in reducing the risk levels in the developed countries, which have experienced high risk so far, global deaths due to CVD will continue to rise because the larger populations of the developing countries constitute the bulk of the distribution. Meaningful impact on global CVD will occur only when preventive measures effectively reduce the risk levels in the developing countries. We need to move the global bell curve of each risk factor leftwards.

Multiplicative risk

The process of identifying and estimating the independent risk associated with any single risk factor led to clinical and preventive strategies targeting it in isolation. However, observational studies like Framingham and MRFIT have clearly revealed that the co-existence of multiple risk factors confers a magnified risk which is multiplicative rather than merely additive. A smoker with modest elevations of cholesterol and diastolic or systolic blood pressure is at a greater risk of coronary death than a non-smoker with severe hypertension or marked hypercholesterolemia. In the MRFIT study, a non-smoker with SBP less than 118 mmHg and a total serum cholesterol level less than 182 mg% had a 20-fold lower risk of coronary death than a smoker with a SBP exceeding 142 mmHg and a serum cholesterol exceeding 245 mg% (age-adjusted CHD mortality of 3.09 vs 62.11, per 10 000 person-years). A smoker who has a SBP of 132–141 mmHg and a serum cholesterol of 203–220 mg% has a CHD mortality risk of 28.87 per 10 000 person-years, compared to a risk of 12.36 in a non-smoker with a SBP below 118 mmHg but with a serum cholesterol exceeding 245 mg%.[70]

The demonstration of such multiplicative risk has led to the concept of "comprehensive cardiovascular risk" or "total risk", quantifying an individual's overall risk of CVD resulting from the confluence of risk factors.[71] Both clinical and preventive strategies are veering away from unifactorial risk reduction to multifactorial risk modification, to reduce this overall risk in individuals as well as in populations.

Prevention

High-risk approach for prevention

Having recognized that environmental risk factors do not affect only a few individuals in isolation but are spread across populations, with a continuous rather than a threshold relationship to disease, how should that influence disease control strategies? The health policy debate, until recently, was on whether to focus the control strategies on individuals at the highest risk of disease (in view of their markedly elevated risk factor levels) or on the population as a whole (aiming to achieve modest reductions in the risk of most members of that community). The high-risk approach aims at identifying persons with markedly elevated risk factors and, therefore, at the highest risk of disease.[66] These individuals are then targeted by interventions which aim to reduce the risk factor levels. If successful, the benefits to individuals are large, because the individual's risks are large. However, since the number of people in this high-risk category is proportionately much smaller than those in the moderate-risk group, the overall benefits to society are limited in terms of deaths or disability avoided.

"High-risk individuals can be defined as those aged between 40–79 years with a history of non-fatal coronary heart disease/cerebrovascular event or having an estimated absolute risk of dying from any cardiovascular event of 15% or more in the next 10 years. Absolute risk can be determined from country-specific risk charts that rely on easily measurable risk factors. (Fig. 8.2). For instance, the absolute risk chart given here was generated by categorizing simulated population according to sex, age, smoking status, systolic blood pressure and Body Mass Index. Countries can adopt different risk prediction strategies and the basic approach described here is only suggestive and not prescriptive. With more sophisticated algorithms that better target those at high risk, such as measurement of cholesterol/plasma glucose, both the costs and benefits can be expected to increase.[72]

Population approach for prevention

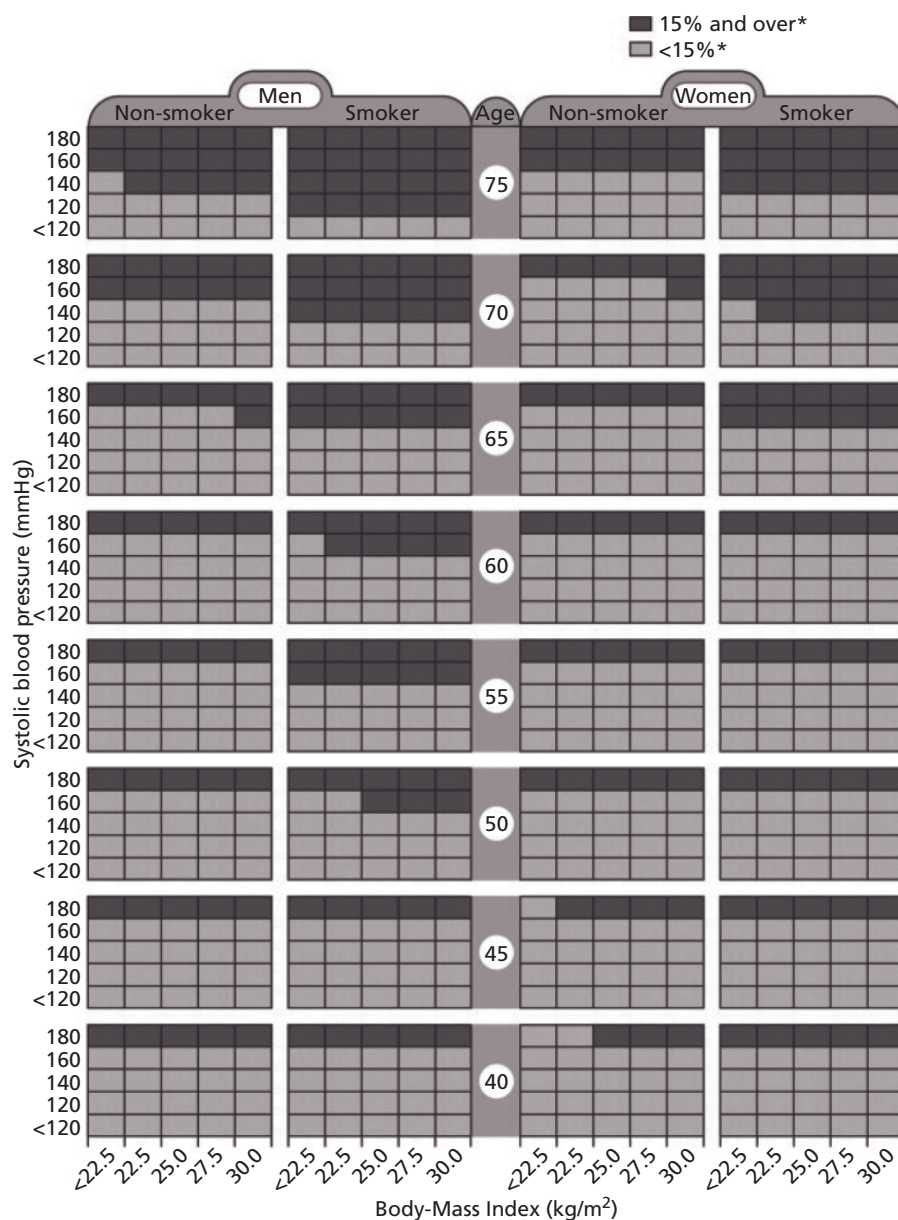
In contrast, the population approach aims at reducing the risk factor levels in the population as a whole, through community action.[68] Because there is a continuum of risk associated with most risk factors, this mass change will result in mass benefit across a wide range of risk. While individual benefits are relatively small, the cumulative societal benefits are large ("the prevention paradox"). The strategy is also behaviorally more appropriate. If the eating habits in the community alter towards preferred consumption of foods with lower saturated fat and salt content and a greater daily intake of fresh fruit and vegetables, even the high-risk individual on a prescribed diet will find a supportive ambience which does not mark him out as a deviant from social norms. If a new generation grows up in an environment where healthy behavior is considered common practice, its average blood cholesterol level may remain below 200 mg% rather than around 240 mg% and thus people will be at a lower risk than even the beneficiary of the high-risk strategy. However, the risks and benefits of such a strategy are less obvious to those in the moderate-risk range. The motivation for change is, therefore, not as strong as for those in the high-risk group. The gratification of achieving readily identifiable success in high-risk indi-


Figure 8.2 Example of an absolute risk chart using age, sex, smoking status, systolic blood pressure, and Body Mass Index. *Numbers are 10-year risk of fatal ischemic heart disease or cardiovascular events in Mexico. (Adapted from Lim *et al.*[72])

viduals, through drugs or other powerful interventions, is also denied to the physicians in the population strategy where the potential beneficiaries, though many, are faceless and nameless. Since such "anonymity of prevention" denies the pleasure of individual rescue acts, physician motivation for community counseling is neither strong nor sustained.[68] Policymakers can, however, ill afford to ignore the imperatives of investing in a population approach which will pay large long-term dividends in the control of lifestyle diseases. Health professionals too must recognize the benefits of this strategy to play a strong advocacy role for health-promoting behaviors in the community.

The impact of the population strategy is likely to be large, as suggested by an estimate that if every American had a diastolic blood pressure value which is a mere 2 mmHg lower than his or her present value, the number of heart attacks that could be prevented would exceed those that could be avoided by effectively treating every person with a diastolic pressure of 95 mmHg or higher. The corresponding benefit for preventing paralytic strokes would be 93% of those avoided by drug therapy.[73] Such blood pressure changes can be effectively achieved and sustained through modest reductions in weight and salt intake or through exercise.

The success of population strategies has been demonstrated both in developed countries (e.g. Finland) and in developing countries (e.g. Mauritius).[74,75] The North Karelia Project demonstrated large reductions in CVD mortality

(50.1% in males and 63.5% in females), CHD mortality (53.4% and 59.8%) and all-cause mortality (39.5% and 40.4%) during the 20 years intervention period. This resulted from a series of community-based strategies designed to change dietary behavior through media campaigns in collaboration with the food industry and agricultural policy changes. As people changed their behavior in terms of dietary preference, the food industry perceived new opportunities and developed products with less oil. Agriculturists developed a new type of rapeseed plant that grew well in the cold northern climate of Finland. This sold well and market proportion of unsaturated to saturated fats increased. Salt reduction was also adopted by food producers.[20]

Another example of a macroeconomic intervention that seems to have had an impact on CVD rates comes from Poland. The fall in heart disease deaths in 1992–94 coincided with a switch in Poland from consuming animal fats to vegetable fats. This resulted from a government decision to cut subsidies for animal fats and impose taxes, thus raising the price of animal fats to consumers and making vegetable oils more competitive. There followed a 23% decline in the availability of animal fats products and a 48% increase in the supply of vegetable fat products.[20]

In a comprehensive community-based project in China, notable outcomes included a reduction in the annual heart disease and stroke deaths among hypertensives from 1.6% to 0.8% between 2000 and 2002. An increase in the proportion of people participating in planned regular physical activity increased from 41% to 84% in the same period.[76] Yet another sodium intervention project (1989–92) demonstrated a significant net reduction in sodium intake among men in different educational and occupational groups. The mean systolic blood pressure decreased by 3 mmHg for the total population.[77] The Mauritius project included a government-led program that changed the main cooking oil from a predominantly saturated fat palm oil to soybean oil high in unsaturated fatty acids. Overall, total cholesterol concentration fell by 14% during the 5-year study (1987–92). These examples demonstrate the ability to change behavior through macroeconomic and health promotion interventions. However, evidence from other countries has yielded mixed results.[20]

Combining the strategies

These strategies are not mutually exclusive but are synergistic, complementary and necessary. The risks and benefits demonstrated in high-risk individuals serve to educate the community about risk factors, while the population approach makes it easier to achieve the desired level of lifestyle change in high-risk individuals. The population-based, lifestyle-linked risk reduction approach is particularly relevant in the context of the developing countries, where it is necessary to ensure that communities currently at low risk are protected from acquisition or augmentation

of risk factors ("primordial prevention"). This is true for adults in the rural regions of most developing countries as well as for children in all populations. It is also eminently applicable to moderate-risk groups in urban areas, where lifestyle-based risk modification will help avoid drug therapy, with its attendant economic and biologic costs. There will still be some people who need such pharmacologic or technologic interventions because of their high-risk status. However, their numbers too will decrease as the risk profile of the whole community gradually shifts.

Case management

Despite these preventive strategies, several individuals will manifest clinical disease because risks are not totally eliminated in the community or because genetic susceptibility is strongly expressed. The success of preventive efforts will reduce their number as well as delay the age of onset of clinical events. Those who develop disease will require optimal clinical care which can avert early death, reduce disability, and assure an adequate quality of life. This mandates early detection of disease and management.

Institution of emergency care and adequate treatment of established cases are also key points for enhancing the outcomes of any cardiovascular event. The GRACE study reveals substantial differences in the management of acute coronary syndrome (ACS) patients based on hospital type and geographic location.[78] However, with improved use of evidence-based pharmacologic and interventional therapies, significant reductions were observed in the rates of new heart failure and myocardial infarction cases at 6 months.[79] A prospective analysis of an ACS registry in India reveals that patients admitted to Indian hospitals have worse prognosis compared to developed countries. Most of the patients were poor and were less likely to get evidence-based treatments and there were delays in access to hospital and provision of affordable treatment that could have resulted in higher 30-day mortality.[80] For those who are at high risk, the individual-based strategies with the greatest accumulated evidence of effectiveness are drugs to prevent cardiovascular disease: blood pressure-lowering drugs, cholesterol-lowering drugs and aspirin. Although these are cost effective in low- and middle-income countries and are available in most markets, their current coverage in high-risk individuals remains low.[81] The contributory factors range from policymaker reluctance to fund provision of CVD drugs in primary healthcare to poor prescribing practices of healthcare providers.

CVD-related expenditure

In developed countries
Several studies in the industrialized world have attempted to estimate the direct healthcare costs of CVD and its clini-

cally expressed risk factors. All have found CVD to be a major driver of rising healthcare costs. Thompson and Wolf in 2001 reviewed studies on the medical care cost burden of obesity. It was estimated to contribute between 2% and 7% of total health expenditures.[82] Annual direct health costs for coronary heart disease, stroke and hypertension in 1995 dollars were $50.8 billion, $18.1 billion and $15.6 billion respectively. It was also determined that half of the estimated annual healthcare costs of chronic diseases came from those aged 18–64 (productive years).[83]

Cost-effectiveness of population-wide approaches is sensitive to the cost of the intervention as well as the expected reduction in the indicators (like cholesterol level). In fact, the cost-effectiveness ratio ranged from being cost saving to $88 000 per life-year gained, depending on the percentage reduction. For example, a nationwide community intervention that expects a 4% reduction in total serum cholesterol and costs $5 per person every year could save more than $2 billion over 25 years.[84] When all the benefits of a nationwide intervention program, including blood pressure reductions and smoking cessation, were included, the results were favorable. Unfortunately, there is less cost information on physical activity interventions to determine their cost-effectiveness on a larger scale.

In developing countries

Healthcare costs for CVD in the developing world are likely to rise as prevalence rises and even if the rates plateau, costs are likely to become increasingly prohibitive as technologic options spread.[20] If nothing is done to reduce the risk of chronic disease, an estimated US$84 billion of economic production will be lost because of heart disease, stroke and diabetes in low- and middle-income countries between 2006 and 2015.[85]

Estimates from China indicate that hospital costs attributable to CVD conditions totaled over $9.6 billion in 1998, or nearly 20% of all hospital costs.[86] Healthcare expenditure increases with the location of the health facility, duration of stay in hospitals and type of health facility (government/private). Patient expenditures are 20% higher in urban than in rural areas, even where government facilities are the locus of care.[20] The effects of CVD on costs extend well beyond the health sector. A 1991 study in South Africa estimated that direct healthcare costs account for only 42% of the total costs for CVD. Hence, for every dollar spent on CVD by the health system, the South African economy pays another $1.38 due to CVD morbidity and mortality manifesting in disability and lost productivity costs.[87]

Cost-effectiveness analysis of multiple interventions in countries of low and middle income seems to be quite favorable. The intervention on salt reduction ranges from cost saving to $200 for each DALY averted across the range of estimates of the cost of the intervention as well as its range of effectiveness.[84] Juxtaposed with these population strategies, strategies involving multi-drug regimens to treat patients with high-risk cardiovascular disease also seem reasonable. All the results fall well under the Gross Domestic Product per head for each region, making them attractive options for scale-up.

Evidence to support action

The knowledge of cardiovascular risk factors continues to evolve, with continued investigation of putative risk factors through animal, human observational and experimental studies. However, there is sufficient information available on the role of major risk factors to enable effective measures for the prevention and control of CVD to be undertaken worldwide. While the application of the knowledge may have to be contextualized to match the sociodemographic profiles of different populations, the global evidence on the causation and prevention of CVD remains relevant to all populations.

The well-substantiated model of health transition enables the prediction of the emerging and anticipated course of the CVD epidemic across different regions of the world. This knowledge should be utilized to telescope the transition and shorten the phase of many mid-life deaths through effective prevention. Never before in human history have we been so clearly forewarned of our impending destiny and so effectively fore-armed to alter it. It is a challenge to human intellect and enterprise to move this knowledge into the arena of action, to reduce the global burden of CVD.

Introduction

Hundreds of millions of premature tobacco deaths could be avoided if effective interventions could be widely applied in all countries. Numerous studies from high-income countries, and a growing number from low- and middle-income countries, provide robust evidence that tobacco tax increases, timely dissemination of information about the health risks from smoking, restrictions on smoking in public and work places, comprehensive bans on advertising and promotion, and increased access to cessation therapies are effective in reducing tobacco use and its consequences. Cessation by the 1.1 billion current smokers is central to meaningful reductions in tobacco deaths over the next five decades. Reduced uptake of smoking by children would yield the benefits chiefly after 2050. Price and non-price interventions are, for the most part, highly cost effective.

This chapter begins with an overview of smoking trends and tobacco's health consequences, with a focus on cardio-vascular disease mortality and morbidity from smoking. A review of the effectiveness of personal and population-level tobacco control interventions in reducing cardiovascular disease burden follows. Finally, the constraints to implementing tobacco control policies are discussed.

Smoking trends

Tobacco use, in both smoked and non-smoked forms, is common worldwide. This chapter focuses on smoked tobacco because smoked tobacco is more common, accounting for about 65–85% of all tobacco produced worldwide,[1]

and causes more disease and more diverse types of disease than does oral tobacco use.

Prevalence

A systematic review of 139 studies on adult smoking prevalence[2] found that over 1.1 billion people worldwide smoke, with about 82% of smokers residing in low- and middle-income countries. Table 9.1 provides an update of these estimates for the population in 2000. Globally, male smoking far exceeds female smoking, with a smaller gender difference in high-income countries. Smoking prevalence is highest in Eastern Europe and Central, Southern and Eastern Asia, where about 50% of all adults are smokers.

While overall smoking prevalence continues to increase in many low- and middle-income countries, many high-income countries have witnessed decreases, most clearly in men. A study in 36 mostly Western countries, from early 1980 to the mid-1990s, suggested that the decrease in smoking prevalence observed among men was due to the higher prevalence in younger age groups of those who have never smoked. Among women, there was little overall change in smoking prevalence because the increasing prevalence of smokers in younger age cohorts counterbalanced increasing cessation in older age groups.[3]

Cessation

Ex-smoking rates are a good measure of cessation at a population level. In some high-income countries, the prevalence rates of ex-smokers have increased over the past two to three decades. For example, in the United Kingdom, smoking prevalence among males over age 30 fell from 70% in the 1950s to 30% in 2000; female smoking prevalence fell from 40% to 20% over the same period. Much of the decrease arose from cessation. Today, there are twice as many ex-smokers as smokers among those currently aged 50 or over. Currently, 40% of the British male population is

Table 9.1 Estimated smoking prevalence (by gender) and number of smokers, 15 years of age and over, by World Bank Region, 2000

World Bank Region	Smoking prevalence (percent)			Total smokers	
	Males	Females	Overall	Millions	Percent of all smokers
East Asia and Pacific	63	5	34	429	38
Europe and Central Asia	56	17	35	122	11
Latin America and the Caribbean	40	24	32	98	9
Middle East and North Africa	36	5	21	37	3
South Asia	32	6	20	178	15
Sub-Saharan Africa	29	8	18	56	6
Low and middle income	49	8	29	920	82
High income	37	21	29	202	18

made up of former smokers.[4] Polish male cessation rates have also increased, partly due to control programs. One out of every four adult Polish males described himself as an ex-smoker.[5] In contrast, the prevalence of male ex-smokers in most developing countries is low: 10% in Vietnam, 5% in India, and 2% in China.[2,6,7] Even these low figures may be falsely elevated because they include people who quit either because they are too ill to continue or because of early symptoms of tobacco-related illness.[8]

The health consequences of smoking

The health consequences of smoking are often assumed to be widely understood. In fact, there is wide ignorance of the magnitude of tobacco hazards, in terms of individual health and population policy. Thus, the salient aspects of tobacco epidemiology are outlined in this section.

Key messages for the individual smoker

Over 50 years of epidemiology on smoking-related diseases have led to three key messages for individual smokers worldwide.[9,10]
• The eventual risk of death from smoking is high, with about one-half of long-term smokers eventually being killed by their addiction.
• These deaths involve a substantial amount of life-years foregone. At least half of all tobacco deaths occur at ages 35–69, losing about 20–25 years of life, compared to the life expectancy of non-smokers.
• Cessation works. Those adults who quit before middle age avoid almost all the excess hazards of continued smoking.
Globally, an estimated 1.6 million cardiovascular deaths were attributable to smoking in the year 2000; that is, 11% of all global cardiovascular deaths over the age of 30.[11] Detailed epidemiologic reviews of worldwide mortality

from smoking are found elsewhere.[7,12–16] The following discussion focuses on the consequences of smoking on adult cardiovascular mortality.

Key messages for heart health

The wealth of evidence linking smoking and cardiovascular disease points to three key messages pertaining to cardiovascular health.
• Heart attacks and strokes can strike suddenly and can be fatal if treatment is not sought immediately.
• Heart attacks and strokes are made more common by smoking.
• Quitting tobacco use reduces the chance of a heart attack or stroke, with benefits seen shortly after quitting.

Risks of cardiovascular disease from smoking

The relative risks of fatal and non-fatal heart disease associated with smoking from selected studies[7,15,17–20] are depicted in Table 9.2. Overall, the relative risk of non-fatal myocardial infarction is higher than that of fatal disease, and risks are higher for males and at younger ages.

Current mortality and disability from smoking

A recent update of indirect estimates of global tobacco mortality[21] estimated that in 2000 there were 5 million premature deaths caused by tobacco. About half (2.6 million) of these deaths were in low-income countries. Males accounted for 3.7 million deaths, or 72% of all tobacco deaths. About 60% of male and 40% of female tobacco deaths were of middle-aged persons (ages 35–69).

In high-income countries and former socialist economies, the 1 million middle-aged male tobacco deaths were largely composed of cardiovascular disease (0.45 million) and lung cancer (0.21 million). In contrast, in low-income countries, the leading causes of death among the 1.3 million male

tobacco deaths were cardiovascular disease (0.4 million), chronic obstructive pulmonary disease (0.2 million), other respiratory disease (chiefly tuberculosis, 0.2 million) and lung cancer (0.18 million). The specific numbers of deaths from tobacco and of total disability-adjusted life-years (DALYs) by gender are shown in Table 9.3.[21,22] Disability estimates are not discussed here; however, disability is highly correlated with mortality in most settings.

Cardiovascular mortality from smoking

Cardiovascular disease (CVD), which includes heart diseases and stroke, is the leading cause of death worldwide. Long a problem in high-income countries, CVD is now recognized as a global problem. CVD accounted for more than one-quarter of all deaths worldwide in 2001, with four-fifths of those deaths occurring in low- and middle-income countries.

Of the 1.6 million cardiovascular deaths worldwide in the year 2000, 1.2 million were among men and 0.4 million among women. There were 0.9 million deaths in industrialized regions and 0.7 million deaths in the developing world. The proportion of adult cardiovascular deaths attributable to smoking was 17% for men and 5% for women.[11]

The estimated numbers of cardiovascular deaths attributable to smoking, disaggregated by region and sex, are depicted in Table 9.4. The proportions of total adult cardiovascular deaths attributable to smoking were generally

highest in industrialized regions (12–22%), where smoking has been common for several decades. At the same time, the increase in smoking over the last quarter of the 20th century in a number of developing regions, including parts of Southeast Asia, Latin America and the Eastern Mediterranean, has resulted in ≥10% of all current adult cardiovascular deaths being attributable to smoking, the number being higher among men.[11]

Disease-specific patterns

Ezzati *et al*[11] have estimated the total cardiovascular mortality attributable to smoking for all adults aged 30 years and over by three clusters of cardiovascular diseases (CVD): ischemic heart disease (IHD), cerebrovascular disease (CeVD), and a cluster of "other cardiovascular diseases including heart failure". IHD accounted for the largest number of cardiovascular deaths attributable to smoking (870 000 deaths; 54% of all smoking-attributable cardiovascular deaths) globally. This was similar in both developing and industrialized regions. The difference between the two regions, however, was that cerebrovascular disease was the second most common cause of deaths (30%) in developing countries while it was least common (22%) in industrialized countries.

Past and future trends in mortality

Future increases in tobacco deaths worldwide are expected to arise from increased smoking by males in developing countries, and by women worldwide. Such increases are a product of population growth and increased age-specific tobacco mortality rates, the latter relating to both smoking duration and the amount of tobacco smoked. Peto *et al*[23] have made the following calculation: if the proportion of young people taking up smoking continues to be about half of men and one-tenth of women, then there will be about 30 million new long-term smokers each year. As noted above, epidemiologic studies in developed and developing countries suggest that half of these smokers will eventually

die from smoking. However, conservatively assuming that "only" about one-third of smokers die as a result of smoking, then smoking will eventually kill about 10 million people a year. Thus, for the 25-year period from 2000–2025, there would be about 150 million tobacco deaths or about 6 million deaths per year on average; from 2025–2050, there would be about 300 million tobacco deaths, or about 12 million deaths per year.

Further estimations are more uncertain but based upon current smoking trends and projected population growth, from 2050–2100 there would be an additional 500 million tobacco deaths. These projections for the next three to four decades are comparable to retrospective and early prospective epidemiologic studies in China,[6,15,16] which suggest that annual tobacco deaths will rise to 1 million before 2010 and 2 million by 2025, when the young adult smokers of today reach old age. Similarly, results from a large retrospective study in India indicate that the annual number of deaths from smoking will be about 1 million during the 2010s, with about 70% (600 000 among men and 100 000 among women) occurring in middle age, rather than old age.[7] With other populations in Asia, Eastern Europe, Latin America, the Middle East and, less certainly, sub-Saharan Africa showing similar growth in population and age-specific tobacco death rates, the estimate of some 450 million tobacco deaths over the next five decades appears to be plausible. Almost all of these deaths will be among current smokers.

Benefits of tobacco cessation

Current tobacco mortality statistics reflect past smoking behavior, given the long delay between the onset of smoking and the development of disease. The prevention of a substantial proportion of these tobacco deaths before 2050 requires adult cessation. For example, halving the per capita adult consumption of tobacco by 2020 (akin to the declines in adult smoking in the United Kingdom) would avert about 180 million tobacco deaths. Continuing to reduce the percentage of children who start to smoke will prevent many deaths, but its main effect will be on mortality rates in 2050 and beyond (Fig. 9.1).[6,24–26]

There is substantial evidence that smoking cessation reduces the risk of death from tobacco-related diseases. Among doctors in the United Kingdom, those who quit smoking before the onset of major disease avoided most of the excess hazards of smoking.[10] The benefits of quitting were largest in those who quit before middle age (between ages 25 and 34 years), but were still significant in those who quit later (between ages 45 and 54 years).

Benefits of cessation on cardiovascular disease burden

Smoking cessation interventions have been identified to be effective in the general population of smokers for primary

prevention of heart disease. In a pooled cohort study of over 19 000 normal adults with a mean duration of follow-up of 13.8 years, it was noticed that people who stopped smoking had a decreased risk of myocardial infarction (hazard ratio (HR) 0.71, 95% confidence interval (CI) 0.59–0.85), after adjustment for other risk factors.[27]

Quitting smoking has also been found to be effective in patients with cardiovascular disease in the prevention of recurrence of further fatal and non-fatal cardiovascular events. Patients who quit smoking after successful percu-

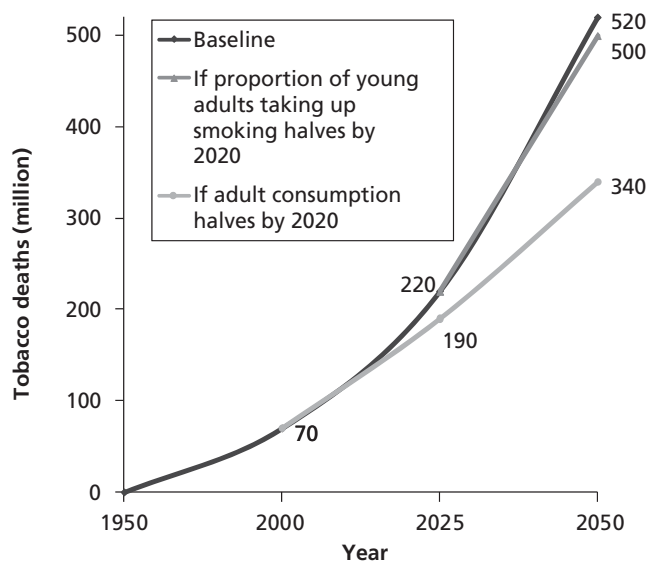
taneous coronary intervention were at lower risk for rein-farction and death than those who continued to smoke.[28] In those who had undergone coronary artery bypass grafting, it was associated with reduced long-term mortal-ity (relative risk (RR) 0.4–0.6) and need for repeat inter-ventions (RR 0.6–0.7).[29,30] Efficacy of tobacco cessation strategies in reducing subsequent cardiovascular mortality up to 50% has been shown in both hospital-based and clinic-based settings for smokers with coronary heart disease.[31–34]


Figure 9.1 Tobacco deaths in the next 50 years under current smoking patterns. Note: Peto and others (1994) estimate 60 million tobacco deaths between 1950 and 2000 in industrial countries. This figure estimates an additional 10 million between 1990 and 2000 in developing countries. The figure also assumes no tobacco deaths before 1990 in developing countries and minimal tobacco deaths worldwide before 1950. Projections for deaths from 2000 to 2050 are based on Peto and Lopez, 2000[24,26].

Interventions to reduce demand for tobacco

Numerous studies, mostly from high-income countries, have examined the impact of interventions aimed at reducing the demand for tobacco products on smoking and other kinds of tobacco use. The small but growing number of studies from low- and middle-income countries provide useful lessons about differences in the impact of these interventions between these countries and high-income countries. The following is a review of the impact of price and non-price interventions to reduce demand for smoking, including a discussion of each intervention's impact on initiation and cessation.

Tobacco taxation

Well over 100 studies from high-income countries clearly demonstrate that increased taxes on cigarettes and other tobacco products lead to significant reductions in cigarette smoking and other tobacco use.[35] The reductions in tobacco use that result from higher taxes and prices reflect the combination of increased smoking cessation, reduced relapse, lower smoking initiation, and decreased consumption among continuing tobacco users.

Studies from the United States, United Kingdom, Canada, and many other high-income countries generally estimate that the price elasticity of cigarette demand ranges from –0.25 to –0.50, indicating that a 10% increase in cigarette prices will reduce overall cigarette smoking by 2.5–5.0%.[35,36] Estimates from a limited number of studies from low- and middle-income countries suggest a greater price elasticity of –0.8 in such countries. A recent study from India shows the "crowding-out" effect of tobacco expenditure and its implications on household resource allocation in India: tobacco-consuming households had lower per capita nutrition intake and also lower consumption of certain commodities such as milk, education, clean fuels, and entertainment.[37] Other studies using survey data have concluded that half or more of the effect of price on overall cigarette demand results from reducing the number of current smokers.[38,39] Higher taxes increase both the number of attempts at quitting smoking and the success of those attempts.[40,41] A study in the United States suggested that a 10% increase in price would result in 11–13% shorter smoking duration or a 3.4% higher probability of cessation.[40]

In the United States and the United Kingdom, increases in the price of cigarettes have had the greatest impact on smoking among the lowest income and least educated populations.[38,42] Furthermore, it was estimated that smokers in US households below median income level are four times more responsive to price increases than smokers in households above median income level. In general, estimates of price elasticity for low- and middle-income countries are about double those estimated for high-income countries, implying that significant increases in tobacco taxes in these countries would be effective in reducing tobacco use.

Restrictions on smoking

Over the past three decades, as the quantity and quality of information about the health consequences of exposure to passive smoking have increased, many governments, especially in high-income countries, have enacted legislation restricting smoking in a variety of public places and private worksites. In addition, increased awareness of the consequences of passive smoking exposure, particularly to children, has led many workplaces and households to adopt voluntary restrictions on smoking. While the intention of these restrictions is to reduce non-smokers' exposure to passive tobacco smoke, the policies also reduce smokers' opportunities to smoke. Additional reductions in smoking, especially among youth, will result from the changes in social norms that are introduced by adopting these policies.[43]

In Western populations, comprehensive restrictions on cigarette smoking have been estimated to reduce population smoking rates by 5–15%,[44,45] and can also lead to

changes in social norms regarding smoking behavior, especially among youth. As with higher taxes, these restrictions reduce both the prevalence of smoking and cigarette consumption among current smokers. Smoking bans in workplaces generally reduce the quantity of cigarettes smoked by 5–25%, and reduce prevalence rates by up to 20%.[45] The no-smoking policies were most effective when strong social norms against smoking helped to make smoking restrictions self-enforcing.

Clean indoor air laws that ban smoking in public places may lead to significant reductions in the prevalence of smoking and cigarette consumption.[46] This may reduce the proportion of population exposed to environmental tobacco smoke which could in turn lead to a reduction in smoking-related diseases. For this and other reasons, many jurisdictions are implementing laws banning smoking in public places. Current interest in preventive cardiology is to examine whether enactment of legislation to require smoke-free workplaces and public spaces might be associated with a decline in hospital admissions for and deaths due to acute myocardial infarction. Some of the earliest and most robust evidence came from the California Tobacco Control Program in the last decade.[47] This program combined a 25 cent tax increase (20% of which went to pay for the tobacco control program) with an aggressive media campaign along with community-based interventions promoting clean indoor air policies. Since then there has been consistent evidence of the positive impact of clean air ordinances on cardiovascular health from North America and Europe where jurisdictions have gone smoke free. These offer non-randomized designs of before-and-after studies (some with concurrent control groups) to assess the efficacy of smoke-free policies to effectively reduce heart disease rapidly (Table 9.5).[47–54] Class of recommendation and level of evidence for these tobacco control interventions are shown using the grading schema as per the ACC/AHA (American College of Cardiology/American Heart Association) guidelines.[55]

Health information and counter-advertising

The 1962 report by the British Royal College of Physicians and the 1964 US Surgeon General's Report were landmark tobacco control events in high-income countries. These publications resulted in the first widespread press coverage of the scientific links between smoking and lung cancer. The reports were followed, in many countries, by policies requiring health warning labels on tobacco products, which were later extended to tobacco advertising.

Research from high-income countries indicates that these initial reports and the publicity that followed about the health consequences of smoking led to significant reductions in consumption, with initial declines of between 4% and 9%, and longer-term cumulative declines of 15–30%.[56,57] Efforts to disseminate information about the risks of smoking and

of other tobacco use in low- and middle-income countries have led to similar declines in tobacco use in these countries.[56] In addition, mass media anti-smoking campaigns, in many cases funded by earmarked tobacco taxes, have generated reductions in cigarette smoking and other tobacco usage.[56,58] Decreases in smoking prevalence were largest in Western countries where the public is constantly and consistently reminded of the dangers of smoking by extensive coverage of issues related to tobacco in the news media.[3]

In many low- and middle-income countries, there continues to be a lack of awareness of the risks of mortality and disease posed by smoking. For example, a national survey in China in 1996 found that 61% of smokers thought that tobacco did them "little or no harm".[59] In high-income countries, smokers are aware of the risks but a recent review of psychologic studies found that few smokers judge the size of these risks to be higher and more established than do non-smokers, and that smokers minimize the personal relevance of these risks.[60]

Bans on advertising and promotion

Cigarettes are among the most heavily advertised and promoted products in the world. In 2001, cigarette companies spent US$11.2 billion on advertising and promotion in the United States alone, the highest spending level reported to date.[61] Tobacco advertising efforts worldwide include traditional forms of advertising on television, radio, and billboards; in magazines and newspapers; favorable product placement; price-related promotions, such as coupons and multi-pack discounts; and sponsorship of highly visible sporting and cultural events.

Numerous econometric studies, mostly from the United States and the United Kingdom, have explored the relationship between cigarette advertising and promotional expenditure and cigarette demand. In general, these studies have resulted in mixed findings, with most studies concluding that advertising has, at most, a small positive impact on demand.[35,57] However, critics of these studies note that econometric methods, which estimate the impact of a marginal change in advertising expenditures on smoking, are ill suited for studying the impact of advertising.[57,61,62] Approaches employed by other disciplines, including survey research and experiments that assess reactions to and recall of cigarette advertising, do support the hypothesis that increases in cigarette advertising and promotion directly and indirectly increase cigarette demand and smoking initiation.[43,63] These studies conclude that cigarette advertising is effective in getting and retaining children's attention, with the strength of the association strongly correlated with current smoking behavior, smoking initiation, and smoking intentions.

Advertising and promotion bans on cigarette smoking should provide more direct evidence on the impact of

advertising.[58] One study using data from 22 high-income countries for the period 1970 through 1992 provides strong evidence that comprehensive bans on cigarette advertising and promotion lead to significant reductions in cigarette smoking. The study predicted that a comprehensive set of tobacco advertising bans in high-income countries could reduce tobacco consumption by over 6%, taking into account price and non-price control interventions.[64] However, the study concludes that partial bans have little impact on smoking behavior, given that the tobacco industry can shift its resources from banned media to other media that are not banned.

Smoking cessation treatments

Near-term reductions in smoking-related mortality depend heavily on smoking cessation. There are numerous behavioral smoking cessation treatments available, including self-help manuals, community-based programs, and minimal or intensive clinical interventions.[36] In clinical settings, pharmacologic treatments, including nicotine replacement therapies (NRT) and bupropion, have become much more widely available in recent years in high-income countries through deregulation of some NRTs from prescription to over-the-counter status.[36,65] The evidence is strong and consistent that pharmacologic treatments significantly improve the likelihood of quitting, with success rates two to three times those when pharmaceutical treatments are not employed.[36,65,66] The effectiveness of all commercially available NRTs seems to be largely independent of the duration of therapy, the setting in which the NRT is provided, regulatory status (over-the-counter versus prescribed), and the type of provider.[65] Over-the-counter NRTs without physician oversight have been used in many countries for a number of years with good success.

While successful in treating nicotine addiction, the markets for NRT and other pharmacologic therapies are more highly regulated and less affordable than are nicotine-containing tobacco products. Recent evidence indicates that the demand for NRT is related to economic

factors, including price.[41] Policies that decrease the cost of NRT and increase availability, such as mandating private health insurance coverage of NRT, including NRT coverage in public health insurance programs, and subsidizing NRT for uninsured or underinsured individuals, would likely lead to substantial increases in the use of these products. Given the demonstrated efficacy of NRTs in treating smoking, these policies could generate significant increases in smoking cessation.

Over a hundred trials using NRT and nearly two dozen trials using bupropion have shown them to be safe and efficacious tobacco cessation interventions. A systematic review of 20 studies by the Cochrane group has shown a 36% reduction in crude relative risk of mortality for patients with CHD who quit compared to those who continued to smoke (RR 0.64, 95% CI 0.58–0.71).[67] A meta-analysis of 12 cohorts also revealed a 46% risk reduction (odds ratio (OR) 0.54, 95% CI 0.46–0.62) displaying consistency of effect across many regions of the world (Table 9.6).[68]

Effectiveness and cost effectiveness of tobacco control interventions

Using a static model of the cohort of smokers alive in 2000, we estimate the number of smoking-attributable deaths over the next few decades that could be averted by (a) price increases, (b) NRT, and (c) a package of non-price interventions other than NRT. Cost effectiveness of these policy interventions was calculated by weighing the approximate public sector costs against the years of healthy life saved, measured in DALYs. The details of this model have been published previously.[69]

Results of model projections

The following is an updated analysis, using higher price increases and a greater effectiveness for NRT. This analysis is conservative in its assumptions about effectiveness, and generous in its assumptions about the costs of tobacco control.

Potential impact of price increases

With a price increase of 33%, it is predicted that 22–65 million smoking-attributable deaths will be averted worldwide, which is approximately equivalent to 5–15% of all smoking-attributable deaths expected among those who smoke in 2000; see Table 9.7. Low- and middle-income countries account for about 90% of averted deaths. Total smoking-attributable deaths averted worldwide ranges from 33 million to 92 million for a 50% price increase and 46 million to 114 million for a 70% price increase. A 70% price increase would avert 10–26% of all smoking-attributable deaths worldwide.

Of the tobacco-related deaths that would be averted by a price increase, 80% would be male, reflecting the higher overall prevalence of smoking in men. The greatest relative impact of a price increase on deaths averted is among younger age cohorts. Note that these projections use conservative price increases. In certain countries, such as South Africa and Poland, recent tax increases have doubled the real price of cigarettes.[70]

Potential impact of nicotine replacement therapy

Provision of NRT with an effectiveness of 1% is predicted to result in the avoidance of about 3.5 million smoking-attributable deaths (Table 9.8). NRT of 5% effectiveness will have about five times the impact. Again, low- and middle-income countries would account for roughly 80% of the averted deaths. The relative impact of NRT (of 2.5% effectiveness) on deaths averted is 2–3% among individuals aged 15–59, and lower among those aged 60 and older (results not shown).

Potential impact of non-price interventions other than NRT

A package of non-price interventions, other than NRT, that decreases the prevalence of smoking by 2% is predicted to prevent about 7 million smoking-attributable deaths (more than 1.6% of all smoking-attributable deaths among those who smoked in 2000; see Table 9.8). A package of interventions that decreases the prevalence of smoking by 10% would have an impact five times greater. Low- and middle-

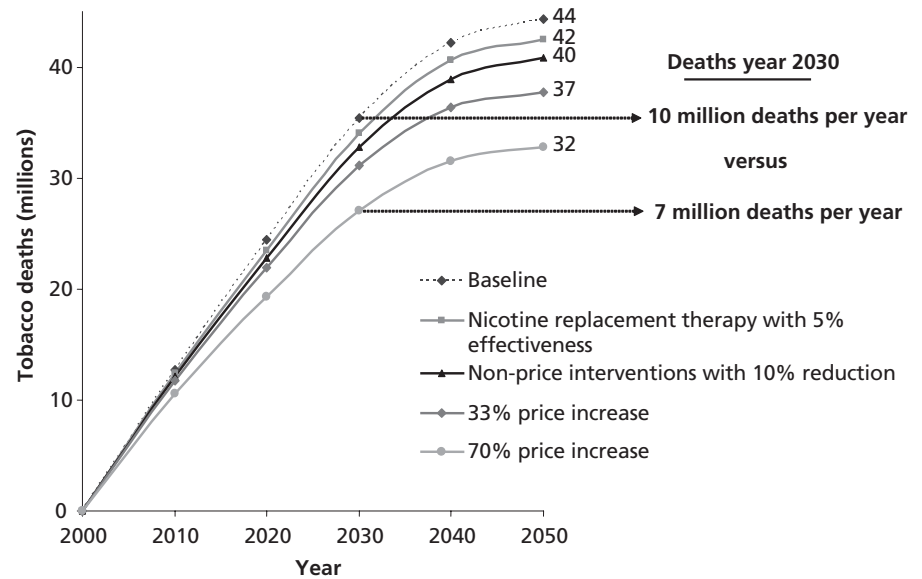
World (percent)	443	−21.8 (−4.9)	−65.3 (−14.8)	−3.5 (−0.8)	−17.4 (−3.9)	−6.9 (−1.6)	−34.7 (−7.8)


Figure 9.2 Potential impact of price increase, NRT use and a package of non-price interventions, 2000[22].

income countries would account for approximately four-fifths of quitters and averted deaths. The greatest relative impact of non-price interventions on deaths averted would be among younger age cohorts.

Figure 9.2 summarizes the potential impact of a set of independent tobacco control interventions, using 33% and 70% price increases (employing a high elasticity of –1.2 for low- and middle-income regions and –0.8 for high-income regions), a 5% effectiveness of NRT, and a 10% reduction from non-price interventions other than NRT. In this cohort of smokers alive in 2000, approximately 443 million are expected to die in the next 50 years in the absence of interventions. A substantial fraction of these tobacco deaths are avoidable with interventions. Price increases have the greatest impact on tobacco mortality, with the most aggressive price increase of 70% having the potential to avert almost one-quarter of all tobacco deaths. Even a modest price increase of 33% could potentially prevent 66 million tobacco deaths over the course of the next 50 year. While NRTs and other non-price interventions are less effective than price increases, they can still avert a substantial number of tobacco deaths (18 million and 35 million deaths, respectively). The greatest impact of these tobacco control interventions would occur after 2010, but a substantial number of deaths could be avoided even before that.

Note that no attempt has been made in this analysis to examine the impact of combining the various packages of interventions (for example, price increases with NRT, or NRT and other non-price interventions). Although a number of studies have compared the impact of price and non-price interventions, few empiric attempts have been made to assess how these interventions might interact. While price increases have been found in this analysis to

be the most cost-effective anti-smoking intervention, policy makers should use both price and non-price interventions to counter smoking. Non-price measures may be required to impact the most heavily dependent smokers, for whom medical and social support in stopping will be necessary. Furthermore, these non-price measures may be effective in increasing social acceptance and support of tobacco price increases.

Comprehensive tobacco control programs

In recent years, several governments, mostly in high-income countries, have adopted comprehensive programs to reduce tobacco use, often funded by earmarked tobacco tax revenues. These programs generally have similar goals for reducing tobacco use, including preventing initiation among youth and young adults, promoting cessation among all smokers, reducing exposure to passive tobacco smoke, and identifying and eliminating disparities among population subgroups.[43] Furthermore, these programs have one or more of four key components: community interventions engaging a diverse set of local organizations; counter-marketing and health information campaigns; program policies and regulations (such as taxes, restrictions on smoking, bans on tobacco advertising, and access to better cessation treatments); and surveillance and evaluation of potential issues, such as smuggling.[43,71] Programs have placed differing emphases on these four components, with substantial diversity among the types of activities supported within each component. Disaggregating current tobacco control program spending reveals that the greatest

impact can be achieved through a focus on macro-level changes, such as policy change. Recent analyses from the United States and United Kingdom clearly indicate that these comprehensive efforts have been successful in reducing tobacco use and in improving public health.[42,43,72] In California, for example, the state's comprehensive tobacco control program has produced a rate of decline in tobacco use double that seen in the rest of the United States.[73]

Current estimates of the costs of implementing a comprehensive tobacco control program range from US$2.50 to US$10 per capita in the United States. The Centers for Disease Control and Prevention recommends spending US$6 to US$16 per capita for a comprehensive tobacco control program in the United States.[74] Canadian spending on tobacco control programs was approximately US$1.65 per capita in 1996.[75] At the highest recommending spending level (US$16 per capita) in the United States, annual funding for a comprehensive tobacco program would equal only 0.9% of US public spending, per capita, on health.

Evidence from the United States demonstrates that states with the greatest prevalence of smoking have a greater marginal impact with their tobacco control spending, suggesting that the potential gains from modest investments in comprehensive tobacco control measures are large. Each US$10 spent per capita on tobacco control annually has resulted in a 55% reduction (variation of 20–70%) in per capita cigarette consumption.[76] In the United States, US$10 translated into 0.03% of per capita GDP in 2003.

Conclusion

Worldwide, there are only two large and growing causes of death. One is HIV-1 infection and the other is tobacco. Tobacco is responsible for 10% of all deaths globally.[77] On current consumption patterns, about 1 billion people in the 21st century will be killed by their addiction to tobacco. There is strong evidence that tobacco tax increases, the dissemination of information about the health risks from smoking, restrictions on smoking in public places and workplaces, comprehensive bans on advertising and promotion, and increased access to cessation therapies are effective in reducing tobacco use. There is increasing evidence that they are also beneficial in reducing cardiovascular mortality and morbidity among both smokers and others. Reduction in tobacco use is at least partially responsible for the decrease of cardiovascular disease burden seen in the US.[78] Despite this evidence, these policies have been applied aggressively only in high-income countries, covering a small proportion of the world's smokers. Limited implementation of effective tobacco control for reducing cardiovascular disease burden in developing countries is due to political constraints as well as the lack

of awareness of the effectiveness and cost effectiveness of these interventions.

10 Tobacco and cardiovascular disease: achieving smoking cessation in cardiac patients

Andrew Pipe
University of Ottawa Heart Institute, Ottawa, Canada

Introduction

Despite overwhelming evidence of the importance and effectiveness of smoking cessation in the prevention and management of heart disease, and the availability of effective cessation interventions it is, regrettably, still the case that smoking cessation has not figured prominently among the interventions provided by cardiologists. In part this may reflect the unfortunate and tragic persistence of outdated attitudes and perspectives: to the uninformed, smoking still remains a "habit" or "lifestyle choice" that can be addressed only by determination and the application of strong will. Some cardiologists may view the responsibility for smoking cessation as resting with others – typically the family physician. More likely, the lack of familiarity with the clinical principles of smoking cessation, a misperception of their efficacy and effectiveness, and a failure to appreciate the need for the systematic identification of smokers combined with the delivery of proven interventions may have contributed to an indifference to intervene in the cardiac setting.

It has been noted that it is difficult to identify any condition that is as prevalent, lethal and yet so prone to neglect as tobacco addiction.[1] One-half of all smokers will die prematurely as a consequence of their tobacco use.[2] In the United Kingdom it has been calculated that 40% of heart disease is attributable to smoking; the burden is similar in the USA and elsewhere in the developed world.[3–5] There can be no doubt of the causative role that tobacco addiction plays in the development and accentuation of cardiac and cardiovascular disease; the evidence is overwhelming and has been accumulating for decades.[6–7] Tobacco use is a principal contributor to the development of coronary artery disease (CAD), acute myocardial infarction (AMI), heart failure and the complications which inevitably follow. Deaths from coronary artery disease in smokers below the age of 45 exceed the mortality produced by any other tobacco-related disease.[8] Smoking cessation may have a greater effect on reducing mortality among smoking patients with CAD than any other intervention or treatment.[9] Sadly, tobacco use has been described as "reflecting a rare confluence of circumstances: (1) a highly significant health threat; (2) a disinclination among clinicians to intervene consistently; and (3) the presence of effective interventions".[10]

> "The rapidity and potency of risk reduction, as well as the other health-enhancing effects associated with smoking cessation, argue for the prioritization of smoking cessation in any program of secondary prevention of coronary disease."
>
> Forrester JS, Merz CNB, Bush TL *et al JACC* 1996;**27**:991–1006

In recent years the prevalence of smoking has declined in the developed world; regrettably rates of smoking in developing nations continue to rise and herald epidemics of tobacco-related disease for years to come. 100 million deaths resulted from tobacco use in the 20th century[11]; it has been estimated that one billion more will occur in the 21st.[12] A significant proportion of these deaths will occur as a result of the development of heart disease.

Cardiovascular physicians pride themselves on the degree to which their practices are based on carefully cultivated evidence derived from large, thoughtfully developed clinical trials which ultimately inform the development of practice guidelines. The evidence defining best practice for the treatment of smoking comes from several sources, principal among which are the influential guidelines that emerge regularly from the US Department of Health and Human Services.[10,13]

Smoking cessation is a very powerful and highly cost-efficient intervention.[14–16] The most recent recommendations

are clear and direct and have specific implications for all cardiologists and cardiovascular professionals: clinicians and health systems must "consistently identify and document tobacco use" among their patients and "treat every tobacco user seen in a healthcare setting"; clinicians should "offer every patient who uses tobacco ... the brief treatments shown to be effective"; and should encourage the "use of the numerous effective medications available for tobacco dependence".[10]

The pathophysiology of smoking and cardiovascular disease

Cigarette smoke contains nicotine, tar, and oxidant gases. Nicotine, the addictive constituent of tobacco, is delivered rapidly to the addiction centers of the brainstem when inhaled in tobacco smoke. Nicotine influences blood pressure and heart rate and, particularly in nicotine-naïve subjects, vasoconstriction. Carbon monoxide impairs the delivery of oxygen, while oxidant gases and their constituents play a major role in the initiation and progression of atheroma.[17]

Atheromatous lesions develop within a blood vessel as the consequence of a combination of pathophysiologic processes which impair vasomotor function, damage the vessel wall, accentuate the effects of elevated lipoproteins, and stimulate platelet aggregation and thrombosis. Cigarette smoking plays a distinct role in each of these processes. The constituents of cigarette smoke interfere with the availability of nitric oxide, thereby disrupting the normal vasomotor responses of the blood vessel wall; increase vascular inflammation, contributing to an accumulation of leukocytes on endothelial surfaces; promote the deposition of inflammatory and proinflammatory materials within the vessel wall; contribute to the elevation of total cholesterol and low-density lipoprotein cholesterol (LDL), and reduce levels of high-density lipoprotein cholesterol (HDL); increase the oxidation of LDL; accentuate platelet aggregation and adhesion; reduce the dissolution of thrombi; and contribute to plaque rupture.[7,18,19] Smoking also leads to elevated levels of carbon monoxide (CO), producing increased levels of carboxyhemoglobin and thereby reducing the blood's capacity to carry and release oxygen (Box 10.1).

Notwithstanding their increased risk of atherosclerosis, heart disease, and coronary events, smokers have been noted to demonstrate improved rates of survival following a myocardial infarction – the "smoker's paradox" – a phenomenon attributable to the younger age at which smokers experience acute coronary events, their more favorable coronary anatomy, and reduced levels of co-morbidity.[20,21]

Second-hand smoke (SHS) is a combination of exhaled *mainstream* smoke (15%) and the *sidestream* smoke pro-

BOX 10.1 The Perfect Storm: cigarette smoke contributes directly to the processes underlying the development of CAD

- Impairs nitric oxide activity
- Diminishes vasomotor responses
- Increases vascular inflammation
- Promotes deposition of inflammatory materials in vessel wall
- Oxidizes lipoproteins
- Accentuates platelet aggregation
- Reduces dissolution of thrombi
- Contributes to plaque rupture
- Increases carboxyhemoglobin levels

duced by an idling cigarette (85%).[18] SHS is harmful and also contributes to platelet activation and endothelial dysfunction, distorts lipoprotein profile, elevates levels of carboxyhemoglobin, accentuates inflammation and contributes to the progression of atherosclerosis.[22–24] Exposure to SHS has predictably deleterious effects on cardiac function; it results in a 30% elevation in the risk for coronary heart disease. [25–28] The ischemic stress of exercise is accentuated upon exposure to SHS which may precipitate anginal symptoms.[29,30] Second-hand smoke exposure has been estimated to cause 35 000 excess cardiovascular events each year in the USA and is the third leading cause of preventable death[24] (**Class I, Level A**).

Smokeless tobacco, whose use has surged in North America in recent years, frequently produces levels of nicotine that are higher, and more sustained, than those seen with smoking. The use of these products is known to produce acute cardiovascular effects.[31] Blood pressure levels are influenced by the high sodium content of smokeless tobacco and the presence of its two pharmacologically active ingredients: nicotine and licorice.[32] Smokeless tobacco users are more likely to have elevated levels of both diastolic and systolic blood pressure,[33] and may have distorted lipoprotein profiles.[34] Insulin resistance and a higher prevalence of diabetes have been noted in smokeless tobacco users.[35,36] Physicians are advised to counsel users of smokeless tobacco products to quit.[37]

The benefits of smoking cessation

Smoking cessation confers distinct and immediate benefits to the smoker with cardiovascular disease. The elimination of exposure to mainstream tobacco smoke (and its multiplicity of toxic constituents) has a rapid impact on the reduction of those factors which contribute to the development and progression of atherosclerosis, removes the deleterious impact of smoking on established indices of

cardiac performance, and eliminates the stimuli for clotting and thrombi formation central to the development of many acute cardiac conditions. The likelihood of sudden death, the propensity for myocardial infarction or re-infarction, the incidence of arrhythmia and an array of postinfarction complications, the adverse impact of smoking on myocardial contractility, and the progression of congestive heart failure (CHF) are all dramatically reduced following smoking cessation[9,38–42] (**Class I, Level A**). A very substantial, 36% relative risk reduction of mortality is experienced following smoking cessation in those with coronary artery disease; this intervention is more potent than other classic secondary preventive strategies (e.g. cholesterol treatment) which, arguably, have received far greater attention in recent years (Table 10.1, Fig. 10.1).[38] Quitting smoking produces a substantial, 30% decline in mortality in those with heart failure, a reduction of risk which equals or exceeds that produced by treatment with metoprolol, enalapril or spironolactone[42] (**Class I, Level A**).

Controling exposure to cigarette smoke

Elimination or reduction of exposure to second-hand smoke has a significant impact on the incidence of acute coronary events for the individual and for the community. Anginal thresholds are reduced upon exposure to second-hand smoke; the benefits to the cardiac patient of the elimination of smoking in the home and work environments are many[19,24,43] (**Class I, Level A**). Evidence continues to accumulate, from North America and Europe, of the beneficial effects of the introduction of smoke-free policies. There has been a distinct and clearly documented reduction in the incidence of acute myocardial infarctions in several cities following the introduction of bans on public smoking[44–48] (**Class I, Level B**). Cardiologists can play a significant role in supporting the introduction of such progressive public health policies.

Table 10.1 Reducing mortality in CHD: the benefits of smoking cessation are greater and accrue more rapidly in comparison to other important preventive interventions

Intervention	Reduction in mortality
Smoking cessation	36%
Statin therapy	29%
Beta-blockers	23%
ACE inhibitors	23%
Aspirin	15%

Nicotine addiction: the fundamental basis of smoking behavior

Minimal exposure to nicotine is all that is required to initiate the profound changes in neuroanatomy and neurophysiology that result in a brain, and a life, ordered and organized to ensure regular intake of nicotine. Only minimal exposure to nicotine via inhalation is necessary to produce addiction. Nicotine is arguably the most destructive of all the addictive drugs encountered in our society. It is the only drug which when used as intended will result in the premature death of one-half of all its users. The effects of nicotine on brain function, and ultimately behavior, are mediated via a number of nicotine receptors, principal among which is the $\alpha_4\beta_2$ nicotinic acetylcholine receptor (nAChR) located in the brainstem. This receptor is felt to be responsible for the initiation and preservation of the nicotine-addicted state.[49] Stimulation of nAChRs, principally the $\alpha_4\beta_2$ subtypes, results in a cascade of neurologic stimulation involving the mesolimbic system, culminating in the release of dopamine and other neurotransmitters in the nucleus accumbens region of the forebrain. Elevated levels of dopamine sustain addiction by producing pleasure, stimulation and mood modulation.[50]

In simple terms, the development of nicotine addiction can be seen as the requirement to maintain ongoing stimulation of nicotine receptors in order to ensure elevated levels of dopamine (Fig. 10.2). A cigarette is a drug delivery device which permits the rapid introduction of nicotine, titration of receptor stimulation, and dopamine release. As addiction develops, so does a degree of tolerance or desensitization at the receptor level which causes an increase in the absolute number of nicotine receptors. Smokers autotitrate their nicotine intake so as to maintain a personalized, idiosyncratic level of nicotine and comfort-maintaining levels of dopamine (Fig. 10.3).[51]

In the absence of nicotine intake, a withdrawal state quickly develops characterized by anxiety, irritation, frustration, depressed mood, lowered levels of concentration and restlessness.[52] As a consequence of the relative deficiency of dopamine that accompanies smoking cessation, a prominent symptom of withdrawal is "hedonic dysregulation" – a feeling that there is minimal or no pleasure in life and that no enjoyment accompanies previously rewarding activities.[53] Smoking cessation is often accompanied by the emergence of depressive symptoms and mood states. It is the discomfort and intensity of withdrawal, in association with the strongly conditioned behaviors, moods, and environmental factors associated with smoking, that can make this addiction so difficult to shed.[54] It is unlikely that non-smokers will ever in their lifetimes have to make the significant, complex life transformation that a smoker must undergo to become a non-smoker.

It is important that clinicians appreciate the difficulties associated with cessation. Unassisted, only a very small proportion of smokers, 3%, are able to remain abstinent from tobacco for a six-month period; most relapse within eight days.[55,56] Tobacco addiction should be viewed as a chronic relapsing addictive disorder requiring specific treatment for its elimination.

Most smokers understand the negative health consequences of their addiction, wish to stop smoking, and make at least one or two private attempts to stop smoking each

Figure 10.2 Nicotine stimulates receptors in the ventral tegmental area of the brainstem, causing the further stimulation, via the mesolimbic pathway, of regions in the nucleus accumbens of the forebrain, resulting in the release of dopamine. The brain rapidly adapts to the presence of increased levels of dopamine. Addiction quickly develops following minimal, repeated exposure to nicotine and the ensuing dopamine release.

Figure 10.3 Smokers autotitrate nicotine intake to maintain plasma levels so as to accentuate "pleasure" and minimize "discomfort". As nicotine levels rise, "pleasure" is experienced; as levels fall below a certain threshold, "discomfort" in the form of withdrawal or craving symptoms is experienced. In the neutral zone comfort is achieved without accentuating arousal and discomfort is avoided as abstinence symptoms do not develop.(Adapted with permission from Benowitz NL. *Med Clin North Am* 1992;**76**:415–37.)

year – the overwhelming majority of which are unsuccessful.[57] Even in the face of compelling reasons for cessation, smoking cessation is difficult – following a myocardial infarction less than one-half of patients are able to stop smoking[58]; 17–40% of cardiac transplant recipients return to smoking at some point after their procedure.[59–62] "Brainstem trumps cerebral cortex": it is important to realize that admonitions and exhortations to smoking patients are likely to be of only limited assistance in addressing this tenacious addiction, one which mandates the ongoing application of more insightful, evidence-based treatment strategies.

It is now understood that there are genetic predispositions affecting receptor density, the rate of nicotine metabolism, the likelihood and tenacity of addiction, and the difficulty that may be experienced in attempting to shed it.[51,63–65] Individuals with certain psychiatric disorders, particularly schizophrenia and its related conditions, bipolar and other affective disorders, and substance abuse problems have a significantly increased likelihood of becoming smokers and a greater difficulty with cessation.[54,66–68] Such patients have a markedly reduced life expectancy, most of which is accounted for by tobacco-related diseases, principal among which is cardiovascular disease (**Class I, Level A**).

Smoking cessation: the fundamental preventive intervention

Smoking cessation should be the priority in the secondary prevention of cardiac disease[69] (**Class 1, Level A**). Sadly, there is evidence that physicians, particularly specialists, do not typically effectively address this preventive priority.[70] The substantial benefits of cessation for a cardiac patient occur rapidly; they equal or exceed those of other preventive therapies. It is important to ensure that a systematic approach is adopted in *every* professional environment (office, clinic, and inpatient settings) which permits the identification of a patient's smoking status; stimulates the delivery of clear, unambiguous, non-judgmental advice regarding the importance of quitting; prompts an offer of ongoing assistance with cessation; ensures familiarity with the prescription (and titration) of commonly used pharmacotherapies for cessation; and facilitates appropriate referral to other physicians, agencies or programs for follow-up where necessary or appropriate[10] (**Class I, Level A**).

The time-honored 5 As (**A**sk – about smoking status; **A**dvise – about the importance of quitting; **A**ssess – the readiness to quit; **A**ssist – by providing effective medications and counseling; **A**rrange – for appropriate follow-up) have informed and influenced professional behavior for years. But not all elements need to be delivered personally,

separately or intensely. Some have suggested that we think of "**A**sking and **A**cting". Consistency is the hallmark of a successful intervention system and unless a systematic approach is adopted in every professional setting, the potential to dramatically enhance cardiac health for our patients and communities will be diminished.[1]

Counseling

The provision of supportive counseling has been a central element of recommended clinical approaches to cessation for many years. Many physicians have misconstrued this recommendation, assuming that it mandates the delivery of time-consuming interventions inappropriate for their practice, environment or skill-set. Contemporary recommendations clearly note that delivering minimal, strategic advice regarding enlisting the support of family and friends; the avoidance of social or environmental stimuli for smoking; compliance with medication; the importance of follow-up; and strategies for relapse management are as effective as more intense, sustained or highly structured behavioral treatments.[10,71] Strategic counseling can be efficiently provided and reinforced by other clinical staff, other physicians or via access to quit-lines or other community cessation programs, further enhancing cessation rates[72,73] (**Class I, Level A**).

Smoking cessation treatment should not be seen as a complex undertaking (the management of anticoagulation or the titration of lipid-lowering or hypertension medication can be far more involved and prolonged). The implementation of a systematized approach ensures effective use of time and resources and assures optimal outcomes in any population of smokers. Ensuring that office or institutional practices capture pertinent smoking information (e.g. at point of patient registration) and prompt an intervention (e.g. with a sticker, chart reminder or a prompt on an electronic medical record) means that clinician time can be used most appropriately. The provision of brief advice regarding smoking cessation by physicians has been demonstrated to produce an increase in cessation; the advice of nurses may enhance cessation rates; systems which support such behavior will only add to effectiveness.[74,75] It is also clear that the failure to involve a patient in supportive counseling does not detract from the ability of pharmacotherapy to significantly assist in achieving cessation.[10]

It has long been recognized that smoking cessation may induce or uncover depressive mood states or disorders[76,77] (**Class I, Level A**). Nicotine use is itself mood modulating as a consequence of its effect in producing changes in levels of dopamine and other transmitters. Smokers are more likely to have a history of depressive illness and may smoke because of the mood-enhancing properties of nicotine; quitting smoking may cause a re-emergence of those symptoms irrespective of the approach used in cessation.[78]

Those with a history of depression or other mood disorders or a history of depression in association with cessation may experience a return of those symptoms and should be so advised while being monitored normally as part of the cessation process.

The hospital

Given that many admitted cardiac patients are smokers (who will frequently begin to experience symptoms of nicotine withdrawal shortly after admission), the majority of whom know the reasons for quitting and wish to quit,[57] there is a unique opportunity in any hospital setting to provide specific, systematic assistance with cessation. Now a standard of care for the treatment of AMI and CHF in US settings, such programs can ensure the consistent delivery of a standardized protocol and enhance rates of cessation.[79,80] The delivery of an intensive smoking cessation intervention, including 12 weeks of follow-up and the provision of free pharmacotherapy to high-risk cardiovascular patients admitted to a coronary care unit, resulted in a dramatic reduction in readmission (relative risk reduction (RRR) = 44%) and all-cause mortality (RRR = 77%) over a 24-month period demonstrating the potential of hospital-based interventions for cessation (Fig. 10.4).[81] Smoking cessation interventions commenced in hospital settings, when coupled with at least one month's follow-up post discharge, demonstrate significant effectiveness in increasing the rate of cessation (Table 10.2)[82] (**Class I, Level A**).

Pharmacotherapy

The use of pharmacotherapy is the mainstay of successful cessation treatment. The benefits of pharmacotherapy are distinct and well documented (**Class I, Level A**). Physicians have access to 'three generations' of first-line pharmacotherapies, each of which has significant, proven efficacy when compared to placebo, in enhancing the likelihood of successful cessation: nicotine replacement therapy, bupropion, and varenicline (Table 10.3).

Nicotine replacement therapy (NRT)

All smokers seek to maintain a certain, personalized level of nicotine. In the absence of smoking, nicotine levels fall and stimulation of nicotinic receptors declines, resulting in a corresponding decline in the levels of dopamine and other neurotransmitters. The smoker will then begin to experience cravings and, in the absence of nicotine intake, the symptoms and discomfort of withdrawal emerge. The administration of amounts of nicotine sufficient to approach familiar levels of nicotine will eliminate craving and the symptoms of withdrawal, allowing a smoker to acquire and experience a repertoire of non-smoking behaviors leading to ultimate cessation. It has been recognized that the dose of NRT and duration of therapy may need to be titrated in order to meet the particular nicotine needs of an individual smoker. Very heavy smokers are unlikely to have their nicotine needs addressed by standard doses of NRT provided in a fixed-dose protocol. A history of heavy smoking, pronounced cravings in previous quit attempts or ongoing craving while using standard doses of NRT indicate that an increase in nicotine dose may be appropriate.

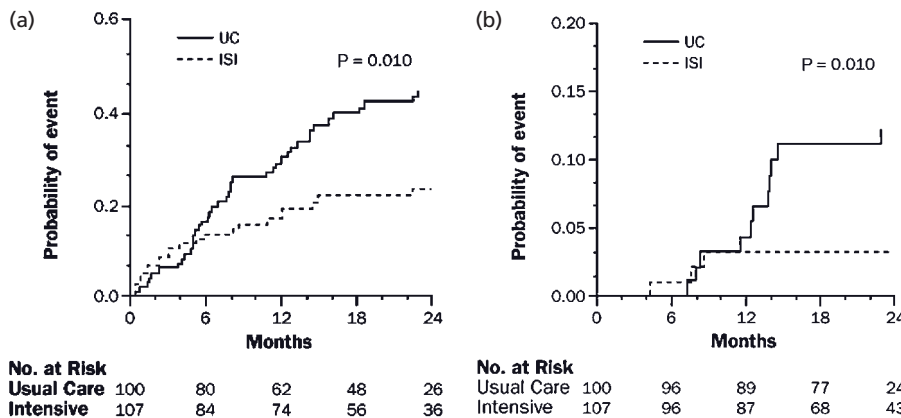
NRT is available in a variety of forms: patch, gum, inhaler/vaporizer, lozenge, and nasal spray. It is important to emphasize that a smoker will receive less nicotine, delivered slowly via the venous system, than they would obtain from continued smoking. At the same time, in contrast to smoking, there will be no arterial delivery of nicotine, carbon monoxide or any of the thousands of other compounds of tobacco smoke. Smokers are tolerant of the vasoactive properties of nicotine and the safety of NRT use in cardiac patients has been established in a variety of settings.[83–89] Many smokers will experience withdrawal symptoms shortly after admission to hospital; this has


Figure 10.4 A demonstration of the effect of an intensive in-hospital smoking cessation program for patients admitted with acute cardiovascular conditions. (a) Hospital readmission in intensive (ISI) vs usual care (UC) smoking cessation groups. (b) All-cause mortality in intensive (ISI) vs usual care (UC) smoking cessation groups. A dramatic reduction in readmission and all-cause mortality is observed over a 24-month follow-up period.(Adapted with permission from Mohuiddin SM *et al Chest* 2007;**131**:446–52.)

Table 10.3 A comparison of the effectiveness of and abstinence rates from medications and combinations of medications compared to placebo at six months post quit date

Medication	Number of arms	Estimated odds ratio (95% CI)	Estimated abstinence rate (95% CI)
Varenicline (2 mg/day)	5	3.1 (2.5–3.8)	33.2 (28.9–37.8)
Nicotine nasal spray	4	2.3 (1.7–3.0)	26.7 (21.5–32.7)
Bupropion SR	26	2.0 (1.8–2.2)	24.2 (22.2–26.4)
Nicotine patch (6–14 weeks)	32	1.9 (1.7–2.2)	23.4 (21.3–25.8)
Patch (long-term; >14 weeks) + ad lib NRT (gum or spray)	3	3.6 (2.5–5.2)	36.5 (28.6–45.3)
Patch + bupropion SR	3	2.5 (1.9–3.4)	28.9 (23.5–35.1)
Patch + inhaler	2	2.2 (1.3–3.6)	25.8 (17.4–36.5)

Adapted from Fiore MC *et al. Treating Tobacco Use and Dependence: 2008 Update*. Rockville, MD: US Dept of Health and Human Services, Public Health Service, 2008.

particular relevance for the cardiac patient. The withdrawal syndrome is frequently manifested by unco-operative, belligerent or aggressive behavior; the provision of NRT in these circumstances can be of assistance in easing the discomfort of withdrawal and facilitating compliance with treatment, while accentuating the likelihood of successful cessation.

The effectiveness and safety of NRT have been extensively studied and documented, establishing it as a first-line choice for smoking cessation. NRT use will significantly enhance cessation when compared to placebo (nicotine patch, OR = 1.9; nicotine spray, OR = 2.3)[89] (**Class I, Level A**). All cardiac professionals should be adept in its use.

Bupropion

The serendipitous recognition that the administration of the antidepressant bupropion significantly increased spontaneous rates of smoking cessation led to clinical trials which ultimately validated the use of this drug as an aid to smoking cessation.[90–92] The development of a large evidence base has since confirmed the benefits of its use; like NRT, bupropion is now considered to be a first-line smoking cessation medication, effectively doubling the rate of smoking cessation when compared to placebo (OR = 2.0).[93] Its effectiveness is similar in both men and women[94] and has been specifically evaluated in the treatment of smokers with cardiovascular disease, where both its safety and effectiveness have been evident[95] (**Class I, Level A**).

It is well known that smoking cessation may unmask depression and that nicotine may have antidepressant effects.[96] It was assumed that bupropion would offer some benefit to those with a history of depression or those in whom smoking cessation unmasked a depressive state; this remains unproven.[91,93] Concerns have been expressed that antidepressants may worsen depression in those being treated for depression; warning statements to this effect have been added to labeling in the USA. Bupropion possesses noradrenergic and dopaminergic properties which were felt to be responsible for its effectiveness in smoking cessation; it is now recognized that it may also function as a nicotine antagonist.

There are known, dose-related side effects with bupropion. Insomnia, dry mouth and nausea are most commonly reported. When side effects occur, they frequently respond to a reduction in dose to 150 mg per day. Reduced dosing has not been associated with any significant decrease in smoking cessation effectiveness over a 12-month period.[97] Seizures, reported to occur in 1 in 1000 patients, are dose related. A history of seizures, anorexia, and recent withdrawal from other drugs of abuse are contraindications to the use of this drug. The usual dose of bupropion for smoking cessation is 150 mg bid, achieved by increasing doses in the days prior to a cessation attempt. Bupropion has been used simultaneously with NRT and demonstrated enhanced benefit in one study, though not in others.[98]

Varenicline

The realization that the leaves of the "Golden Rain" shrub (*Cytisus laburnum*) were used as a tobacco substitute during WWII prompted consideration of its use as an aid in combating tobacco dependence.[99] Smoking the leaves of this plant had been advised as a strategy to quit smoking.[100] In Eastern European countries, cytisine, the active ingredient of "Golden Rain", has been used for more than 40 years in smoking cessation. Cytisine stimulates nAChRs while blocking the ability of nicotine to do the same. Refinements of the molecular structure of cytisine have resulted in the creation of a new compound, varenicline, which binds avidly to the nicotine receptor, stimulates it only partially, and prevents nicotine binding. The result of this "partial agonist" and "antagonist" activity is diminished stimulation of the pathways leading to dopamine release, reduced

levels of dopamine, and an elimination of the pleasurable sensations associated with smoking. An individual taking varenicline is less likely to crave a cigarette because of lessened but ongoing release of dopamine. Varenicline is almost completely excreted by the kidneys, and does not interact with commonly prescribed medications or the cytochrome P450 mechanisms.

Principal side effects of varenicline include nausea, insomnia and headache which diminish over time and are associated with low discontinuation rates. Persistent nausea may be addressed by reducing the dose to 0.5 mg twice daily; varenicline at this dose is still more efficacious than placebo.[101] The FDA and European Medicines Agency have warned prescribers and users of varenicline to monitor changes in behavior and mood due to postmarketing reports of depression, agitation and suicidal ideation and behavior in patients attempting smoking cessation with varenicline. No causal relationship has been determined.[102]

Varenicline is prescribed in stepped doses over a seven-day period to a dose of 1.0 mg twice a day, in order to minimize the development of nausea. Clinical trials have consistently demonstrated the superiority of varenicline for smoking cessation in comparison to placebo (OR = 3.2) and bupropion (OR = 1.66) when assessing continuous abstinence at 52 weeks[103] (**Class I, Level A**). Additional studies comparing varenicline to NRT and investigating its use in chronic obstructive airway disease (COPD) and CVD patients are under way.

Titration of pharmacotherapy

Evidence accumulates of the additional efficacy of modifying the dose of or prolonging the period of treatment with smoking cessation therapies. Thus NRT doses may be increased to achieve appropriate nicotine replacement levels, the dose of bupropion or varenicline may be reduced to control side effects, and consideration can be given to extending the initial period of treatment with all three therapies. It is likely that a willingness to use these medications in this manner will increase their effectiveness in clinical practice. It should be noted that the medication protocol producing the greatest effect on abstinence rates is long-term NRT in association with ad libitum NRT (Table 10.4).[10]

Other pharmacotherapy considerations

Combination therapies It is now recognized that combinations of pharmacotherapies may enhance the likelihood of cessation. In particular, combinations of NRT (patch plus inhaler, patch plus gum) may allow more accurate and precise titration of nicotine; a meta-analysis comparing the effectiveness of long-term patch use in association with either gum or inhaler showed the combination to be significantly more effective than patch alone (OR = 1.9).[10]

Largely on the basis of one study,[98] the combination of NRT with bupropion was also more effective than patch alone (OR = 1.3) (**Class I, Level A**).

Clonidine The antihypertensive clonidine has been shown to be effective in smoking cessation, approximately doubling cessation rates in comparison to placebo (OR = 2.1) (**Class I, Level A**). Its side effect profile, lack of approval for smoking cessation, and the need to establish a specific dosing regimen have limited its use. It is recommended as a second-line therapy whose use might be considered in patients unable to use preferred medications. When compared to the use of the NRT patch, it was not significantly more efficacious (OR = 1.1).[10]

Mecamylamine This medication has not been proven to be effective in smoking cessation in the two trials that have been performed and its use is not recommended.[10]

Nortriptyline A meta-analysis has demonstrated that the use of this antidepressant has consistently elevated rates of smoking cessation approximately twofold in comparison to placebo (OR = 2.34), but appears less effective than NRT patch use (OR = 0.9)[93] (**Class I, Level A**). This medication has not been approved for smoking cessation, has a distinct side effect profile, and is recommended only as a second-line therapy.[10]

Rimonabant This compound, a selective type 1 cannabinoid receptor antagonist, has been subjected to clinical trials which have suggested it may be of help in smoking cessation (OR = 1.61) in comparison to placebo but has not received approval for use as an aid to smoking cessation. Central cannabinoid receptors have been implicated in

Table 10.4 A comparison of the effectiveness of and abstinence rates using various medications relative to the nicotine patch

Medication	Number of arms	Estimated odds ratio (95% CI)
Nicotine patch (reference group)	32	1.0
Varenicline (2 mg/day)	5	1.6 (1.3–2.0)
Nicotine nasal spray	4	1.2 (0.9–1.6)
Bupropion SR	26	1.0 (0.9–1.2)
Patch (long-term; > 4 weeks) + NRT (gum or spray)	3	1.9 (1.3–2.7)
Patch + bupropion SR	3	1.3 (1.0–1.8)
Patch + inhaler	2	1.1 (0.7–1.9)

Adapted from Fiore MC *et al. Treating Tobacco Use and Dependence: 2008 Update*. Rockville, MD: US Dept of Health and Human Services, Public Health Service, 2008.

appetite control and in the development of dependence and habituation.[104]

Nicotine vaccine At least three nicotine vaccines are in development; there are challenges in associating the small nicotine molecule with a carrier (usually a virus). It is anticipated that a vaccine would induce and maintain significantly elevated levels of antibodies to nicotine, resulting in the production and persistence of nicotine–antibody complexes which are too large to cross the blood–brain barrier. Stimulation of brain nicotine receptors would not then be possible and the 'priming' role of minimal smoking in initiating a relapse would be eliminated.[105] Clinical trials continue.[105]

Other therapies

A variety of therapies have been suggested as being helpful in cessation and subjected to varying forms of evaluation. There is no evidence to support the use of hypnosis,[106] acupuncture, laser therapies[107] or nutritional strategies as being efficacious for smoking cessation.

Conclusion

Evidence continues to accumulate of the devastation wrought by tobacco and the important role it plays in the initiation and accentuation of heart disease. Stopping smoking in those who have cardiac disease produces clinical benefits that are substantial and accrue more rapidly than any other preventive intervention. Cardiovascular specialists can dramatically reduce the anticipated excess morbidity and mortality in their smoking patients to the extent that they are able to assist with cessation. The development and implementation, in every professional setting, of a systematic approach to the identification of all smokers; the provision of specific advice regarding, and assistance with, quitting; the prescription or provision of effective pharmacotherapies for cessation; and the organization of appropriate arrangements for follow-up will significantly enhance the quality of care provided to all patients and optimize the likelihood of cessation (Box 10.2). Smoking cessation is the most important and most cost-effective of all preventive interventions. The personal, unambiguous, and non-judgmental advice of a cardiologist consistently expressed at every patient visit emphasizing the relevance and primacy of cessation in managing a cardiac condition can have a significant impact on eventual rates of cessation.

The likelihood of cessation can be significantly increased by the use of one of three effective pharmacotherapies. All cardiac physicians should become familiar and proficient with the prescription and use of the first-line cessation therapies: nicotine replacement therapy (NRT), bupropion, and varenicline. In the hospital setting, the development and implementation of a systematic approach to the delivery of smoking cessation services to all admitted smokers can be expected to significantly increase the number of smokers who make quit attempts and achieve cessation success. Smoking cessation is a fundamental clinical responsibility of those treating smoking patients. The chances of cessation success are enhanced by "doing ordinary things extraordinarily well".[108]

BOX 10.2 A systematic approach to smoking cessation

The essential elements of a systematic approach can be incorporated into office or clinic protocols, and hospital care maps. The introduction of a systematic approach will ensure that all smoking patients are identified and offered specific advice and assistance (including pharmacotherapy) in association with appropriate follow-up.

1. **Identification of Smoking Status:**
   - "Have you used any form of tobacco in the past six months?"
2. **Documentation:**
   - Smoking history (pack-years)
   - Previous cessation attempts
   - Time to first cigarette
3. **Counseling:**
   - Specific advice on benefits of quitting
   - Educational resources
   - Staff trained in delivery of cessation advice and assistance
4. **Pharmacotherapy:**
   - Available on formulary
   - Medical and nursing staff familiar with use
   - Treatment of withdrawal and initiation of smoking cessation
5. **Follow-up:**
   - Clinics, community resources, automated technologies

11 Lipids and cardiovascular disease

Malcolm Law
Wolfson Institute of Preventive Medicine, London, UK

Introduction

Elevated serum cholesterol was the single most important cause of the 20th-century pandemic of ischemic heart disease, with the high-fat diet typical of many Western countries over the greater part of the 20th century extending more recently to non-Western countries. Modern cholesterol-lowering drugs (statins) can reduce risk more than any other single intervention.

Serum total and low-density lipoprotein cholesterol

Typical values of serum total and low-density lipoprotein (LDL) cholesterol in Western countries are high in comparison with those in agricultural and hunter-gatherer communities, because of the high saturated fat content of the Western diet. Average serum cholesterol concentrations (in men aged 45–60) are about 3–3.5 mmol/L in hunter-gatherer societies and rural China (where heart disease is rare), but over much of the 20th century they were about 5.0 mmol/L in Japan, 5.5 mmol/L in Mediterranean populations, and 6 mmol/L in the USA, Britain and Northern Europe.[1] Use of the term "normal" in reference to usual or average Western cholesterol values may therefore be misleading (we are all "high"). In recent years cholesterol levels in Japan have risen while those in the USA, Britain and Northern Europe have fallen a little. Average levels of LDL cholesterol are about 2 mmol/L lower than total cholesterol.[1]

Of the average total serum cholesterol in Western populations, two-thirds is LDL cholesterol and one-quarter is high-density lipoprotein (HDL) cholesterol. The atherogenic properties lie in the LDL fraction (sometimes measured as its carrier protein, apolipoprotein B, with which it is highly correlated). Many of the large epidemiologic studies and the earlier randomized trials measured only total serum cholesterol; total serum cholesterol has been used as a surrogate for LDL cholesterol. Fortuitously, the approximation is a good one. The absolute reduction in total serum cholesterol produced by diet and by most drugs (including statins[2–12]) is similar to the reduction in LDL cholesterol. Observational differences in total cholesterol between individuals in cohort studies are a little greater than the corresponding differences in LDL cholesterol, but this "surrogate dilution bias" can readily be corrected.[13] Much epidemiologic and clinical trial data are therefore available to estimate quantitatively the effect of lowering serum LDL cholesterol on the risk of ischemic heart disease.

Serum cholesterol and ischemic heart disease

For about two decades we have had evidence from genetics, animal studies, experimental pathology, epidemiologic studies and clinical trials indicating conclusively that elevated serum cholesterol is an important cause of ischemic heart disease and that lowering serum cholesterol reduces the risk.[14] Ten large randomized trials of statins, published over a 10-year period, have ensured that this is now widely accepted.[2–12] Three important practical questions arise: the nature of the dose–response relationship, the size of the effect, and the speed of the reversal of risk. To answer these questions, data from both cohort studies (or prospective observational studies) and randomized controlled trials are necessary: the two are complementary. Table 11.1 summarizes the advantages of each.

The nature of the dose–response relationship: is there a threshold?

A plot of ischemic heart disease mortality on total serum cholesterol in the Prospective Studies Collaboration (PSC)

meta-analysis of 61 cohort studies showed a near-perfect straight-line dose–response relationship linking *proportional* differences in ischemic heart disease mortality (the vertical axis uses a logarithmic scale) to absolute differences in serum cholesterol, across the range of cholesterol values in Western populations[15] (Fig. 11.1). Based on a

Table 11.1 Relative advantages of cohort studies and randomized trials in assessing the relation between serum cholesterol and ischemic heart disease

Objective	Advantage (comment)
Statistical power	Cohort studies (recorded seven times more ischemic heart disease events than the trials: 91 800 v 12 500[15,16])
Dose–response relationship	Cohort studies (observation across a wide range of cholesterol values, from 3 to 14 mmol/L)
Wide age range	Cohort studies (ischemic heart disease events at ages 35–89, but mostly 55–65 in trials)
Long-term effects of cholesterol differences	Cohort studies (the cholesterol differences between individuals observed at the start of the study will have been present for decades previously)
Short-term effects of cholesterol differences	Randomized trials (on recruitment serum cholesterol was the same in intervention and control groups)
Avoid bias	Randomized trials (not a major advantage – bias in cohort studies can be allowed for)

single (baseline) cholesterol measurement, there was a continuous straight-line relationship between baseline total cholesterol values of 3 mmol/L and 14 mmol/L, using the baseline cholesterol measurements to divide the cohort into subgroups. However, using a repeat measure to estimate the mean cholesterol of each subgroup ("usual total cholesterol"), thereby allowing for regression dilution bias, the straight-line relationship extended between usual cholesterol values of 4 and 9 mmol/L. The straight line establishes that there is no threshold below which a further decrease in serum cholesterol is not associated with a further decrease in risk of ischemic heart disease. The exponential relationship indicated by the straight line means that a given absolute difference in serum cholesterol concentration from *any* point on the cholesterol distribution is associated with a constant proportional difference in the incidence of ischemic heart disease.

The absence of a threshold has in the past been contentious. However, the cohort study evidence (itself conclusive)[15,16] is supported by subgroup analyses according to baseline cholesterol in a meta-analysis of randomized controlled trials showing similar proportional reduction in coronary heart disease (CHD) from all baseline levels,[17] by randomized trials showing a greater CHD risk reduction and a greater degree of coronary artery atheroma regression with more intensive than less intensive LDL cholesterol reduction (from 2.6 to 2.0 mmol/L),[18,19] by ecologic studies,[1,14] and by experimental data on the transfer of cholesterol from the blood into atheromatous lesions which exclude a threshold as low as 1 mmol/L.[20] People at higher

Figure 11.1 IHD mortality (33 853 deaths) in categories defined only by the baseline cholesterol measurement versus: (a) risk versus a single measurement of cholesterol – mean of baseline values in each group and (b) risk versus resurvey (usual) cholesterol – mean of first resurvey values in each group (approximating mean usual values). risk of an ischemic heart disease event should be offered a statin irrespective of their existing level of total or LDL cholesterol.

The size of the effect

Table 11.2 shows estimates of the long-term percentage decrease in the risk of an ischemic heart disease event according to age at event, from the Prospective Studies Collaboration. A reduction in total or LDL cholesterol of 1 mmol/L is associated with a decrease in risk of ischemic heart disease of about 61% at age 45, 46% at 55, 31% at 65, 20% at 75 and 17% at 85. Statins (for example, simvastatin 40 mg, atorvastatin 10 mg) reduce LDL cholesterol by 1.8 mmol/L;[16] from the dose–response relationship this would reduce the risk of ischemic heart disease events by about 60% on average in people aged 50–69 years.

Speed of reversal and consistency of observational and trial data

Efficacy of serum cholesterol reduction according to duration has been determined from the results of randomized trials by separate meta-analysis of all CHD events occurring in the first year of trials, all occurring in the second year of trials, etc.[16] Results are summarized in Table 11.2, applicable to age 60 (the average age of sustaining an ischemic heart disease event in the trials). The estimate of the long-term effect of cholesterol reduction, from the cohort studies (in which the cholesterol differences between individuals are longstanding), is also shown. The proportional reduction in risk increases continuously with the duration of the cholesterol reduction: there is relatively little effect

Table 11.2 PSC age-specific estimates of relative risk of ischemic heart disease for a 1 mmol/L lower total serum cholesterol,[15] and estimates adjusted for the surrogate dilution bias,[13] both for a 1 mmol/L lower LDL cholesterol

Age	Relative risk estimate		% reduction in ischemic heart disease
	published	adjusted	
40–49 (45–54)	0.44	0.39	61% ⎫
			⎬ 54%
50–59 (55–64)	0.58	0.54	46% ⎭ ⎫
			⎬ 39%
60–69 (65–74)	0.72	0.69	31% ⎭ ⎫
			⎬ 26%
70–79	0.82	0.80	20% ⎭
80–89	0.85	0.83	17%

(11% reduction) in the first year, but a 33% reduction by the third year and (from cohort studies) a 39% reduction in the long term. The similarity of the estimates of effect from the cohort studies and from the trial data from the third year onwards indicates that the reversal of risk is near maximal after two years – a surprisingly rapid effect.

The estimates of effect are similar in men and women, in people with and without previous ischemic heart disease, and for coronary death and non-fatal myocardial infarction.[15,17] Four randomized controlled trials have attained average LDL cholesterol reductions (treated minus placebo) exceeding 1.5 mmol/L (1.6 mmol/L on average).[16] In these four trials the average reduction in incidence of ischemic heart disease events from the third year onwards was 51% (95% confidence interval (CI) 42–58%, compared to an expected value from cohort studies of 55%).[16] Trial data therefore show directly that LDL cholesterol reductions attainable with statins reduce risk by over half. Importantly, most randomized trials of statins do not show their full potential for preventing ischemic heart disease events because of "contamination" – some patients allocated to the treated group leave the trial and stop taking the tablets, some patients allocated to the placebo group take statins, and the results are necessarily analyzed on an intention-to-treat basis. The randomized trials therefore confirm the dose–response relationship shown in the cohort studies (the greater the cholesterol reduction, the greater the reduction in heart disease events[16]) and confirm the estimates from the cohort studies in Table 11.2 of the long-term reduction in risk.

As a parallel to the observation that a few years are necessary before serum cholesterol reduction is fully effective, follow-up of the participants in one randomized trial after the trial had terminated showed that the protective effect persisted in previously treated patients for some years after the termination of the trial (LDL cholesterol was similar in the former treated and placebo groups during this follow-up period).[21]

Dietary fat and serum cholesterol

The relationship between dietary saturated fat and serum cholesterol is shown by the data from Japan and Britain in Table 11.3. This comparison is a useful one because dietary saturated fat differs greatly, yet dietary polyunsaturated fat and cholesterol are similar in the two countries, so the serum cholesterol difference is attributable to the saturated fat difference. As in other situations (salt and blood pressure, for example), the size of the association varies with age, yet there has been a tendency to generalize to older age groups the results of studies conducted in younger age groups. Many dietary trials, for example, have been conducted in people under 30. The few that have been

Table 11.3 Decrease in ischemic heart disease events for a cholesterol decrease of 1 mmol/L, according to duration of the cholesterol decrease, from randomized trials[16] and cohort studies[15]

	Duration of cholesterol difference	Decrease in risk (95% CI) of ischemic heart disease event	
Randomized trials:	1st year	11%	(4–18%)
	2nd year	24%	(17–30%)
	3rd–5th years	33%	(28–37%)
	≥6 years	36%	(26–45%)
Cohort studies:	decades	39%	(37–41%)

Table 11.4 Serum cholesterol and dietary saturated fat in Japan and Britain. Data compiled from national surveys in each country[1]

Age	Japan	Britain	Difference
Dietary saturated fat (% calories)			
All ages	6%	16%	10%
Serum cholesterol (mmol/L)			
20–29	4.5	5.0	0.5
30–39	5.0	5.6	0.6
40–49	5.1	6.0	0.9
50–59	5.2	6.2	1.0
60–69	5.0	6.2	1.2

conducted in people over 50 tend to support the above Japan–Britain comparison.[14] In older people a reduction in dietary saturated fat equivalent to 10% of calories will lower serum cholesterol by about 1 mmol/L, which in turn will reduce ischemic heart disease mortality in the long term by about 40%.

The chain lengths of saturated fatty acids influence the extent to which they increase blood cholesterol. Palmitic ($C_{16:0}$) and myristic ($C_{14:0}$) acids have the major effect, lauric acid ($C_{12:0}$) some effect, and stearic acid ($C_{18:0}$) and medium chain fatty acids have little or no effect.

Trans unsaturated fatty acids are also important: randomized trials show that they increase serum total and LDL cholesterol by about as much as these longer chain saturated fatty acids.[22,23] They are scanty in naturally occurring fats but are generated by the hydrogenation of vegetable oils for use as hardening agents in manufactured foods. They constitute 6–8% of dietary fat, or 2% of calories, in Western diets.

Naturally occurring *cis* unsaturated fatty acids reduce serum cholesterol by approximately half as much as longer chain saturated fatty acids increase it. Reduction in dietary cholesterol has a small effect on blood cholesterol concentration. Substitution of *cis* unsaturated for saturated fats in the Western diet is thus the most effective change in lowering the high levels of blood cholesterol in Western populations.

The reduction in serum total or LDL cholesterol that can easily be attained by individuals trying to alter their diet in isolation from family, friends and workmates is relatively small (about 0.3 mmol/L or 5%). A larger serum cholesterol reduction, about 0.6 mmol/L (10%), is realistic on a community basis, as the availability of palatable low-fat food increases when other family members or the community alter their diet, and the dietary change is perceived more positively. A reduction by about 7% of calories, a realistic target for a high-fat population, would lower serum cholesterol by 0.6 mmol/L, which in turn would reduce the mortality from ischemic heart disease at age 60 by 25–30%. Reductions in serum cholesterol of about 0.6 mmol/L through dietary change have occurred in entire Western communities, in the United States and Finland for example.[1] Measures that facilitate such a change include wider public education, labeling of foods sold in supermarkets, and the provision of information on the fat content of restaurant meals. Most important is the implementation of national and international policies on food subsidies that are linked to health priorities.

Serum cholesterol and circulatory diseases other than ischemic heart disease

Stroke

Cohort studies show a continuous dose–response relationship between serum cholesterol and ischemic stroke, similar to that with ischemic heart disease, but for hemorrhagic stroke (intracranial and subarachnoid) they show an *excess* risk at lower serum cholesterol levels.[15,16,24] These associations are particularly strong in cohort studies in which computed tomography (CT) scans or autopsy were used to distinguish ischemic and hemorrhagic strokes;[16,24] clinical criteria alone are unreliable and may result in misclassification. Cohort studies that do not distinguish the two types of stroke tend to show little or no association between cholesterol and stroke mortality, consistent with the two associations canceling each other out. Whether the association of lower cholesterol with hemorrhagic stroke is cause and effect is uncertain. It is more difficult to see how a spurious (non-causal) association with intracranial hemorrhage might arise through the disease (or predisposition to the disease) lowering serum cholesterol than was the

case with depression and suicide or cancer. It is also difficult to see any mechanism by which the inverse association might be cause and effect, although experimental data lend some support to an interpretation of a causal effect of low cholesterol in that the endothelium of intracerebral arteries might be weaker at very low serum cholesterol levels.[25]

The randomized trials of serum cholesterol reduction, especially the statin trials, have shown a lower incidence of stroke (all types combined) in treated than control patients.[2–12] However, the strokes occurring in trials will mostly be ischemic strokes, for three reasons: they were mostly all non-fatal strokes (ischemic stroke has a lower case fatality than hemorrhagic stroke, and the cohort studies recorded total stroke), the trials tended to recruit patients in the upper half of the serum cholesterol distribution, where ischemic stroke will be more common because of its positive association with serum cholesterol, and many trials recruited patients with coronary artery disease on entry, in whom ischemic stroke will be more common than hemorrhagic. These observations can probably reconcile the reduction in the incidence of stroke in trials (where most of the strokes will have been ischemic) with the absence of an association between serum cholesterol and stroke mortality in cohort studies. Trials that distinguished ischemic from hemorrhagic stroke showed that the risk of ischemic stroke was significantly reduced by a statin,[16] but the trials recorded too few hemorrhagic strokes to confirm or refute the inverse association with cholesterol shown in cohort studies. Meta-analysis of the trials showed a 20% (95% CI 14–26%) reduction in all strokes and a 28% (20–35%) reduction in ischemic stroke for a 1 mmol/L reduction in LDL cholesterol.[16]

Even if the association between low cholesterol and hemorrhagic stroke were cause and effect, however, the increased mortality from hemorrhagic stroke at very low cholesterol concentrations is small compared to the lower mortality from ischemic heart disease and ischemic stroke. Patients who have had an ischemic stroke are at high risk of a recurrent event and should receive statins, as should patients with carotid artery disease and others at high risk. Patients who have had a hemorrhagic stroke should in general not receive statins.

Peripheral arterial disease

Observational data show an association between serum cholesterol and peripheral arterial disease.[26] Randomized trials show that statins reduce the incidence of intermittent claudication and, in patients with diagnosed peripheral arterial disease, increase pain-free walking time and reduce the need for surgical procedures.[27–29]

Abdominal aortic aneurysm

The pathology of this condition is complex, but abdominal aortic aneurysms are more common in people with coronary artery or peripheral arterial disease, and are associated with a higher serum LDL cholesterol and triglyceride and a lower HDL cholesterol. Moreover, aneurysms show a tendency to develop in atheromatous areas of the aorta. Randomized trial data on statins and aortic aneurysms are scanty, and the opportunity to conduct randomized trials has probably passed because statins and other therapy are now widely used in patients with abdominal aortic aneurysms too small for surgical resection and, whether or not they reduce the rate of expansion of such aneurysms, statins are indicated because of the increased risk of ischemic heart disease. It is unfortunate that the opportunity to conduct a trial, when statins were less widely used, was missed; a trial with aortic rupture as an endpoint would have been unrealistic but a small trial would have sufficed to show a reduced rate of aneurysmal expansion. A nonrandomized observational study showed that the rate of expansion of abdominal aortic aneurysms is about 40% lower in people who took statins than in those who did not.[30]

Other circulatory diseases

Cohort studies show a strong association between serum cholesterol and mortality from "circulatory diseases other than ischemic heart disease and stroke".[15] Deaths from peripheral arterial disease and abdominal aortic aneurysm are too infrequent to account for this. It will be attributable mainly to poorly certified ischemic heart disease: deaths certified due to atrial fibrillation, heart failure, myocardial degeneration and atherosclerosis, for example.

Safety of cholesterol reduction

The uncertainty concerning the excess mortality from hemorrhagic stroke at low serum cholesterol concentrations is unresolved. This apart, there are no material grounds for concern about hazard. Trials of "statin" drugs, particularly informative on safety because of the large reduction in serum cholesterol that they achieve, have resolved the issue of safety because they show no excess mortality from non-circulatory causes.[2–12,17] The excess mortality from cancer and accidents and suicide at very low serum cholesterol in observational studies is attributable to the cancer or depression lowering serum cholesterol, not the reverse.[25] Further reassurance on safety is provided by the condition of heterozygous familial hypobetalipoproteinemia, in which serum cholesterol levels are as low as 2–3 mmol/L. Life expectancy is prolonged because coronary artery

disease is avoided, and no adverse effects from the low cholesterol are recognized[31,32] – an important natural experiment.

Statins as drugs are safe, with few adverse effects. Muscle disorders, particularly the rare complication of rhabdomyolysis, have received attention with the withdrawal from the market of cerivastatin and the 80 mg dose of rosuvastatin. With other statins, rhabdomyolysis is rare. The incidence is 3.4 per 100 000 person-years of statin use, an estimate derived from two cohort studies and supported by data from a meta-analysis of randomized controlled trials, with a case fatality of 10%.[33] The most important preventive measure is to avoid co-prescribing statins with gemfibrozil or with drugs that inhibit the CYP3A4 enzyme system (of which erythromycin and the azole antifungals are the most widely used).[33] Creatine kinase (CK) monitoring is ineffective; the elevated CK that characterizes rhabdomyolysis is a consequence of the disease, not a precursor of it. The incidence of lesser degrees of muscle pain and weakness, sufficient to consult a doctor but insufficient to warrant hospital admission (referred to as "myopathy" or other relatively non-specific terminology) is only about 11 per 100 000 person years, less common than is often thought.[33] Importantly, muscle symptoms are almost as common in the placebo groups as in the statin groups in randomized trials; most muscle symptoms occurring in people taking statins will not be attributable to the statin.[33] The evidence indicates that the incidence of liver disease and kidney disease is not increased by taking statins; it is likely that statins cause peripheral neuropathy but the incidence is rare (12 per 100 000 person-years) and the peripheral neuropathy generally reverses after the statin is stopped.[33]

Why was cholesterol reduction contentious?

It is perhaps surprising to recollect that for many years the issue of lipids and cardiovascular disease was seen as contentious and difficult to resolve. Unfavorable evidence was reported at regular intervals between the 1960s and the early 1990s. The earliest trials used toxic agents to lower serum cholesterol, notably estrogen (in men) and thyroxine. Some early trials were short in duration[34] and showed no reduction in risk, because little occurs in the first year after lowering cholesterol (see Table 11.3). Cross-sectional studies of dietary saturated fat and serum cholesterol showed little or no relationship, an observation that was wrongly interpreted as indicating that lowering dietary saturated fat did not reduce cholesterol, until randomized trials established that it did. (The weak cross-sectional association arises because the inaccuracy in measuring individual dietary saturated fat is large in comparison to the small degree of variation between individu-

als in true saturated fat consumption.[35]) Clinicians were reluctant to accept that there was benefit in lowering average levels of serum cholesterol in high-risk patients: the notion that the average serum cholesterol in entire Western populations is high appeared counterintuitive. The issue of safety caused concern, as discussed above. Lastly, it has seemed inconsistent that serum cholesterol is a poor screening test yet an important cause of heart disease, as discussed below. All these issues are now satisfactorily resolved.

Triglycerides

Serum triglyceride concentration was associated with the risk of ischemic heart disease in many cohort studies, but the association is subject to confounding by serum LDL and HDL cholesterol, diabetes and other factors.[36,37] Whether an independent association exists is contentious. Very high serum levels of triglyceride caused by genetic defects (familial lipoprotein lipase deficiency, for example) are not associated with atheroma or coronary artery disease, and this observation, together with the potential for confounding in cohort studies, suggests that a material cause and effect relationship between serum triglyceride and heart disease is unlikely.

High-density lipoprotein (HDL) cholesterol

Cohort study data show an inverse association between HDL cholesterol (or apolipoprotein A1) and ischemic heart disease. The association is continuous across the range of values of HDL cholesterol in Western populations (0.9–1.7 mmol/L), with about a threefold difference in ischemic heart disease mortality across that range.[15] The association is similar in men and women but is age dependent; at age 40–49 the relative risk of ischemic heart disease was 1.63 for a 0.33 mmol/L lower usual HDL cholesterol.[15] The association is widely accepted as cause and effect; the threefold risk gradient, the continuous "dose–response" relationship and the observation that the association is independent of LDL cholesterol or any other evident source of confounding or bias support a causal interpretation. Moreover, a randomized trial of bezafibrate recorded a negligible change in LDL cholesterol but a significant increase in HDL cholesterol, and reported a 29% reduction in myocardial infarction (P = 0.02).[38] The higher HDL cholesterol in alcohol drinkers contributes to their lower risk of heart disease,[39] the lower HDL cholesterol in smokers contributes to their increased risk. Statins increase HDL cholesterol relatively little. Certain other cholesterol-lowering

drugs (such as fibrates and niacin) increase HDL cholesterol more, but even in persons with relatively low HDL cholesterol the overall protective effect of these drugs is smaller because they reduce LDL cholesterol less, and so they should not be preferred to statins.

In a large randomized placebo-controlled trial the drug torcetrapib increased HDL cholesterol (by 0.9 mmol/L) and reduced LDL cholesterol (by 0.6 mmol/L), but surprisingly showed a 25% (95% CI 9–44%) excess risk of cardiovascular events and a 22% (−2–+52%) excess risk of major coronary events after one year.[40] The trial was terminated prematurely and plans to market torcetrapib were abandoned. The absence of a protective effect after one year might be explained if an increase in HDL cholesterol, as with a decrease in LDL cholesterol (see Table 11.3), showed little effect in the first year, and the excess cardiovascular mortality might, at least in part, be explained by the action of torcetrapib in increasing blood pressure (by 4.5 mmHg systolic/2.1 mmHg diastolic) and decreasing serum potassium.

Lipids as screening tests

Serum cholesterol reduction is important in reducing the risk of ischemic heart disease, but cholesterol and other lipids are poor population screening tests for ischemic heart disease. The reason for the apparent discrepancy is that the screening potential of a factor depends not only on the strength of its relationship with disease, but also on its variation in magnitude across individuals in a community. In the case of lipids, the high average values in Western societies place everyone at risk, and the variation between individuals is too small for use in population screening. By analogy, if everybody smoked between 15 and 25 cigarettes per day, cases of lung cancer would not cluster in the minority who smoked 25 cigarettes a day to the extent that those who smoked 15 or 20 could be ignored. Moreover, the Gaussian distribution of serum cholesterol means that many people have values around the average and few have relatively high values, so that most ischemic heart disease events will occur in people whose serum cholesterol is about average.

Among men aged 35–64, the 5% with the highest serum total cholesterol experience only about 12% of all deaths from ischemic heart disease – their risk is little more than double the population average.[36] The 5% of men with highest LDL cholesterol (or its carrier protein, apolipoprotein B) experience 17% of the heart disease deaths.[36] Including HDL cholesterol improves this poor detection by only about one percentage point. Lipids cannot identify a small minority of the population in whom the majority of future heart disease deaths will cluster. In a small proportion of the population, however, notably persons with familial

hypercholesterolemia, the absolute risk of death from ischemic heart disease at a young age is so great that it warrants identification and treatment of affected persons, even though the condition accounts for a fraction of all heart disease deaths in a population.

Appropriate policy

Because screening cannot identify a group who would *not* benefit from a reduction in dietary fat and serum cholesterol, such measures should be directed at the entire population. Serum cholesterol reductions of 0.6 mmol/L (10%), as discussed above, have occurred in entire Western communities, facilitated by health education, the wider availability of healthy food in restaurants and supermarkets, and a positive image of healthy eating. A reduction of 0.6 mmol/L is less likely when an individual attempts dietary change in isolation. The most important measures to lower cholesterol in healthy people therefore involve wider public education, encouragement of labeling of the nutrient content of foods, and the widespread availability of palatable low-fat foods.

Clinicians need to direct their activities towards high-risk patients, and the most important high-risk group are patients who have had a myocardial infarction or have known coronary artery disease. As a group, these patients face a risk of death from ischemic heart disease of about 5% per year (untreated), a risk that varies relatively little with age or sex. As in healthy people, serum cholesterol testing cannot identify a substantial group at either materially higher or materially lower than average risk of death. Also, the evidence strongly indicates that there is no threshold below which serum cholesterol reduction is not effective. It follows that serum cholesterol should be reduced in all such patients. Simvastatin 40 mg and atorvastatin 10 mg lowers serum cholesterol by 1.8 mmol/L (30%) and this will reduce mortality from heart disease by about 60% after two years, a substantially larger reduction in risk than can be achieved by any other single intervention. Other high-risk groups, including patients with an ischemic stroke, carotid artery disease and peripheral arterial disease and diabetics, should also receive statins routinely. Among people with no clinical history of vascular disease, the strongest risk marker is age. If coronary risk is computed in a person from measurements of risk factors that exclude age and some target is set (for example, 0.5% per year, 1% per year, 2% per year) almost all of us will cross that target at some age, and the age range across which most of us would cross it is relatively narrow. If the first clinical manifestation of ischemic heart disease (which could be death) is to be prevented, however, there is a case for everybody in Western populations to take a statin above some threshold of age or computed coronary risk.

Conclusion

The high levels of serum cholesterol found in Western populations are a major cause of the high mortality from ischemic heart disease and, to a lesser extent, stroke and other circulatory diseases. Realistic dietary change in a community can lower serum cholesterol by 0.6 mmol/L (10%) and reduce heart disease mortality by about 25–30%. Simvastatin and atorvastatin can lower cholesterol by 1.8 mmol/L (30%) and reduce the risk of heart disease death by about 60% from the third year onwards, and should be offered to all high-risk survivors. Despite the importance of lowering cholesterol, lipids are poor screening tests of individual risk, because the average risk is high and the range across a population is relatively narrow.

> ### Key points
>
> **Serum cholesterol and ischemic heart disease**
>
> Grade A
> - The effect of serum cholesterol reduction on ischemic heart disease mortality is large and important.
> - There is little reduction in risk in the first year, but the expected reduction in risk is largely attained from the third year onwards.
> - There is no threshold across the range of cholesterol values in Western countries below which reducing serum cholesterol reduction is not worthwhile.
> - The greater the reduction in serum cholesterol, the greater the reduction in risk.
> - Simvastatin and atorvastatin can lower cholesterol by 1.8 mmol/L (30%) and reduce the risk of heart disease death at age 60 by about 60% from the third year onwards; their use should be routine in people at higher risk.
> - Realistic dietary change in a community can lower serum cholesterol by 0.6 mmol/L (10%) and reduce the risk of heart disease death by 25–30% at age 60. In an individual acting alone, the realistic change is half this.
> - The proportional benefits are similar in men and women.
>
> Serum cholesterol and other circulatory diseases
> - Statins reduce the risk of ischemic stroke and peripheral arterial disease and should be used in high-risk patients.
> - Cohort studies show excess mortality from hemorrhagic stroke at very low cholesterol levels. The interpretation is uncertain. The possible hazard, however, is greatly outweighed by the benefit of low mortality from heart disease at very low cholesterol levels.
>
> Screening
> - Lipids are poor screening tests for predicting heart disease death in an individual; it is not possible to identify a small minority in a community who will experience the majority of heart disease deaths.
> - The 5% of men with highest total serum cholesterol experience only about 12% of heart disease deaths.
> - In the extremity of the distribution, familial hypercholesterolemia is important to detect because the absolute risk of heart disease death at a young age is high, even though the condition accounts for only a small proportion of heart disease deaths.

12 Use of lipid-lowering agents in the prevention of cardiovascular disease

R Alan Failor and Jeffrey L Probstfield
University of Washington, Seattle, WA, USA

Introduction

The primary purpose of this chapter is to review the evidence regarding plasma lipid-altering medications, their mechanisms of action, dosages and dosing schedules, effects on lipid and lipoprotein variables, adverse effects, and clinical uses. The 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitor agents (statins), which are highly effective LDL-C lowering agents, are reviewed, as are niacin, bile acid-sequestering agents (resins), fibrates, and ezetimibe. The evidence for cholesterol lowering in such subgroups as the elderly, women, diabetic patients, and those with small-dense LDL particles is also summarized.

Major trials have clearly demonstrated that decreases in low-density lipoprotein cholesterol (LDL-C) are associated with reductions in total mortality,[1–3] coronary heart disease (CHD) mortality,[1–3] fatal and non-fatal CHD as well as strokes.[1–4] Other major trials have also shown that lowering LDL-C can retard the progression of coronary artery atherosclerosis[5] and carotid atherosclerosis and may even cause their regression, as well as slowing the progression and occlusion of atherosclerosis in saphenous vein bypass grafts.[6] In both primary[2] and secondary[1,3] CHD prevention settings, decreases in total and cause-specific mortality have been demonstrated, and these benefits have been shown in subjects with elevated,[1,2] average,[4] and normal LDL-C levels. A brief review of the costs/1% LDL-C lowering/year and cost effectiveness concludes this chapter.

The National Cholesterol Education Program (NCEP) has been instrumental in developing and promulgating guidelines for initiating LDL-C lowering. These guidelines, developed on the basis of the patient's established baseline LDL-C and presence or absence of CHD or its risk factors, recommend treatment goals to attain desired levels of plasma LDL-C. To date, the NCEP has issued three Adult Treatment Panel (ATP) reports. ATP I emphasized primary prevention of CHD in persons with high (>160 mg/dL or 4.15 mmol/L) or borderline-high LDL levels (130–159 mg/dL or 3.18–4.15 mmol/L) and >2 risk factors for development of CHD. In ATP II, persons with established CHD were targeted for intensive lipid-lowering therapy.

ATP III, disseminated in 2001, identifies elevated LDL-C as the primary target of cholesterol-lowering therapy and maintains attention on intensive treatment of patients with CHD.[7] It expands the indications for intensive therapy to lower levels of cholesterol in clinical practice. A major new feature is that intensive LDL-C lowering treatment is a primary prevention measure for persons with multiple risk factors for developing CHD, as identified by the estimated 10-year CHD risk score developed from the Framingham data. ATP III sets the optimal LDL-C level as <100 mg/dL (2.60 mmol/L) and defines low HDL-C as <40 mg/dL (1.04 mmol/L) (previous cutpoint was <35 mg/dL (0.91 mmol/L)).[7]

In 2004, recommendations for modifications to footnote the ATP III LDL-C treatment algorithm were issued.[8] Based upon the results of five major clinical outcome trials completed since the ATP III guidelines were published, a therapeutic option of an LDL-C goal of <70 mg/dL (1.82 mmol/L) for those at very high risk was considered a reasonable clinical strategy. This more aggressive goal was also extended to those at high risk who have baseline LDL-C <100 mg/dL (2.60 mmol/L). In addition, it was recommended that those at high risk who also have high triglycerides, or low HDL-C levels, be considered for combination therapy of nicotinic acid or a fibrate along with an LDL-C lowering agent. When those at high risk, or moderately high risk, are treated with LDL-lowering therapy, it was recommended that the intensity of treatment be sufficient to achieve at least a 30–40% reduction in LDL levels.[8]

ATP III also recommends that persons with the metabolic syndrome – characterized by abdominal obesity, elevated blood pressure, insulin resistance, and athero-

genic dyslipidemia – elevated triglycerides, small LDL particles, and low HDL-C should be targeted for intensive therapeutic lifestyle modifications. Atherogenic dyslipidemia should be treated with lipid-altering agents.[7]

It has recently been demonstrated by the INTERHEART study that the Apo B to Apo A1 ratio will most completely capture the risk associated with dyslipidemia.[9] The role of

triglycerides as an independent risk factor for the development of atherosclerosis remains controversial. The risks and therapeutic benefits of treatment have been recently reviewed.[12]

Boxes 12.1–12.5 summarize the major new recommendations of ATP III and classifications of cholesterol levels.[7]

Use of individual lipid-altering agents

In this short, evidence-based overview, we focus on documented activities of known lipid- and lipoprotein-altering drugs on lipid and lipoprotein variables, and their related adverse effects. We identify those issues that remain more speculative as such. The interested reader is referred to the excellent and more complete reviews by Lousberg et al,[10] as well as the ATP III guidelines.[7]

BOX 12.1 New features of adult treatment panel III

- Focus on multiple risk factors
- Raises persons with diabetes without CHD, most of whom display multiple risk factors, to the risk level of CHD risk equivalent
- Uses Framingham projections of 10 year absolute CHD risk (that is, the percent probability of having a CHD event in 10 years) to identify certain patients with multiple (2+) risk factors for more intensive treatment
- Identifies persons with multiple metabolic risk factors (metabolic syndrome) as candidates for intensified therapeutic lifestyle changes
- Modifications of lipid and lipoprotein classification
- Identifies LDL-C <100 mg/dL (2.60 mmol/L) as optimal
- Raises categorical low HDL-C from <35 (0.91) to <40 mg/dL (1.04 mmol/L)
- Lowers the triglyceride classification cutpoints to give more attention to moderate elevations

Adapted from *Third Report of the National Cholesterol Education Program (NCEP) Expert Panel on detection, evaluation, and treatment of high blood cholesterol in adults (Adult Treatment Panel III)*[7]

BOX 12.2 ATP III classification of LDL, total and HDL cholesterol

LDL cholesterol:
<100 mg/dL (2.60 mmol/L) optimal
Near optimal/above optimal
Borderline high
High
≥190 mg/dL (4.94 mmol/L), very high

Total cholesterol:
<200 mg/dL (5.19 mmol/L), desirable
Borderline high
≥240 mg/dL (6.23 mmol/L), high

HDL cholesterol:
<40 mg/dL (1.04 mmol/L), low
≥60 mg/dL (1.56 mmol/L), high

Adapted from the *Third Report of the National Cholesterol Education Program (NCEP) Expert Panel on detection, evaluation, and treatment of high blood cholesterol in adults (Adult Treatment Panel III)*[7]

BOX 12.3 Major risk factors (exclusive of LDL cholesterol) that modify LDL goals*

- Cigarette smoking
- Hypertension (blood pressure >140/90 mmHg or on antihypertensive medication)
- Low HDL cholesterol (<40 mg/dL)[†]
- Family history of premature CHD (CHD in male first-degree relative <55 years; CHD in female first-degree relative <65 years)
- Age (men >45 years; women >55 years)

*Diabetes is regarded as a coronary heart disease (CHD) risk equivalent.
[†]HDL cholesterol >60 mg/dL (1.56 mmol/L) counts as a "negative" risk factor; its presence removes 1 risk factor from the total count.
Adapted from *Third Report of the National Cholesterol Education Program (NCEP) Expert Panel on detection, evaluation, and treatment of high blood cholesterol in adults (Adult Treatment Panel III)*[7]

BOX 12.4 Three categories of risk that modify LDL cholesterol goals

Risk category	LDL goal (mg/dL)
CHD and CHD risk equivalents	<100 (2.60 mmol/L)
Multiple (2+) risk factors*	<130 (3.38 mmol/L)
0–1 risk factor	<160 (4.16 mmol/L)

*Risk factors that modify the low density lipoprotein (LDL) goal are listed in BOX 12.3. CHD indicates coronary heart disease.
Adapted from *Third Report of the National Cholesterol Education Program (NCEP) Expert Panel on detection, evaluation, and treatment of high blood cholesterol in adults (Adult Treatment Panel III)*[7]

BOX 12.5 Recommendations for modifications to footnote the ATP III treatment algorithm for LDL-C

- Therapeutic lifestyle changes (TLC) remain an essential modality in clinical management. TLC has the potential to reduce cardiovascular risk through several mechanisms beyond LDL lowering.
- In high-risk persons, the recommended LDL-C goal is <100 mg/dL (2.60 mmol/L)

  An LDL-C goal of <70 mg/dL ((1.82 mmol/L) is a therapeutic option on the basis of available clinical trial evidence, especially for patients at very high risk (e.g. continued smoking).
  - If LDL-C is >100 mg/dL, an LDL-lowering drug is indicated simultaneously with lifestyle changes.
  - If baseline LDL-C is <100 mg/dL, institution of an LDL-lowering drug to achieve an LDL-C level <70 mg/dL is a therapeutic option on the basis of available clinical trial evidence.
  - If a high-risk person has high triglycerides or low HDL-C, consideration can be given to combining a fibrate or nicotinic acid with an LDL-lowering drug. When triglycerides are >200 mg/dL (2.26 mmol/L), non-HDL-C is a secondary target of therapy, with a goal 30 mg/dL (0.34 mmol/L) higher than the identified LDL-C goal. The risks and therapeutic benefits of treatment associated with elevated levels of triglycerides have recently been reviewed.[12]
- For moderately high-risk persons (2+ risk factors and 10-year risk 10–20%), the recommended LDL-C goal is <130 mg/dL (3.38 mmol/L); an LDL-C goal <100 mg/dL (2.60 mmol/L) is a therapeutic option on the basis of available clinical trial evidence. When LDL-C level is 100–129 mg/dL (2.60–3.38 mmol/L) at baseline or on lifestyle therapy, initiation of an LDL-lowering drug to achieve an LDL-C level <100 mg/dL (2.60 mmol/L) is a therapeutic option on the basis of available clinical trial evidence.

  New evidence suggests that the Apo B to Apo A1 ratio will most completely capture the risk associated with dyslipidemia.[9]
- Any person at high risk or moderately high risk who has lifestyle-related risk factors (e.g. obesity, physical inactivity, elevated triglyceride, low HDL-C or metabolic syndrome) is a candidate for TLC to modify these risk factors regardless of LDL-C level.
- When LDL-lowering drug therapy is employed in high-risk or moderately high-risk persons, it is advised that intensity of therapy be sufficient to achieve at least a 30–40% reduction in LDL-C levels.
- For people in lower risk categories, recent clinical trials do not modify the goals and cutpoints of therapy.

Adapted from Grundy *et al*.[8]

HMG-CoA reductase inhibitors (statins)

These agents have a powerful LDL-C lowering effect and those currently approved for use differ only in their dose–response curves and unit cost.

Mevastatin was first isolated in 1976 by Endo and colleagues as a natural product from *Penicillium* species. A related natural product, lovastatin, was approved by the FDA for cholesterol lowering in 1987. Subsequently, simvastatin, pravastatin, fluvastatin, atorvastatin, cerivastatin, and rosuvastatin were developed and approved for use in the US.[11] Cerivastatin was withdrawn later because of adverse effects.

Mechanism of action: lipid-altering effects

Brown et al demonstrated that lovastatin inhibits HMG-CoA reductase, the rate-limiting enzyme in cholesterol biosynthesis.[13] Statins occupy a portion of the binding site of HMG-CoA reductase, blocking access to the active site of the enzyme.[14] Total body cholesterol synthesis is reduced by at least 20%. Ultimately a critical reduction in cholesterol concentration occurs in the liver cell, leading to enhanced production of hepatic LDL receptors[15] and increased cellular uptake of LDL-C. Further, reduced very (V) LDL biosynthesis occurs via an effect upon hepatic Apo B secretion, as well as an increased rate of VLDL catabolism.

Pleiotropic effects

In addition to reducing cholesterol biosynthesis, other potential antiatherogenic mechanisms of action for the statins are under current, intense investigation but remain speculative. Pleiotropic effects of statins on the vascular system and the arterial walls – affecting endothelial function, inflammation, coagulation, plaque stabilization, and smooth muscle cell migration – have been identified.[16–18] The small GTP-binding protein, Rho, has membrane localization and may mediate the direct vascular effects of statins.

The PRINCE study provides clinical evidence of anti-inflammatory properties of a statin.[19] In this prospective, randomized, cohort study, pravastatin lowered levels of C-reactive protein (CRP), an inflammatory biomarker that is predictive of cardiovascular risk. Decreased CRP levels were seen as early as 12 weeks in pravastatin-treated participants ($P < 0.001$). Pravastatin lowered the median CRP level by 16.9% versus placebo ($P < 0.001$) at 24 weeks. The decreases occurred in both the primary and secondary prevention groups and regardless of sex, age, smoking, body mass index, baseline lipid levels, diabetes, and use of aspirin or hormone replacement therapy.[19]

Results of the PPP Project – a meta-analysis of three large, placebo-controlled, randomized trials including almost 20 000 patients and 102 559 person-years of follow-

up – provide further clinical evidence that statins may be anti-inflammatory and/or antithrombotic. In particular, statins may be beneficial in reducing strokes.[20] Pooled data from two of the trials, CARE and LIPID, involving more than 13 000 patients, showed a 22% reduction in total strokes and a 25% reduction in non-fatal stroke [20] The third trial, WOSCOPS, had a smaller trend for reduction in total stroke. Pravastatin reduced the risk of non-hemorrhagic stroke over a wide range of lipid values in patients with documented CHD.[20]

In the MIRACL trial, atorvastatin (80 mg/day) reduced early recurrent ischemic events in patients with acute coronary syndromes.[21] The statin was initiated 24–96 hours after an acute coronary syndrome to over 3000 adults with unstable angina or non-Q-wave myocardial infarction (MI). In the atorvastatin group, 14.8% of patients had a primary endpoint (death, non-fatal acute MI, cardiac arrest with resuscitation or recurrent symptomatic myocardial ischemia requiring emergency rehospitalization) versus 17.4% in the placebo group ($P = 0.048$).[21] The MIRACL investigators suggest that patients with acute coronary syndromes begin statin therapy before hospital discharge, regardless of baseline LDL-C levels.

AVERT compared the efficacy of aggressive cholesterol-lowering therapy versus percutaneous transluminal coronary angioplasty in low-risk, stable patients with CHD. Aggressive lipid lowering was superior to angioplasty in patients with mild to moderate CHD. Atorvastatin was associated with a 36% reduction in ischemic events and a significant delay in time to first ischemic event.[22]

The CTT study, a meta-analysis of 14 randomized trials using statins in the prevention of CHD, found an approximate 1% reduction in coronary mortality and major vascular events for every 2 mg/dL reduction in LDL-C. These benefits were significant within the first year, but were greater in subsequent years. These results were consistent in all subgroups. There was no evidence that statins increased the incidence of cancer overall, or of any specific site.[23]

Dosage

The recommended dosages and described effects of these agents are shown in Table 12.1.[11]

Impact on lipid levels

All of these agents except atorvastatin and rosuvastatin will lower plasma total cholesterol by 20–40% and LDL-C by 25–45% at maximum approved doses. Triglycerides are reduced by 10–30%. HDL-C plasma levels are frequently increased by 5–10%, but the increases may be more modest or absent in patients with inherently low levels. Lp(a) levels are not affected.[11] Statin therapy alters small-dense LDL particles to a larger more buoyant form and also nor-

Table 12.1 Dose–response lipid and lipoprotein changes (% change)

Total dose (mg/d)	5	10	20	40	80
Total cholesterol reductions					
Lovastatin BID	19	24	29	34	
Simvastatin	19	23	28	31	36
Pravastatin		16	24	25	27

From *Physicians' Desk Reference*[11]

malizes the responsiveness of coronary vessels to vasoactive stimulus.[18]

Atorvastatin and rosuvastatin are more powerful members of the statin class. At the maximal dose of 80 mg/day, atorvastatin has resulted in reductions in total cholesterol of 45–50%, LDL-C of up to 60%, triglycerides of 35–45%, and Apo B levels of 35–40%.[11] Changes in plasma levels of Lp(a) are small, and increases in HDL-C are inconsistent, but may reach 12%.[24] Rosuvastatin is the most recently approved statin and is the most powerful agent of the class on a per mg basis. It has a long half-life (20 hours) and is not metabolized by the cytochrome P450 3A4.[25] It has been shown to reduce LDL-C by up to 65%. Atorvastatin and rosuvastatin are somewhat more effective in lowering triglycerides than the other statins, and do so in a dose-dependent fashion.[26]

Part of the variability of the lipid response, and side effects of the statins, may be due to genetic differences in the rate of drug metabolism. The CYP2D6 phenotype can

affect both lipid lowering and tolerability of simvastatin.[27] In addition, it has been shown that polymorphisms of the HMG-CoA reductase gene can affect lipid response to statin therapy.[28]

Adverse reactions

Overall adverse reactions occur in less than 2% of individuals. From 1% to 3% of persons taking a statin will have dose-related, elevated, hepatic enzyme levels.[29] While most studies document no abnormalities,[1,3,30] most abnormalities that do occur are seen within the first three months of treatment and require monitoring.[29] In patients who abuse alcohol, there is an increased risk of hepatic toxicity. An extremely low incidence of adverse events (not significantly different from placebo) has been documented over 5.5 years in the Heart Protection Study (HPS).[3]

Statins compete with other drugs for specific metabolic pathways of the cytochrome P450 system, whose enzymes act as a major catalyst for drug oxidation in the liver.[31] Lovastatin and simvastatin undergo extensive first-pass metabolism by CYP3A4, and caution is urged in using them with cyclosporin (a known inhibitor of CYP3A4), particularly when other inhibitors of the cytochrome P450 system, such as azole-derived antifungal drugs, erythromycin and clarithromycin, are in use, as well as nefazodone and many HIV protease inhibitors. Atorvastatin is also at least partially metabolized by this pathway. Fluvastatin is metabolized mostly by CYP2C9 and few drug–drug interactions have been noted. Pravastatin has less potential for drug interaction with other substrates, inhibitors or inducers of the CYP3A4 and CYP2C9 systems than the other statins because it is metabolized by sulfation, not the cytochrome system.[31]

About 10% of individuals taking statins may develop myalgias, but perhaps 90% of these symptoms are not related to statin therapy. Statin-induced myalgias and myopathy are most commonly associated with progressive, symmetric symptoms of the hip and shoulder girdles. Many of these patients report muscle pain without concomitant elevations of creatinine kinase (CK). Caution must be used in interpreting CK elevations as they can be increased due to even minor trauma or in sporting activities, and can be caused by other conditions such as hypothyroidism. However, one should consider discontinuing statin therapy if CK increases by more than threefold. Rare (less than 0.1%) and reversible increases of greater than 10-fold in CK levels have been described. The mechanism of muscle injury with statins remains poorly defined, although according to a recent publication it may be related to the HMG-CoA reductase mediated isoprenylation of muscle proteins.[32] Statin-associated myopathy, although rare, can progress to rhabdomyolysis.[33] This effect can be seen with any statin; however, cerivastatin was voluntarily withdrawn from the world market in 2001 because of an increased rate of rhabdomyolysis compared with other statins.

There are reports of statin use associated with a variety of other potential adverse effects including renal dysfunction, cognitive impairment, increased risk of cancer, peripheral neuropathy, a drug-induced lupus-like state, and cataracts. Despite extensive and widespread use of these agents, no report has established a causal relationship to the use of statins.

Clinical use

Although the biggest proportional reduction in LDL-C levels occurs at low doses, the clinical response to statins is dose dependent, and it appears to be independent of patient characteristics, such as age, gender, smoking status and initial lipid and lipoprotein levels.[34] ATP III calls for LDL-C lowering drug therapy in persons with CHD and CHD risk equivalents when the LDL-C is ≥130 mg/dL (3.38 mmol/L).[7] In persons with two or more risk factors for the development of CHD, ATP III suggests that lipid-lowering drug therapy also begin at LDL-C levels ≥130 mg/dL (3.38 mmol/L).[8] For those at very high risk, a more aggressive LDL-C goal of <70 mg/dL (1.82 mmol/L) is considered a therapeutic option. This goal should also be considered in those at high risk but with a baseline LDL-C level <100 mg/dL (2.60 mmol/L).[8]

ATP III also recommends that LDL-C be measured, either at admission or within 24 hours, in all patients hospitalized with a major coronary event.[7] Lipid-lowering drug therapy should be initiated at hospital discharge in a person with a coronary event or procedure if LDL-C is ≥130 mg/dL (3.38 mmol/L).[7] Treatment initiation at hospital discharge takes advantage of patients' likely higher motivation to comply with therapy at that time and may avoid the "treatment gap" that can occur if outpatient follow-up is less consistent.

Nicotinic acid

In the early 1950s Attschult noted profound reductions in plasma total cholesterol and triglyceride levels in association with use of nicotinic acid. Nicotinic acid has the most marked clinical effect on triglycerides and HDL,[35] and is the only lipid-altering agent to consistently lower Lp(a) plasma levels.[36] It also can alter small-dense LDL particles to larger, more buoyant forms.[36] A complete review of this agent has recently been published.[37]

Mechanism of action

Nicotinic acid's predominant effect on plasma lipid levels is to reduce production of VLDL particles, with sub-

sequently reduced production of intermediate-density lipoprotein (IDL) and LDL particles. Nicotinic acid's major effect on VLDL metabolism results from inhibition of hormone-sensitive, lipase-induced lipolysis in adipose tissue, and decreased triglyceride esterification in the liver. It has recently been demonstrated that niacin exerts its effects by acting as a pharmacologic ligand for the adipocyte and macrophage G protein coupled receptor HM74.[39] The physiologic ligand for this receptor is beta-hydroxybutyrate.[40] Niacin increases HDL-C to a greater extent than other lipid treatment drugs, and this effect appears to be related to reduced Apo A-I clearance and increased production of Apo A-II.

Dosage

Crystalline nicotinic acid is available in 0.1 and 0.5 g tablets. There is a sustained-release form in dosages of 0.125, 0.25 and 0.5 g and the maximum daily dose is usually 3 g (Table 12.2). A new extended-release form of niacin has relatively mild hepatic effects, and can be taken at bedtime to lessen cutaneous flushing. Extended-release niacin is essentially equivalent to immediate-release niacin in increasing HDL-C. Newer agents that reduce flushing are in development.

Results

Regardless of the patient's clinical lipoprotein abnormality, dose-dependent reductions in total and LDL-C and plasma triglycerides have been achieved with use of nicotinic acid. HDL-C levels may increase 15–40%; the average increase is 25%, with increases commonly plateauing at a dosage between 1.5 and 3.0 g/d. Reductions in Lp(a) of 25–30% can be achieved.[41] As noted above, small-dense LDL particles become larger and more buoyant during nicotinic acid therapy.[42]

Adverse reactions

Even at very low doses (0.05–0.10 g), nicotinic acid often causes cutaneous flushing (>80%) and pruritus (50%). This effect is due to the subcutaneous release of prostaglandin D2 and is mediated by niacin's interaction with the G protein coupled receptor HM74 (as is its lipolytic effect, see above).[43] There is an ongoing search for agents that block this prostaglandin D2-mediated flushing. In individuals with a history of gout it can precipitate acute gouty attacks. Other frequently noted adverse effects are gastrointestinal symptoms (5–20%), liver enzyme elevations (3–10%, and

Table 12.2 Summary of effects of non-statin lipid-altering agents

Agent	Lipid/lipoprotein indication	Dosage and dosing	Response expected	Common adverse effects	Comments
Nicotinic acid	↑Triglyceride (TGs) ↑LDL-C ↓HDL-C ↑Lp(a)	1–3 g/d 6–8 g/d maximum Dose 3–4 admin/d	↓TGs 20–80% ↓LDL-C 25–40% ↑HDL-C 25% ↓Lp(a) 10–30%	Cutaneous flushing, pruritus, GI symptoms, "Flu-like" syndrome	Start low dose Advance slowly Relative contraindications: ↑FBS, ↑Liver function test (LFTs)
Bile acid sequestrants	↑LDL-C ↓HDL-C	4–24 g cholestyramine 5–30 g colestipol 2 admin/d,1 at major meal	↓LDL-C 25–35% at maximum dose ↑TGs 15–20% ↑HDL-C 4–7%	GI symptoms	Premix, slow admin Alters absorption of other drugs, for example, glycosides, warfarin, etc. Contraindicated in hypertriglyceridemia

more common with slow release prerparations), and uric acid increases (5–10%). The clinical picture of mild liver function abnormalities usually resolves with continued therapy or reduced doses.

Some 5–10% of patients taking nicotinic acid will have abnormal glucose tolerance tests or elevated fasting blood sugar levels due to nicotinic acid-induced insulin resistance.[44] A flu-like syndrome that can include hepatitis-like findings on liver biopsy, a secretory defect with profound decreases in LDL-C, decreases in HDL-C and a prothrombin time abnormality may occur. This clinical picture is dose dependent and resolves when the agent is stopped.[45] Blurred vision with macular edema occurs very rarely.

Clinical use

Many non-prescription forms of nicotinic acid are available in the US and are usually less expensive, but bioavailability may be a problem. Crystalline-form tablets are scored, which allows easy tailoring of the therapeutic regimen, e.g. 0.1 or 0.25 g/d as a starting dose. Dosing with the crystalline form requires three or four administrations a day. No regimen has been shown to be superior to multiples of 0.1 g crystalline tablets administered four times a day. Patients will have little or no effect from two administrations a day, unless using sustained-release preparations. Increases in the dosage are implemented every few days.[46] Clinicians commonly reduce the number of administrations to three times per day and use 0.5 g tablets starting with 0.25 g qd for the first week.

Nicotinic acid should always be taken with food, without hot drinks or alcoholic beverages. Dosages should be reduced or perhaps restarted if several successive doses are missed. Cutaneous flushing and pruritus will occur routinely if these precautions are not followed. If symptoms occur, they are the most severe during the first administration. Pretreatment with aspirin or ibuprofen may lessen cutaneous reactions.

Although nicotinic acid may profoundly alter glucose metabolism in some, many diabetic patients have had their lipid disorders successfully managed with this agent. A fasting blood sugar >115 mg/dL predicts subjects who will lose the acute insulin response with an intravenous glucose tolerance test. In patients who have a history of diabetes or glucose intolerance or are at increased risk of diabetes, it is prudent to follow blood sugars closely during initiation of nicotinic acid therapy.

Bile acid-sequestering agents (resins)
(see Table 12.2)

This class of agents was first developed for the treatment of cholestasis-related pruritus by Carey and Williams in 1960. Hashim and Van Itallie subsequently demonstrated that cholestyramine lowered plasma cholesterol and it has been in clinical use for 30 years. Other agents in this class are colestipol and the recently approved colesevelam.

Mechanism of action

The enterohepatic circulation of bile acids allows for only 6% or 7% of them to be excreted each day. These polymers have a molecular weight of over 10^6 and are not absorbed and function by binding bile acids in the gastrointestinal lumen. An increase in bile acid excretion causes an increased production of bile acids in the liver. This results in a relative depletion of cholesterol from the liver cells, thereby inducing inducing an increased level of hepatic LDL receptor activity.[47] The net effect is an increase in the catabolism of LDL-C and decreased plasma levels.

Dosage

Resins are dispensed in individual packets and are also available in a bulk formulation. Scoops, equivalent in size to the number of grams in one packet (cholestyramine, 4 g; colestipol, 5 g), are used to dispense from the parent container. Both of these agents are available in 1 g tablets. The newest resin, colesevelam, has a hydrogel tablet formulation.

Results

Resins are associated with significant reductions in plasma total and LDL-C and with small increases in plasma HDL-C levels.[48] Plasma triglycerides are inconsistently affected, but substantial increases may occur, if resins are used in those with already elevated plasma triglyceride levels.[49] In familial dysbetalipoproteinemia (type III or remnant removal disease) plasma triglyceride levels may increase by more than threefold.

Adverse reactions

No long-term adverse effects have been demonstrated.[48] Drugs that are highly charged, including the cardiac glycosides, the anticoagulant warfarin, diuretic agents, as well as thyroid hormone, will have their absorption affected[49] if taken in close proximity to resin administration. Concomitant warfarin and resin therapy may be extremely challenging. If a resin's effect on the absorption of a specific medication is not known, the resin should be taken at least four hours before or two hours after other medications. The absorption of fat-soluble vitamins may also be reduced.

Clinical use

The biggest proportional reduction in lipid levels occurs at low doses and in those who have moderately elevated

levels of cholesterol. Careful selection of the vehicle and logistics used in resin administration will promote long-term patient adherence. Premixing with cold water (taking advantage of the resin's hygroscopic nature) and drinking the preparation slowly is by far the most frequent and successful method of administration. Still, some patients prefer mixing with a heavily textured juice. Pre-existing gastrointestinal symptoms should be addressed before resin therapy is started. Bloating, belching and increased flatus are related to rapid ingestion. Dyspepsia and increased stool consistency or frank constipation can be managed with increases in fluids or dietary fiber intake.

The newest agent in the resin class is colesevelam, which is a polymeric, high-potency, water-absorbing hydrogel with a non-systemic mechanism of action.[50] Based on data from approximately 1400 subjects, colesevelam reduced LDL-C by a median of 20%; the reduction is dose dependent. When combined with lovastatin, simvastatin or atorvastatin, colesevelam will reduce LDL-C levels by 8–16% over that seen with the statin alone.[50] Colesevelam has also been shown to increase HDL-C up to 9%; however, increases in triglycerides, as much as 25%, have also been reported.[50] Colesevelam does not cause constipation and is formulated as a tablet, which should eliminate palatability problems.[51] Colesevelam has been co-administered with digoxin, warfarin, sustained-release metoprolol and verapamil, quinidine and valproic acid, and no clinically significant effects on absorption were reported.[52]

Fibric acid derivatives (see Table 12.2)

The fibrates currently marketed in the US are gemfibrozil and fenofibrate for the treatment of hypertriglyceridemia. Fibrates available in other countries include bezafibrate, fenofibrate, ciprofibrate, beclafibrate, etiofibrate and clinofibrate. In a WHO study clofibrate was shown to reduce modestly ($P < 0.05$) all cardiovascular events. However, increases in non-cardiovascular morbidity and mortality and total mortality occurred.[53] In the Helsinki Heart Study, gemfibrozil was associated with a 35% reduction in MIs, particularly in those with elevated levels of plasma LDL-C and triglycerides and low levels of plasma HDL-C. Increases in non-cardiovascular deaths and no reduction in total mortality were observed,[54] leading to concerns about the use of fibrates. No fibrate trial has yet shown a significant decrease in total mortality.

Gemfibrozil has been shown to lower the risk of CHD and stroke in men with previous CHD, and low HDL-C and low LDL-C levels. In VA-HIT,[55] 2531 men with CHD (mean HDL-C 31.5 mg/dL and mean LDL-C 111 mg/dL) were randomized to receive gemfibrozil 1200 mg/day or placebo. There was a 22% reduction in CHD over five years.[55] A more recent VA-HIT analysis describes the effect on stroke. There were 134 confirmed strokes (90% ischemic), 76 and 58 in the placebo and gemfibrozil groups, respectively ($P = 0.03$). This is the first suggestion that stroke can be reduced with a form of lipid-altering therapy that has little effect on LDL-C. Risk reduction was evident after 6–12 months of gemfibrozil use. Adjusted for baseline variables, the relative risk reduction was 31%.[56] Attributing the reduction in CHD to a change in HDL-C levels has been questioned by some. Clearly the reduction in CHD may more properly be associated with changes in other lipoprotein particles[57] than with modest changes in HDL-C levels. The use of fenofibrate in type 2 diabetes mellitus has been assessed in the FIELD trial.

Mechanism of action

Decreased synthesis of VLDL with more efficient lipolysis and increased VLDL triglyceride catabolism has long been suggested as the mechanism of action of fibrates on lipid metabolism. Schoonjans *et al* offered direct evidence that fibrates and fatty acids work as ligands for a class of compounds called peroxisome proliferator-activated receptors (PPAR), of the nuclear receptor superfamily.[41] PPAR alpha partially mediates the inductive effects of fibrates on HDL-C levels by regulating the transcription of HDL apolipoproteins, Apo A-1 and Apo A-II. Four specific actions are noted:
- increased hydrolysis of plasma triglycerides due to induction of LPL and reduction of Apo-CIII expression
- stimulation of cellular fatty acid uptake and conversion to acyl-CoA derivatives due to increased expression of genes for fatty acid transport protein and acyl-CoA synthetase
- increased peroxisomal and mitochondrial beta-oxidation
- decreased synthesis of fatty acids and triglycerides with a concomitantly decreased production of VLDLs.

Gemfibrozil was associated with a greater reduction in clinical events than the change in lipid variable would predict.[55] This suggests that its effects on CHD are mediated by a different mechanism, possibly related to its effects on other lipoprotein particles. Fibrates also shift the size of LDL particles from smaller, denser forms to larger, more buoyant forms, which should be less atherogenic.

Results

In patients with familial combined hyperlipidemia, LDL-C levels may be reduced by fibrates but, particularly in those with elevated baseline levels of plasma triglycerides, there will almost uniformly be an increase in LDL-C levels as VLDL-C levels decrease. Gemfibrozil and clofibrate have similar impacts on lipids and lipoproteins. In patients with moderate to severe forms of hypertriglyceridemia, reduc-

tions in plasma triglycerides of 40–60% may occur with concomitant increases of 12–30% in HDL-C levels, but 100% increases in LDL-C may occur.[12]

Adverse reactions

Fibrates are associated with adverse effects in 5–10% of patients. Gastrointestinal side effects (5%) are the most common, but only rarely are these sufficient to warrant discontinuation of the medication. The increased incidence of hepatobiliary disease (particularly gallstones) occurs with all agents in this class.[58] Transient and dose-dependent minor alterations in several plasma biochemical values may occur. The effective non-toxic dose range is narrow, and at high doses fibrates may cause myositis or rhabdomyolysis, although the incidence of myositis may be specifically related to the concomitant use of statins and fibrates. They may potentiate the effects of oral anticoagulants and oral hypoglycemics.

Clinical use

The primary indication for the use of these agents has shifted to treatment of severe hypertriglyceridemia and more specifically familial dysbetalipoproteinemia or remnant removal disease. Long-term adverse effects on hepatobiliary function and the potential for increases in LDL-C levels, liver function tests and LDL-C levels must be monitored closely. Chronic renal failure requires a 50% reduction in gemfibrozil dose.[59]

Selective cholesterol absorption inhibitor

Ezetimibe is a novel cholesterol absorption inhibitor that selectively and potently inhibits intestinal absorption of dietary and biliary cholesterol without affecting the absorption of triglycerides or fat-soluble vitamins.[60] In a randomized, double-blind, placebo-controlled trial, ezetimibe at a dose of 10 mg/day reduced LDL-C by 17%.[61] Ezetimibe has been found to be effective when added to a statin, demonstrating essentially additive effects.[62] It is frequently used with a statin, allowing lower doses of the statin with the same LDL-C goal, which may be helpful in limiting muscle side effects. It is available in fixed combination with simvastatin.

Ezetimibe has been well tolerated in clinical trials.[61,63] When used alone, the incidence of transminase elevations or myopathy is similar to placebo. When used with a statin, the incidence of transaminase elevations is modestly higher than with a statin alone. There are rare reports of myalgia and rhabdomyolysis being associated with the use of ezetimibe, but a causal relationship has not been established. The fibrates have been shown to increase ezetimibe levels[64]

but the clinical significance is unknown. The combination has been used successfully, and safely.[65]

Reports (unpublished at present) for the ENHANCE study have raised questions about the usefulness of ezetimibe in a regimen with a statin for LDL lowering. To date, the reports on this trial using a surrogate outcome measure with limited power to assess clinical events suggest that we need further evaluation of this agent before we can form a definitive opinion about its effectiveness.

Novel agents

Policosanol is a phytochemical that is a mixture of higher primary aliphatic alcohols isolated from sugar cane wax.[66] At dosages of 10–20 mg/day, it decreased total-C by 17–21% and LDL-C by 21–29%, while raising HDL-C by 8–15%.[50] Policosanol appears to have an acceptable safety/tolerability profile.

Cholesterol ester transfer protein (CETP) inhibitors have generated much excitement due to their potential to raise HDL-C levels. These agents have been shown to decrease diet-induced atherosclerosis in rabbits, and to be very effective in raising HDL-C levels in humans.[67] However, there has been skepticism about the potential for benefit in reducing atherosclerotic complications based on the assertion that the HDL particles that result from CETP inhibition, although increased in numbers, are "dysfunctional" and unable to function appropriately in reverse cholesterol transport.[68]

Recent trials evaluating coronary atherosclerosis by intravascular ultrasound, and carotid intimal thickness by ultrasound demonstrated no benefit of a combination of atorvastatin plus the CETP inhibitor torcetrapib versus atorvastatin alone, and did demonstrate a significant increase in systolic blood pressure as well as HDL-C.[69,70] A large clinical trial of approximately 15 000 CHD patients randomized to atorvastatin or a combination of atorvastatin plus torcetrapib was prematurely terminated by the data and safety monitoring committee because of excess mortality ($P < 0.01$). In patients who received torcetrapib there was an increased risk of cardiovascular events (hazard ratio, 1.25, $P = 0.001$) and death from any cause (hazard ratio, 1.58, $P = 0.006$).[70] Whether these negative and adverse outcomes represent a class effect remains to be seen.

There are other means of attempting to utilize reverse cholesterol transport in the amelioration of atherosclerotic disease. Five weekly infusions of Apo A1 Milano complexed with phospholipids provided more benefit on atheroma regression assessed by intravascular ultrasound than 18 months of treatment with 80 mg/day of atorvastatin.[71] More recently, a trial of reconstituted HDL, administered as four weekly infusions in CHD patients, were compared to placebo by intravascular ultrasound. A 3.4%

reduction in total atheroma volume versus baseline was reported ($P < 0.001$), but no difference was seen versus the placebo group.[72]

Combination therapy

Combination drug therapy should be used when diet and single drug therapy do not reduce LDL-C to desired levels. Verification of adherence to and the efficacy of a prescribed regimen should be undertaken. Table 12.3 describes a stepped approach to combination therapy depending on the lipid or lipoprotein variable(s) that are the therapeutic objective. Reduction in LDL-C is the only alteration in lipid(s) or lipoprotein(s) that has been unequivocally demonstrated to reduce risks for CHD in clinical trials. Epidemiologic data demonstrate an increased risk associated with reduced levels of HDL-C,[41] increased plasma Lp(a) (usually in association with increased LDL-C levels) and, to a lesser extent, increased plasma triglyceride levels (usually in association with other risk factors).

Guidelines for selecting combination therapy

Practitioners should review four issues before adding other agents to initial diet and lipid-altering drug regimens.
• Document adherence to and efficacy of the initial regimen.
• Fasting hypertriglyceridemia is a relative contraindication to the use of bile acid-sequestering agents.
• Document the presence of chronic disease or chronic conditions which may be contraindications to the addition of other lipid-altering agents.
• Consider the total costs of a lipid-altering drug therapy regimen before the addition of each agent.

Efficacy of various combinations

Selected examples of maximum lipid and lipoprotein alterations are given in Table 12.4. Prior to the development of atorvastatin, the maximum lowering of LDL-C was demonstrated with a combination of lovastatin (40 mg/day), colestipol (30 g/day) and nicotinic acid (5.5 g/day) at 70%. Triglyceride reductions of 80% can be effected with nico-

tinic acid alone with little to be gained in efficacy by adding another agent. Lp(a) levels are affected substantially only by nicotinic acid. HDL-C can be consistently raised by 25% with nicotinic acid alone with little further gain by adding other agents.

Adverse effects

The important adverse effects of single agents are described in Table 12.2. The most serious interaction is seen when a statin drug is used in combination with ciclosporin and myopathy develops. While cessation of the statin allows symptomatic myopathy and elevated muscle enzymes to resolve, continued therapy at the same dose may lead to frank rhabdomyolysis. Statins have also been associated with myopathic syndromes in patients using erythromycin, niacin and gemfibrozil. Reduced levels of any statin should be used in transplant patients in association with niacin and gemfibrozil with careful monitoring of muscle enzyme levels. Erythromycin use is absolutely contraindicated in transplant patients already on ciclosporin and a statin.

Clinical use

Although single-drug therapy offers a simple regimen, combination therapy with low-dose statin and low-dose bile acid sequestrant has been investigated.[73,74] Since the largest portion of lipid alteration is effected at low doses of both of these classes of agents and they work by very different mechanisms, an additive or synergistic response may occur. Low-dose combinations provide a good clinical alternative for patients who have symptoms at higher statin dosages and for organ transplant patients. They also appear to be more cost effective than using a statin as a single agent. The combination of simvastatin and ezetimibe is available as a single tablet. It also is significantly more cost effective than using the individual agents in combination.

The newest resin, colesevelam, has been studied in combination with statins. Low-dose colesevelam and low-dose lovastatin were given to 135 hypercholesterolemic patients.[75] The combination lowered LDL-C by 34% and 32%. Both combinations were superior to either agent alone, and both decreased total-C by 21%. Neither combination treatment significantly changed HDL-C or

triglycerides.[75] The resin was also studied alone or in combination with low-dose atorvastatin in hypercholesterolemic men and women. Combination therapy reduced LDL-C by 48%, but did not affect triglycerides.[76] All treatment groups had similar frequency of adverse effects and the combination was well tolerated.[76] Colesevelam, in combination with simvastatin, was given to 251 hypercholesterolemic patients in a randomized, double-blind, placebo-controlled format. Among all combination treatment groups, the mean decrease in LDL-C was 42%; this exceeded the decrease with either simvastatin or colesevelam alone.[77]

Informed decisions about "gray zones"

Data have now accumulated on the use of lipid-lowering drugs in previously less well-studied subgroups such as the elderly, women, and diabetic patients. How and when should we use lipid-lowering drugs in the following groups?

The elderly

While some have suggested that risk attenuates for those who have hypercholesterolemia at older age, the absolute risk for developing CHD outcomes in the elderly over a short time interval is much higher than it is in younger individuals. Most new CHD events and most coronary deaths occur in persons older than 65 and a high LDL-C/low HDL-C level still has predictive power for development of CHD in an older person.[7]

WOSCOPS[2] (primary intervention, or PI) included patients up to the age of 64 years, 4S[1] (secondary intervention, or SI) up to the age of 70 years, Post-CABG[6] (SI) up to 74 years and CARE[4] (SI) previously provided limited data for those up to 75 years. All except Post-CABG showed benefit on CHD and CVD mortality. WOSCOPS and 4S showed benefit on total mortality, although statistical significance of the data from WOSCOPS was marginal. When data from WOSCOPS were pooled in the PPP, pravastatin significantly reduced relative risk of coronary events in older patients.[78]

The Heart Protection Study (HPS) enrolled over 20 000 participants – including 5082 women, 3982 type 2 diabetic patients and 1263 elderly patients between the ages of 75 and 80 years. It also enrolled 3421 subjects with low baseline LDL-C levels, and follow-up lasted for 5.5 years.[3] Recently reported results show that a dose of 40 mg simvastatin once daily yielded striking results: 12% reduction in total mortality, 17% reduction in vascular mortality, 22% reduction in CHD events, 27% reduction in all strokes, and 16% reduction in non-coronary revascularizations.[3] Statin therapy appeared to be beneficial at all cholesterol levels – even in participants whose baseline levels were well below the currently recommended target levels of 100 mg/dL (2.60 mmol/L).[3]

The PROSPER trial randomized 5804 patients (men and women) aged 70–82 with a history of, or risk factors for, vascular disease to either 40 mg pravastatin or placebo.

There was a significant reduction in coronary death, non-fatal myocardial infarction or stroke (hazard ratio 0.81), but no decrease in all-cause mortality.[79]

The SAGE trial compared intensive and moderate statin therapy in patients age 65–85 with known CHD. Subjects were randomly assigned to 80 mg atorvastatin or 40 mg pravastatin. There was no difference in duration of ischemia on ambulatory monitoring at month 12, although there was a trend towards a reduction in the composite endpoint of major cardiovascular events in the intensive treatment group (hazard ratio (HR) 0.71) and a post hoc analysis demonstrated a significant reduction in mortality (HR 0.33).[80] In the TNT study, atorvastatin at 80 mg/day was compared to 10 mg/day in 10 001 patients with stable coronary heart disease. The more intensively treated group had a significantly reduced risk for major cardiovascular events in both those greater and those younger than 65 years of age. In a prespecified secondary analysis, those over 65 years of age were found to have a 2.3% absolute risk reduction, and a relative risk reduction of 19% for major cardiovascular events that favored the high-dose atorvastatin group.[81]

There appears to be ample evidence to support the use of lipid-lowering regimens in the secondary prevention of CHD in elderly individuals, while there are only limited data relevant to the use of lipid-lowering therapy in the primary prevention.

According to ATP III, "hard-and-fast" age restrictions do not appear to apply to the use of lipid-lowering drugs in elderly persons with established CHD.[7] For primary prevention, ATP III recommends therapeutic lifestyle changes, including low-fat diet, exercise, and weight loss if overweight, and LDL-lowering drugs if older persons are at increased risk because of multiple risk factors or advanced subclinical atherosclerosis.[7]

Women

The relationship between increases in plasma cholesterol and CHD exists for women at all ages. Based on recent secondary and primary prevention trials that did not convincingly show that hormone replacement therapy reduced CHD risk in postmenopausal women and did show benefits with statins, ATP III recommends a cholesterol-lowering drug over hormone replacement for CHD risk reduction in women.[10] The later onset of CHD in women should be factored into clinical decision making regarding cholesterol-lowering drugs.[7] In the PPP, pravastatin significantly reduced relative risk of coronary events in women.[20]

The first CHD primary prevention trial of statins to include women was the AFCAPS/TexCAPS trial.[53] Among 997 postmenopausal women who received either placebo or lovastatin (20–40 mg/day), statin therapy showed consistent but statistically insignificant decreases in first acute coronary major events and in all prespecified secondary endpoints.[53]

In HPS, 34% of subjects were women; male and female participants experienced similar reductions in risk.[3] In the CTT meta-analysis there was no significant difference in the vascular or mortality benefits of statin therapy in women versus men.[82]

Diabetic patients

Although aggressive control of blood glucose levels in type 2 diabetic patients reduces microvascular clinical outcomes, its effect on macrovascular disease outcomes remains unknown. The ACCORD study, currently in progress, may help answer this question.[38] Other traditional CHD risk factors are believed to increase dramatically the risk for clinical CHD events in these patients. Inherent in the diabetic disease process is an abnormality of lipoprotein lipase activity that is incompletely corrected by optimal glucose control. Any additional lipid and lipoprotein disorder(s) present in diabetic patients because of either inherited or secondary causes (obesity, alcohol consumption, etc.) accelerate atherosclerotic progression and increase the risk of clinical CHD events. Treatment of lipid disorders in diabetic patients with commensurate lowering of blood cholesterol levels suggests a similar treatment benefit in diabetic as in non-diabetic patients.[1,2,4,23]

The use of niacin in diabetic patients has not been recommended because of concerns about adverse effects on glycemic control. In ADMIT, however, niacin was given to diabetic patients in a prospective, randomized, placebo-controlled study enrolling 468 subjects, 125 of them with diabetes and diagnosed peripheral arterial disease.[44] Niacin was given at 3000 mg/day or to maximally tolerated dose, for up to 60 weeks. Niacin significantly increased HDL-C and decreased triglycerides and LDL-C in all participants ($P < 0.01$: niacin versus placebo for all). It modestly raised glucose levels in all participants while HbA_{1c} was unchanged from baseline through follow-up.[72] The ADMIT investigators conclude that lipid-modifying doses of niacin can be safely used in patients with diabetes and that niacin may be considered an alternative therapy in such patients who do not tolerate statins or in whom statins do not correct hypertriglyceridemia or low HDL-C levels.[44]

In CARE, 586 normocholesterolemic diabetic patients with CHD (14% of total sample) were given pravastatin or placebo for five years; there were 8% and 25% reductions respectively in absolute and relative risks of coronary events, and a 32% relative risk reduction in revascularization procedures.[53] In subjects who were not diabetic but who had impaired glucose tolerance, pravastatin also sub-

stantially lowered the risk of recurrent coronary events.[83] In PPP, pravastatin significantly reduced the relative risk of coronary events in diabetic patients.[78]

The HPS trial included 3980 persons with diabetes of whom 2930 had no CVD. As noted above, the event reductions seen with simvastatin occurred in diabetic patients as well. There was a 24% decrease in CVD and a 25% decrease in total CHD.[3] In the CTT meta-analysis, the vascular benefit of statin therapy was not significantly different in diabetic and non-diabetic subjects.[23] There were comparable reductions in all identified subgroups.

CARDS enrolled 2838 subjects with type 2 diabetes mellitus and without known cardiovascular disease. Participants were randomly assigned to receive 10 mg atorvastatin daily or placebo. The trial was stopped for early efficacy (median duration of follow-up of 3.9 years) as cardiovascular events were reduced by 37% in the atorvastatin group compared to placebo.[84] ASPEN had similar lipid inclusion criteria, although it included subjects with, and without, known CHD. After a median follow-up of four years there was no statistically significant reduction in the primary composite endpoint.[85] Adherence was a major confounding factor in ASPEN.

The FIELD trial randomly assigned 9795 type 2 diabetic patients to receive 200 mg micronized fenofibrate or placebo. Approximately a quarter of the patients had known prior cardiovascular disease. The fenofibrate was well tolerated as both monotherapy and in those who used it in combination with a statin. However, after a median follow-up of five years, a non-significant decrease in the modified primary outcome of coronary events was seen in the fenofibtate goup compared to the placebo (hazards ratio 0.89, 95% confidence interval (CI) 0.75–1.06). There was a non-significant increase in the original primary outcome of coronary mortality (HR 1.19, 95% CI 0.90–1.57), and a non-significant increase in all-cause mortality (HR 1.11, 95% CI 0.95–1.29).[86]

Peripheral vascular disease

In the Rancho Bernardo studies, patients with peripheral vascular disease had a several-fold increased risk of dying of CHD.[87] Greater than 80% of these individuals have CHD although some will manifest few symptoms. It is reasonable, but unsubstantiated, to treat these individuals as if they have CHD.

Small-dense LDL-C particles (phenotype B)

The entire population may be generally divided into two categories on the basis of the predominant LDL species present in plasma. People with a predominance of smaller, more dense LDL particles exhibit an increased propensity for oxidative susceptibility of these species. These individuals have a higher risk for CHD, which may be associated with changes in other plasma lipids, specifically an increase in triglycerides and reduced plasma levels of HDL. Alternatively, this pattern may be related to the insulin resistance syndrome, or syndrome X, which consists of impaired glucose tolerance, increased insulin levels, hypertension and abnormalities of coagulation factors. No trial of clinical outcomes and intervention on LDL subspecies has been done.

Key points for prevention of CHD/CVD

- Initiate LDL cholesterol-reducing therapy in individuals at increased risk of CHD. It is effective at reducing the incidence of CHD events in men and women and in ages up to at least 80 years of age **Class I, Level A**
- Initiation of LDL cholesterol-reducing therapy is cost effective in individuals above the age of 35.
- **Class I, Level A**
- Initiate LDL cholesterol-reducing therapy in individuals status post coronary artery saphenous vein bypass grafts. It extends the patency of such grafts. **Class I, Level A**
- In assessing CHD risk, the best single tool is the ApoB/ApoA1. **Class I, LevelA**
- Assess variables (NIDDM, hypertension, increased plasma triglycerides, low plasma HDL-C, small-dense LDL and increased PAI-1 levels) that are components of the so-called "insulin resistance syndrome". These variables appear to be a marker for individuals with small-dense LDLs. **Class II, Level C1**
- Assess plasma triglyceride and HDL-C levels in individuals with CHD. Although alteration in these levels has not been demonstrated conclusively to improve outcomes, there is a strong theoretical basis to support such intervention. **Class IIa, Level B**
- Consider initiation of appropriate therapy in high-risk individuals without initial determination of plasma lipid and lipoprotein levels, as treatment is effective even in those with low initial LDL levels. **Class I, Level A**
- Monitor LDL-C levels during treatment to assess for attainment of goals, and to monitor compliance. **Class I, Level C1**

Costs and cost effectiveness of lipid alterations for CHD prevention

True benefits for individuals and the public health have only been demonstrated for alteration of plasma LDL-C. One method for comparing the costs of cholesterol lowering is shown in Table 12.5 where the cost of the various statins is given in terms of the number of dollars per percentage of LDL-C lowering per year.

Until the release of results from the 4S study, reductions in CHD morbidity from plasma cholesterol-related CHD had been modest and reductions in CHD and total

Table 12.5 Comparative cost, dose and LDL-C lowering of statins

Agent	Dose (mg)	LDL-C b (%)[b]	↓	AWP ($/day)[c]	Cost/1%/LDLR ($/yr)
Lovastatin	10[a]	−21		1.36	23.63
	20	−24		2.37	36.04
Simvastatin	10[a]	−30		2.80	34.07
	80	−47		4.89	66.07
Pravastatin	20[a]	−32		3.27	37.29
	80	−37		4.79	47.29
Fluvastatin	20[a]	−22		2.53	41.97
	40	−24		2.53	38.47
Atorvastatin	10[a]	−39		3.03	28.35
	80	−60		4.32	26.16
Rosuvastatin	5[a]	−28		3.50	45.63
	10	−43		3.50	29.71

[c] From *Red Book Update*. Montvale, NJ: Medical Economics Company; 2007

Cost/1%/LDLR was derived as cost/year/1% LDL reduction.

mortality had not been demonstrated. Since elevated plasma cholesterol is a major risk factor for CHD and is prevalent in Western countries, evaluation of the cost effectiveness of plasma cholesterol lowering is important because of the size of the potential population for intervention and the associated healthcare costs of what can be lifelong medical therapy. In a sensitivity analysis,[88] data from 4S demonstrate cost effectiveness of intervention for both men and women from 35 to 70 years and at plasma cholesterol levels above 213 mg/dL. The estimates of treatment costs for benefits observed in the 4S study indicate that treatment is cost effective in both men and women and at all plasma cholesterol levels between 213 and 309 mg/dL and with evidence of vascular disease.

A WOSCOPS economic analysis comparing pravastatin with dietary changes alone showed the economic efficiency of therapeutic intervention with a statin.[89] Caro *et al* used a generalized model of cardiovascular disease prevention and followed hypercholesterolemic men over a given time period to quantify the effect on cardiovascular diseases avoided. Over a broad range of inputs and regardless of country, cost-effectiveness ratios are below $35 000 per life-year gained. Pravastatin is cost effective in preventing CHD.[89] Based on US medical price levels and the clinical trial evidence up to 1998, Hay *et al* concluded that statin therapy is cost effective (that is, cost less than $50 000/year of life saved) in any patient with an annual CHD risk >1%, including those with previous CHD or diabetes.[90]

In a recent cost-effectiveness analysis of the VA-HIT trial, the cost per year of life gained with gemfibrozil was estimated. Using prices for gemfibrozil paid outside the VA
Figure 12.1 Comparison* of cost effectiveness of different strategies in prevention. * Estimates from previous studies are in 1994–1995 UK pounds. (Adapted from Malik *et al*[92].)

system (a lower price has been negotiated by the VA), the cost of a quality-adjusted life-year saved by gemfibrozil ranged from $6300 to $17 000. This cost of a life-year saved is well below the threshold considered cost effective.[91]

Malik *et al*[92] provide a graphic demonstration of how cost effective statin therapy is versus other widely used therapies for CHD, such as ACE inhibitors, beta-blockers, and non-CV interventions, such as driver's side air bags (Fig. 12.1). The cost effectiveness threshold here is £25 000/year of life saved (US $50 000/year of life saved).

Future directions

The benefits of statins beyond the coronary vascular bed are now being intensively investigated. In addition to their lipid-lowering properties, statins demonstrate pleiotropic effects on many aspects of atherosclerosis, such as plaque thrombogenicity, cellular migration, endothelial function, and thrombotic tendency.[18] Whether or not these effects can be related to a decrease in progression of atherosclerosis or to reductions in acute coronary syndromes remains to be seen. Another area for more study is the benefit of moderate versus aggressive LDL lowering. For example, what are the risks and benefits of lowering LDL-C to 75 mg/dL compared to about 100 mg/dL? Heretofore, the major effort to ameliorate CHD through the treatment of lipid disorders has concentrated on LDL-C reduction. More recently, efforts to assess the benefits of manipulating HDL-C levels have intensified. The CETP inhibitors, although filled with promise, await further developments. It has recently been demonstrated that HDL-C levels are predictive of cardiovascular events in patients treated with statins, even in those with LDL-C levels less than 70 mg/dL.[93] Ongoing studies such as AIM-HIGH will help define potential benefits from treating low HDL-C levels. The increasing incidence of type 2 diabetes mellitus emphasizes the importance of delineating the most effective treatment strategies for diabetic dyslipidemia. Ongoing studies such

as ACCORD should contribute to our understanding of this issue, although this will remain an important area for further study.

Conclusion

The HMG-CoA reductase inhibitors are an important advance in the treatment of CHD and there is compelling evidence that LDL-C lowering with these agents can decrease the risk of CHD events and total mortality in both primary and secondary prevention. In addition to their effects on LDL-C, statins have pleiotropic effects, which may affect the development and the occurrence of clinical events of atherosclerosis. Lipid-lowering therapy benefits the elderly, women, and diabetic patients, even if these individuals have normal LDL-C levels. Effective single and combination-agent regimens for intervention for other plasma lipid and lipoprotein variables are also available.

Key points for using lipid-altering agents

Document the diagnosis of hyperlipidemia.

Do the patient's current medications cause dyslipidemia or offer potential for drug interactions with hypolipidemic therapy?

Assess the total risk for CAD by considering all risk factors.

ALWAYS start the therapeutic regimen with diet and other lifestyle modifications. **Class I, Level C1**

The statins act as a class of agents, but possess different dose–response curves. Some may have substantial levels of adverse effects. **Class I, Level A**

The currently approved statins have powerful lipid-altering effects and a very low order of adverse effects. **Class I, Level A**

Nicotinic acid is a powerful agent which can be effective in many people, including some diabetic patients when used carefully. **Class I, Level A**

Nicotinic acid is the most effective of any agent on HDL-C levels and the only one with a substantial effect on Lp(a). **Class I, Level B**

Resin therapy can be effective for lowering LDL-C plasma levels with careful attention to details of dosing and administration, particularly when added to low-dose statin or low-dose niacin. **Class I, Level A**

Fasting hypertriglyceridemia is a relative contraindication to primary or combination resin therapy. **Class I, Level B**

Fibrates are effective agents for lowering triglyceride, particularly when extremely high, and moderately raising HDL-C levels, but changes in LDL-C levels need to be monitored. **Class I, Level A**

Consider direct and indirect costs before initiating primary lipid-altering therapy and with the addition of each agent to the regimen.

Definition and classification

The Seventh Report of the Joint National Committee on the Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7)[1] defines normal blood pressure (BP) as systolic blood pressure (SBP) below 120 mmHg and diastolic blood pressure (DBP) below 80 mmHg. Hypertension is defined as SBP 140 mmHg or greater and/or DBP 90 mmHg or greater. Individuals with SBP 140–159 mmHg and/or DBP 90–99 mmHg are classified as stage 1 hypertension while those at or above SBP 160 mmHg and/or DBP 100 mmHg constitute stage 2 hypertension.

A new category designated prehypertension has been added, and it is defined as SBP between 120 and 139 mmHg and DBP between 80 and 90 mmHg (Table 13.1). Prehypertension is a designation chosen to identify individuals at high risk for developing hypertension, so that both patients and clinicians are alerted to this risk and encouraged to intervene and prevent or delay the hypertension from developing. Individuals who are prehypertensive are not candidates for drug therapy based on their level of BP and should be firmly and unambiguously advised to practice lifestyle modification in order to reduce their risk of developing hypertension in the future. This classification does not stratify hypertensive individuals by the presence or absence of risk factors or target organ damage in order to make different treatment recommendations. Should either or both be present, JNC 7 suggests that all people with hypertension (stages 1 and 2) be treated. The treatment goal for individuals with hypertension and no other compelling conditions is <140/90 mmHg. The goal for individuals with prehypertension and no compelling indications is to lower BP to normal levels with lifestyle changes, and

prevent the progressive rise in BP using the recommended lifestyle modifications.

Impressive evidence has accumulated to warrant greater attention to the importance of SBP as a major risk factor for cardiovascular disease (CVD). Clinical trials have demonstrated that control of isolated systolic hypertension (ISH), defined as SBP ≥160 mmHg and DBP <90 mmHg, reduces total mortality, cardiovascular mortality, stroke, and heart failure.[2,3] A Clinical Advisory Statement[4] recommends that SBP should be the principal measure for the detection, evaluation, and treatment of hypertension in both middle-aged and older individuals.

Diagnosis and evaluation of hypertensive patients should include assessment of other cardiovascular risk factors or concomitant disorders that may affect prognosis and guide treatment (Box 13.1) and looking for identifiable causes of high BP. Identifiable causes of high BP include chronic kidney disease, coarctation of the aorta, Cushing's syndrome and other glucocorticoid excess states including chronic steroid therapy, drug-induced or drug-related hypertension, obstructive uropathy, pheochromocytoma, primary aldosteronism and other mineralocorticoid excess states, renovascular hypertension, sleep apnea, and thyroid or parathyroid disease.[1]

Prevalence

Hypertension affects 20–30% of the world's population.[5,6] When the new JNC 7 classification was applied to a nationally representative sample of US adults, it was found that in populations aged 20 or greater, an estimated 41.9 million men and 27.8 million women have prehypertension, 12.8 million men and 12.2 million women have stage 1 hypertension, and 4.1 million men and 6.9 million women have stage 2 hypertension.[7] A higher percentage of men than women have hypertension before age 45. From age 45 to age 54, the percentages of men and women with hypertension are similar. After that, a much higher percentage of

Table 13.1 JNC 7 blood pressure classification for adults aged 18 years and older*

Category	Systolic/diastolic (mmHg)
Normal	<120/80
Prehypertension	120–139/80–89
Hypertension	≥140/90
Stage 1	140–159/90–99
Stage 2	≥160/100

*The classification is based on the average of two or more properly measured, seated BP readings in individuals not taking antihypertensive drugs and not acutely ill. When systolic and diastolic BP fall into different categories, the higher category should be selected to classify the individual's BP status. For example, 160/92 mmHg should be classified as stage 2 hypertension. Isolated systolic hypertension is defined as SBP ≥140 mmHg and DBP <90 mmHg and staged appropriately. For example, 170/82 mmHg is defined as stage 2 isolated systolic hypertension.

BOX 13.1 Components for cardiovascular risk stratification in patients with hypertension

Major risk factors
Tobacco usage, particularly cigarettes
Dyslipidemia*
Diabetes mellitus*
Age older than 65 years for women, 55 years for men
Estimate glomerular filtration rate (GFR) <60 mL/min
Family history of cardiovascular disease: women under age 65 or men under age 55
Microalbuminuria
Obesity* (body mass index ≥30 kg/m^2)
Physical inactivity

Target organ damage/clinical cardiovascular disease
Left ventricular hypertrophy
Angina/prior myocardial infarction
Prior coronary revascularization
Heart failure
Stroke or transient ischemic attack
Chronic kidney disease
Peripheral arterial disease
Retinopathy

*Components of the metabolic syndrome

women have high BP than do men.[8] The age-related changes in BP explain the increase in overall prevalence of hypertension with age and the increase in the prevalence of ISH with advanced age. From 1988–1994 to 1999–2002, the prevalence of hypertension in adults increased from 35.8% to 41.4% among blacks, and it was particularly high among black women, at 44.0%. Prevalence among whites also increased from 24.3% to 28.1%.[9] Prevalence of prehypertension in African Americans is lower at older ages because of a higher prevalence of hypertension.[10]

Natural history

Hypertension is one of the major risk factors for cerebrovascular disease (stroke), coronary heart disease (acute myocardial infarction (MI) and angina pectoris), congestive heart failure, and chronic renal disease. The risk is directly associated with the BP level and with the presence of target organ manifestations and other cardiovascular risk factors. Ferrucci et al[11] calculated the cardiovascular risk score for each participant in the Systolic Hypertension in the Elderly Program (SHEP) using the multiple risk factor assessment equation.[12] This simple risk score is based on age, sex, total and high-density lipoprotein (HDL)-cholesterol, SBP, smoking, and diabetes. In the placebo group, the five-year rates of MI, stroke, and heart failure were progressively higher with higher quartiles of risk score in those who were free of cardiovascular disease at baseline. The *relative* event protection conferred by chlorthalidone-based treatment was similar across quartiles of risk. Thus, the *absolute* risk reduction increased by quartile of risk. This was reflected in a 2- to 10-fold lower "number needed to treat" (NNT) to prevent hypertensive complications in the highest-risk quartile (Fig. 13.1). The authors concluded that hypertensive patients with additional cardiovascular risk factors should be the prime candidates for antihypertensive treatment. Even in the absence of additional cardiovascular risk in individuals 40–70 years of age, each increment of 20 mmHg in SBP or 10 mmHg in DBP doubles the risk of CVD across the entire BP range from 115/75 to 185/115 mmHG.[13] The classification of "prehypertension" introduced by the JNC 7[1] recognizes this relationship and signals the need for increased education of healthcare professionals and the public health to reduce the BP levels in the general population.

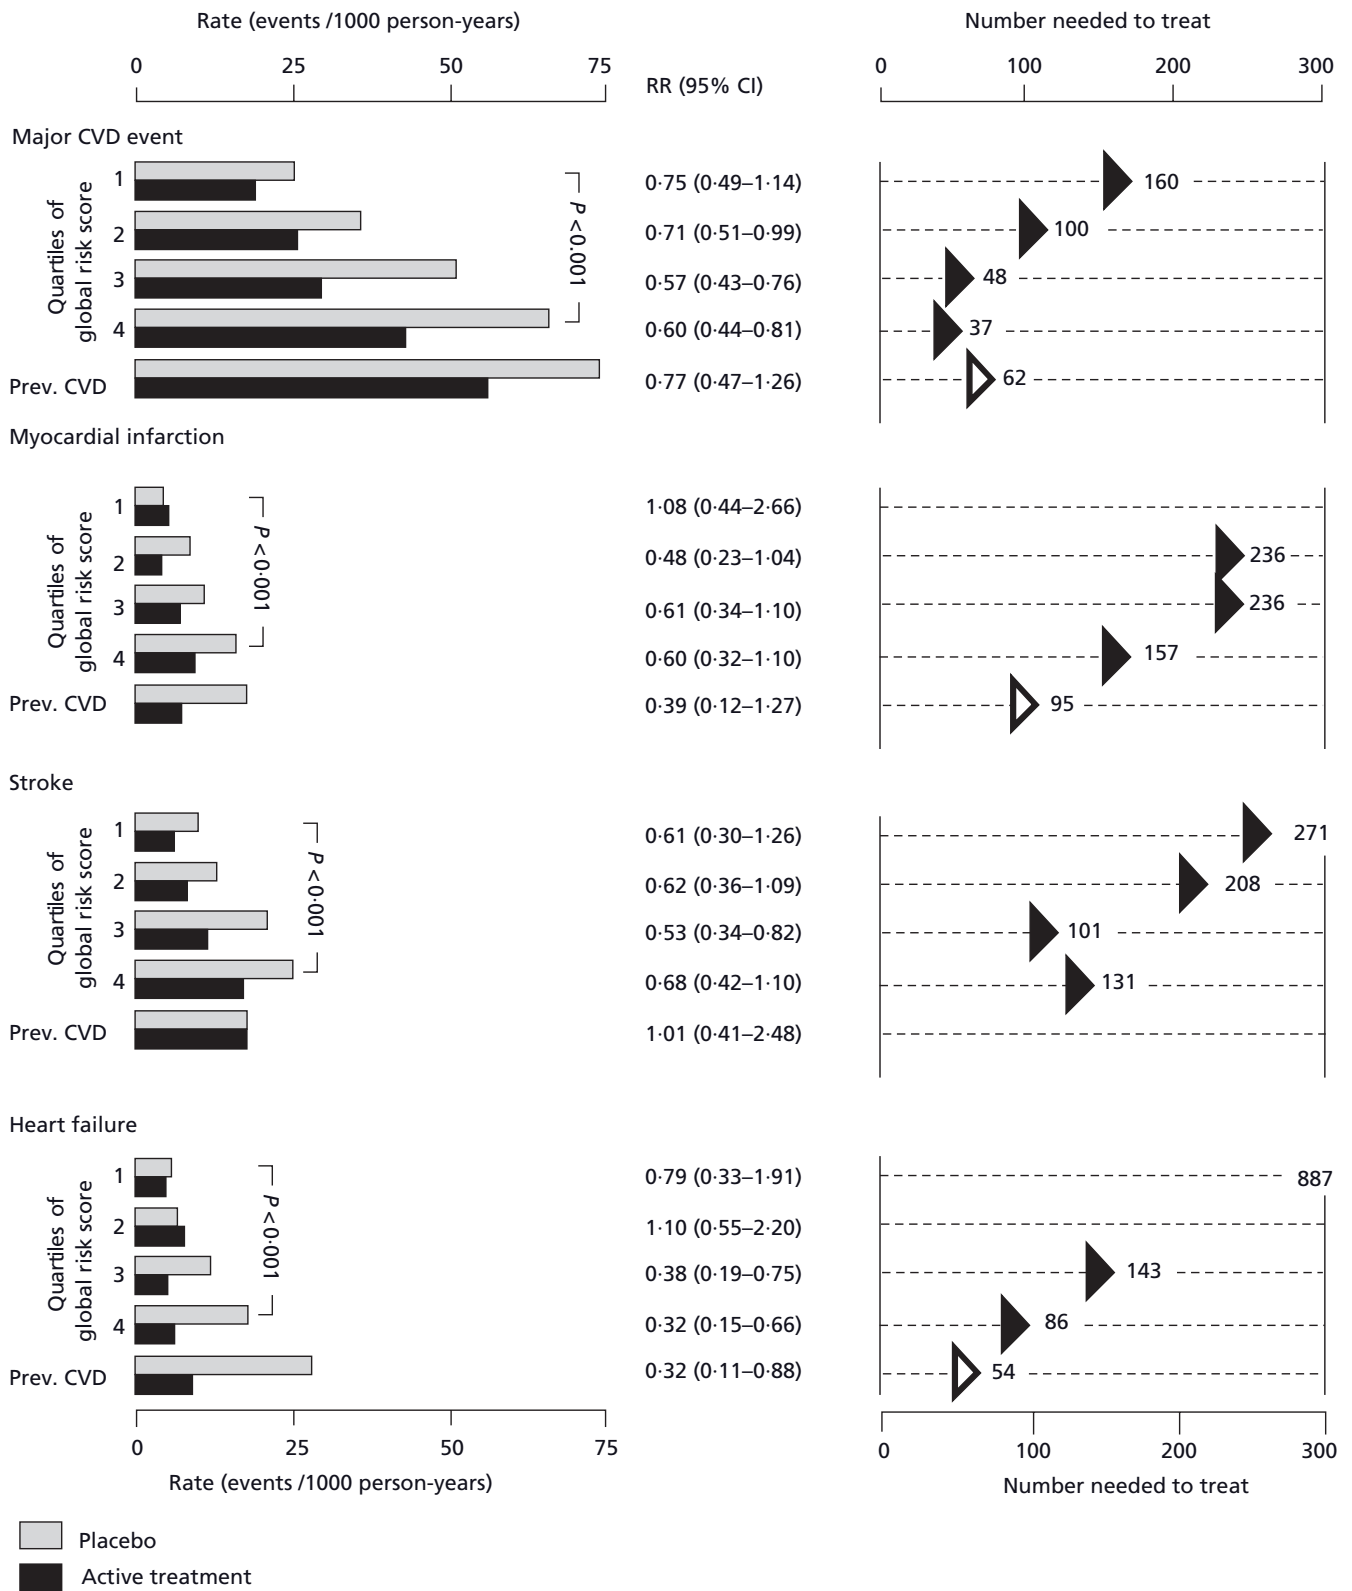
The article by Franklin and colleagues[14] provides additional data on the natural history of BP ranges of 130–139 systolic or 80–89 diastolic (prehypertension as defined by the JNC 7). After adjustment for age and sex, the incidence of ISH per 100 person-years was 22.8 among individuals with BP 120/80 to 129/84 and 35.4 among individuals with BP 130/85 to 139/89, as opposed to only 6.6 among individuals with BP less than 120/80. Furthermore, 59% of subjects who developed ISH did not have diastolic hypertension at the baseline visit or at any other visit before ISH onset. These data provide further support to the argument that prehypertension, intended as the combination of normal plus high-normal BP categories, is a useful working definition in the setting of cardiovascular disease prevention because it identifies individuals at increased risk of


Figure 13.1 Rates of new cardiovascular events, relative risks (RR), and 95% confidence intervals and estimates of NNTs by quartile of global risk score for SHEP participants free of CVD. The fifth group of bars in each panel shows data for subjects with prevalent (prev.) CVD at baseline. (Adapted from Ferrucci *et al.*[11])

developing progressive vasculopathy with stiffening of the aorta and elastic arteries over time.

Burden

Worldwide prevalence estimates for hypertension may be as much as 1 billion individuals, and approximately 7.1 million deaths per year may be attributable to hypertension.[15] It has been identified as the leading risk factor for cardiovascular mortality, and is ranked third as a cause of disability-adjusted life-years.[16] From 1994 to 2004, the age-adjusted death rate from hypertension increased 25.2%, and the actual number of deaths rose 54.6%. The 2004 overall death rate from hypertension was 17.9%. Death rates were distributed as follows: 15.6% for white males, 49.9% for black males, 14.3% for white females, and 40.6% for black females.[17] Data from "Ambulatory care visits to physician offices, hospital outpatient departments, and emergency departments in the US" showed that the number of visits for essential hypertension was 45.3 million in 2002.[18] This is projected as an estimated direct and indirect cost of high BP in 2007 to be $66.4 billion.[17] Since as many as half of all hypertensives (defined as ≥140/90) remain untreated, the annual drug costs could easily double, unless we can change lifestyles more successfully or be more efficient in allocating resources.

Prevention of hypertension

Despite the established benefits of antihypertensive treatment, concerns are often raised about the prospect of use of antihypertensive drugs over decades by 25% or more of the adult population. All drugs have adverse effects and the cost of medical care for hypertension is considerable. Also, the 12-year follow-up of approximately 350 000 middle-aged men screened for the Multiple Risk Factor Intervention Trial shows that 32% of the coronary heart disease (CHD) deaths related to elevated BP occurred below the level at which drug treatment would be considered.[19]

The multifactorial etiology of hypertension is reflected by the large number of non-pharmaceutical approaches that have been tested.[20–22] Two types of populations have been examined. In individuals with above-optimal (prehypertension stage according to the JNC 7) but non-hypertensive BP levels, lifestyle interventions have been tested to determine their effect on BP. The outcome has been either BP reduction in short-term trials or prevention of BP elevation with age and reduction in the incidence of hypertension in long-term trials. Trials have also been conducted in hypertensive patients with the objective of determining the BP-lowering effects of various non-pharmacologic interventions. One rationale has been that the findings are likely to be generalizable to non-hypertensive individuals. Another rationale has been to determine the efficacy of lifestyle modifications as definitive first-line or adjuvant therapy for hypertension. All treatment guidelines recommend lifestyle modifications as the first therapeutic approach in newly diagnosed, less severe hypertensive patients, with pharmacologic treatment to follow only in those who fail to respond adequately.

Cross-sectional or longitudinal observational studies have found the following factors to be associated with BP and prevalence or incidence of hypertension: adiposity, physical inactivity, alcohol consumption, high intake of sodium, low intake of potassium, magnesium, calcium, and certain types of dietary fiber, intake of certain macronutrients, and chronic stress.

Trial results on the efficacy of interventions for prevention of hypertension are summarized in Table 13.2. Based on literature reviews, including meta-analysis, evidence of efficacy is conclusive for weight loss, exercise, diets high in fruits and vegetables, reduction in alcohol and sodium intake, and potassium supplementation (**Level A**). A weight reduction of 10 lb (4.5 kg) can be expected to lower the BP by approximately 4/3 mmHg. Since exercise, as part of efforts to achieve caloric balance, influences weight, distinguishing an exercise effect on BP from the effect of weight loss can be difficult, but there is good evidence of BP reduction from fitness training.[23] Low-intensity/high-frequency activity appears as effective as or more effective than high-intensity exercise. A sodium reduction of 80–100 mmol/day induces an average BP reduction of 5/3 mmHg in hypertensives and 2/1 mmHg in non-hypertensives.[21] Similar BP effects were observed in trials that accomplished alcohol reductions of about 85% (a mean consumption of 3 drinks/day reduced to 3 drinks/week).[24]

The BP effects of lifestyle modifications are modest, but they appear to be additive under some circumstances.[25] A short-term study reported substantial BP reductions in adults given a diet rich in fruits, vegetables, and low-fat dairy foods, and reduced saturated and total fat.[26] A further reduction of SBP (2–8 mmHg) was observed when the sodium intake was reduced to below 100 mmol per day (2.4 g sodium or 6 g sodium chloride).[27–29] However, counseling, if required on an indefinite basis through a traditional clinical setting, may not be more cost effective than drugs. Therefore, interventions (such as reducing salt intake by modifying processed foods) that can potentially be accomplished on a population basis are attractive. The efficacy of supplementation with magnesium, fiber, fish oil or calcium has been judged to be limited or unproven at this time.[20] The trial findings are discordant and the effect sizes are small. Potassium supplementation (50–100 mmol KCl or equivalent increase from food) moderately reduces BP, especially in those who have a high sodium intake.[22]

In conclusion, long-term trials in individuals with high-normal BP have documented that sodium reduction,[21,25]

Table 13.2 Trial results on efficacy of interventions for primary prevention of hypertension

Intervention	References	Duration (months)	Change in targeted factors	Change in BP, mmHg (systolic/diastolic)
Sodium reduction	25	6	−50 mmol/day	−2.9/−1.6
	25	18	−43 mmol/day	−2.0/−1.2
	25	36	−40 mmol/day	−1.2/−0.7
	21	0.5–36	−76 mmol/day	−1.9/−1.1
Weight loss	30	6	−4.4 kg	−3.7/−2.7
	30	18	−2.0 kg	−1.8/−1.3
	30	36	−0.2 kg	−1.3/−0.9
Exercise	23	1–16	To 65% maximum exercise capacity	−2.1/−1.6
	31	1.5–7	30–90% of 1 repetition maximum	−3/−3
	32	0.7–24	Low–medium exercise intensity	−3.8/−2.6
Alcohol reduction	24	1.5	−2.6 drinks/day	−3.8/−1.4
	33	0.25–24	16–100% reduction in the daily consumption	−3.3/−2.0
Potassium increase	22	0.3–36	+46 mmol/day	−1.8/−1.0
Dietary pattern	26, 27	2	Increased fruit, vegetables, low fat dairy, protein, lower saturated fat, dietary cholesterol	−3.5/−2.1

weight loss,[30] exercise,[31,32] alcohol reduction,[24,33] and potassium supplementation[22] can reduce the incidence of hypertension by as much as half (**Level A**). The most impressive results are from a five-year trial of a multifactorial intervention.[34] The cumulative incidence of hypertension was 19.2% in the control group and 8.8% in the intervention group. The main factors contributing to this BP reduction were weight loss and sodium reduction.[25] Overweight adults with prehypertension appear to be prime candidates for this intervention. Lifestyle modification is an integral part of management of hypertension. The BP-lowering effects are on average modest. Some patients do not respond or are unable to modify their lifestyles, while others respond well. As a consequence, many patients do not have to be placed on antihypertensive drugs and, if they are, lower drug doses or fewer drugs may be required. The challenge is to sustain the lifestyle modifications.

Drug treatment

Placebo-controlled trials

Despite efforts at lifestyle modifications, most hypertensive patients require pharmacologic treatment. In the US, almost 25 million adults are currently taking antihypertensive medications.[17] This high level of drug use to treat an asymptomatic condition has been justified by the high population burden of major morbidity and mortality causally related to untreated hypertension, and by strong evidence of treatment efficacy and safety from large, long-term

clinical trials. In SHEP,[35] which enrolled older adults ≥60 years with isolated systolic hypertension (SBP ≥160 mmHg), the five-year event rates for the combined endpoints of CHD and stroke per 100 patients were 13.6 in the placebo group and 9.4 in the active group. The risk difference of 4.2% means that about 24 older adults need to be treated for five years in order to prevent one coronary or cerebrovascular event. It must be recognized that calculating the NNT in this manner from randomized clinical trials produces an underestimate for several reasons, chiefly the selection or self-selection of lower-risk patients into trials and the dilution of effects due to drop-in to active treatment by patients in the control group. For middle-aged populations, who are at lower risk, the NNT would be much higher. Because many people must receive therapy so that a few will benefit, even uncommon adverse effects may minimize or eliminate the BP-lowering benefits of antihypertensive therapy. Only with large, long-term trials such as SHEP can we be assured that the health benefits actually outweigh the health risks of particular therapies.

In a meta-analysis by Psaty *et al*,[36] the evidence from large, long-term, controlled clinical trials of antihypertensive therapy was reviewed. The 18 randomized trials included 48 220 patients followed for an average of about five years. Clinical trials were classified according to the primary treatment strategy. While most studies used more than one drug, the agents were generally used in a stepwise fashion, and it was usually easy to identify the first-line therapy.

Compared with controls, beta-blocker therapy was effective in preventing stroke and congestive heart failure

(Table 13.3). Similarly, high-dose diuretic therapy, which typically started with the equivalent of 50 mg/day of hydrochlorothiazide and often went to 100 mg/day, was associated with a reduced risk of stroke and heart failure. Despite lowering BP by an average of about 5–6 mmHg, neither beta-blocker therapy nor high-dose diuretic therapy demonstrated significant reduction of coronary disease events (**Level A**) (see Table 13.3).

Compared with controls, low-dose diuretic therapy prevented not only stroke and heart failure but also CHD and cardiovascular and total mortality (see Table 13.3). In contrast to high-dose diuretic therapy, the adverse metabolic effects of low-dose diuretic therapy are minimal. The safety and proven effectiveness make low-dose diuretic therapy the logical first-line pharmacologic treatment for hypertension. The JNC 7[1] appropriately identifies low-dose diuretics as preferred first-line agents in the treatment of hypertension (**Class I, Level A**).

It is not clear why low-dose diuretic therapy prevents CHD, but neither high-dose diuretic therapy nor beta-blocker therapy is associated with a reduced risk of coronary disease. The low-dose trials (see reference 36 for references) were conducted mainly in older adults while the high-dose trials were conducted largely in middle-aged adults. Evidence from observational studies suggests that, compared with low-dose diuretic therapy, high-dose diuretic therapy is associated with an increased risk of sudden death.[37] For high-dose diuretics, the most likely explanation for this increased risk of sudden death is the dose of the diuretics rather than the age of patients. Abrupt withdrawal of beta-blocker therapy is associated with an increased risk of MI in patients with high BP.[38] It is possible that withdrawal reactions from non-compliance with beta-blockers may have minimized the drugs' ability to prevent CHD in hypertensive patients, who generally represent a low-risk population group.

The findings for beta-blocker and high-dose diuretic therapy provide direct evidence that BP lowering alone is not adequate to predict the effect of an antihypertensive medication on important health outcomes. "In light of all previous cardiovascular trials …" Topol and colleagues remark, "surrogate endpoints cannot be considered authentic measures of true clinical efficacy and safety".[39] Evidence from individual comparative trials and meta-analyses of comparative trials strongly indicates that it matters how elevated BP is lowered (see below). Although average BP reductions are similar across different classes of drugs, important differences exist between these classes in terms of their effects on major morbid events, especially heart failure and acute MI.[40] Yet drug regulatory agencies currently approve antihypertensive medications primarily on the basis of their ability to lower BP.

A so-called network meta-analysis by Psaty *et al*[41] included trials through 2002. The database included 192 478 patients from 42 trials randomized to seven major treatment strate-

Table 13.3 Meta-analysis of randomized, placebo-controlled clinical trials in hypertension according to first-line treatment strategy

Outcome drug regimen	Dose	Trials (n)	Events, active treatment/ control	RR (95% CI)
Stroke				
Diuretics	High	9	88/232	0.49 (0.39–0.62)
Diuretics	Low	4	191/347	0.66 (0.55–0.78)
Beta-blockers		4	147/335	0.71 (0.59–0.86)
HDFP	High	1	102/158	0.64 (0.50–0.82)
Coronary heart disease				
Diuretics	High	11	211/331	0.99 (0.83–1.18)
Diuretics	Low	4	215/363	0.72 (0.61–0.85)
Beta-blockers		4	243/459	0.93 (0.80–1.09)
HDFP	High	1	171/189	0.90 (0.73–1.10)
Congestive heart failure				
Diuretics	High	9	6/35	0.17 (0.07–0.41)
Diuretics	Low	3	81/134	0.58 (0.44–0.76)
Beta-blockers		2	41/175	0.58 (0.40–0.84)
Total mortality				
Diuretics	High	11	224/382	0.88 (0.75–1.03)
Diuretics	Low	4	514/713	0.90 (0.81–0.99)
Beta-blockers		4	383/700	0.95 (0.84–1.07)
HDFP	High	1	349/419	0.83 (0.72–0.95)
Cardiovascular mortality				
Diuretics	High	11	124/230	0.78 (0.62–0.97)
Diuretics	Low	4	237/390	0.76 (0.65–0.89)
Beta-blockers		4	214/410	0.89 (0.76–1.05)
HDFP	High	1	195/240	0.81 (0.67–0.97)

Trials (n) indicate number of trials with at least 1 endpoint of interest. Abbreviations: RR, relative risk; CI, confidence interval; HDFP, Hypertension Detection and Follow-up Program Study (5484 subjects in stepped care and 5455 in referred care). For these comparisons, the numbers of participants randomized to active therapy and placebo were 7768 and 12 075 for high-dose diuretic therapy; 4305 and 5116 for low-dose diuretic therapy; and 6736 and 12 147 for beta-blocker therapy. Because the Medical Research Council trial included two active arms, the placebo group is included twice in these totals, once for a diuretic comparison and again for beta-blocker comparison. The total numbers of participants randomized to active therapy and control therapy were 24 294 and 23 926, respectively.[36]

gies, including placebo. For all major outcomes, low-dose diuretics were superior to placebo: coronary heart disease (CHD; relative risk (RR) 0.79; 95% confidence interval (CI) 0.69–0.92); congestive heart failure (CHF; RR 0.51; 95% CI 0.42–0.62); stroke (RR 0.71; 95% CI 0.63–0.81); cardiovascular disease events (RR 0.76; 95% CI 0.69–0.83); cardiovascular disease mortality (RR 0.81; 95% CI 0.73–0.92); and total mortality (RR 0.90; 95% CI 0.84–0.96). When the effects of low-dose diuretics on the six outcomes were compared to

the other five active treatment strategies (beta-blockers, angiotensin-converting enzyme (ACE) inhibitors, calcium channel blockers (CCBs), alpha-blockers and angiotensin receptor blockers), diuretic treatment was significantly better for eight outcomes in the 30 possible comparisons. None of the remaining comparisons showed a statistically significant difference in favor of a comparator drug. This analysis provides compelling evidence that low-dose diuretics are the most effective first-line treatment for preventing the occurrence of cardiovascular disease morbidity and mortality.

Results from several long-term, placebo-controlled trials of the newer classes of antihypertensive agents have been published since 1997 (Table 13.4). A placebo-controlled trial of nitrendipine in ISH (Syst-Eur) found a statistically significant reduction in stroke risk and showed trends for reductions in risks of acute MI and congestive heart failure.[42] Two placebo-controlled trials in patients with type 2 diabetes and nephropathy, the Irbesartan Diabetic Nephropathy Trial (IDNT)[43] and the Reduction of Endpoints in NIDDM with the Angiotensin II Antagonist Losartan (RENAAL) Study,[44] investigated two different angiotensin II receptor blockers. The primary endpoint in both trials was a composite renal outcome defined as a doubling of serum creatinine, development of end-stage renal disease or death from any cause. The primary results were very similar: the composite renal outcome was lowered by 20% in IDNT by irbesartan and by 16% in RENAAL by losartan ($P = 0.02$ in both trials). IDNT also evaluated the effect of amlodipine, a calcium channel blocker, that did no better than placebo for the renal outcome (RR 1.04). In neither trial did the active treatments significantly reduce the risk of a composite cardiovascular outcome in comparison to the placebo controls.

The Perindopril Protection against Recurrent Stroke Study (PROGRESS) reported that ACE inhibitor-based treatment reduced the risk of stroke by 28% and the risk of total major vascular events by 26%.[45] Those receiving the combination of perindopril and the diuretic indapamide (56% of the population) benefited the most. In this subgroup, the mean reduction in BP was 12/5 mmHg and the reduction in stroke risk was 43%. However, those assigned to perindopril alone experienced a small reduction in BP, 5/3 mmHg, with no significant reduction in stroke risk.

In conclusion, placebo-controlled trials conducted through the early 1990s documented conclusively that low-dose diuretics and beta-blockers used as first-line drugs markedly reduce the devastating cardiovascular complications experienced by hypertensive patients. However, the role of beta-blockers as a first-line treatment has been challenged when compared to active treatment (see below) (**Level B**). The placebo-controlled trials have had two important consequences. First, they established low-dose diuretics as the proper control group for comparative trials. Second, they limited the opportunity for conducting long-term, placebo-controlled trials, since withholding active treatment generally became ethically unacceptable. Only in specific subgroups of hypertensive patients – for example, those with major co-morbidity such as nephropathy and cerebrovascular disease – were placebo-controlled designs considered acceptable. The focus of clinical research in hypertension has shifted from answering the question "Is BP lowering beneficial?" to asking "Does it matter how elevated BP is lowered?". The latter question requires comparative or active-controlled trials.

Active-controlled trials

Over the past decade, clinical trials of BP-lowering drugs shifted focus from placebo-controlled to actively controlled

Table 13.4 Clinical effects of newer antihypertensive agents from recent placebo-controlled trials

Trial	Study population	First-line treatment	Outcome	RR (95% CI)
Syst-Eur[42]	ISH	Nitrendipine	Stroke	0.58 (0.40–0.83)
			AMI	0.70 (0.44–1.09)
			Heart failure	0.71 (0.47–1.10)
IDNT[43]	Diabetic nephropathy	Irbesartan	Composite renal	0.80 (0.66–0.97)
			Composite CV	0.91 (0.72–1.14)
		Amlodipine	Composite renal	1.04 (0.86–1.25)
			Composite CV	0.88 (0.69–1.12)
RENAAL[44]	Diabetic nephropathy	Losartan	Composite renal	0.84 (0.72–0.98)
			Composite CV	0.90 (NA)
PROGRESS[45]	Stroke, TIA	Perindopril alone	Stroke	0.95 (0.77–1.19)
			Major vascular	0.96 (0.80–1.15)
		Perindopril + indapamide	Stroke	0.57 (0.46–0.70)
			Major vascular	0.60 (0.51–0.71)

CV, cardiovascular; TIA, transient ischemic attack.

designs. ALLHAT, initiated in 1994,[46] was one of the first major active-controlled or comparative outcome trials to examine whether the type of drug used to lower high BP matters. While the study hypotheses were formally two-sided, the primary interest was a test of superiority, with the overall objective being to determine whether each of three drugs from newer drug classes (ACE inhibitors, CCBs, and alpha-blockers), when used as first-line therapy, are superior to low-dose diuretics in reducing the risk of cardiovascular events. The alpha-blocker (doxazosin) arm was terminated early in 2000[47] for two reasons – a 25% excess of major cardiovascular events, primarily congestive heart failure, and a very small likelihood of observing that it is superior to low-dose diuretics in reducing major coronary events (Table 13.5). The fact that excess cardiovascular events with doxazosin occurred despite BP reduction that was similar to the diuretic group points to the importance of drug selection in the treatment of hypertension. In the other two arms of ALLHAT that continued until 2002,[48] chlorthalidone was as effective as ACE inhibitors or CCBs and was even superior in preventing one or more major forms of CVD (see Table 13.5). The low cost of diuretics represents a definite advantage over other drugs. Based on available data from placebo-controlled trials evaluating low-dose diuretics, major health outcomes for chlorthalidone and other thiazide-like drugs appear similar.[49] Hence, low-dose diuretics have emerged as first-line therapy for treatment of hypertension (**Level A**).

Unlike low-dose diuretics, the role of beta-blockers as treatment for primary hypertension has been challenged.[50] A preliminary analysis showed that atenolol was not very effective for treatment of hypertension.[51] To confirm that conclusion and to assess other beta-blockers, Lindholm *et al*[52] conducted a meta-analysis that included more data on atenolol and data on all other beta-blockers. Thirteen randomized controlled trials (n = 105 951) were included in their meta-analysis. Seven studies (n = 27 433) compared beta-blockers and placebo or no treatment. The relative risk of stroke was 16% higher for beta-blockers (95% CI 4–30%) than for other drugs. There was no difference for myocardial infarction. When the effect of beta-blockers was compared with that of placebo or no treatment, the relative risk of stroke was reduced by 19% for all beta-blockers (7–29%), about half of that expected from previous hypertension trials. There was no difference for myocardial infarction or mortality. These results raise questions about the appropriateness of beta-blockers as first-line therapy.

A meta-analysis of nine randomized comparative clinical trials of intermediate- and long-acting CCBs was conducted by Pahor *et al*.[53] The comparators were mostly low-dose diuretics, beta-blockers, and ACE inhibitors. The mean BP reduction was almost identical in the CCB and non-CCB groups. In the database that included nearly 120 000 person-years of treatment, use of CCBs was associated with approximately 25% excess rates of both congestive heart failure and acute MI ($P < 0.005$) (see Table 13.5). No differences were observed between the groups for stroke or all-cause mortality. When the database from a second meta-analysis[54] was used to examine the same question – CCBs versus non-CCBs – the results were similar and statistically significant.[55] In a similar type of meta-analysis, the benefit of ACE inhibitors was compared to that of non-ACE inhibitors, primarily CCBs in patients with diabetes.[56] The pooled analysis, supported subsequently by another trial,[57] strongly suggested that ACE inhibitors have advantages over non-ACE inhibitors in reducing the risk of acute myocardial infarction and major cardiovascular events, in spite of similar BP reduction in diabetic patients (see Table 13.5).

The evidence concerning the relevance of how elevated BP is lowered comes from two relatively recent trials with similar design in patients with nephropathy (see Table 13.5). The achieved BP levels were similar for the two therapies – amlodipine versus a drug blocking the renin– angiotensin system. In the AASK trial,[58] among patients with non-diabetic nephropathy, the amlodipine group was terminated early owing to a more rapid decline in renal function and a 60% higher risk of a composite renal outcome – renal disease progression, end-stage renal disease or death compared to the ramipril group. Amlodipine was also inferior to irbesartan in patients with diabetic nephropathy in IDNT.[43] The risk of the composite renal outcome was 32% higher in the amlodipine group compared to the irbesartan group. There was no group difference for a composite cardiovascular outcome.

In the LIFE trial[59] among patients with ECG-determined left ventricular hypertrophy, treatment with ARB (losartan) was more protective against a composite cardiovascular endpoint than treatment with a beta-blocker (atenolol) despite very similar BP reductions. In fact, the benefits were largely attributable to a protection against stroke and were particularly striking in the diabetic subgroup (see Table 13.5).

In the VALUE trial[60] 15 245 patients, aged 50 years or older with treated or untreated hypertension and high risk of cardiac events, were randomly assigned to either valsartan, an ARB drug, or amlodipine. The primary outcome of composite cardiovascular disease did not differ between treatment groups. Unequal reduction in BP initially might account for differences between groups in cause-specific outcomes. The findings emphasize the importance of prompt BP control in hypertensive patients at high CV risk (see Table 13.5).

In the Anglo-Scandinavian Cardiac Outcomes Trial (ASCOT),[61] high-risk patients were randomly assigned to amlodipine and perindopril or atenolol and bendroflumethiazide. Though not statistically significant, fewer individuals on the amlodipine-based regimen had a primary endpoint (non-fatal myocardial infarction and fatal CHD). However, this difference could be largely explained by the

Table 13.5 Clinical effects of newer antihypertensive agents from recent active-controlled trials and meta-analyses

Study	Study population	Treatment		Outcome	RR (95% CI)
		Study	Control		
ALLHAT[47]	Elderly, high-risk	Doxazosin	Chlorthalidone	CHD	1.03 (0.90–1.17)

difference in SBP in the two groups. The incidence of new-onset diabetes was also less on the amlodipine-based regimen (see Table 13.5). The Avoiding Cardiovascular Events through Combination Therapy in Patients Living with Systolic Hypertension (ACCOMPLISH) trial, reported that a combination of benazepril and amlodipine reduce a composite outcome of cardiovascular events compared to a combination of benazepril and hydrochlorothiazide by 19.6% in 3 years. The clinical relevance of the trial is limited by the fact that amlodipine was given in a full dose, while hydrochlorothiazide was given in half the recommend dose. It has been documented that chlorothalidone and hydrochlorothiazide have similar benefits,[49] but the effective dose of the latter is twice the that of the former.

In conclusion, these reports document that in certain circumstances it matters how elevated BP is lowered. In the reviewed trials, it appears that two types or classes of drugs, alpha-blockers and CCBs, are as effective as other antihypertensive agents in reducing SBP and DBP, but less effective in reducing the risk of heart failure (both classes) and MI (CCBs). In elderly high-risk hypertensive patients, doxazosin was less effective than chlorthalidone in reducing risk of congestive heart failure and stroke (**Level A**). There was no difference in risk of major coronary events. It is likely that these observations from ALLHAT apply to all alpha-blockers. Two-thirds of the heart failure cases were either hospitalized or fatal. Several sources of data[53–58] show that CCBs are inferior to other agents in reducing the hypertensive complications of congestive heart failure and acute MI. These findings may be especially relevant in patients with type 2 diabetes.[56,57] Since diuretics and ACE inhibitors are effective in the treatment and prevention of heart failure and most CCBs are not recommended in patients with this condition, these observations should not be surprising. In comparison with other antihypertensive drugs, the effect of beta-blockers is less than optimum, with a raised risk of stroke.[58] Hence, beta-blockers should not be first choice in the treatment of primary hypertension and should not be used as reference drugs in future randomized controlled trials of hypertension.

Some newer antihypertensive drugs

New classes of antihypertensive drugs and new drugs in the established classes have recently emerged. These include the aldosterone receptor blockers,[63] vasodilator beta-blockers (carvedilol, nevibolol, and celiprolol),[64] renin inhibitors (aliskiren),[65] endothelin receptor antagonists (bosantan, darusentan, sitaxsentan, and tezosentan),[66] and dual endopeptidase inhibitors (omapatrilat).[67] Only the specific aldosterone receptor blockers and the vasodilator beta-blockers appear to be promising in treating systemic hypertension in routine clinical practice.

Genetics, hypertension, and some potential drug–gene interactions

The phenotype of high BP represents a complex trait influenced by both genes and environment. Essential hypertension, generally mild to moderate elevations of BP in the population, has been associated with several genetic polymorphisms. Detection of such genetic polymorphisms have been adopted by many projects such as genome-wide scan for hypertension in sibships to identify possible hypertension loci on chromosomes (HyperGEN,[68] the BRIGHT study,[69] and the GENIHUSS study[70]). The National Millennium Project of Japan has already investigated 100 000 single nucleotide polymorphism markers in an attempt to identify genetic variations linked to the development of hypertension.[71] Polymorphism in the genes encoding for a number of substances has been found to be associated with hypertension; some of these include human atrial natriuretic peptide,[72] subunit of the epithelial Na+channel,[73] a-adducin,[74] beta 2- and beta 3-adrenoceptors,[75] cytochrome CYP1A1,[76] cytochrome CYP3A5,[77] ACE,[78] bradykinin B2 receptor,[79] aldosterone synthase (CYP11B2),[80] lipoprotein lipase,[81] angiotensin II type 2 receptor,[82] endothelin-2,[83] tyrosine hydroxylase,[84] and G(s) protein alpha-subunit.[85]

The genetic studies of hypertension are very important for understanding the biologic and molecular etiologies of high BP and, potentially, for the design of new drugs. The public health importance of variations in candidate genes for hypertension remains to be determined. While this work has enhanced our knowledge of molecular biology, the polymorphisms associated with essential hypertension, though some are common, tend to have small effects. As Corvol has aptly observed, "Most molecular variants lead to a low attributable risk in the population or a low individual effect at the individual level".[86]

Pharmacogenetics

The studies in molecular biology and genetics are occurring at a breath-taking pace. There are some studies that report the effectiveness of antihypertensive therapy based upon the genotype of selected patients. Amiloride was found to be effective as monotherapy in hypertensive patients with Thr594Met polymorphism in the epithelial sodium channel who have increased amiloride-sensitive sodium channel activity.[87] The therapeutic response to the ARB losartan was much greater in patients on the basis of AT1 receptor A1166C polymorphism.[88] The M235T polymorphism in the angiotensinogen gene was found to be an independent predictor of the BP response to ACE inhibition.[89] Polymorphism in the GNAS1 locus, encoding the G(s) protein alpha-subunit (FokI allele), was related to the BP response to beta-blockers.[90]

Single nucleotide polymorphisms in the angiotensinogen gene were associated with the BP-lowering response to atenolol.[90] However, correlations between gene polymorphism and high BP are not consistent and are often limited to a certain ethnicity[81] and sex,[83] and influenced by environmental factors. Studies have to show a health benefit, a reduction in cost or both before these genetic tests could be widely used.

In conclusion, it is too early to make any recommendation of a specific drug (class) for optimal treatment according to a patient's genotype.

Immunotherapy of hypertension

There are some recent developments in the area of immunotherapy of hypertension. In a small study, hypertensive patients responsive to an ACE inhibitor or ARB were given three or four injections of PMD3117, a vaccine based upon Ang I antigen, over a six-week period. The antibody titer rose from the second injection and peaked in six weeks, but it was not enough to influence BP. However, it blunted the fall in plasma renin after withdrawal of the ACE inhibitor or ARB and decreased aldosterone excretion significantly, indicating suppression of the RAS. The authors believe that much higher titers will be required to have an influence on BP.[91] Treatment of human hypertension with vaccines is feasible but is not likely to be available in the near future.

Cost effectiveness

Hypertension is a worldwide health problem that poses an increasing economic burden on health resources. Recent data suggest that 26.4% of the world adult population have hypertension, and the number is projected to increase to 29.2% by 2025.[92] The shift away from the less expensive, often generic diuretics and beta-blockers to the newer, generally more expensive ACE inhibitors, CCBs, alpha-blockers and angiotensin II blockers has been costly to society. Unfortunately, formal cost-effectiveness analyses are not possible for the newest antihypertensive agents because of the lack of data on effectiveness. Hence, it is predicted that future medical treatment of hypertension will be increasingly affected by cost considerations.

Although reducing high BP to lower levels is advisable in principle, economic factors either at the individual level or at the health system level become obstacles in achieving that goal. The question from a cost-effectiveness viewpoint is not whether treatment is effective, but whether the benefits justify the costs in light of competing healthcare needs. In the context of healthcare systems in which priorities are being established (fixed budgets), the prime candidates for antihypertensive drug treatment should be patients at high risk such as elderly patients, patients with moderate to severe hypertension, patients with other cardiovascular

risk factors, and patients with target organ manifestations. These patient groups (among others) are at a higher risk of clinical hypertensive complications. Since clinical trials have demonstrated similar relative reductions in risk of stroke, acute MI, congestive heart failure, and mortality in low-risk compared to high-risk patients, the absolute benefit expressed as NNT to prevent one event or as number of events prevented per 100 patients treated is substantially greater in the high-risk groups described above.

Unanswered questions

• What is the optimal second-line drug to be added to low-dose diuretics if the BP is not controlled?
• What is the best method for risk stratification? How can we implement feasible and acceptable risk stratification in the clinical setting, thus allowing treatment decisions to be based on an individual's overall cardiovascular risk?
• What is the optimal achieved level of treated BP? Should the treatment goals be even lower than 140 mmHg (systolic) or 90 mmHg (diastolic) for certain high-risk subpopulations?
• Should the BP goal be <140 mmHg for elderly with ISH?
• What are the optimal method(s) for long-term lifestyle modifications?
• How can we best reduce the incidence of hypertension?
• Will genetic information improve the efficacy and safety of drug treatment with specific antihypertensive agents?

Key points

• In persons older than 50 years, SBP greater than 140 mmHg is a much more important cardiovascular disease (CVD) risk factor than DBP (**Level A**).
• The risk of CVD beginning at 115/75 mmHg doubles with each increment of 20/10 mmHg; individuals who are normotensive at age 55 have a 90% lifetime risk for developing hypertension (**Level A**).
• Individuals with a SBP of 120–139 mmHg or a DBP of 80–89 mmHg should be considered as prehypertensive and require health-promoting lifestyle modifications to prevent developing hypertension (**Class I, Level A**).
• Low-dose diuretics is the drug of choice in drug treatment for most patients with uncomplicated hypertension, either alone or combined with drugs from other classes. Certain high-risk conditions are compelling indications for the initial use of other antihypertensive drug classes (**Class I, Level A**).
• Most patients with hypertension will require two or more antihypertensive medications to achieve goal BP (<140/90 mmHg or <130/80 mmHg for patients with diabetes or chronic kidney disease) (**Level A**).
• Major differences in direct drug cost between low-dose diuretics and the newer and heavily promoted agents ought to be a strong incentive for use of the former (**Class I**).

14 Dysglycemia and the risk of cardiovascular events

Hertzel C Gerstein and Zubin Punthakee

McMaster University, Hamilton, Ontario, Canada

Introduction

Diabetes mellitus (DM) is diagnosed when plasma glucose levels rise above predefined thresholds. People diagnosed with DM have a high future risk of serious health consequences including cardiovascular events. Indeed, they develop cardiovascular disease approximately 15 years earlier than their non-diabetic counterparts[1] and have a cardiovascular risk up to fourfold higher than in people without DM.[1–4] The magnitude of this increased risk is progressively related to the degree of glucose elevation above normal. Moreover, this relationship is not restricted to people with DM and there is growing recognition that a progressive relationship exists between glucose levels and cardiovascular risk that begins at glucose levels well below the diagnostic thresholds for DM and that extends right into the diabetic range.[5] Thus, like low-density lipoprotein (LDL) cholesterol or systolic blood pressure, glycemia, as measured by fasting glucose level, postload glucose levels or HbA1c levels, is a progressive cardiovascular risk factor. Whether glucose lowering or prevention of the rise in glucose levels with time can reduce cardiovascular risk in people with various degrees of glucose elevation (i.e. impaired glucose tolerance, impaired fasting glucose, newly detected DM or established diabetes) is currently being actively studied.

What is diabetes and how common is it?

Diagnosis and classification

DM is a common chronic condition that is defined on the basis of high glucose levels, and that is an independent risk factor for a growing list of serious diseases including, but not limited to, blindness, renal failure, amputations, claudication, stroke, myocardial infarction, and premature death. It is diagnosed when there is evidence of persistently elevated glucose levels that are above specific thresholds or cutpoints (Table 14.1).[6] These thresholds were originally based on epidemiologic studies relating the risk of diabetic eye disease to the glucose level achieved two hours after drinking a 75 g oral glucose tolerance load.[7] People with higher levels were at high risk of diabetic retinopathy and nephropathy, whereas those with levels below this threshold were at low risk for these health consequences.[8,9]

Recent data have confirmed the general relevance of these thresholds for eye disease, and have shown that people with glucose levels below these thresholds have a lower (but not negligible) incidence of retinopathy.[10,11] More importantly, they have also highlighted the fact that these thresholds are not relevant to many of the other chronic consequences of DM that are listed in Table 14.2. Thus, as noted below, the risk of cardiovascular disease is progressively related to glucose levels extending from normal levels right into the DM range.

When the diagnostic thresholds for DM were established it was clear that many people had glucose levels that fell below the diabetic threshold but that were nevertheless still abnormal and could rise into the DM range with time. This led to the classification of impaired glucose tolerance (IGT) and impaired fasting glucose (IFG) which identified people at low risk for diabetic retinopathy and nephropathy but at very high risk for developing DM.[9] Table 14.1 summarizes the current diagnostic thresholds for IGT and IFG (sometimes referred to as "prediabetes") and Table 14.3 lists the relative risk and incidence of DM in people with these two dysglycemic states.[12] Of note, the American Diabetes Association has adopted lower thresholds for impaired fasting glucose (i.e. 5.6 mmol/L) to optimize its sensitivity and specificity for predicting future DM;[13] however, this lower threshold has not been adopted globally.[14]

Table 14.1 Diagnostic thresholds for diabetes, impaired glucose tolerance, and impaired fasting glucose

Classification	Random plasma glucose	Fasting plasma glucose	Two-hour postload plasma glucose[a]
Diabetes mellitus	≥11.1 mmol/L + classic signs & symptoms of hyperglycemia[b]	≥7.0 mmol /L[b]	≥11.1 mmol/L[b]
Impaired glucose tolerance	N/A	<7.0 mmol/L	≥7.8 and <11.1 mmol/L
Impaired fasting glucose (WHO)	N/A	≥6.1 and <7.0 mmol/L	N/A
Impaired fasting glucose (ADA)	N/A	≥5.6 and <7.0 mmol/L	N/A

WHO, World Health Organization; ADA, American Diabetes Association; [a] measured during a 75 g oral glucose tolerance test (OGTT); [b] must be confirmed on a subsequent day by any one of the three methods.

Table 14.2 Major chronic consequences of diabetes

Eye disease (cataracts, retinal disease)	Early death
Kidney disease (renal failure, nephropathy)	Ischemic heart disease
Nerve disease (sensory, motor)	Stroke
Foot disease (pain, ulceration, callus, infection)	Peripheral vascular disease
Lower limb amputation	Cognitive decline
Steatohepatitis and cirrhosis	Depression
Hip fractures	Connective tissue abnormalities
Imbalance and frailty	Erectile/sexual dysfunction

Table 14.3 Risk of diabetes and risk of death in "prediabetes"

Diagnostic category	Relative risk of future diabetes	Annual incidence of diabetes	Relative risk of death
Any impaired fasting glucose*	4.7 (2.5–6.9)	2–10%	1.2 (1.1–1.4)
Isolated impaired fasting glucose	7.5 (4.6–10.5)	2–10%	N/A
Impaired glucose tolerance	6.4 (4.9–7.8)	2–10%	1.3 (1.1–1.5)
Any impaired glucose tolerance	5.5 (3.1–7.9)	2–10%	N/A
Both impaired fasting glucose and impaired glucose tolerance	12.1 (4.3–20)	10–15%	N/A

Data are from a systematic overview and meta-analysis of prospective studies.[12]

* Defined as a fasting plasma glucose level ≥ 6.1 mmol/L (i.e. WHO criterion); N/A, not available.

Prevalence

The estimated prevalence of DM in 2003 was 5.1% of all adults in the world.[15] This prevalence has been rapidly rising and is currently reaching alarming proportions throughout much of the world. For example, in Ontario, Canada, the prevalence of DM rose from 5.2% of all adults in 1995 to 8.8% in 2005.[16] This prevalence rises with age, approaching 20% of all people over the age of 70 in Canada[16,17] and the USA.[18] It also varies with race and ethnicity, with the highest prevalence in people from aboriginal populations throughout the world, followed by those with South Asian, Middle Eastern, African and European ancestry.[15] In response to this epidemic, on December 20 2006 the United Nations formally recognized DM as a "chronic, debilitating and costly disease", which "poses severe risks for families, countries and the entire world" and encouraged countries "to develop national policies for the prevention, treatment and care of diabetes".

The prevalence of impaired glucose tolerance varies in a similar pattern; in most populations it is somewhat higher than the prevalence of diagnosed diabetes. Thus in 2003, the estimated prevalence of impaired glucose tolerance in the world was 8.2% of all adults.[15]

Etiology

DM emerges when an individual is unable to secrete sufficient pancreatic insulin to maintain normoglycemia in response to various glucose-raising stimuli (such as meals, stress, etc.) throughout the day. This may occur due to a number of causes.[19] Thus people with type 1 DM typically suffer from autoimmune damage to their beta cells and have minimal to absent insulin secretion. Conversely, people with type 2 DM or gestational DM may make abundant insulin; nevertheless, the absolute amount made is insufficient to maintain normal glucose homeostasis and to overcome whatever "insulin resistance" is present (due to obesity, inactivity or other factors). As insulin is the primary

Table 14.4 Etiologic classification of diabetes mellitus

Name	Characteristics	Etiology	Epidemiology
Type 1	Primarily due to pancreatic islet beta-cell destruction; prone to ketoacidosis	Autoimmune or idiopathic	~10% of people with diabetes; 0.2% of the general population
Type 2	Insufficient insulin secretion to compensate for resistance to insulin's effect	Strong familial component	~90% of people with diabetes; up to 10% of all adults
Gestational diabetes	Diabetes with onset or first recognition in pregnancy	Usually due to hormonal changes in pregnancy and usually resolves postpartum	~4% of pregnancies in the United States
Other specific types	Related to a genetic, congenital, pancreatic, endocrine, or infectious acquired disease, or drug induced	Examples include hemochromatosis, pancreatitis, hypercortisolemia	~2% of all patients with diabetes

Adapted from reference 6. Note that patients with any form of diabetes may require treatment with insulin at some stage of their disease. Use of insulin does not in itself classify the patient.

hormone that prevents hyperglycemia, by both inhibiting hepatic glucose production and facilitating glucose clearance by muscle, insufficient insulin quickly results in an elevated glucose level. The etiologic classification of DM and the associated characteristics and suspected causes of each type are listed in Table 14.4.

How much does dysglycemia increase cardiovascular risk?

Relative risk of cardiovascular disease with diabetes

People diagnosed with DM are two to four times more likely to suffer a cardiovascular (CV) event than people without a diagnosis of DM,[1–4] and people with DM develop cardiovascular disease approximately 15 years earlier than their non-diabetic counterparts.[1] Moreover, the relative risk is highest for young individuals, and is higher in women than in men. Thus, men and women aged 20–34 have a relative risk of myocardial infarction (MI) of 12 and 37.8 respectively, whereas by age 75 or older the risks are 1.86 and 2.41 respectively.[1] Figure 14.1 summarizes the incidence and risk of MI (Fig. 14.1a) and death (Fig. 14.1b) by sex and age group based on data from a population-based cohort of 9.4 million people (approximately 400 000 with diabetes) followed for six years from 1994 to 2000.[1] These findings are supported in a recent large meta-analysis of 37 prospective studies performed from 1966 to 2005, comprising 447 064 people followed for 4–36 years in five continents, which reported that compared to people without diabetes, the age-adjusted relative risk of fatal coronary heart disease was 3.69 and 2.16 in women and

men respectively; adjustment for other risk factors only modestly attenuated the risk to 3.12 and 1.99 respectively.[20] The fact that the high risk of cardiovascular disease in people with DM cannot be explained by the co-existence of other cardiovascular risk factors has focused attention on the factor that is pathognomonic of diabetes: the elevated glucose level.

Relationship of glycemia to cardiovascular disease in diabetes

Several prospective studies in people with DM have now clearly shown a graded relationship between HbA1c level and the incidence of cardiovascular outcomes. For example, the Wisconsin Epidemiologic Study of Diabetic Retinopathy followed a population-based sample of 1210 patients with DM presenting before the age of 30 and 1780 patients with DM presenting at or after the age of 30.[21] In both groups of subjects, 10-year mortality increased with the baseline glycated hemoglobin quartile. After controlling for other risk factors, a 1% increase in glycated hemoglobin was associated with a 10% (older onset subjects) to 18% (younger onset subjects) increase in the hazard of dying from ischemic heart disease. In an epidemiologic analysis of data from the United Kingdom Prospective Diabetes Study, a 1% higher HbA1c was associated with a 14% higher risk of death, a 14% higher risk of myocardial infarction and a 12% higher risk of stroke.[22] In another analysis of 1626 people with DM in the United States, a 1% higher HbA1c was associated with a 14% higher risk of myocardial infarction, fatal coronary heart disease or revascularization.[23] Finally, the best estimate of this relationship was reported in a recent meta-analysis of 10 prospective studies in which a 1% higher HbA1c was associated with an 18%
(a)
(b)

Figure 14.1 Myocardial infarction (MI) and death in men and women with diabetes. The hazard and rates (insert) of MI and death in men and women with diabetes in Ontario, Canada, between 1994 and 2000 by age range is shown in panels A and B respectively.[1] Data are from the cited article.

higher risk of coronary heart disease or stroke in people with type 2 diabetes; a similar relationship was noted in studies of people with type 1 DM.[24]

Relationship of glycemia to cardiovascular disease regardless of diabetes status

As noted above, prospective studies have consistently showed that the relationship between glucose levels and the subsequent risk of cardiovascular disease extends well below the diabetic threshold. For fasting glucose levels, a prospective 14-year study of 3458 non-diabetic men and women aged 40–70 with a fasting plasma glucose <7.8 mmol/L (140 mg/dL) reported that the age-adjusted ischemic heart disease mortality rates approximately doubled in men as the fasting glucose rose from 5 to 7 mmol/L (90–126 mg/dL), and tripled in women as the fasting glucose rose from 6 to 7.2 mmol/L (108–130 mg/

dL).[25] For postload glucose levels, a 10-year follow-up of 18050 non-diabetic male civil servants revealed up to a twofold increase in coronary heart disease and stroke mortality in subjects whose two hour postload capillary glucose value was greater than 5.4 mmol/L (97 mg/dL) compared to those with lower glucose levels; this increase was independent of age, smoking, blood pressure, cholesterol, and occupation.[26,27] Moreover, over a 33-year period, participants in this study had a 12% higher risk of coronary heart disease death per 1 mmol/L (18 mg/dL) higher two-hour glucose level (above 4.6 mmol/L or 83 mg/dL) after adjusting for several other cardiovascular risk factors.[28] Other cohort studies also subsequently showed a relationship between cardiovascular events and both fasting and postload glucose levels.[29]

In a 1998 systematic overview and meta-analysis of published cohort studies describing more than 1 million person-years of follow-up of mainly non-diabetic populations, the risk of cardiovascular disease increased continuously with fasting and postload glucose levels above 4.2 mmol/L (75 mg/dL).[30] In a more recent meta-analysis of several large prospective studies comprising more than 1 million person-years of follow-up of people with and without diabetes, a 1 mmol/L higher fasting glucose level was associated with a 20% higher risk of various cardiovascular outcomes.[31]

Prospective studies have also demonstrated a relationship between HbA1c and cardiovascular outcomes regardless of DM status. Thus, in a nine-year prospective study of 1326 people with no history of diabetes, the risk of myocardial infarction, fatal coronary heart disease or revascularization rose 68% per 1% point increase in the absolute HbA1c level, after accounting for other cardiovascular risk factors.[23] Moreover, in a six-year prospective study of 10232 people (243 with established diabetes) the age-adjusted risk of a cardiovascular disease event rose 30% per 1% point increase of HbA1c and 20% per 1% point increase of HbA1c after adjustment for many other risk factors.[32] These studies also suggest that the relationship between glucose and cardiovascular disease may be more marked in the prediabetes or early DM range than it is in people with established diabetes.

Therefore, glucose appears to be a continuous cardiovascular risk factor, similar to cholesterol or blood pressure in its dose–response relationship,[33,34] and dysglycemia rather than DM *per se* has been used to best capture this concept.[35,36] Thus people with dysglycemia alone are at risk for cardiovascular disease, people with dysglycemia and impaired glucose tolerance (IGT) are at higher risk for cardiovascular disease as well as DM, and people with DM are at even higher risk for cardiovascular disease as well as eye, kidney, and nerve disease (Fig. 14.2).
Figure 14.2 Frequency distribution of glucose levels in the general population. The significance of glucose as a risk factor for chronic disease depends on the level. Glucose levels above the diabetic threshold are associated with an increasing risk of cardiovascular and microvascular (e.g. retinal) disease, levels above the IGT threshold are associated with an increasing risk of diabetes, and elevated levels above some as yet undefined "dysglycemic" threshold are associated with an increasing risk of cardiovascular disease. CV, cardiovascular; DM, diabetes mellitus; IGT, impaired glucose tolerance.

Explanation of the dysglycemia–cardiovascular disease connection

Possible explanations for a glucose–cardiovascular disease relationship have been reviewed[5] and are summarized in Figure 14.3. They include:
- direct toxic effects of glucose
- decreased insulin effect due to reduced insulin secretion, reduced insulin action (i.e. insulin resistance)
- a genetic and/or environmental abnormality that predisposes individuals to both DM and cardiovascular disease; and
- a combination of these abnormalities.

Direct toxic effect of glucose

Glycation of a variety of proteins may directly promote cardiovascular disease.[37] Glycated albumin promotes albuminuria and endothelial cell dysfunction; glycated red cell membranes are less deformable; glycated LDL apoproteins are more susceptible than non-glycated LDL to uptake by scavenger cells (which would increase foam cell formation), oxidation, and increased platelet aggregation; glycated high-density lipoprotein (HDL) is less able to transport cholesterol; and glycated fibrin and platelet membranes adversely affect vascular homeostasis. Advanced glycation endproducts (AGE) also accumulate on vessel walls and in the vessel matrix, and may

Factors that Increase the Risk of Both Diabetes and Cardiovascular Disease

Mediators of Metabolic/Vascular Effects
(e.g. Glycation, Glycoxidation, Dyslipidemia, Hyperinsulinemia, Inflammation, Procoagulant State, Endoplasmic Reticulum Stress, Activated Hexosamine and Other Cellular Pathways, Mitochondirial Damage)

Diabetes Mellitus

Cardiovascular Disease

Figure 14.3 Possible explanations for the relationship between dysglycemia and cardiovascular disease. Insufficient insulin effect due to either reduced secretion, increased resistance or both leads to an elevated glucose level. Both the elevated glucose level and the reduced insulin effect may promote a variety of processes that in turn lead to both diabetes and cardiovascular disease. Antecedent factors may promote both diabetes and cardiovascular disease directly and/or by reducing insulin secretion or action, thereby increasing glucose levels.

adversely affect endothelial cell function and promote atherosclerosis.[38,39]

Glucose metabolism may also promote cellular damage. Excess glucose entry into cells may activate at least four different pathways implicated in atherosclerosis:[40,41]

• the polyol pathway, which depletes reduced glutathione (an intracellular antioxidant) and increases oxidative stress
• the hexosamine pathway, which promotes glycation of various intracelullar proteins, transcription of proinflammatory and prothrombotic signals, endoplasmic reticulum stress and apoptosis[42–48]
• the glyceraldehyde-3-phosphate pathway which increases protein kinase C and reactive oxygen species, and which increases formation of advanced glycation endproducts
• mitochondrial production of reactive oxygen species which may damage mitochondrial or cellular DNA.[41,47,49]

Decreased insulin effect

Glucose is the major stimulus for insulin secretion, which in turn prevents rises in glucose levels. Therefore an elevated glucose level implies a lack of sufficient insulin to maintain normoglycemia. Such a lack of *sufficient* insulin may occur in the presence of both low and high absolute levels of insulin, depending on the degree of insulin resistance. Indeed, the observation that apparently "normoglycemic" people with insulin resistance have slight glucose elevation[50] suggests that "insulin resistance" may represent a state of insufficient insulin effect, with hyperinsulinemia representing the pancreas' (unsuccessful) efforts at compensating for the reduced insulin effect. Such a possibility

may account for the association between hyperinsulinemia and markers of cardiovascular disease.[51,52] A number of observations support the possibility that insufficient (and not excess) insulin may be related to cardiovascular disease.

Patients with both type 1 DM (with no endogenous insulin secretion) and type 2 DM (who are not able to make sufficient insulin to maintain normoglycemia) are at high risk for cardiovascular disease.

Patients with cardiovascular disease have increased levels of proinsulin and split products[53,54] – a biochemical marker of a failing beta cell.

Insulin inhibits lipolysis and the lipolytic effect of stress hormones such as cortisol and catecholamines. Insufficient insulin effect therefore promotes free fatty acid flux which:

• reduces the effect of insulin at target tissues[55]
• promotes ectopic fat deposition in beta cells (which may damage them, further reducing insulin secretion)[56]
• promotes the synthesis of atherogenic lipoproteins[55,56]
• inhibit glycolysis and anaerobic ATP production in ischemic cardiac muscle.[57]

Insulin has anti-inflammatory properties[58] and reduces PAI-1 levels; therefore insulin insufficiency may promote inflammation and arterial thrombosis, thereby leading to atherosclerosis. Insufficient insulin may reduce ischemic preconditioning in heart muscle.[59] Insulin promotes endothelial nitric oxide synthesis and vasodilation, especially in response to ischemia[59]; insufficient insulin may therefore inhibit these effects.

Patients with insulinomas who are insulin resistant, hyperinsulinemic, and *hypoglycemic* have normal lipid profiles and blood pressure, and no clinical evidence of car-

diovascular disease.[60] Studies of intensified insulin therapy in patients with type 1 DM taking multiple daily doses of insulin suggest a reduced and not an increased risk for cardiovascular events.[61]

Association with other risk factors

Both hyperglycemia and cardiovascular disease are associated with hypertension, smoking, excess energy intake, visceral/ectopic fat deposition, genetic variants, poor socioeconomic status, low birth weight, and intrauterine factors (see Fig. 14.3). As such, the observed association between dysglycemia and cardiovascular disease may be caused by one or more of these "proximal" risk factors or some other common antecedent such as an unrecognized environmental toxin. If true, these factors may directly cause both cardiovascular disease and DM and the association between dysglycemia and cardiovascular disease may be due to confounding with one or more of these proximal factors.[5]

All of the above

The most likely explanation for the link between dysglycemia and cardiovascular disease is some combination of the factors described above, that may together magnify each one's incremental effects.

Does glucose lowering reduce cardiovascular outcomes?

Glucose-lowering trials in people with diabetes

As of June 2008, several randomized controlled trials of intensive versus standard glucose lowering approaches have been completed in people with type 1 DM (in which different insulin regimens were used to lower glucose levels) and people with type 2 DM (in which different regimens of oral agents and/or insulin were used to lower glucose levels).

In **type 1** diabetes, the Diabetes Control and Complications Trial in 1441 relatively young people (mean age 27 years) studied the effect of an initial 6.5-year period of intensive insulin therapy targeting normoglycemia (which achieved a HbA1c of 7.4%) versus conventional insulin therapy (which achieved a HbA1c of 9.1%). No clear cardiovascular effect was detected at the end of the active treatment phase of the trial. Following this phase, 97% of the 1441 participants were followed passively for a further 11 years until at least 50 participants in the group originally allocated to standard therapy had a predefined cardiovascular outcome. During that time the HbA1c level in both groups was similar; nevertheless, by the end of passive

follow-up people who were allocated to the intensive group experienced a 42% (95% confidence interval (CI) 9–63%) reduction in a predefined cardiovascular composite outcome and a 57% (95% CI 12–79%) reduction in the first occurrence of non-fatal myocardial infarction, stroke or cardiovascular death.[61] Of note, adjustment for the 2% HbA1c difference between groups achieved in the active phase of the trial rendered the cardiovascular outcome difference non-significant. This suggests that the cardiovascular difference may be explained by the achieved HbA1c difference and strongly suggests that intensified insulin therapy targeting normoglycemia for at least six years reduces cardiovascular events in people with type 1 diabetes.

Several studies have now reported the effect of glucose-lowering in people with **type 2** diabetes. These studies include:

• the United Kingdom Prospective Diabetes Study (UKPDS) which recruited 3867 people with newly diagnosed DM at low cardiovascular risk and which tested the effect of intensive versus conventional glucose control starting with insulin, sulfonylurea or (in obese participants) metformin[62]

• the Action in Diabetes and Vascular Disease (ADVANCE) trial of 11 140 people with established DM (mean duration eight years) and high cardiovascular risk[63]

• the Veterans Administration Diabetes Trial (VADT) of 1791 people (mainly men) with established DM and high cardiovascular risk[64] (final report not published)

• the Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial of 10 251 people with established DM (mean duration 10 years) and high cardiovascular risk[65]

• the Prospective Pioglitazone Clinical Trial in Macrovascular Events (PROACTIVE) study[66] which tested the effect of pioglitazone versus placebo in 5238 people with established DM (mean duration eight years) and high cardiovascular risk.

Table 14.5 lists the key characteristics and findings of these trials. These findings support several conclusions. First, they are consistent with the hypothesis that a glucose-lowering intervention may reduce cardiovascular outcomes in people with type 2 diabetes. The myocardial infarction trends favoring a 14% reduced risk in the UKPDS during 10 years of follow-up,[67] a 17% reduced risk in PROACTIVE during 2.9 years of follow-up[68] and the 24% reduction in ACCORD during 3.5 years of follow-up[65] all favor this possibility. This is also supported by the trends favoring a reduced risk of the composite cardiovascular outcomes in PROACTIVE, ACCORD, ADVANCE, and VADT. Unfortunately, the low cardiovascular event rate in the UKPDS (which recruited patients at low risk for cardiovascular events), the short follow-up of PROACTIVE, the truncated follow-up of the ACCORD study (due to the mortality signal discussed below), and the low power of the VADT study (due to overestimation of the event rate prior to

Table 14.5 Cardiovascular events and mortality in large outcome trials of glucose-lowering therapies

Study	N	Participants	Study duration	Median HbA1c contrast	Therapy tested	Relative risk reduction (95% CI)		
						MI	Primary CV outcome	Mortality
UKPDS[67,76]	3867	New DM	10 yrs	From 7.1% → 7.0% vs. 7.9%	Insulin or SU	16% (0, 29)	N/A	6% (−10, 20)
	753	Obese, new DM	10.7 yrs	From 7.2% → 7.4% vs. 8.0%	Metformin	39% (11, 59)	N/A	36% (9, 35)
PROACTIVE[68]	5238	DM [mult] 8 yrs High CV risk	2.9 yrs	From 7.9% → 6.9% vs. 7.5%	Pioglitazone	17% (−6, 35)	10% (−1, 20)	4% (−18, 22)
ACCORD[65]	10251	DM [mult] 10 yrs High CV risk	3.5 yrs	From 8.1% → 6.4% vs. 7.5%	Multiple therapies	24% (8, 38)	10% (−4, 22)	−22% (−1, −46)
ADVANCE[63]	11140	DM [mult] 8 yrs High CV risk	5 yrs	From 7.2% → 6.4% vs. 7.0%	SU + multiple therapies	2% (−23,22)	6% (−6, 16)	7% (−6, 17)
VADT (ADA Presentation)	1791	DM [mult] 11.5 yrs High CV risk	6.3 yrs	From 9.5% → 6.9% vs. 8.4%	Multiple therapies	N/A	13% (−4, 27)	N/A

UKPDS, United Kingdom Prospective Diabetes Study; ACCORD, Action to Control Cardiovascular Risk in Diabetes; ADVANCE, Action in Diabetes and Vascular Disease; ADA, American Diabetes Association; DM, diabetes mellitus; Dx, diagnosis; MI, myocardial infarction; CVD, cardiovascular disease; SU, sulfonylurea; N/A, not available.

starting the study) reduced the ability of the currently completed studies to detect a benefit, even if one truly exists.

Second, participants most likely to benefit from a glucose-lowering intervention may be those with better glycemic control. The UKPDS, which studied people with newly diagnosed diabetes, and the ACCORD trial, which reported a clear reduction in the cardiovascular composite outcome exceeding 20% in participants whose baseline HbA1c level was less than 8% (see Table 14.5), both support this possibility. Third, the fact that the glycemic intervention in the ACCORD trial was stopped early after the Data Safety and Monitoring Board noted an absolute excess mortality of 0.3% and a relative excess of 22% ($P = 0.04$) suggests that a therapeutic strategy that attempts to intensively lower glucose levels to non-diabetic levels may cause harm within the first 2.5–3 years. The fact that the differences in mortality are small and were not observed in the other trials suggests that they could be related to the intensity of the intervention or participant characteristics, could represent an early adverse event of intensive glucose control in "poorly controlled" patients that may or may not persist, or could even be a chance finding.

Glucose-lowering trials in people with impaired glucose tolerance or impaired fasting glucose

As noted above, there is a progressive relationship between glycemia and cardiovascular risk that extends from normal levels right into the DM range. Moreover, this relationship may be more profound for people without established DM than for people with DM.[23,32] The possibility that glucose-lowering therapies may reduce cardiovascular events in people with IGT or IFG (sometimes called "prediabetes") was suggested by an analysis of data from a trial of acarbose to prevent DM in people with IGT.[69] Such an effect has not been seen in other prevention studies to date[70–73] which generally recruited people at low risk for cardiovascular outcomes, were short term, and reported few cardiovascular events. However, the recent finding that DM prevention with rosiglitazone also reduced a predefined renal outcome (albuminuria or a fall in the estimated glomerular filtration rate) in people with impaired glucose tolerance or impaired fasting glucose[74] is consistent with this possibility in light of the strong link between renal and cardiovascular disease.

The effect of glucose lowering in people with impaired glucose tolerance is currently being tested within two ongoing trials: the Nateglinide and Valsartan in Impaired Glucose Tolerance Outcomes Research (NAVIGATOR) trial (using nateglinide) and the Acarbose Cardiovascular Evaluation (ACE) trial (using acarbose). This possibility is also being assessed in the Outcome Reduction with an Initial Glargine Intervention (ORIGIN) trial in which 18% of participants did not have established DM at the time of randomization.[75]

Key points

Taken together, the body of research reviewed above supports a number of cardiovascular conclusions.

- Intensified insulin therapy targeting normoglycemia that is started while young reduces cardiovascular outcomes in people with type 1 diabetes.
- Metformin may reduce cardiovascular outcomes and mortality in newly diagnosed people with type 2 diabetes; these observations need replication.
- The effect of other specific glucose-lowering drugs on cardiovascular outcomes remains unknown.
- In people who start with poor glucose levels, intensive glucose lowering for a period of approximately 3.5 years that is achieved with a menu of medications and lifestyle approaches: a) does not clearly reduce cardiovascular outcomes; b) may reduce cardiovascular outcomes in people with lower glucose levels or less severe cardiovascular disease; and c) increases mortality. The cardiovascular and mortality effects of intensive glucose lowering after a longer follow-up period of at least five years are unclear and need to be established.
- The cardiovascular benefits and risks of DM prevention or of therapies that prevent the rise of glucose levels with time in people with impaired fasting glucose, impaired glucose tolerance or DM remain unknown.

Conclusion

Dysglycemia is clearly an independent risk factor for cardiovascular disease and there are a number of direct and indirect biologic pathways linking elevated glucose levels to cardiovascular disease.

Similar to dyslipidemia, in which ongoing studies are continuing to show the therapeutic value of reducing even minimally elevated lipid levels, therapies that reduce elevated glucose levels may reduce the risk of cardiovascular disease. However, they may also cause harm. As with other therapies, both benefits and risks may apply to specific drugs and to specific subsets of individuals and need to be carefully characterized. The ongoing ORIGIN, NAVIGATOR and ACE studies are clarifying these benefits and risks in people with early dysglycemia and several other cardiovascular risk factors.

These and other studies with newer classes of glucose-lowering drugs may provide novel ways of preventing cardiovascular disease in a growing number of individuals with dysglycemia. Until they are completed, cardiovascular prevention needs to focus on applying proven preventive therapies including blood pressure lowering with a variety of drugs, statin use, smoking cessation, and ACE inhibitor use.

15 Physical activity and exercise in cardiovascular disease prevention and rehabilitation

Ray W Squires
Mayo Clinic College of Medicine, Rochester, MN, USA

Introduction

A sedentary lifestyle has been established as a major modifiable coronary risk factor by the American Heart Association.[1] Unfortunately, approximately 70% of adults in the United States are sedentary or underactive, and almost one-half of America's young people aged 12–21 years are not physically active on a regular basis.[2] The reasons for this observation are closely related to industrialization, automation, and the resultant decreased requirement for occupational, household, and leisure-time physical activity in the past several decades. The need to walk, climb stairs, perform energy-requiring tasks around the home or engage in physical activity in the workplace has dramatically decreased for the vast majority of people. In the 21st century, individuals must make a conscious choice to be physically active.

The definitions of *physical activity, exercise* and *cardiorespiratory fitness* are important to the understanding of this chapter. The 1996 National Institutes of Health Consensus Conference on Physical Activity and Cardiovascular Health defined *physical activity* as "bodily movement produced by skeletal muscles that requires energy expenditure and produces health benefits".[3] Physical activity is informal in nature and structure and includes everyday activities such as walking or bicycling or stair climbing for transportation, as well as household or yard tasks, occupational tasks and low-intensity sports such as golf. Physical activity occurs within the structure of the requirements of usual daily living. Recently, energy expenditure due to changes in posture and movement associated with the routines of daily life, termed non-exercise activity thermogenesis (NEAT), was compared in lean and obese subjects.[4] Lean subjects expended an average of 350 kilocalories more each day in NEAT than did obese subjects, underscoring the importance of physical activity in coronary risk.

Exercise, also called exercise training, was defined as "planned, structured, and repetitive bodily movement done to improve or maintain one or more components of physical fitness".[3] It is characterized by periodic formal workouts involving sustained moderate- to high-intensity effort. It usually involves specific clothing, such as footwear, and equipment, as is present in fitness facilities, but is not an absolutely necessary part of the daily routine. It may involve sporting activities, such as basketball, racquet sports or soccer (non-American football).

Cardiorespiratory fitness (peak exercise oxygen uptake) is defined as the capacity to take in and process oxygen for the production of energy via aerobic metabolism for physical activity or exercise. This component of physical fitness is most closely associated with coronary risk. Cardiorespiratory fitness is directly influenced by the performance of habitual exercise training, but is also influenced by genetic potential,[5] age and gender, as well as by underlying chronic diseases that affect the cardiorespiratory systems, nervous system, blood and musculoskeletal system.

The goal of this chapter is to discuss the roles of physical activity and formal exercise in the prevention and rehabilitation (secondary prevention) of coronary heart disease (CHD). The following topics are included for this purpose:
- observational data concerning the relationship of occupational and leisure-time physical activity and exercise to coronary risk
- studies evaluating the relationship of cardiorespiratory fitness or change in cardiorespiratory fitness and coronary risk
- data addressing the results of exercise training in persons with established CHD with regard to disease progression and coronary events
- the risks of acute exercise
- potential mechanisms for the observed cardioprotective effects of physical activity and exercise training
- recommendations for physical activity and exercise training.

Observational studies in the prevention of coronary heart disease

Due to methodologic and ethical issues, there are no randomized trials of physical activity and exercise on clinical cardiovascular outcomes. Observational studies have been performed, however. An inherent limitation of observational data is selection bias. For example, individuals may be sedentary because of undetected pathology or physically active because of superior general health. However, investigations of either occupational or leisure time physical activity, exercise and coronary risk provide valuable information if the studies include large numbers of subjects.

Studies of occupational physical activity attempt to quantify the amount of physical activity that occurs during the performance of job duties. Most studies of this type report occupational physical activity by category, i.e. most active, moderately active, and least active. Because the requirement for occupational physical activity has decreased precipitously in the last several decades in developed countries, investigators have more recently turned attention to the relationship of leisure-time physical activity and exercise to coronary risk. This type of exercise is undertaken by people during discretionary time outside work, domestic tasks, and other routine activities of daily living.

Occupational physical activity

Multiple investigators have demonstrated an inverse relationship between the amount and intensity of job-related physical activity and coronary risk. The following three studies are illustrative of this finding.

A large population of US railroad workers (191 609 men, age range 30–64 years) was evaluated by Taylor and associates.[6] Occupational physical activity was determined by job class: sedentary clerks, more active switchmen, and most active section men. Potential confounding variables were not controlled. Death caused by atherosclerosis was more frequent for clerks (relative risk 2.03) and switchmen (relative risk 1.46) when compared with the more physically active section men.

Morris and colleagues studied 667 male London bus drivers and conductors (age range 30–69 years) for five years.[7] Physical activity on the job was assessed by specific work duties: drivers were sedentary whereas conductors moved about the double-decker buses collecting fares. The incidence of CHD was much lower for the more active conductors than for the drivers (age-adjusted relative risk 1.8).

Paffenbarger *et al* followed 6351 San Francisco longshoremen (35–74 years of age) for 22 years.[8] Physical activity was defined by specific job requirements and categorized as light (1.5–2.0 kcal/min, 1.3–1.8 metabolic equivalents (METs) for a 70 kg person), moderate (2.4–5.0 kcal/min, 2.0–4.3 METs) or heavy (5.2–7.5 kcal/min, 4.4–6.4 METs). Death attributable to CHD was inversely related with job energy expenditure (relative risk (RR) 1.8 for light and 1.7 for moderate, compared with heavy physical activity).

Leisure-time physical activity and exercise

Several studies have investigated the association between the amount and intensity of leisure-time physical activity or exercise and CHD endpoints. The most prominent investigation in this group is the Harvard Alumni Study of Paffenbarger and associates.[9] Beginning in 1962 and continuing until 1978, 16 936 men were followed for a variety of endpoints including first myocardial infarction (MI), cardiovascular death, and CHD death. An index of energy expenditure for physical activity and exercise in kcal/week was estimated for each subject based on self-reported physical activity, including number of blocks walked, stairs climbed, and participation in vigorous exercise. Among the findings of the study was an inverse relationship between the amount of habitual physical activity and/or exercise and first MI (age-adjusted relative risk 1.64 for men with <2000 kcal/week versus men with >2000 kcal/week). Interestingly, having participated in athletics as a young person was not associated with a lower risk unless there was evidence of current physical activity or exercise. After adjustment for age, smoking and hypertension, there remained a significant dose–response relationship. Figure 15.1 illustrates this dose–response relationship, as well as the cardioprotective advantage of vigorous exercise over less vigorous physical activity.
Figure 15.1 Exercise and physical activity and the reduction in risk of first myocardial infarction: the Harvard Alumni Study. (From Paffenbarger & Hyde[9].)

In 1977, a second physical activity and exercise questionnaire was administered to the Harvard Alumni Study cohort. A subgroup of 12 516 survivors without documented CHD were followed until the end of 1993.[10] After adjustment for age and multiple well-established coronary risk factors, subjects who expended more than 1000 kcal/week experienced an approximately 20% lower coronary event rate than subjects who expended less than 1000 kcal/week. A third questionnaire was given to 7307 Harvard Alumni Study subjects in 1988, and included questions regarding the frequency and duration of each episode of physical activity and exercise.[11] Follow-up concluded at the end of 1993 and revealed that after adjustment for total energy expenditure, the duration of each episode of physical activity or exercise had no independent effect on coronary risk. As long as the total energy expenditure was similar, longer sessions of physical activity or exercise did not result in a greater risk reduction.

Morris and colleagues studied 17 944 British male civil servants, aged 40–64 years, for an average of 8.5 years.[12] Baseline levels of physical activity and exercise were assessed by a unique 48-hour recall of leisure-time activities. Vigorous exercise was defined as an energy expenditure of at least 7.5 kcal/minute (6.4 METs for a 70 kg person). During follow-up, there were 1138 coronary events (fatal and non-fatal first MI). The age-adjusted relative risk of a coronary event for men reporting non-vigorous physical activity versus those reporting vigorous exercise was 2.2.

The Nurses' Health Study enrolled 72 488 women, aged 40–65 years, who were initially free from CHD.[13] Habitual patterns of physical activity and exercise, including walking, cycling, jogging, swimming, racquet sports, calisthenics, aerobics, stairs climbed, and walking pace were collected in 1986 and subsequently updated in 1988 and again in 1992. After eight years of follow-up, 645 coronary events (MI, CHD death) occurred. There was a graded, inverse relationship between amount of physical activity or exercise and coronary events. The multivariate adjusted relative risk for the most physically active versus the least physically active quintile of the population was 0.66. Walking distance was inversely associated with risk. Vigorous exercise was associated with a 30–40% reduction in coronary events. Subjects who were initially sedentary and became more active during follow-up enjoyed a lower coronary risk than sedentary subjects who remained inactive.

The Women's Health Study included 39 372 health professionals who were at least 45 years of age and free of CHD at enrollment.[14] Habitual levels of physical activity and exercise, including walking, pace of walking, flights of stairs climbed, and sporting pursuits were assessed. After an average follow-up interval of 5 years, 244 cases of CHD occurred (MI, coronary revascularization, CHD death). The multivariate adjusted relative risk for the most active

(>1500 kcal/week) versus the least active (<200 kcal/week) quartiles was 0.75. The time spent walking was more important in coronary risk reduction than was the pace of walking. For women with coronary risk factors such as obesity, cigarette smoking and dyslipidemia, physical activity and exercise were protective. Subjects who walked one hour per week experienced one half of the risk of subjects who did not walk.

Cardiorespiratory fitness and coronary death

When estimated with maximal graded exercise testing, cardiorespiratory fitness has been shown to be inversely related with cardiovascular risk. The following are examples of investigations, some that included both genders as well as younger and older subjects. An important limitation of these studies is that genetic potential plays a central role in cardiorespiratory fitness, independent of habitual exercise.[5]

Blair and associates studied patients of the Aerobics Center in Dallas, Texas, who had an initial evaluation including a maximal treadmill exercise test. Men (n = 10 224) and women (n = 3120) were categorized by fitness level (low, moderate, high), based on treadmill exercise performance, and followed for an average of eight years.[15] The coronary death rate decreased dramatically with increasing fitness level for both genders (Table 15.1). However, there were relatively few coronary deaths in this population of rather young subjects (66 deaths in men, seven deaths in women). Blair also assessed the effects of improvement in cardiorespiratory fitness on coronary risk with subjects at the Aerobics Center.[16] A large cohort of men (n = 9777, age range 20–82 years) underwent two maximal treadmill exercise tests at a mean interval of 4.9 years. The subjects were followed for an average of 5.1 years. There were 87 cardiovascular deaths during follow-up. Relative to subjects who remained unfit, subjects who improved their fitness category experienced an age-adjusted relative risk of 0.48 (95% confidence interval (CI) 0.31–0.74).

A cohort of 1960 Norwegian men (age range 40–59 years) underwent maximal graded exercise testing and were followed for an average of 16 years.[17] Eighty-seven cardiovascular deaths occurred. After extensive statistical control of potential confounding factors, a strong inverse relationship between cardiorespiratory fitness and coronary risk was found. Compared with men in the lowest fitness quartile, the relative risks for quartiles 2, 3, and 4 were 0.59, 0.45, and 0.41, respectively.

Two studies involving all residents of Olmsted County, Minnesota, who underwent maximal treadmill exercise testing in the late 1980s provide additional insight into the relationship of cardiorespiratory fitness and coronary risk.

Table 15.1 Rates of coronary death by fitness level: the Aerobics Center Study (from Blair et al.[15])

N	Mean age	Follow-up
10224 ♂	41.5 years	8 years
3120 ♀	40.8 years	8 years

Fitness level	Coronary death rate per 10000 person-years	
	Male	**Female**
Low	24.6	7.4
Moderate	7.8	2.9
High	3.1	0.8

Figure 15.2 Physical activity and death rates in patients with coronary artery disease in the Harvard Alumni Study. (From Paffenbarger & Hyde[9].)

Observational data

In the Harvard Alumni Study, reviewed previously in this chapter, a subset of 782 subjects of the entire 16936-person cohort had documented coronary heart disease at the beginning of the study.[9] Over a follow-up interval of approximately 12 years, the more physically active subjects (those who expended more than 2000 kcal/week in leisure-time physical activity and exercise) experienced a 30% lower coronary event rate than less active subjects (Fig. 15.2). The beneficial effect of exercise persisted after statistical adjustment for smoking, blood pressure, body weight, family history of coronary heart disease and age.

In the British Regional Heart Study, 772 of the 5934 men in the cohort had documented coronary heart disease at the onset of the trial.[21] A baseline assessment of habitual physical activity, including intensity of activity, was performed. After five years of follow-up, 131 deaths had occurred (94 from cardiovascular disease). Compared with inactive subjects, persons who performed light, moderate or vigorous exercise experienced a substantially lower all-cause and cardiovascular mortality (Table 15.2). These results were similar for younger and older (>65 years of age) subjects.

Roger and colleagues followed 1452 men and 741 women who had treadmill exercise tests in 1987 and 1988 for approximately six years.[18] Cardiovascular endpoints included cardiac death, non-fatal myocardial infarction, and congestive heart failure. A total of 160 cardiovascular endpoints occurred during follow-up (106 in men, 54 in women). After multivariate adjustment, peak treadmill workload in METs was the only variable associated with the outcome measures. For each 1 MET increment in cardiorespiratory fitness, cardiac events were reduced by 25%, with a similar effect for both genders. Using similar methods, Goraya and associates followed 3107 Olmsted County residents who underwent maximal treadmill exercise testing in 1987 to 1989 and were followed for a median of six years.[19] Both genders were included and 514 of the subjects were over 65 years of age. For each 1 MET increase in cardiorespiratory fitness, cardiovascular events were reduced by 14% and 18% for younger and older (>65 years) subjects, respectively.

Exercise training in established coronary disease

For patients with coronary heart disease, exercise training improves exercise capacity and symptoms. After three months of aerobic exercise training, peak oxygen uptake improves by 15–20%.[20] Symptoms of angina pectoris may be markedly improved by exercise training. Resistance training results in improvements in muscle strength and maintains muscle mass. There are also data available to demonstrate that physical activity and exercise training improve important clinical outcomes for patients with coronary heart disease. These data are the result of both observational and randomized controlled trials.

Randomized trials

Kallio and colleagues randomized 301 men and 74 women with a history of myocardial infarction to a comprehensive rehabilitation program (exercise training, dietary and smoking cessation advice, psychosocial counseling) or to a control group.[22] Compared with the control group, the intervention group experienced an improvement in habitual physical activity, blood lipids and blood pressure. The three-year cumulative mortality was 18.6% in the intervention group versus 29.4% in the control group (P = 0.02). The

Table 15.2 Cardiovascular mortality by activity level in the British Regional Heart Study (from Wannamethee et al.[21])

Activity level	Cardiovascular mortality	
	Age-adjusted RR	*Fully adjusted RR
Inactive/occasional	1.00	1.00
Light	0.33	0.38
Moderate	0.39	0.50
Moderate to vigorous/ vigorous	0.49	0.61

*Adjusted for age, smoking, social class, self-rated health status, diabetes, and history of myocardial infarction and stroke.

difference was primarily the result of a reduction in the incidence of sudden cardiac death in the intervention group (5.8% versus 14.4%, $P < 0.01$). The rate of non-fatal reinfarction was similar for both groups.

Hamalainen and associates reported 10-year follow-up data for the same subjects.[23] No organized intervention occurred after the first three years of the study. At 10 years, the incidence of sudden cardiac death was less for the intervention group (12.8% versus 23.0%, $P = 0.01$). Cardiac mortality was also lower for intervention subjects (35.1% versus 47.1%, $P = 0.02$). The largest difference in mortality was observed during the first year of the investigation when beta-blocker use was similar for both groups.

Hambrecht et al randomized 101 men with stable coronary artery disease and exercise-induced myocardial ischemia to either percutaneous coronary intervention (PCI) or exercise training (20 minutes per day).[24] Medical therapy was similar for both groups. After one year, the investigators found that both treatment arms were equally effective in improving angina, although symptom improvement was more rapid for PCI. Exercise training was superior to PCI in the combined clinical endpoint of cardiac death, stroke, coronary bypass surgery, PCI, myocardial infarction and hospitalization for angina (event-free survival 88% exercise versus 70% PCI, $P < 0.02$).

Meta-analyses

Although there are many randomized controlled trials of cardiac rehabilitation including exercise training, no other studies besides the first two discussed above have provided evidence for a statistically significant reduction in mortality. Many of these trials have been plagued by insufficient numbers of subjects to achieve adequate statistical power and by subject drop-outs and cross-overs. Investigators have used meta-analysis to partially overcome these limitations and to determine pooled estimates of benefits.

In 1989, O'Connor and colleagues performed a meta-analysis of 22 randomized trials of exercise training and standard coronary risk factor intervention of varying intensity, resulting in a total sample of 4554 postmyocardial infarction patients.[25] Compared with control subjects, patients who were randomized to the exercise intervention experienced a reduction in total mortality, cardiovascular mortality, and fatal reinfarction of 20%, 22%, and 25%, respectively.

A more recent, expanded meta-analysis by Jolliffe and associates was published in the Cochrane Database.[26] The authors searched electronic databases for appropriate randomized trials from the earliest date until the end of 1998. They included studies with both genders, and included subjects with diagnoses of myocardial infarction, coronary bypass surgery, percutaneous revascularization, angina pectoris, and angiographically documented coronary atherosclerosis. All accepted trials used exercise training as a component of the intervention. Endpoints included mortality, morbidity, health-related quality of life and standard coronary risk factors. A total of 32 trials were included in their analysis, with 8440 subjects. A 31% reduction (relative risk 0.69) in cardiac mortality for intervention subjects was found. There was no effect on non-fatal myocardial infarction.

Exercise training in chronic heart failure

For patients with stable, compensated chronic heart failure (CHF), exercise training provides substantial benefits: improved exercise capacity, reduced symptoms, decreased evidence of neurohormonal activation, better quality of life and possibly improved mortality.[27] Early observational studies published in the 1970s and 1980s established the safety of exercise training for stable CHF patients and documented improvements in exercise capacity.[28]

More than 30 randomized controlled trials of exercise training in patients with CHF have been published, although the numbers of subjects in the trials were limited. A meta-analysis of the trials reported that the average improvement in VO_{2peak} after training was 17%.[29] Giannuzzi and colleagues randomized 90 patients with stable CHF to a six-month exercise program or a control group.[30] The exercise group demonstrated an improvement in exercise capacity as well as evidence of reverse cardiac remodeling with a decrease in end-diastolic and end-systolic volumes and a small increase in left ventricular ejection fraction.

ExTraMATCH was a collaborative meta-analysis which included nine parallel randomized controlled trials of exercise training in 801 CHF patients. With a mean follow-up of 705 days, there were 88 deaths in the exercise arm and 105 deaths in the control arm (hazard ratio 0.65, 95% confidence interval 0.46–0.92, $P = 0.015$)[31]. Additional studies with larger numbers of subjects are needed to fully assess the effects of exercise training on recurrent hospitalizations and mortality.

Recently, results from HF ACTION (Heart Failure: A Controlled Trial Investigating Outcomes of Exercise Training: 2331 subjects) were published.[32,33] After a median follow-up of 2.5 years and after adjustment for prognostic predictors, subjects in the exercise arm experienced a modest but significant reduction in both all-cause mortality and hospitalization. Although the improvement in VO_2 peak with training was modest, exercise subjects reported significant improvements in self-reported health status. Exercise training was found to be safe in these stable subjects with reduced ejection fraction.

Risks during acute exercise

Previous sections of this chapter have provided clear evidence for the cardioprotective effects of regular physical activity or exercise training. However, during an acute bout of exercise the risk of sudden cardiac death or myocardial infarction is transiently increased.[34] Acute exertion may trigger a cardiac event in a susceptible individual. Exercise-related cardiac events usually occur in persons with structural heart disease. Mittleman and colleagues interviewed 1228 survivors of acute myocardial infarction.[35] In approximately 5% of cases, heavy exertion apparently triggered the infarction.

The annual incidence of exercise-related cardiac arrest in previously healthy persons is 5.4/100 000.[34] The incidence is 56 times higher than that at rest for sedentary men and five times higher for physically active men.[36] The risk of myocardial infarction during exercise is 2–6 times higher than at rest.[34] Women experience a much lower risk of sudden death during exercise than do men.[37]

Even highly trained endurance athletes are not immune to exercise-associated cardiac death, although the risk is extremely low. In a survey of 215 413 marathon runners, four deaths were documented during running (prevalence of 0.002%).[38] Three of the four deaths were due to previously undetected coronary atherosclerosis.

Survey data from the 1980s and 1990s are available regarding the incidence of cardiac events in patients with coronary heart disease who exercise under supervision in cardiac rehabilitation programs.[39] The rates per 1 000 000 patient-hours of exercise for cardiac arrest, acute myocardial infarction and cardiac death were 8.6, 4.5 and 1.3, respectively.

Pathophysiologic mechanisms for exercise-related cardiac events

In young persons (<40 years of age), congenital cardiovascular abnormalities are generally responsible for exercise-related sudden death.[39] Examples of such abnormalities include the following.
- Hypertrophic cardiomyopathy
- Anomalous coronary artery anatomy
- Aortic stenosis
- Marfan's syndrome resulting in aortic rupture
- Mitral valve prolapse
- Arrhythmogenic right ventricular cardiomyopathy

For individuals older than 40 years, coronary artery disease is the most common pathologic finding. While not completely understood, the following are accepted as potential mechanisms for death during exertion in patients with coronary disease.

1 Hemodynamic stress may result in rupture and subsequent thrombus formation in a high-risk coronary plaque. Burke and associates reported autopsy evidence of this type of occurrence in 68% of cases of sudden cardiac death associated with exertion.[40] Acute exercise may increase platelet activation, thereby increasing risk of thrombus formation.[39] Plaque rupture and thrombosis may result in acute myocardial infarction, as well.

2 Myocardial ischemia is an important contributor to malignant ventricular arrhythmia. In patients with coronary atherosclerosis, an acute bout of exercise may cause constriction of diseased coronary segments, unlike the usual exertion-related vasodilation of healthy coronary arteries. This increases the likelihood of the development of ischemia. The reasons for this paradoxical coronary vasoconstriction include excessive sympathetic nervous system activation, endothelial dysfunction and platelet aggregation.[41]

3 Autonomic nervous system imbalance (autonomic dysfunction), with inappropriate activation of the sympathetic division and diminished parasympathetic activation, may result in ventricular arrhythmia independent of myocardial ischemia.[42]

How does habitual exercise decrease coronary risk?

The following discussion highlights some of the potential mechanisms for the cardioprotective effect of exercise.

Structural improvements in coronary arteries

Habitual physical activity and exercise may result in structural adaptations of the epicardial coronary arteries such as:
- increased cross-sectional area of the lumen[43]
- improved capacity for vasodilation, resulting from enhanced endothelial function[44]
- potential increased collateral circulation in patients with ischemic left ventricular dysfunction.[45]

Improvement in hypertension, blood lipids, obesity and depression

Observational data from the Harvard Alumni Study are consistent with the concept that habitual exercise appears to reduce the chances of developing hypertension.[46] Regular

exercise may modestly lower blood pressure in hypertensive patients and in normal individuals by an average of 6–9 mm Hg for both systolic and diastolic pressures.[47]

Regular exercise results in modest improvements in the blood lipid profile. A meta-analysis revealed an average reduction in total cholesterol of 7–13 mg/dL, low-density lipoprotein cholesterol of 3–11 mg/dL, and triglycerides of 14–22 mg/dL.[48] High-density lipoprotein cholesterol increased by an average of 2 mg/dL. There is marked inter-individual variability in the effect of exercise training on blood lipids.

Exercise, in adequate amounts, is effective as part of a comprehensive approach to reduce fat weight in obesity. McGuire and colleagues studied differences in obese subjects who were successful in maintaining an average 37 lb weight loss over seven years compared to subjects who were not.[49] The average number of weekly sessions of physical activity were higher (8.4 versus 5.5), as were the number of strenuous exercise sessions each week (2.8 versus 1.8), for subjects who maintained the weight loss. Exercise training reduces abdominal fat to a greater extent than gluteal or femoral fat in obese men.[50] In the Aerobics Center Longitudinal Study, over 5000 men and women underwent three treadmill exercise tests (between 1970 and 1994) and were followed for an average of 7.5 years.[51] Subjects who increased fitness from one treadmill test to the next, presumably by increasing habitual exercise, attenuated the usual age-related increase in body weight.

Symptoms of depression consistently improve with habitual physical activity and exercise.[52] Physically active persons appear to be at lower risk for the development of depression. In patients with documented coronary heart disease, exercise has been shown to improve anxiety, emotional distress, and depression.[20]

Metabolic syndrome

Patients with three or more of the following risk factors have the metabolic syndrome and a markedly increased coronary risk: abdominal obesity, elevated triglycerides, low high-density lipoprotein cholesterol, hypertension and impaired fasting blood glucose.[53] The causes of the metabolic syndrome for the overwhelming majority of patients are incorrect diet and too little physical activity. First-line therapy for the metabolic syndrome is increased physical activity and weight reduction.[54]

Impaired glucose metabolism and type 2 diabetes mellitus

Persons who perform exercise training have lower plasma insulin concentrations and improved insulin sensitivity compared with sedentary individuals.[55] With cessation of regular training, insulin concentration and sensitivity return to levels observed in sedentary persons.

Table 15.3 Weekly exercise amount and the risk of developing type 2 diabetes in the Nurses' Health Study, 1980–1996 (from Hu et al[56])

Weekly exercise duration	Relative risk
<0.5 h	1.0
0.5–1.9 h	0.89
2.0–3.9 h	0.87
4.0–6.9 h	0.83
≥7.0 h	0.71

Exercise and proper nutrition have been shown to improve glucose metabolism and to prevent the onset of type 2 diabetes mellitus. A one-year program of exercise and diet change resulted in an average weight loss of 10 kg and a decrease in fasting blood glucose and insulin concentrations.[49] In the Nurses' Health Study, subjects who performed more than 30 minutes of exercise per week experienced a much lower relative risk of developing diabetes over the 16 years of follow-up (Table 15.3).[56] The Diabetes Prevention Study was a randomized, controlled trial of an intervention of exercise and diet in 552 middle-aged men and women with impaired glucose tolerance but not type 2 diabetes mellitus.[57] After three years, intervention subjects had lost an average of 3–4 kg and experienced a 58% reduction in the incidence of diabetes (diabetes occurred in 11% of intervention subjects versus 23% of controls).

Autonomic nervous system dysfunction

Autonomic dysfunction, defined as a sustained increase in sympathetic activity and a decrease in parasympathetic activity, is associated with increased coronary risk and mortality.[42] Clinical indicators of autonomic dysfunction include: resting heart rate >90 beats/min, inability to achieve 85% of age-predicted maximal heart rate during graded exercise testing, abnormally slow heart rate recovery after maximal exercise (failure to decrease heart rate >12 beats/min during the first minute of recovery), and decreased heart rate variability (failure to change heart rate by ≥10 beats/min during one minute of slow deep breaths). Autonomic dysfunction may result in endothelial dysfunction, coronary vasospasm, left ventricular hypertrophy, and malignant ventricular arrhythmias. Exercise training results in a favorable decrease in sympathetic activity and an increase in parasympathetic tone in both healthy subjects[58] and in patients with coronary disease.[59]

Improved endothelial function

Endothelial dysfunction occurs in response to exposure to coronary risk factors and is an early and late player in
Figure 15.3 Energy expenditure per week and changes in angiographic coronary lesion morphology over one year. (From Hambrecht et al.[63])

Figure 15.4 Effects of 12 months of exercise training on heart rate (HR), systolic blood pressure (SBP), and the rate pressure product (RPP) at stages I and II of the Bruce treadmill exercise testing protocol. All variables were significantly lower ($P < 0.01$) after training. (From Ehsani et al.[66])

atherogenesis.[60] The following abnormalities may result: impaired coronary vasodilation, increased vasospasm, increased permeability to lipoproteins and other blood constituents, and increased adhesion of platelets and glycoproteins. Endothelial dysfunction may result in reduced myocardial perfusion and plaque rupture, leading to acute coronary syndromes.[61] Exercise training improves measures of endothelial function (endothelial-dependent vasodilation) in patients with coronary atherosclerosis.[62]

Reduced progression of coronary atherosclerosis

Exercise training in sufficient amounts appears to slow the progression of, or even modestly reverse, coronary atherosclerosis. A one-year randomized controlled trial of supervised, moderate-intensity exercise and a low-fat diet without the use of lipid-lowering medications was performed in approximately 60 subjects.[63] Angiographically determined progression of disease occurred in 45% of controls and 10% of exercise subjects. A modest degree of regression of disease was found in 28% of exercisers versus 6% of controls. Figure 15.3 shows that partial regression of coronary atherosclerosis was present in patients who expended an average of at least 2200 kilocalories per week in exercise (approximately 5–6 hours of moderate-intensity exercise per week).

Decreased thrombosis risk

Acute exercise causes transient activation of the coagulation system, resulting in an increased risk of thrombosis.[64] However, habitual exercise training results in an overall decreased thrombotic risk by the following mechanisms:[65–67]
• reduced fibrinogen concentration
• reduced platelet aggregation

• decreased plasminogen activator inhibitor-1
• increased endogenous tissue plasminogen activator.

Improvement in myocardial ischemia

Exercise training may improve myocardial ischemia by decreasing myocardial demand and improving oxygen delivery to the heart.[68–70] As seen in Figure 15.4, after exercise training, at a standard submaximal exercise intensity the rate-pressure product is reduced resulting in a lower myocardial oxygen requirement. This enables the patient to perform a higher intensity of physical activity before exceeding the ischemic threshold.

The rate pressure product at the ischemic threshold is increased by exercise training, independent of changes in other risk factors or anti-ischemic medications, suggesting that myocardial blood supply has improved.[71] Exercise-induced myocardial ischemia, measured by exercise thallium perfusion imaging and without alteration in the rate pressure product, has been shown to improve substantially after training.[69,70]

Recommendations for types and amounts of physical activity and exercise for patients with cardiovascular diseases

Exercise training provides benefits not only for patients with coronary heart disease, but also for individuals with chronic heart failure, heart transplantation, and valvular replacement or repair.[72] The following types and amounts of physical activity and exercise training are recommended.[73]
• Physical activity: accumulate 30–60 minutes of moderate-intensity physical activity ≥5 days week; examples are walking for transportation, housework, yardwork, stair climbing, low-intensity games and sports
• Aerobic exercise training:
  3–5 sessions per week
  50–80% of exercise capacity

20–60 minutes

Walk, treadmill, cycle, row, stair climber, arm/leg ergometer, etc.

- Resistance training:
  2–3 sessions per week (non-consecutive days)
  10–15 repetitions to moderate fatigue
  1–3 sets of 8–10 different exercises for both the upper and lower body
  Calisthenics, elastic bands, hand weights, weight machines

Table 15.4 provides additional information regarding exercise program components for persons with and without cardiovascular disease.

Table 15.4 Exercise program components from the American College of Sports Medicine* for persons with and without cardiovascular (CV) disease

Persons without CV disease	Persons with CV disease
Warm-up: 5–10 minutes low-intensity, large muscle activity, low-intensity stretching	Same
Conditioning phase: endurance exercise, 20–60 minutes, 3–5 days/week, 55–90% maximal heart rate; resistance training, 1 + sets 3–20 repetitions to volitional fatigue, exercises for the major muscle groups, 2–3 days/week; flexibility exercises	*Supervised setting*: minimum of 6 sessions
	Intensity: moderate, below ischemic and anginal thresholds, systolic blood pressure <250 mmHg, diastolic blood pressure <115 mmHg
	Resistance training: begin 5 weeks after cardiac surgery or myocardial infarction, 3 weeks after percutaneous intervention; 1 set of 10–15 repetitions, exercises for the major muscle groups, perceived exertion "fairly light to somewhat hard"
Cool-down: 5 minutes low-intensity, large muscle activity, stretching exercises for the major muscle groups	Same

Conclusion

The data presented in this chapter demonstrate that habitual exercise and physical activity are effective in reducing coronary risk. While an acute bout of exercise transiently increases the risk of a coronary event, the absolute risk is very small. The data for primary prevention are observational in nature, and randomized trials have not been performed due to logistical and ethical constraints. Occupational as well as leisure-time activities are cardioprotective. Cardiorespiratory fitness is inversely related to coronary risk. Investigations for secondary prevention include both observational studies and randomized trials. Individual trials were generally underpowered to detect differences in mortality and reinfarction, but meta-analyses have consistently demonstrated a protective effect of habitual physical activity and exercise training.

The data are consistent with the concept that the greater the total energy expenditure in physical activity or exercise, the lower the coronary risk. Most of the data suggest that higher intensity exercise is more protective than lower intensity activity.

The potential mechanisms responsible for the cardioprotective action of exercise and physical activity are not completely understood, but include improvement in classic coronary risk factors, reduction in autonomic nervous system and endothelial cell dysfunction, decreased thrombosis and increased fibrinolysis, less progression and possible modest regression of coronary atherosclerosis, and a reduction in myocardial ischemia. This information provides a solid evidence base for the use of exercise training and physical activity as part of a comprehensive approach to primary and secondary prevention of coronary heart disease.

16 Psychosocial factors

Annika Rosengren
Sahlgrenska University Hospital, Goteborg, Sweden

Introduction

In the world of evidence-based medicine, psychosocial factors occupy a precarious position. With few exceptions, there are not many meta-analyses, systematic reviews, and randomized controlled trials of interventions. These designs yield a high level of evidence but such studies are mostly lacking in studies of psychosocial factors. Most data are purely descriptive and observational, derived from prospective cohort studies or case–control designs. There is a lack of consensus on the measurement and validation of psychosocial constructs, and a very real risk of publication bias. Even though psychosocial factors may be counted among the modifiable risk factors for cardiovascular disease, interventions, medical or otherwise, are only rarely investigated. Accordingly, the data available can be categorized as, at most, providing mid-range evidence.

This is not to say, however, that psychosocial factors are unimportant in the study of cardiovascular health. In contrast, there is a wealth of indicators that psychosocial factors may be at least as important as biologic factors as causes of cardiovascular disease.[1,2] In one of the few studies attempting to quantify population attributable risk of both psychosocial factors and biologic/lifestyle factors, a composite of stress (at home, at work, financial), low locus of control, life events and depression was found to have a population attributable risk of 32%, comparable to the effect of smoking.[3] Even so, the importance of psychosocial factors is still controversial and it has been argued, based on prospective data, that factors such as vital exhaustion, psychologic stress, and social class add little to the overall prediction of coronary heart disease.[4]

This chapter aims **to review the strength of the data on how** psychosocial factors can influence the disease pro-cesses in cardiovascular diseases, chiefly coronary heart disease (CHD). Factors investigated in the literature pertaining to the psychosocial area as causal factors for CHD are reviewed, as are the same factors with respect to prognosis in patients with established CHD. Finally, psychosocial intervention studies, which aim to improve prognosis in patients, are explored.

Potential mechanisms

Psychosocial risk factors affect disease processes via biobehavioral pathways, for example through unhealthy behaviors like smoking, inactivity or adverse dietary patterns with increased risk for obesity, hypertension and the metabolic syndrome, or through biologic characteristics like increased cardiovascular/neuroendocrine reactivity in response to acute or chronic stress, increased platelet activation, increased inflammatory cytokines or demonstrable progress in atherosclerosis. In patients with established cardiovascular disease, psychosocial factors can affect treatment adherence and lifestyle improvement.

Several studies indicate that adverse psychosocial factors are associated with higher levels of risk factors.[5–7] Chronic stress may be a contributory factor to a positive energy balance leading to obesity and to the metabolic syndrome, as prospective investigations in the Whitehall II cohort have shown.[8,9] However, associations between adverse risk factor patterns and psychosocial risk factors are not consistently found. For example, with respect to socioeconomic status, higher rates of current and ever smoking among less well-educated subjects were found in some but not all of 11 European countries investigated.[10] In a Swedish study high occupational status was associated with better lipid levels and lower blood pressure in women, but not men.[11]

By and large, two methods for investigating psychobiologic pathways are used: laboratory or clinical studies of acute physiologic stress responses, and observational

studies involving the effect of chronic or recurrent psychosocial stimuli on morphology or physiologic function. An extensive literature in this area exists and has been reviewed,[12] with the conclusion that disturbed psychobiologic reactivity as in, for example, lower socioeconomic status adults is present for some stimuli but not others, and interactions need to be studied. One investigation cited, relevant to this, is the study by Everson *et al* in which progression of carotid atherosclerosis over 4 years was greatest among middle-aged men who were high stress responders, and had also been exposed to the chronic stress of high work place demands.[13]

Several other studies pertaining to stress tests in relation to other psychosocial factors have been published. Prolonged impairment of *endothelial function* was demonstrated to occur in healthy men after a brief episode of mental stress, potentially representing a link between stress and the atherogenic process.[14] In 34 male survivors of acute myocardial infarction (AMI), *platelet activation* in response to a stress test was heightened in men who had stated acute negative emotion in the two hours before the event.[15] *Coronary flow velocity reserve* was significantly reduced in healthy men during and after a mental stress test.[16] A recent study investigating 22 healthy middle-aged men who underwent a mental stress test demonstrated significant changes in coagulation measures, indicating that stress may elicit a hypercoagulable state.[17] These data corroborate an extensive earlier review which critically reviewed 68 articles, investigating psychosocial factors in both experimental and observational settings, with the conclusion that associations between psychologic factors and several coagulation and fibrinolysis variables provide a plausible biobehavioral link to coronary artery disease.[18]

Several observational studies have also investigated associations between psychosocial factors and putative pathophysiologic mediators. A Dutch study in 109 male white-collar workers investigated *cardiovascular reactivity* in relation to effort–reward imbalance and overcommitment (including inability to unwind after work). High imbalance was associated with a higher heart rate during work and directly after work, a higher systolic blood pressure during work and leisure time, and a lower 24-hour vagal tone.[19]

Following the results of early animal studies on psychosocial influences on atherosclerosis,[20] a recent US cross-sectional study, which investigated the effect of psychosocial measures on *coronary calcification* using electron beam tomography in 783 middle-aged men and women, found that indicators of social isolation were independently associated with elevated risk for the presence of calcification,[21] whereas there was no independent association with socioeconomic status. However, in a study of 155 healthy women with measures of positive and negative affect/cognitions, coronary calcification was unrelated to these measures whereas there was evidence of associations of psychosocial

attributes with aortic calcification.[22] Depressive symptoms, anger, anxiety, and chronic stress burden were not associated with coronary calcification in asymptomatic adults.[23]

The effects of acute psychologic stress on circulating *inflammatory factors* in humans have been reviewed in a meta-analysis suggesting a modest increase in circulating inflammatory markers following laboratory-induced psychologic stress.[24] Additionally, in a recent overview, potential additional mechanisms for the association between stress and cardiovascular morbidity were extensively reviewed.[25]

Prospective studies

In a systematic review updated until 2001, aiming to assess the relative strength of the epidemiologic evidence for causal links between psychosocial factors and CHD incidence among healthy populations, and prognosis among CHD patients, over 100 prospective cohort studies were included.[26] A previous systematic review, by the same team of researchers, was published in 1999.[2] For inclusion, papers had to meet four quality criteria relating to design, size, psychosocial variable specification and outcomes. Only prospective studies were accepted and they had to include at least 500 participants (etiologic studies in healthy populations) or 100 participants (for prognosis in patients with established CHD). Psychosocial factors were included if they were reported in at least two eligible study populations. In this review, unspecified "stress" was not included because it was considered too vague to be informative. Valid outcomes were limited to fatal CHD, sudden cardiac death, non-fatal myocardial infarction (MI), incident angina, incident heart failure and all-cause mortality (for prognostic studies only). In the first review,[2] 65 papers were included while the updated review identified an additional 71 papers, of which 41 were published between 1998 and June 2001. The factors evaluated were type A behavior pattern and hostility, depression, anxiety and distress, and psychosocial work characteristics.

With respect to type *A behavior and hostility*, both eliciting much interest because of early positive reports from North American populations,[27,28] 18 prospective studies were included in the review. The majority (12/18) of the studies did not support type A/hostility as a risk factor, and the studies did not show hostility alone to be a risk factor either. Whether type A might predict incident CHD was again investigated in a more recent study in middle-aged men. Over a nine-year follow-up, there was no overall increased risk of CHD associated with any type A score, but further analysis showed an increase in risk over the first five-year period and a decreased risk between five and nine years, indicating that type A may be a potential trigger, rather than affecting the process of atherosclerosis.[29] Other

personality types incude *type D personality*, a construct which has not been widely studied as a potential risk factor but which nevertheless has attracted attention. Type D personality is characterized by a propensity for experiencing negative emotions, while simultaneously inhibiting these emotions in social contacts with others.[30,31] Although potentially indicating worse prognosis in cardiac patients, there are no data to support that type D personality predicts cardiovascular events in healthy populations.

In a systematic search of the literature on *depression* and risk of CHD to May 2000, Rugulies identified 11 studies.[32] Depression was associated with a significant increased risk of CHD in seven of the 11 studies, with clinical depression a stronger and more consistent predictor than depressive mood. A subsequent systematic review by Kuper *et al* found 22 prospective studies which investigated the association between depression and CHD in healthy populations.[26] Roughly one-third found no clear association, with the rest finding moderate or strong effects. There was no apparent difference in strength of association between studies with shorter or longer follow-up, indicating that findings from studies with shorter follow-up were probably not confounded by early disease causing depression. In another, more recent systematic review of studies of depression as a risk factor for coronary disease in people without clinical evidence of prior heart disease and with at least four years follow-up, and which also controlled for other major coronary disease risk factors, 10 studies met inclusion criteria. Nine reported significantly increased risk, including two with mixed results; one study reported no increased risk. The combined overall relative risk of depression for the onset of coronary disease was 1.64.[33] Since this review appeared, additional studies have been published, further supporting depression as a risk factor for CHD.[34,35] A concept which is related to depression, but where there is little conclusive evidence for effects over and above depression, or pre-existing disease, is *vital exhaustion*.[36,37]

Anxiety and/or stress were investigated in eight studies identified by Kuper *et al*, with inconsistent results, and studies with longer follow-up less likely to find an association.[26] Other than these, the INTERHEART Study, the largest study reported so far, which used a case–control design in 11 119 patients with a first MI from 52 countries and 13 648 controls matched for age, sex, and region, found that stress was more commonly reported by cases than by controls.[38] Psychosocial stress during the previous 12 months was assessed with two single-item questions about stress at work and stress at home. In these questions stress was defined as feeling irritable or anxious, or as having disturbed sleep because of conditions at home or at work. Compared with controls, cases reported more frequent periods of stress at home during the previous 12 months as well as more frequent periods of stress at work.

This study is limited because of the retrospective case–control design, where cases were interviewed during hospitalization following an acute MI and were asked to report on psychosocial risks during the 12 months before the event. However, prospective studies using similar questions on self-perceived stress have also been performed, providing additional, albeit moderate, support for the contention that stress is related to CHD. One study, using the same question as in INTERHEART, found self-perceived stress to predict CHD as well as cardiovascular mortality over a 12-year follow-up period from baseline,[39] with an odds ratio of 1.7 for cardiovascular disease (CVD) death after adjustment for occupational class and other relevant risk factors, although the predictive power for CHD incidence waned after two decades.[40]

Number of work stressors has been associated with increased cardiovascular mortality in the Multiple Risk Factor Intervention Trial.[41] During a nine-year follow-up of 12 336 men, those with three or more work stressors had an increased risk of CVD death of 26%, while the experience of divorce increased risk by 33%. Similar results were observed in a large prospective study involving 281 cases in 73 424 Japanese men and women.[42] An extreme stressor, such as the death of a child, was associated with an increased risk of MI in parents, particularly for fatal MI.[43] Even so, there are also several studies with no or very limited relation between various measures of stress and CHD[44–46] and the concept of stress as an independent risk factor has also been criticized on the grounds that self-reported stress is related to health-related behaviors and largely due to confounding by socioeconomic position[47] or by a greater propensity to report symptoms and to be hospitalized.[48]

The review of studies on *work stress* presented a particular challenge because of the wide variety of measures and lack of standardization. However, of the 13 etiologic studies reviewed by Kuper *et al*, only three did not find a clear association, whereas 10 were moderately supportive, supportive for at least a subset or showed strong evidence for an effect of work stress on incidence of CHD.[26] Several studies have been added to the literature since this review. Within the Whitehall II Study, a ratio of high efforts to rewards predicted higher risk of CHD, though only modestly so.[49] In a multinational study of six European cohorts from four European countries (Belgium, France, Spain and Sweden) consisting of 21 111 middle-aged male subjects, the Karasek job strain model of psychologic demands was used.[50] This model emerged as a moderate but independent predictor of acute coronary events. Recent findings from the Framingham Offspring Study did not, however, support high job strain as a significant risk factor for CHD in men or women.[51] Possibly, effects for women differ from those for men, with recent prospective studies not showing a relation between job stress and CHD for women.[52,53]

Social supports and networks relate to the number and quality of a person's social contacts, including emotional support. Heterogeneous approaches have been used to measure this construct. The systematic review by Kuper *et al* included nine studies, with three not showing an association, four moderately supportive, and two strongly supportive.[26] In one of the latter, a subsequent follow-up found that both social integration and emotional support protected against CHD over an extended follow-up of 15 years.[54] In a prospective cohort study of 9011 British civil servants, negative aspects of close relationships were weakly but independently associated with future CHD events, including angina pectoris, over a 12-year follow-up period.[55] Further confirmation for the role of social support is provided in a review by Lett *et al*,[56] although more research is needed to determine which types of functional and structural support are most strongly related to outcome.

There is a large body of literature concerning *socioeconomic status (SES)* and coronary heart disease. A much-cited review published in 1993[57] indicated that there is a substantial body of evidence for a consistent relation between SES and the incidence and prevalence of cardiovascular disease, secular trends in cardiovascular mortality, survival with cardiovascular disease, and the prevalence of cardiovascular risk factors. By and large, more recent findings have not challenged these conclusions, at least not for Western populations.

There are several ways of measuring SES, with education, income, and occupational position most often used, but there is an increasing awareness that these variables cannot be used interchangeably.[58] In a study using Swedish and German register data, correlations between education, income, and occupational class were only low to moderate.[59] Which of these yielded the strongest effects on health depended on the type of health outcome in question. MI morbidity and mortality showed a mixed picture, with steeper gradients in the German than in the Swedish population. In mutually adjusted analyses each social dimension had an independent effect on each health outcome in both countries. The authors concluded that treating education, income, and occupational class as indicators of the same fundamental cause will understate their independent and distinct contributions to health.

Because there are differences in the distribution of risk factors, there has been a debate whether the effect of SES merely reflects these differences or whether there is an independent effect.[60,61] In addition, a relation between low SES and occupation has not been consistently observed in all populations. In one study in Europe a north–south gradient was observed, with CHD mortality strongly related to occupational class in England and Wales, Ireland, Finland, Sweden, Norway, and Denmark but not in France, Switzerland, and Mediterranean countries.[62] Ignoring SES in risk factor estimation has been suggested to underestimate CVD risk in deprived people.[63]

Adverse socioeconomic circumstances in childhood may confer a greater risk for adult CVD. A recently published systematic review identified 40 studies, the majority of which found a robust inverse association between childhood circumstances and CVD risk, although findings sometimes varied among specific outcomes, socioeconomic measures, and sex.[64]

Psychosocial factors and prognosis in cardiovascular disease

Several literature reviews[2,65,66] have concluded that of various psychologic and social variables related to prognosis in CHD patients, the cumulative evidence is strongest for depression. Two recent systematic reviews have shown that, in people with established coronary heart disease, depression predicts an approximate twofold increase in all-cause mortality and cardiac mortality.[67,68] While not a formal meta-analysis, a narrative review paper summarizing a large number of studies found that depression confers a relative risk between 1.5 and 2.0 for the onset of CHD in healthy individuals, whereas depression in patients with existing CHD confers a relative risk between 1.5 and 2.5 for cardiac morbidity and mortality.[69]

However, studies have not consistently found this association.[70–72] In addition, these meta-analyses have been criticized on the grounds that they have not adequately considered the role of reverse causality, commenting that patients with severe CHD at baseline, and consequently worse prognosis, may be more likely to report depressive symptoms and that this may confound the association between depression and CHD prognosis. In a subsequent meta-analysis which sought to address these issues, 34 prognostic studies were identified, with a pooled relative risk of 1.80.[73] Adjustment for left ventricular function was done in only eight studies; this attenuated the relative risk from 2.18 to 1.53, a 48% reduction. Accordingly, almost half of the increased risk in patients with depression was accounted for by severity of CHD at baseline, suggesting an important role for reverse causality.

It has also been questioned whether the effect of depression assessed at different time periods may differ. A recent investigation seeking to investigate the long-term impact of depression on cardiac mortality after MI and to assess whether the timing of depression influences the findings found that depression was not associated with cardiac mortality, whether detected immediately before MI, 12 months after MI or at both time points.[74] The authors concluded that association between depression and post-MI mortality is complex, possibly being limited to depression immediately after MI, which they did not measure. Further, when

comparing prognosis in patients post-MI with incident depression, as compared with ongoing or recurrent depressions, it was found that only patients with incident post-MI depression had an impaired cardiovascular prognosis.[75] However, despite these considerations, the available evidence suggests an independent prognostic role for depressive symptoms in patients with CHD.

With respect to personality traits, *type A/hostility* was not associated with an adverse prognosis in patients with CHD in the systematic review by Kuper *et al*.[26] In contrast, non-systematic reviews have concluded that cardiac patients with *type D personality*, "a gloomy, anxious, and socially inept worrier",[30] are at increased risk for cardiovascular morbidity and mortality independent of cardiac risk factors. These conclusions were, however, based on comparatively few studies and most were derived from the same group of researchers. In addition, the extent to which the findings for type D personality are confounded by depression and other psychosocial factors is still unclear. Accordingly, more studies are needed to establish the role of type D personality as a negative prognostic factor in patients with CHD.

SES is usually not considered to be among the modifiable risk factors although low SES is often associated with an adverse lifestyle. Mortality from CHD has been associated with SES.[57,76] In comparison, far less is known about the effect of SES on prognosis after AMI. Associations between individual SES and long-term prognosis after AMI have been investigated.[77–79] In one US study of 3423 confirmed cases of AMI among metropolitan Worcester residents, a 30% higher death rate was estimated after AMI for patients living in census tracts with the most residents living below the poverty line compared with patients living in the wealthiest census tracts. Similarly, patients living in census tracts with the highest proportion of residents with less than a high school education experienced a 47% higher death rate than patients living in census tracts with the lowest proportion of residents with less than a high school education.[80] In one recent study of 3407 patients who were hospitalized for AMI in 53 large-volume hospitals in Canada, income was strongly and inversely correlated with two-year mortality rate. However, after adjustment for age and pre-existing cardiovascular events or conventional vascular risk factors, the effect of income was greatly attenuated, which suggests that the "wealth–health gradient" in cardiovascular mortality may be partially ameliorated by improved management of known risk factors.[81]

In one prospective study of women with CHD, level of marital stress, according to the Stockholm Marital Stress Scale, was associated with a higher risk of recurrent events.[82] Stress from family or work life may accelerate coronary disease processes in women, whereas relative protection may be obtained from a satisfactory job and a happy marriage. In a study of 80 female CHD patients who were evaluated for stress exposure and coronary atherosclerosis progression using serial quantitative coronary angiography, women with high stress from either family or work had significant disease progression over three years, whereas those with low stress had only slight progression.[83] One recent study found that a high level of anxiety in patients with documented chronic ischemic heart disease (IHD) constitutes a strong risk of subsequent myocardial infarction or death.[84]

The association of job strain with the risk of recurrent CHD events after a first MI has been documented in only two relatively small prospective studies whose findings were inconsistent.[82,85] However, in a recent prospective cohort study of 972 men and women who returned to work after a first MI, where a combination of high psychologic demands and low decision latitude was evaluated, chronic job strain was associated with a doubled risk of recurrent CHD which persisted in a multivariate model adjusted for 26 potentially confounding factors.[86]

Interventions

Stress management training aims to reduce stress and this, as well as other psychologic interventions, can form part of cardiac rehabilitation programs. A recent Cochrane review aimed to determine the effectiveness of psychologic interventions, in particular stress management interventions, on mortality and morbidity, psychologic measures, quality of life, and modifiable cardiac risk factors, in patients with coronary heart disease.[87] Randomized controlled trials of non-pharmacologic psychologic interventions until 2001, with a minimum follow-up of six months, were identified. Thirty six trials with altogether almost 13 000 patients were included. The quality of many trials was considered to be poor, with the majority not reporting adequate concealment of allocation or blinded assessment of outcome. Combining the results of all trials showed no strong evidence of effect on total or cardiac mortality, or revascularization. There was a reduction in the number of non-fatal reinfarctions in the intervention group but the two largest trials (comprising over a third of all randomized patients) were neutral, and there was statistical evidence of publication bias. The reviewers concluded that, overall, psychologic interventions showed no evidence of effect on prognosis with respect to total or cardiac mortality. Small reductions in anxiety and depression in patients were found. Trials which specifically considered stress management did not differ from the overall findings for all the trials. The authors considered that the poor quality of trials, heterogeneity observed between trials and significant publication bias made the pooled finding of a reduction in non-fatal myocardial infarction uncertain.

Psychologic treatment is sometimes a component of comprehensive cardiac rehabilitation, a broad class of interventions targeting lifestyle, for instance smoking, lack of exercise, poor eating habits, and often also psychologic distress. Most interventions use cognitive-behavioral interventions to reduce distress but the prognostic benefit of added psychologic treatment in cardiac rehabilitation programs is still in question. In a meta-analysis of 37 studies, the effects of psychoeducational (health education and stress management) programs for coronary heart disease patients were examined, with a suggested 34% reduction in cardiac mortality, a 29% reduction in recurrence of MI, and significant positive effects on blood pressure, cholesterol, body weight, smoking behavior, physical exercise, and eating habits.[88] However, the interventions used were highly heterogeneous and, in addition, studies with non-randomized designs were included. In a review from 2007, the authors identified 23 randomized trials of psychologic treatments which reported mortality data.[89] There was an overall beneficial effect on mortality for up to two years, but not thereafter. In addition, mortality benefits only applied to men, and for studies initiated at least two months after an event. Relaxation therapy, defined as teaching means to reduce tension, was reviewed, with relevant publications included in a meta-analysis, which, however, included non-randomized trials.[90] The most relevant findings were reduced heart rate, anxiety and angina. There were also reductions in cardiac events and in mortality, although the authors point out that there were few events.

Even though depression has been shown to be a negative prognostic factor in patients with IHD, it is at present not proven that *treatment of depression* helps improve survival. However, antidepressants have been demonstrated to be safe to use after an MI and effective in treating depression. The SADHART Study found sertraline to be a safe treatment for depression post-MI, but there was little difference in depression status between groups receiving sertraline and placebo after 24 weeks of treatment.[91] However, the effect of sertraline was greater in the patients with severe and recurrent depression. The study was not designed to assess the effects of treatment on cardiovascular prognosis, but severe cardiovascular events during the six-month treatment tended to be less frequent in the sertraline group.[91] In a randomized controlled trial (Enhancing Recovery in Coronary Heart Disease patients – ENRICHD) which examined the effect of cognitive behavior therapy, supplemented with a selective serotonin reuptake inhibitor when indicated, the intervention did not increase event-free survival.[92] Positive subgroup analyses have been reported from ENRICHD, but these findings require confirmation.[93,94] In a more recent substudy of the ENRICHD study the psychosocial intervention did not affect late mortality, but intervention patients whose depression did not improve were at higher risk for late mortality than were

patients who responded to treatment.[95] Additionally, in the Myocardial INfarction and Depression-Intervention Trial (MIND-IT) which sought to determine, using a randomized controlled design, whether antidepressant treatment for depression post-MI improved depression or cardiovascular prognosis, no differences were observed between intervention and control groups with respect to depression. The cardiac event rate was 14% among the intervention group and 13% among controls.[96]

Although *low levels of support* are associated with increased risk for CHD events, it is not clear what types of support are most associated with clinical outcomes in healthy persons and CHD patients.[56] Additionally, there is little scientific evidence about how, and how well, social support interventions work. Hogan *et al*, using a computerized search strategy, found 100 studies that evaluated the efficacy of a range of such interventions targeting a wide variety of problems.[97] Some of the studies using individual interventions through professionals targeted patients with ischemic heart disease, with positive effects on myocardial infarction recurrences and mortality. However, a similar intervention, which tried to replicate the results from earlier interventions, found that the supportive intervention had no survival impact.[98] Additionally, women in the treatment group had marginally higher cardiac and all-cause mortality than women in the control group. Neither of the two reviews found any conclusive evidence that interventions targeting social support improves outcome with respect to mortality or new events but, on the other hand, few studies have been specifically designed to answer this question.

Conclusions and directions for the future

Altogether, studies strongly suggest a role for psychosocial factors as causes and prognostic factors in cardiovascular disease. There are, however, several limitations to many studies in this area. A large proportion of the literature on psychosocial factors is derived from secondary analyses of data collected for other purposes, and accordingly, there is no means to keep track of analyses that have been done or which potentially could be performed. Accordingly, publication bias cannot be systematically evaluated. Further bias may occur after publication, where positive results may be more frequently cited than neutral or negative findings. Additionally, with few exceptions, data are derived from predominantly Caucasian, Western populations with very few data from other parts of the world, where most cases currently occur. Data from low- and middle-income countries and non-Western high-income countries are badly needed.

There is, so far, no or little evidence that any interventions targeting psychosocial factors improve prognosis in patients with cardiovascular disease, partly because of the

Key points

Potential influence of psychosocial factors on incidence, prognosis and interventions in coronary heart disease – summary

In healthy populations
Type A/hostility – no evidence
Depression/anxiety – moderate to strong evidence
Psychosocial work characteristics – moderate evidence
Chronic general stress/distress – moderate evidence
Vital exhaustion – no evidence
Social isolation and lack of social support – moderate evidence
Low socioeconomic status – strong evidence

Impaired prognosis in CHD patients
Type D/negative affect – limited evidence of independent effect
Depression/anxiety – strong evidence
Psychosocial work characteristics – moderate evidence
Low socioeconomic status – moderate evidence

Interventions aimed at improving prognosis through influencing psychosocial factors have been carried out targeting:
Stress/distress – no evidence
Depression – no evidence
Social support – no evidence

Taken together, these studies strongly suggest a role for psychosocial factors as causes and prognostic factors in cardiovascular disease. However, there is, so far, no or little evidence that any interventions targeting these factors improves prognosis in patients with cardiovascular disease.

heterogeneity, sometimes doubtful designs and non-optimal methodology of some studies. Equally, however, it is not possible to entirely dismiss potential beneficial prognostic effects on the basis of the data available. In the future, considerable attention needs to be given to methodologic and design issues, not least since the population sizes needed will require multicenter and probably multinational participation.

17 The social determinants of cardiovascular disease

Martin McKee[1] and Clara K Chow[2]

[1]London School of Hygiene and Tropical Medicine, London, UK
[2]Hamilton General Hospital, Hamilton, Ontario, Canada

Introduction

Research over the past four decades has greatly increased our understanding of the proximal determinants of cardiovascular disease, beginning with the pioneering work of Ancell Keys and his colleagues in the Seven Countries Study, which identified the role of cholesterol,[1] and progressing by means of international collaborations such as the MONICA project[2] to, most recently, the INTERHEART Study.[3] The last of these studies, which included subjects from 52 countries in all regions of the world, showed how nine risk factors (abnormal lipids, smoking, hypertension, diabetes, abdominal obesity, psychosocial factors, consumption of fruits, vegetables, and alcohol, and regular physical activity) could account for almost all the variation observed in myocardial infarction. Studies such as these provide an answer to the question "Why are some people healthy and others not?".[4] However, they raise the further question, first posed by Geoffrey Rose, of why some *populations* are healthy and others are not.[5] These risk factors are not distributed at random in the population but are geographically and socially patterned.

The consequence is that deaths from cardiovascular disease vary markedly among and within populations and their distribution is constantly changing. Beginning as a disease of the upper classes in industrialized countries, its subsequent increases among the lower classes would soon reverse the social gradient.[6] More recently, marked declines among those better off have not been seen among the poor, leading to a widening social gap.[7] The long-standing advantage enjoyed by countries in Southern Europe is now being eroded,[8] at a time when once very high rates in Nordic countries are falling rapidly. In the former Soviet Union death rates have fluctuated dramatically over the course of the past two decades, while remaining consistently very much higher than in Western Europe.[9]

It is also important to note, in a situation where medicine is increasingly dominated by the search for genetic explanations of disease, that levels of risk change when individuals move from one setting to another, elegantly described in studies of Japanese migrating to Hawaii and California.[10] The risk of cardiovascular disease is substantially influenced by the environment that the individual inhabits.

The reasons for some of the patterns that can be observed are either obvious or have been understood through research. Those living in the countries bordering the Mediterranean benefited from their geographical location and consequently their climate, which allowed them to produce the components now referred to as the Mediterranean diet, rich in fruit and vegetables and olive oil. Contemporary increases in mortality in some parts of Greece can plausibly be explained by a failure to reduce smoking rates. In Russia and its neighbors, the high cardiovascular mortality can be explained by, in addition to the traditional risk factors, the widespread practice of episodic heavy drinking, especially of surrogate products such as aftershaves.[11] coupled with weaknesses in the healthcare system and, especially, the management of hypertension.[12] Within societies, differences in smoking and diet, which are shaped by the environments that people inhabit, can also go some way to explaining social inequalities, and indeed some research has suggested that they may themselves be sufficient.[13]

However, there is an extensive body of research suggesting that psychosocial factors play a part. The largest of these studies, INTERHEART, found that those suffering a myocardial infarction were significantly more likely to have experienced stress at work or at home, financial stress or major life events in the past year. Put another way, those suffering several episodes of stress or permanent stress at work were more likely to suffer an infarction (respectively, odds ratios (OR) 1.38, 99% confidence interval (CI) 1.19–

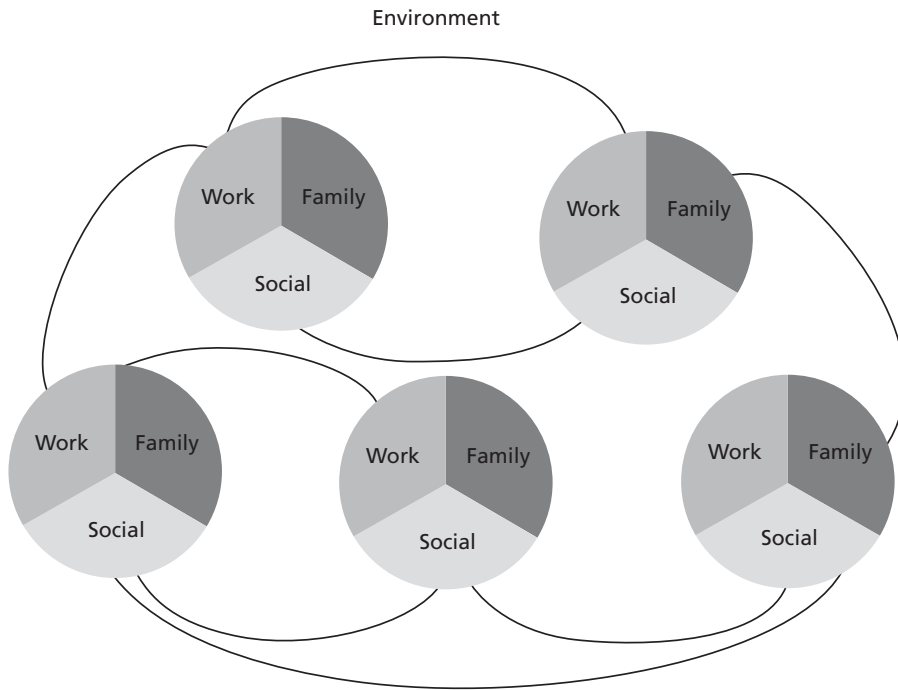
Environment


Figure 17.1 A simplified model of a community.

1.61, and OR 2.14, 99% CI 1.73–2.64), after adjustment for age, sex, geographic region, and smoking. The corresponding figures for several episodes or permanent stress at home were OR 1.52 (99% CI 1.34–1.72) and OR 2.12 (1.68–2.65). Severe financial stress and stressful life events in the past year showed similar associations (OR 1.33, 99% CI 1.19–1.48, and OR 1.48, 99% CI 1.33–1.64, respectively).[14]

This chapter begins from the intentionally simplified position that individuals inhabit three often overlapping communities, defined by their families, their work environment, and their social life. In each of these they have relations with other individuals. The roles that they fulfill and the relationships that they experience within each of these communities may impact on their risk of cardiovascular disease or their ability to survive it. Individuals also live within a larger community, where ties may be much looser but which surrounds them and whose environment is characterized by its physical, political, economic, social, and cultural attributes. This environment may impact on their risk of cardiovascular disease by virtue of the ease which it enables them to make healthy choices or constrains them from doing so. This framework is illustrated in Figure 17.1, with five individuals who are connected to each other through families, work, and social ties. Much of the rest of this chapter will focus on the evidence linking the nature and intensity of these connections, in these three domains, to cardiovascular disease, and on the way that the environment in which people live influences their degree of risk.

Family networks

The most intense social relationships are within the immediate family. There is considerable evidence that marriage is protective against cardiovascular disease, at least for men, who have been most intensively studied. Some research has been able to explain this on the basis of differences in risk factors.[15] Divorce is associated with taking up smoking or, among ex-smokers, relapsing, for both men and women.[16,17] In the Health Survey for England, single men and those with low social support were less likely to have hypertension adequately treated.[18] A small Israeli study found a more harmful pattern of lipids among divorced, separated or widowed women than in their married counterparts that was unexplained by age, smoking or physical activity.[19]

However, there is also considerable evidence that the excess risk associated with being unmarried persists after adjustment for conventional risk factors. In the British Regional Heart Study, single (never-married) men were at increased risk of dying from cardiovascular disease (relative risk (RR) 1.5, 95% CI 1.0–2.2) after adjustment for potentially confounding variables.[20] Men who were divorced or widowed at recruitment did not exhibit an increased risk but risk was greater among those who divorced during follow-up (RR 1.9, 95% CI 0.9–3.9), again unexplained by conventional risk factors. An increased risk associated with divorce was also found in the Multiple Risk

Factor Intervention Trial, which included men without evident cardiovascular disease at recruitment but who were at above-average risk on the basis of conventional risk factors.[21] In contrast, an analysis of the Whitehall Study found an excess risk of ischemic heart disease mortality associated with widowhood (RR 1.46, 95% CI 1.08–1.97). As it is possible that this could be associated with acute stress associated with bereavement, a subsequent analysis excluding deaths occurring in the first two years was undertaken, with the effect persisting.[22] In a cohort of over 90 000 Japanese men and women followed over 10 years, never-married men, compared with married men, were at a greater risk of cardiovascular mortality (RR 3.05, 95% CI 2.03–4.60) after adjustment for potentially confounding variables. Never-married women were also at greater risk, although less so than for men (RR 1.46, 95% CI 1.15–1.84). An increased risk was also seen among divorced and widowed men but not women.[23]

Some studies have also looked at the association between marital status and survival among those with established cardiovascular disease. Among men and women found to have significant disease at angiography, those who were unmarried and without a close confidant were more likely to die within three years than those who were married with a close confidant (OR 3.34, 95% CI 1.8–6.2).[24] Among those in the placebo arm of the Multicenter Diltiazem Post-infarction Trial, living alone was associated with an increased risk of major cardiac events, which included deaths and non-fatal myocardial infarction.[25] However, other research, in a German MONICA sample, found an increased risk of death among men living alone but not among women living alone, after adjustment for conventional risk factors,[26] with another study showing that men but not women living alone are also disadvantaged in terms of survival following myocardial infarction.[27]

Social networks

There has long been evidence that social networks are beneficial to health, with lower all-cause mortality observed in those engaging most frequently in activities such as cultural events.[28]

A few studies have looked at the effects of social networks on the incidence of myocardial infarction. A Swedish study following men over 15 years examined the association between incident coronary heart disease and two measures of social support: "emotional attachment" and "social integration". The hazard ratio (HR) for those in the highest quartile for social integration compared with the lowest was 0.45 (95% CI 0.24–0.84). The corresponding figure for emotional attachment was 0.58 (95% CI 0.37–0.91).[29] A cohort of over 13 000 Swedes, followed for three years, found that low social participation was significantly associ-

ated with first-time acute myocardial infarction, after adjustment for age, sex education, economic stress, daily smoking, physical activity and body mass index.[30] However, some other studies have not found an increased risk of incident disease in those with poor social networks.[31,32]

Other research has used mortality as an endpoint. For example, a study of approximately 30 000 male health professionals found that those defined as socially isolated men (not married, fewer than six friends or relatives, no membership in church or community groups) had a greater risk of cardiovascular disease mortality than those with the highest level of social networks at both four [32] and 10 years (relative risk. adjusted for a range of factors including traditional cardiovascular risk factors, 1.82, 95% CI 1.02–3.23).[33] In the Japanese Komo-Ise Study over 11 000 subjects were followed over seven years. Men who did not participate in hobbies, club activities or community groups had significantly higher relative risk of circulatory system mortality (RR 1.6), after adjustment for established risk factors.[34]

This seeming discordance between some of the evidence on incidence and the much more consistent finding with mortality has focused attention on how social networks may be more important in reducing case fatality than in preventing incident disease.[35] Participants in the Beta Blocker Heart Attack Trial who were socially isolated were twice as likely to die during three years of follow-up than those who were not after adjustment for conventional risk factors.[36] Those who scored highly on social isolation and on a measure of life stress (which included divorce, exposure to traumatic events, and financial difficulty) had an over fourfold increase in risk.

Participants in a population-based study in New Haven who were hospitalized with myocardial infarction were more likely to die in hospital and at up to one year if they had no social support. This result was consistent for men and women, at all ages, and regardless of the severity of disease. In a multivariate model adjusting for sociodemographic, psychosocial, and clinical factors, the excess risk (odds ratio) of mortality among those with no support compared to those with at least one source of support was 2.9 (95% CI 1.2–6.9).[37]

There is also some evidence that the nature of networks is important, with one study of patients undergoing coronary bypass grafting finding that those who were not members of voluntary organizations, including religious ones, or who do not draw support from faith, were seven times more likely to die.[38]

The preceding studies examined the networks that individuals inhabited. There is also a growing body of research looking at the characteristics of the communities in which individuals live. Some of this work employs the concept of social capital, a term that has been defined in a variety of ways.[39–41] However, the definitions are all characterized by notions that it relates to a community and not an individual

and that its existence brings benefits that go beyond those who generate it. It is often measured by characteristics such as trust in others, perceived reciprocity, and density of membership in civic organizations.

Social capital can be assessed in a variety of ways. In one ecologic study, social surveys undertaken in 39 American states were used to obtain information on levels of trust and of membership of voluntary organizations, which were then related to state-level mortality from cardiovascular disease. Lower levels of both were associated with increased cardiovascular mortality, after adjusting for poverty.[42] Another study categorized Swedish neighborhoods in terms of violent crime and unemployment rates.[43] Residents aged 35–64 were followed up for a year. Those living in neighborhoods with higher levels of violent crime or unemployment had a higher incidence of coronary heart disease, affecting both men and women. For violent crime, the odds ratios were 1.75 (CI 1.37–2.22) and 1.39 (CI 1.19–1.63) for women and men, respectively. The corresponding figures for neighborhood unemployment were 2.05 (CI 1.62–2.59) and 1.50 (CI 1.28–1.75). These figures changed very little when a range of individual variables were included.

Finally, one study has examined prognosis. This used the Petris Social Capital Index, which characterizes neighborhoods according to level of employment in religious and community organizations.[44] Of almost 35 000 people in California previously admitted with acute coronary syndrome, the recurrence rate was lower in neighborhoods with higher scores on the index (after adjustment for medication, previous revascularization, and standard sociodemographic variables), but only among individuals living in poorer areas.

The work environment

An individual will only spend a relatively small proportion of their entire lives at work, perhaps 40 hours a week between the ages of 20 and 65. Yet, their experiences at work have a disproportionate impact on their lives, influencing how they spend their leisure time, their well-being in retirement, and their psychological well-being.

Interest in the potential impact of the work environment arose from research suggesting that observed social inequalities in cardiovascular disease could only partially be explained by the risk factors then being studied[45] (a more limited set of those included in more recent research such as the INTERHEART study).[3] It has grown in the light of concerns about the changing nature of work and, in particular, the greater insecurity of employment in many countries.

The literature on the health effects of the work environment is dominated by two explanatory models: the demand–control model and the effort–reward imbalance model. Both begin from the position that a work environment that provides opportunities for contributing in a meaningful way to the task in hand and which provides appropriate feedback is likely to be health enhancing while an environment that fails to do so may be health damaging. Two elements in particular have been highlighted. The first is self-efficacy or the belief that one can do what is asked of one.[46] An environment that encourages self-efficacy will allow those in it to make greatest use of their skills and to exercise control over their work. The second is self-esteem or feeling of one's own worth. An environment that encourages self-esteem will allow an individual to interact positively with others and obtain feedback following good performance. In contrast, repeated failure to recognize effort and success can be corrosive.

The demand–control model was developed in Sweden in the early 1980s.[47] In a study that combined a cohort and case–control design, those in what was described as "a hectic and psychologically demanding job" had an increased risk of developing cardiovascular disease and of dying from it, as had those in jobs where they had little discretion about how they did their work or how they scheduled it. The associations were especially marked among those with the least education and persisted after controlling for age, education, smoking, and overweight.

The demand–control model has been developed to include the extent to which the work environment encourages active learning, by which the worker can develop their self-efficacy, and some researchers have suggested inclusion of a third dimension, social support at work.[48] It has also been suggested that a high level of self-efficacy has effects that extend beyond the work environment into other aspects of the worker's life, including their involvement in social and cultural activities which, as the previous section showed, may itself be beneficial for health.[49]

The second, and complementary, model involves effort–reward imbalance.[50] It arises from the concept of social reciprocity, whereby individuals expect that their efforts will be rewarded appropriately. This may break down in a number of situations, such as where there are few alternative sources of employment, but can also arise in individuals who underestimate the demands placed upon them while overestimating their ability to cope.

Interpretation of the empiric evidence is complicated by the diverse range of measures employed to capture the work environment, the use of both objective measures and self-report, the use of both cohort[51] and case–control designs,[52] differing outcomes, and differences in the extent to which other risk factors are adjusted for. Much of the existing literature has been summarized in some recent systematic reviews.[53,54]

In brief, some of the earlier studies, prior to the generation of the theories described above, looked simply at job

strain. Some found no effect[55] but others found a significant positive association, after adjustment for sociodemographic and biologic risk factors.[56]

Research on the demand–control model has also yielded conflicting results, with some finding a protective effect of high control and demand[57] while in others the findings were more equivocal[58] and others found that high demands increased risk with no effect for control.[59]

A number of empiric studies of the effort–reward imbalance model have also been undertaken,[60–63] with most finding a positive association between this form of psychologic stress and incident coronary heart disease or mortality, with odds or hazard ratios lying between 1.3 and 4.5, again after adjustment for sociodemographic and biologic risk factors.

Finally, some studies have found significant associations in one sex but not the other. While this could be due to chance, it should be noted that there is some evidence that different mechanisms may be at play, especially in relation to secretion of cortisol[64] (discussed further below).

Mechanisms and interpretation

Interpretation of these findings is complicated by the very diverse methods used. Thus, any conclusions must be surrounded by caveats. In particular, in many of the studies it is difficult to know whether all important confounders have been addressed. For example, one twin study found evidence that some of the measures often used in research on cardiovascular disease to assess psychological status were themselves partially inherited.[65] Conversely, care is needed when interpreting negative findings. Beyond the usual concerns about sample size and length of follow-up, no study has looked comprehensively across all three elements of the lives of subjects, including family, work, and social networks. It is entirely plausible that strong but unmeasured support in one area could overcome weaknesses in another. Thus, it has been suggested that the presence of high levels of social capital in Hawaii might explain why social isolation seems to exert little effect in that society.[31]

Yet while noting these caveats, theory-driven research that has adjusted for potential confounders does suggest that psychosocial factors play a role in the epidemiology of cardiovascular disease. In very general terms, those who have greater support, whether in their families or their broader social circle, or who have a work environment that is supportive, rewarding their efforts appropriately and giving them control, seem less likely to develop cardiovascular disease. The benefits of these relationships may be greater for those who have already developed disease and it is plausible that those with greater support would be more likely to access healthcare promptly.

This raises the question of what the biological mechanisms might be that can explain these findings. Research has focused on three mechanisms: the hypothalamic-pituitary-adrenal axis, inflammation, and coagulation. The available evidence does not suggest any major role for changes in lipid levels, which normally dominate discussion on the etiology of cardiovascular disease.[66]

It has been hypothesized that chronic stress, which may arise in many of the circumstances described above, may activate the hypothalamic-pituitary-adrenal axis. This has led to the concept of allostatic load, in which prolonged exposure to cortisol and noradrenaline leads to organ damage.[67] The evidence that psychosocial factors contribute to a high allostatic load is, however, inconsistent[68,69] and may differ in men and women. The precise mechanisms by which it might lead to cardiovascular disease are unclear although most commentators note an association with metabolic syndrome or hypertension.[70]

The second strand of evidence relates to inflammation, which is hypothesized to contribute to cardiovascular disease through its effects on endothelial function. Hence, one study found that endothelial dysfunction was associated with depression and improved by antidepressants.[71] The finding that some markers of inflammation are associated with a flat cortisol response provides a possible link with the first mechanism.[72] A number of different markers of inflammation have been studied, including heat shock protein 60,[72] C-reactive protein and interleukin 6.[73] High levels of C-reactive protein and interleukin 6 have both been associated with low socioeconomic position[73] and attitudes (cynical distrust).[74]

The third possible mechanism involves increased coagulability, as a result of elevated fibrinogen levels. These have been found to be associated with high work strain[75] and in men with low activity levels inside or outside the home and few social activities.[76] However, again the results are inconsistent, with evidence of differences between men and women.[77]

Finally, it is important to note that there have been a number of negative findings, including those where conventional risk factors were sufficient to explain observed social gradients and those that looked in detail at many of the putative factors but found no consistent associations.[78]

The broader environment

The previous sections have looked at influences on the development of and survival following cardiovascular disease after adjusting for conventional risk factors. However, it is also important to recognize that the levels of these risk factors are themselves shaped by the environment in which people live. A consideration of the social

determinants of cardiovascular disease is incomplete without considering how the environment shapes their distribution within a population. This section will look at three of the major risk factors for cardiovascular disease: smoking, physical inactivity, and poor nutrition.

There is now extensive evidence of how smoking rates are influenced by prevailing social norms, which change over time and which can be modified by public policy. In some countries smoking is widespread and socially acceptable and individuals seeking a smoke-free environment will search in vain. Conversely, as in California, nonsmoking has become the norm and those who wish to smoke must go into the open air. These norms can change rapidly, illustrated by the rapid acceptance of the ban on smoking in bars and restaurants in Ireland, something that many commentators had predicted would fail.

There is now a considerable volume of evidence, reviewed in detail elsewhere, about the effectiveness of policies designed to reduce smoking. A 10% increase in price, brought about through higher taxes, will reduce smoking by between 3% and 5%. The effect is greater among the young, those on low incomes, and light smokers. Bans on smoking in workplaces and leisure facilities are also effective, as are advertising bans and warnings on cigarette packs, ideally highly visible and accompanied by graphics. Limiting sales to those above a certain age has the potential to reduce smoking amongst adolescents but only if there are mechanisms to ensure effective compliance by retailers. These policies are synergistic, with the best results being achieved by a combination of measures.

The Tobacco Control Scale is an attempt to quantify the degree of implementation and to identify areas needing to be addressed. When applied to 30 European countries, it revealed wide diversity, with scores ranging from 26 out of 100 (Luxembourg) to 74 (Ireland).[79]

Smoking rates are also shaped by prevailing societal norms, which change over time. The Social Unacceptability Index is derived from survey data on individual attitudes towards smoking. Research in the United States has found that those states with higher values (and thus where smoking is less acceptable) have lower smoking rates independent of the price of cigarettes. A 10% increase in the index was associated with a 3.7% fall in consumption.[80]

The second major risk factor for cardiovascular disease is physical inactivity. Again, there is an extensive body of research showing how the environment can encourage or discourage physical activity. Environments supportive of physical activity are characterized by extensive footpaths and easy pedestrian access to shops and recreational areas,[81–84] attractive neighborhoods, and safe surroundings.[85] Such environments have been found, in a number of studies, to be associated with lower levels of obesity.[86–89]

As with smoking, it is possible to assess the extent to which environments encourage physical activity. Two approaches have been used: employing perceptions and objective measures. Perception-based measures are derived from surveys of how individuals view accessibility to facilities, opportunities for physical activity, safety, and aesthetics,[85,90] Objective measures involve systematic observation, increasingly involving use of satellite maps and geographic information systems.[91] These measure density of buildings or traffic, and distances to neighborhood facilities. These approaches have been employed to create a number of standardized instruments, such as the Neighborhood Walkability Scale,[85] the Built Environment Assessment Tool,[92] and the Urban Sprawl Index.[93] High levels of the last of these have been shown, in the USA, to correlate with the prevalence of obesity and hypertension.

The diet that an individual consumes is influenced by the resources that are available to them to purchase food and by the food that is available to them at an affordable price. Research in the USA has shown how healthier foods are less easily available in poor communities and those with large concentrations of African Americans and Hispanics, largely because the latter are served predominantly by convenience stores where much of what is sold is processed food.[94] In contrast, more affluent areas are better served by supermarkets, which stock large amounts of fresh fruit and vegetables. The Atherosclerosis Risk in Communities (ARIC) Study, which included over 10 000 participants in four American states, found that the presence of supermarkets was associated with a significantly lower prevalence of obesity and overweight (obesity prevalence ratio (PR) 0.83, 95% CI 0.75– 0.92; overweight PR 0.94, 95% CI 0.90–0.98), while the presence of convenience stores was associated with a higher prevalence (obesity PR 1.16, 95% CI 1.05–1.27; overweight PR 1.06, 95% CI 1.02–1.10).[95] These findings do, however, appear to be context specific. Thus, similar research from the United Kingdom and Australia found that those living in rich and poor areas had equal access to nutritious food and to supermarkets[96] and no independent association between neighborhood retail food provision and fruit and vegetable intake.[97]

Other research has looked at the role of fast-food outlets, given the high energy density and low price of many of their products. In North America, the density of fast-food outlets is highest in low-income neighborhoods[98] and a positive association has been found at state level between the density of these outlets and obesity.[99] In the United Kingdom, fast-food outlets are also concentrated in deprived areas[100] but in this case an association with obesity has not been found.[101] There are a number of possible explanations for these divergent results, including differing patterns of land use, social distance between income groups, and shopping patterns.

Finally, although the evidence base linking it to obesity and other cardiovascular risk factors is still somewhat limited, research on diet and physical activity has given

rise to the concept of the *obesogenic environment*.[102] This concept, which has emerged from a wide range of disciplinary perspectives, is defined as "the sum of influences that the surrounding opportunities or conditions of life have on promoting obesity and individuals or populations".

Conclusion

The current state of knowledge on the social determinants of cardiovascular disease can be compared to a jigsaw in which only some of the pieces are in place. This is not surprising, given the complexity of the task. A recent report on obesity, which is only one of the risk factors for cardiovascular disease, by the UK government's Foresight program,[103] set out its known social determinants in a diagram with so many interconnecting lines that it has been described as looking like an upturned plate of spaghetti.

The researcher studying social determinants is confronted with a range of overlapping domains (family, work, and social) in which risk factors might act. The theoretical basis needed to develop standardized instruments is relatively recent and much of the available work uses very different measures. There may be differences between self-reported and objective measures. The influence of social risk factors is probably context dependent, as suggested by the finding that formally measured social isolation is less important in a society characterized by high levels of cohesion. It is difficult to account for confounding and this is anyway complicated by the possibility that some possible biologic confounders may lie along the same causal pathway as some psychosocial factors. Here, it is important to be aware of one study, among employees in Scottish factories, that found an implausible protective effect of stress, which was most marked for smoking-related cancers even after adjustment for smoking.[104] As the authors note, their finding was almost certainly due to undetected confounding but this is equally likely to occur in studies that produce the "expected" result.

So what, therefore, can be concluded from the available evidence? First, there is unambiguous evidence that the incidence and mortality from cardiovascular disease vary within populations, typically with higher rates in those who are materially disadvantaged. These differences cannot be explained by genetic factors (although this does not exclude some gene–environment interactions) and while differences in conventional risk factors, such as diet and smoking, clearly play a part, they do not seem able to explain all of the variation.

Although there are many studies with negative findings, there are sufficient that find that lack of family and social support and work characterized by high demands and low control, or high effort that is unrewarded, are associated with an increased risk of cardiovascular disease, with some evidence suggesting that the effects are greater for survival following the onset of disease than for incidence. It also seems that men lacking social support are more vulnerable than women. The mechanisms by which these characteristics lead to cardiovascular disease remain uncertain but the available evidence suggests that it may involve a combination of endothelial dysfunction and increased coagulability.

While the existing evidence is incomplete and there are some methodologic concerns, from a policy perspective it is important not to focus on cardiovascular disease in isolation. There is considerable evidence to link social isolation, job strain, and lack of control over one's life to a wide range of other adverse outcomes and, even if it was not possible to demonstrate any health effects, it is arguable that any policies that address these factors are intrinsically desirable.

[2] Royal Alexandra Hospital, Edmonton, Alberta, Canada

Introduction and historical perspective

Obesity is a highly prevalent and complex chronic disease that results from the accumulation of excessive adipose tissue. Hippocrates (ca. 460–370 BC) was one of the first to warn of the dangers of obesity when he wrote, "It is very injurious to health to take in more food than the constitution will bear, when, at the same time one uses no exercise to carry off this excess". In modern times, the continued rise in obesity prevalence occurring throughout the world[2] threatens to reverse gains made in prolonging life expectancy[3] and reducing the morbidity from coronary disease and other chronic health problems.[4] On a very simplistic level, the rapid rise of obesity in modern society can be thought of as the inevitable consequence of placing a population preselected for efficient fat storage into a sedentary environment of caloric overabundance. However, our understanding of how and why obesity develops is still incomplete, partly due to the complex interplay of socio-economic, behavioral, cultural, metabolic and genetic factors that contribute to the obesity epidemic.[5,6] Developing a clear understanding of these factors, reversing the rise in obesity prevalence and treating the multitude of associated obesity-related complications represents a challenge of considerable magnitude for current and future generations.

Nomenclature and definitions

Definitions of overweight and obesity in adults have varied over time.[7] Ideally, a health-oriented definition of obesity would be based on the amount of excess body fat that correlates with the weight-responsive health risk in a given

individual.[8] Body mass index (BMI), defined as weight in kilograms divided by height in meters squared (kg/m^2), is an easily obtained measure that is now widely used, as it has a high correlation with excess body fat or adiposity. However, BMI is not a measure of body fat and does not convey information on regional fat distribution. The latter is important, as it is now well established that central or visceral fat deposition is a major independent determinant of the metabolic and cardiovascular risk associated with increased body fat mass.[9–12] Recent evidence-based guidelines therefore recommend the use of both BMI and waist circumference in the assessment of overweight or obese patients.[5,6] Table 18.1 summarizes the current classification of overweight and obesity by BMI, waist circumference and associated disease risk. It should be noted that the waist circumference cut-off levels of 88 cm for women and 102 cm for men were primarily chosen because they correspond to BMI levels of $30 kg/m^2$ and not because validation studies have demonstrated these cut-off points to have greater discriminatory power in predicting obesity-related events.[5] In fact, lower, ethnic specific cut-off levels to predict disease risk have been recently proposed, particularly for Asian and South Asian populations, but these are preliminary and require further study and validation.[5]

Although there are benefits to the identification of cut-off points for monitoring overweight and obesity, it is important to realize that (as for other risk factors) health risks associated with increasing weight are part of a continuum, and individuals with BMI $<25 kg/m^2$ can have substantial weight-associated health problems (for example, impaired glucose tolerance, hypertension), whereas others may have no identifiable health problems at BMI levels significantly greater than $25 kg/m^2$. Individualized assessment of risk status and conditions associated with obesity must therefore form an integral part of patient assessment, before deciding on the potential benefits to be derived from weight management in an individual patient (Fig. 18.1).[5,6]

Table 18.1 Classification of overweight and obesity by body mass index (BMI), waist circumference, and associated disease risk[6]

	BMI, kg/m²	Disease risk* relative to normal weight and waist circumference	
		Men, 102 cm Women, 88 cm	Men, >102 cm Women, >88 cm
Underweight	<18.5	–	–
Normal[†]	18.5–24.9	–	Increased
Preobese	25.0–29.9	Increased	High
Obesity, class			
I	30.0–34.9	High	Very high
II	35.0–39.9	Very high	Very high
III	40	Extremely high	Extremely high

*Disease risk for type 2 diabetes, hypertension and cardiovascular disease.

– indicates that no risk at these levels of BMI was assigned.

[†]Increased waist circumference can also be a marker for increased risk even in persons of normal weight.

BOX 18.1 Health hazards associated with obesity

- Type 2 diabetes, prediabetes (impaired glucose tolerance, impaired fasting glucose)
- Hypertension
- Dyslipidemia
- Metabolic syndrome
- Cardiovascular disease: coronary artery disease, stroke, congestive heart failure, atrial fibrillation
- Non-alcoholic fatty liver disease
- Respiratory disease: sleep apnea, obesity-hypoventilation syndrome, restrictive lung disease
- Cancers, particularly gastrointestinal and reproductive
- Osteoarthritis
- Cholelithiasis
- Gastrointestinal reflux disease
- Infertility
- Venous stasis
- Frequent infections, including cellulitis and intertrigo
- Urinary incontinence
- Idiopathic intracranial hypertension
- Psychosocial: psychiatric disease (with severe obesity), reduced employment, increased absenteeism, limited mobility, discrimination, reduced quality of life

Incidence, natural history and prognosis

The worldwide prevalence of obesity is currently estimated at over 300 million individuals, with an additional 800 million people classified as overweight.[2] Approximately 40–70% of the adult population in industrialized countries and a substantial proportion in developing countries are now considered overweight or obese.[13] Particularly concerning is the disproportionately rapid rise in the prevalence of severe (Class III) obesity, currently estimated at 5% in the US.[14,15] Severely obese individuals are at much higher risk of developing obesity-related complications and premature death and use substantially more healthcare resources than those with milder degrees of obesity.[16]

Monogenic obesity syndromes such as congenital leptin deficiency present with early-onset severe childhood obesity but are extremely rare.[17] Most individuals have a polygenic and environmental cause for excess adipose tissue and develop obesity later in life, with the majority of women experiencing their largest amount of weight gain after pregnancy and men, after activity wanes in the second and third decades of life.[18] Slow, progressive weight gain is the general rule; due to the highly precise nature of body weight regulation, only a small positive daily caloric intake is needed to cause substantial weight gain over a long time period. For example, a weight gain of 9.1 kg (20 lbs) over a period of 30 years corresponds to an excess intake of only 0.3% of ingested calories.[19] Therefore, it is remarkably easy to gain weight and modest weight gain over the short term often remains unrecognized.

Obesity leads to a number of health hazards (Box 18.1), many of which develop only after decades spent in the obese state. The most significant risk associated with obesity is type 2 diabetes. Compared to individuals with a normal BMI level, the 10-year risk of developing diabetes is increased approximately 20-fold in individuals with a BMI of ≥35 kg/m².[20] Weight gain has also been associated with a significant increase in coronary risk. A weight increase of 15 kg after age 21 is associated with an increased coronary risk of 83% in women and 46% in men.[21] Ultimately, obesity diminishes life expectancy: a 40-year-old obese non-smoker can expect to die 6–7 years prior to a non-obese counterpart.[22] A meta-analysis of 57 observational studies involving nearly 900 000 participants demonstrated that mortality is lowest with BMI levels between 22.5–25 kg/m². Above this range, each 5 kg/m² increment in BMI was associated with a 30% higher overall mortality (HR 1.29; 95% CI, 1.27–1.32) and significant increases in cause-specific mortality (vascular, diabetic, renal, hepatic, neoplastic, and respiratory).[23]

Pathophysiology

Major factors associated with an increased risk of weight gain include low birth weight,[24] absence of history of breast feeding,[25] obesity in later childhood and adolescence,[26] pregnancy,[27] sedentary lifestyle,[28] obesity within a family member or close social contact,[26,29] smoking cessation,[30] and poor dietary restraint.[31]

Overweight or obese adult

- Measure BMI
- Measure waist circumference if BMI is > 25 and ≤ 35 kg/m²

Important message

- A modest weight loss of 5%-10% of body weight is beneficial
- Weight maintenance and prevention of weight regain should be considered as long-term goals

If BMI is > 25 kg/m² or waist circumference is above cutoff point*

Conduct clinical and labortatory investigations to assess comorbidities

(Blood pressure, heart rate, fasting glucose, lipid profile [total cholesterol, triglycerides, LDL and HDL cholesterol, and ratio of total cholesterol to HDL cholesterol])

Assess and screen for depression, eating and mood disorders

Treat comorbidities and other health risks if present

Assess readiness to change behaviours and barriers to weight loss

Devise goals and lifestyle modification program for weight loss and reduction of risk factors

Weight-loss goal: 5%-10% of body weight, or 0.5-1 kg (1-2 lb) per week for 6 months

Health team to advise lifestyle modification program

Lifestyle modification program

Nutrition: Reduce energy intake by 500-1000 kcal/d

Physical activity: Initially 30 minutes of moderate intensity 3-5 times/wk; eventually ≥ 60 minutes on most days. Add endurance exercise training. (Medical evaluation is advised before starting activity program)

Cognitive-behaviour therapy

Satisfactory progress or goal achieved?

Yes

No

No

Regular monitoring
- Assist with weight maintenance
- Reinforce healthy eating and physical activity advice

Weight maintenance and prevention of weight regain
- Nutrition therapy
- Physical activity
- Cognitive-behaviour therapy

Address other risk factors; periodic monitoring of weight, BMI and waist circumference every 1-2 years

Pharmacotherapy
- BMI ≥ 27 kg/m² + risk factors
  or
- BMI ≥ 30 kg/m²

Adjunct to lifestyle modification; consider if patient has not lost 0.5 kg (1 lb) per week by 3-6 months after lifestyle changes

Bariatric surgery
- BMI ≥ 35 kg/m² + risk factors
  or
- BMI ≥ 40 kg/m²

Consider of other weight loss attempts have failed. Requires lifelong medical monitoring

Figure 18.1 Algorithm for the assessment and treatment of obesity. (Adapted from the Canadian Clinical Practice Guidelines on the Management and Prevention of Obesity.[5])

The mechanisms underlying the relationship between obesity and hypertension remain poorly understood. Several theories implicate increased sympathetic activity, sodium and volume retention, renal abnormalities, insulin resistance and, more recently, hyperleptinemia.[32,33]

Obesity predisposes towards type 2 diabetes primarily by increasing insulin resistance.[34] Hormones secreted by adipocytes (adipokines), such as tumor necrosis factor alpha (TNF-alpha[35]), are important promoters of inflammation and insulin resistance. Elevated free fatty acid levels, which are commonly found in the obese state, impair insulin secretion and enhance insulin resistance.[36]

Management

Achieving weight loss

Prior to or in conjunction with developing a treatment plan, one must assess and treat co-morbidities and determine barriers to weight loss including identifying readiness to change (see Fig. 18.1). In-depth explanation of these issues is beyond the scope of this chapter and the reader is referred to more detailed discussions.[5] Successful weight loss often requires the combination of multiple interventions and strategies, including diet, physical activity, behavior modification, pharmacotherapy and surgery (see Fig. 18.1). Because obesity is a chronic condition, all treatment, including pharmacotherapy, should be initiated with the expectation that, if successful, it will be continued over the long term.[5,6]

Goals of treatment

The primary goals of obesity treatment are to reduce body weight, maintain weight loss over the long term, improve obesity-related co-morbidity and increase quality of life.[5,6] Weight loss should be recommended for all patients with excess weight and obesity.[5,6] The initial recommended minimal weight loss target of 5–10% of baseline should be achieved gradually through a 500–1000 kcal/d (2092–4184 kJ/day) deficit, which should lower weight by 1–2 lbs per week in most individuals.[6] This degree of weight loss may appear trivial but is associated with improvements in obesity-related co-morbidities, as detailed below. The amount of weight loss and rate at which weight loss is achieved may be slower in patients with type 2 diabetes compared to non-diabetics.[6]

Lifestyle modification

With regard to dietary therapy, a review of 34 RCTs[6] concluded that an average weight loss of 8% can be obtained over six months with a 500–1000 kcal/day deficit diet, and that this weight loss is associated with a decrease in abdominal fat (**Class I, Level B**). An updated review of 41

randomized controlled trials (RCTs) of at least one year in duration found that counseling to reduce caloric intake and increase physical activity reduced weight by approximately 3–5 kg (**Class I, Level B**).[37] Treatment is more successful with intensive therapy (defined as follow-up more frequently than monthly) and with multimodal interventions (diet, exercise and/or behavioral therapy).[37] Dietary therapy generally produces the greatest amount of weight loss within the first year, with 50% of the weight initially lost regained within the first three years (**Class I, Level B**).[38]

Very low-calorie diets (VLCDs), generally involving the use of protein and dietary supplements and a caloric intake of 800 kcal/d or less, can produce greater initial weight losses than LCDs, but long-term (>1 year) weight loss appears to be only marginally higher than LCDs (**Class I, Level B**).[39] The most important element of dietary therapy appears to be caloric restriction. Varying dietary macronutrient composition (e.g. low carbohydrate, low fat or low glycemic index) does not result in materially greater amounts of weight loss (**Class I, Level B**).[40–42] Importantly, unless accompanied by physical activity, weight loss through dietary modification alone does not appear associated with an improvement in cardiorespiratory fitness as measured by maximum oxygen consumption.[6]

Physical activity alone does not appear to materially reduce weight but improves cardiorespiratory fitness, reduces abdominal fat and, in conjunction with dietary modification, assists with long-term weight maintenance (**Class I, Level B**).[6,43] A standard recommendation is that individuals engage in at least 30 minutes of moderate intensity physical activity 5–7 days per week. Individuals who achieve over 200 minutes of activity per week achieve greater weight loss than individuals performing 150 minutes per week or less.[5,44] There is also emerging evidence that accumulated, shorter bouts of activity throughout the day achieve the same health benefits as a single, longer activity session (**Class I, Level B**).[45]

There also appears to be additional value in behavioral therapy for selected patients as an adjunct to diet and exercise therapy.[6,37] Standard behavior modification techniques include self-monitoring and goal setting, modifying eating behaviors (e.g. slowing the rate of eating, controling where eating occurs, delaying gratification), stimulus control and reinforcement management.[5] In a meta-analysis of six short-term (<1 year) RCTs involving 467 overweight or obese adults, behavioral therapy resulted in 4.7 kg (95% confidence interval (CI) 4.5–4.9) greater weight loss compared to diet and exercise therapy alone (**Class I, Level B**).[46] There is a need for longer-term studies of behavioral therapy to confirm these findings.

Hypertension

A meta-analysis of 25 RCTs enrolling 4874 patients and with a mean follow-up duration of 66 weeks demonstrated

that a net weight reduction of 5.1 kg (95% CI 4.3–6.0), by means of energy restriction, increased physical activity or both, reduced systolic blood pressure by 4.4 mmHg (95% CI 3.0–5.9) and diastolic blood pressure by 3.6 mmHg (95% CI 2.3–4.9). Blood pressure reductions were 1.1 mmHg (95% CI 0.7–1.4) systolic and 0.9 mmHg (95% CI 0.6–1.3) diastolic when expressed per kilogram of weight loss (**Class 1, Level B**).[47] A subsequent meta-analysis of 14 observational and randomized controlled studies with a duration of follow-up of two years or greater demonstrated that the blood pressure reductions associated with weight loss over the long term were about half that predicted by shorter term studies (**Class 1, Level B**).[48] In this analysis, for every 10 kg of weight loss, diastolic blood pressure was reduced by 4.6 mmHg and systolic blood pressure by 6.0 mmHg.

Which antihypertensive agent is best suited for the obese hypertensive patient? Current hypertension guidelines do not make specific recommendations on this issue, likely because of the lack of availability of high-quality data.[49] A 16-week study of 171 obese patients treated with felodipine/ramipril, verapamil/trandolapril or metoprolol/hydrocholorthiazide and randomized to sibutramine versus placebo found no significant difference in blood pressure control amongst the study arms (**Class I, Level B**).[50] Beta-blocker/thiazide therapy, however, was associated with a 2–3 kg incremental weight gain compared to the other antihypertensive combinations, which was likely due to the beta-blocker component.[51] In observational studies and post hoc/secondary analyses of RCTs, beta-blocker therapy and thiazide diuretics have been associated with an increased risk of type 2 diabetes whereas angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers have been associated with a decreased risk (**Class I, Level B**).[52,53] However, a three-year randomized trial of 5269 patients at high-risk for type 2 diabetes found no significant effect of ramipril on the incidence of type 2 diabetes (hazard ratio (HR) 0.91, 95% CI 0.81–1.03) (**Class I, Level A**), although there was a significant increase in the proportion of individuals with impaired glucose tolerance (IGT) or increased fasting glucose (IFG) who regressed to normoglycemia.[54] These accumulated data, although not definitive, suggest that ACE inhibitor or angiotensin receptor blockers may be preferentially prescribed to control hypertension in obese patients at high risk for developing type 2 diabetes.

Diabetes

A large number of studies have documented the benefits of even moderate (5–10%) weight loss in improving metabolic control in diabetic patients.[5,6] However, the impact of weight reduction on the long-term incidence of diabetic complications and survival has not been demonstrated. Improvement in metabolic control depends more on the amount of weight loss, rather than on the method by which this is achieved. A 5 kg weight loss should decrease fasting plasma glucose levels in a diabetic individual by 1 mM or 18 mg/dL.[21] This is of a magnitude similar to that provided by many of the oral hypoglycemic agents. Although pharmacologic or surgical weight loss does not appear to improve glucose control beyond that achieved by lifestyle changes alone, both the degree of loss and the number of individuals achieving and maintaining weight loss are generally higher when lifestyle changes are combined with medication or surgery.[5,6]

Evidence from a meta-analysis of 10 randomized prospective trials indicates that lifestyle modification including modest weight reduction will markedly reduce the incidence of type 2 diabetes in high-risk individuals (HR 0.51, 95% CI 0.44–0.60) (**Class I, Level A**).[55] The best known of these trials, the Diabetes Prevention Program (DPP), employed a lifestyle intervention which aimed to reduce body weight by 7% and increase physical activity to at least 150 minutes per week in non-diabetic persons (mean BMI 34) with elevated fasting and postload plasma glucose concentrations. Over 2.8 years, this lifestyle intervention reduced the incidence by 58% compared with controls and was also significantly more effective than metformin in reducing diabetes incidence.[56] A large, 11.5-year RCT of 5145 patients with type 2 diabetes using the lifestyle intervention employed in the DPP trial is currently under way.[57] This study, known as the Look AHEAD (Action for Health in Diabetes) trial, is the first study to examine the impact of intentional weight loss through lifestyle modification on cardiovascular morbidity and mortality.

In contrast to metformin and acarbose, other antidiabetic medications, including sulfonylureas, thiazolidinediones and insulin, promote weight gain. Weight gain in patients with both type 1 and type 2 diabetes is associated with an increase in blood pressure and deterioration of metabolic control.[58,59] In a secondary analysis of the UK Prospective Diabetes Study, metformin was more effective than sulfonylureas or insulin in reducing diabetes-related endpoints and all-cause mortality.[60] Furthermore, metformin appears cost-saving when used as first-line pharmacologic therapy in overweight type 2 diabetics.[61]

Dyslipidemia

Lipid abnormalities in overweight and obese individuals are typically characterized by high triglycerides, increased small low-density lipoprotein (LDL) particles and low high-density lipoprotein (HDL) cholesterol levels.[5,62] In the presence of abdominal obesity, high serum triglycerides are commonly associated with a clustering of metabolic risk factors known as the metabolic syndrome (atherogenic lipoprotein phenotype, hypertension, insulin resistance, glucose intolerance, prothrombotic and proinflammatory

states). Thus, in obese patients, elevated serum triglycerides are a marker for increased cardiovascular risk. The US National Cholesterol Education Program (NCEP) Adult Treatment Panel (ATP III) therefore recognizes the metabolic syndrome as a secondary target of risk reduction therapy, after the primary target, which is LDL cholesterol.[62]

Numerous studies document the short- and medium-term benefits associated with lifestyle modification on blood lipid levels.[63] Current evidence-based guidelines thus recommend weight reduction and increased physical activity as first-line therapies for all lipid and non-lipid risk factors associated with the metabolic syndrome.[5]

Pharmacotherapy

Antiobesity drug therapy can augment diet, physical activity and behavioral therapy to reduce weight and improve obesity-related co-morbidity[5,6] According to current guidelines, adjunctive drug treatment may be added in patients refractory to lifestyle modification alone who have a BMI level of 27–29.9 kg/m^2 and concomitant obesity-related risk factors (e.g. hypertension, dyslipidemia, type 2 diabetes) or a BMI level of 30 kg/m^2 or greater.[5,6] Drug therapy should be discontinued if 5% weight loss or improvement in obesity-related co-morbidity has not been achieved within the first 3–6 months.[64] Three antiobesity drugs are currently approved for long-term use (Table 18.2). Orlistat is a gastrointestinal lipase inhibitor that reduces enteral fat absorption by approximately 30%.[65] Sibutramine is a centrally acting monoamine (serotonin, norepinephrine and dopamine) reuptake inhibitor that primarily reduces hunger and increases satiety.[64] Rimonabant, the newest agent, is an endocannabinoid receptor blocker that reduces weight via a number of putative mechanisms including decreased appetite, increased satiety, enhanced thermogenesis and increased lipogenesis.[64] Orlistat and sibutramine have been approved by licensing authorities in most countries. Rimonabant was available in the European Union and other jurisdictions but has not been approved in North America (see below).

A meta-analysis of 16 orlistat, 10 sibutramine and four rimonabant weight loss and maintenance trials with follow-up periods of 1–4 years reported placebo-subtracted

Table 18.2 Medications approved for the long-term treatment of obesity

	Orlistat	Sibutramine	Rimonabant
Trade names	Xenical®	Reductil/Meridia®	Acomplia®
Mechanism of action	Lipase inhibitor	Monoamine reuptake inhibitor	Endocannabinoid receptor blocker
Dosage	120 mg 3 times/day prior to meals	5–15 mg/day	20 mg once daily
Cost (approximate UK price)	£40/month	£45/month	£55/month
Most frequent side effects	Flatulence with discharge, fecal urgency, fecal incontinence, steatorrhea, oily spotting, increased frequency of defecation, decreased absorption of fat-soluble vitamins	Dry mouth, headache, insomnia, constipation, anorexia, increase in heart rate, increase in blood pressure*	Nausea, depression, anxiety, insomnia, irritability, suicidal ideation, insomnia
Potential drug interactions	Reduction in absorption of ciclosporin and amiodarone	SSRIs, MAOIs, centrally active anorexants, sumatriptan, dihydroergotamine, dextromethorphan, meperidine, pentazocine, fentanyl, lithium, tryptophan	Metabolized by CYP 3A4 cytochrome system and may compete for metabolism with similar drugs
Contraindications	Chronic malabsorption syndromes, cholestasis	Uncontrolled hypertension, severe renal impairment, severe hepatic dysfunction, narrow-angle glaucoma, history of substance abuse, coronary artery disease, congestive heart failure, arrhythmias, stroke	Ongoing major depression or use of antidepressants, severe hepatic impairment, severe renal impairment, seizure disorders

*If there is a sustained increase in blood pressure or heart rate, either a reduction in the dose or discontinuation should be considered.

Table 18.3 Effect of orlistat, sibutramine and rimonabant on selected secondary cardiovascular risk factors

Parameter	Orlistat	Sibutramine	Rimonabant
LDL cholesterol (mmol/L)	–0.26 (–0.22 to –0.30)	NS	NS
Triglycerides (mmol/L)	NS	–0.18 (–0.07 to –0.30)	–0.24 (–0.17 to –0.34)
HDL cholesterol (mmol/L)	–0.03 (–0.01 to –0.04)	+0.04 (0.01 to 0.08)	+0.10 (0.08 to 0.11)
Systolic blood pressure	–1.6 (–0.9 to –2.2)	+1.7 (0.1–3.3)	–1.8 (–0.8 to –2.8)
Diastolic blood pressure	–1.4 (–0.8 to –2.1)	+2.4 (1.5–3.3)	–1.2 (–0.5 to –1.9)
A1C in patients with diabetes (%)	–0.38 (–0.18 to –0.59)	NS	–0.7 (–0.56 to –0.84)

weight reductions of 2.9 kg (95% CI 2.5–3.2 kg) with orlistat, 4.2 kg (95% CI 3.6–4.7 kg) with sibutramine and 4.7 kg (95% CI 4.1–5.3 kg) with rimonabant (**Class I, Level B**).[66] The number of patients achieving a 10% weight loss threshold was 12–21% higher with active therapy compared to placebo. Similarly, the number of patients achieving a 5% weight loss threshold was 21–33% greater and a significant reduction in waist circumference of 2–4 cm was noted. The major limiting factor in most studies was high attrition rates, averaging 30–40% across studies.[66] Such high drop-out rates limit the validity of these trials and the possibility that clinical efficacy was overestimated should be considered.

The three drugs have modest and somewhat differing effects on secondary cardiovascular risk factors (Table 18.3). Orlistat significantly improves glycemic control, reduces diabetes incidence in high-risk patients, reduces LDL cholesterol levels and improves blood pressure. Rimonabant and sibutramine improve triglyceride and HDL cholesterol profiles and rimonabant also lowers blood pressure.[66]

Orlistat, sibutramine and rimonabant also have differing major adverse effect profiles (see Table 19.2).[66] Orlistat increases the risk of gastrointestinal adverse effects (abdominal cramping, diarrhea, fecal incontinence) but appears devoid of serious systemic adverse effects. Small, dose-dependent increases in heart rate (3–5 bpm) and blood pressure (see Table 19.3) have been consistently noted with the use of sibutramine.[66] In some instances (1–5%) patients may experience a clinically significant rise in blood pressure (>10 mmHg). Nevertheless, weight reduction in hypertensive patients is often accompanied by a fall in both systolic and diastolic pressure, and several randomized controlled studies have shown that sibutramine can be used in overweight and obese patients with well-controlled hypertension.[66] Sibutramine therapy should be discontinued if a patient experiences an increase in resting heart rate of >10 bpm or uncontrolled hypertension develops. Similarly, treatment should be withdrawn in the event of previously well-controlled hypertension shifting to a

pattern of blood pressure >145/90 mmHg on two consecutive visits, or signs of progressive dyspnea, chest pain or ankle edema.

Rimonabant increases the risk of mood disorders (3% absolute increase in incidence (95% CI 2–5%)) and is contraindicated in patients with major depression or taking antidepressant medication.[66,67] A preliminary meta-analysis of all rimonabant trials (obesity, smoking cessation and other indications) by the Food and Drug Adminstration reported an increased risk of suicidality (OR 1.9, 95% CI 1.1–3.1).[68] Because of concern regarding this increased risk of mood disorders, rimonabant has recently been withdrawn from the market.[67] Until further data are available, we recommend that the drug not be prescribed in patients with any history of mood disorders.

Currently, there are no data demonstrating that anti-obesity drug therapy reduces mortality or major cardiovascular morbidity.[64] However, there is one large-scale study under way. The SCOUT (Sibutramine Cardiovascular OUTcomes) trial, a multicenter, double-blind, placebo-controlled randomized trial of over 10 000 obese and overweight patients, is evaluating the effect of sibutramine on myocardial infarction, stroke and cardiovascular mortality and is due to report in 2009.[69] The CRESCENDO (Comprehensive Rimonabant Evaluation Study of Cardiovascular ENDpoints and Outcomes) study, a double-blind, placebo-controlled randomized trial examining the impact of rimonabant on myocardial infarction, stroke and cardiovascular death in 17 000 centrally obese patients at high cardiovascular risk has been terminated.[70]

Surgery

Within the last decade, bariatric surgery has emerged as the preferred therapy for selected patients with medically refractory, moderate-to-severe obesity.[71,72] Surgery is currently indicated in patients with BMI levels of ≥40 kg/m^2 or BMI levels of 35–39.9 kg/m^2 with a major obesity-related

A restrictive band is placed around the proximal stomach and gradually inflated over successive follow-up visits. (c) Roux-en-Y gastric bypass. A stapler fired across the cardia of the stomach creates a 20–30 mL pouch. The jejunum is divided distal to the ligament of Treitz with the distal end anastomosed to the upper stomach. (d) Biliopancreatic diversion with duodenal switch. A sleeve resection of the greater curvature of the stomach is performed. The first portion of the duodenum is divided and the proximal duodenum and approximately half of the length of the small intestine (biliopancreatic limb) is excluded from digestive continuity. The small bowel is divided approximately 300 cm above the ileocecal junction and the distal end is anastomosed to the first portion of the duodenum (alimentary limb). The distal end of the biliopancreatic limb is anastomosed the the ileum 50–100 cm proximal to the ileocecal junction.

co-morbidity (e.g. hypertension, diabetes, sleep apnea).[5,6] Surgery can substantially reduce weight, increase lifespan, markedly improve co-morbid conditions, and enhance quality of life (**Class I, Level C**). Physical domains of quality of life appear to demonstrate the greatest degree of improvement.[73]

The two major types of bariatric procedures are those that purely restrict gastric volume and those that, in addition to restricting gastric size, also bypass a portion of the small intestine (Fig. 18.2). Depending on the type of procedure performed, weight losses average 30–40% of initial body weight within the first several years of surgery (Table

Table 18.4 Weight loss and complications associated with bariatric procedures[71,72,87,89]

Surgery	Average Weight Loss (%)	Perioperative mortality	Perioperative complications	Longer-term postoperative complications
Purely restrictive (gastric banding, vertical banded gastroplasty)	25–30	0.1–0.4%	DVT/PE (1–3%); anastomotic leaks (1–5%); major wound infections (1–5%); major bleeding (0.5–1%); respiratory and cardiac complications (15%)	Symptomatic gallstone formation (up to 35%); vomiting/reflux (8–18%); band erosion (3%) or band slippage (2–14%) requiring reoperation (10–20%)
Roux-en-Y Gastric bypass	35	0.5 to 1.0%		Symptomatic gallstone formation (up to 35%); vomiting/reflux/dumping syndrome (10–15%); vitamin deficiencies (up to 50%); hernia (5–25%); anastomotic ulcers (1%); bowel obstruction (1%); stomal stenosis (6%); stricture (3–27%)
Biliopancreatic diversion	40			Dumping syndrome/vomiting/GI symptoms (38%); protein calorie malnutrition (3–5%); vitamin deficiency (30–50%)

18.4).[72] Weight losses are greater with combined restrictive/bypass procedures; however, perioperative mortality rates and complication rates are also higher compared to restrictive procedures alone. A laparoscopic (versus open) approach is generally preferred because of reduced lengths of stay, postoperative pain, tissue injury and perioperative morbidity.[74,75]

Restrictive procedures include gastric banding and vertical banded gastroplasty and involve banding or stapling the stomach to markedly restrict its size to about 15 mL (see Fig. 19.2). Vertical banded gastroplasty is not commonly performed because of poor long-term weight loss maintenance and/or a high incidence of gastrointestinal reflux and stenosis.[76] Combined restrictive/bypass procedures include Roux-en-Y gastric bypass and biliopancreatic diversion. Roux-en-Y gastric bypass is currently the most commonly performed procedure worldwide and restricts stomach capacity to about 30 mL.[77] Biliopancreatic diversion is less commonly performed and involves less restriction and more malabsorption. In both types of bypass procedures, biliopancreatic secretions in the bypassed intestinal limb do not mix with food until they enter the common limb at the point where the intestines have been rejoined. By increasing or decreasing the length of the common limb, the amount of malabsorption and weight loss is correspondingly decreased or increased.[76] In addition to restrictive and malabsorptive effects, emerging evidence suggests that favorable alterations in weight-regulating hormones such as ghrelin may contribute to the effectiveness of gastric bypass.[78] Reasons for choosing one bariatric procedure over another include patient preference, surgeon experience, the amount of weight loss targeted (bypass preferred if greater weight loss needed) and the desire for lower perioperative risk or future reversibility (banding preferred).

High-quality data from RCTs designed to examine the impact of surgery on cardiovascular morbidity or overall mortality are lacking.[79] The evidence base for bariatric surgery is, therefore, largely based upon observational data (controlled and uncontrolled retrospective and prospective cohorts and non-consecutive case series from selected centers).[71,72] Nevertheless, surgery is the only therapy associated with substantial, persistent long-term reductions in weight (averaging 33% after 2–3 years[72] and 18% after 10 years[80]), total mortality (29–89% reduction) and myocardial infarction (**Class I, Level C**).[81,82] The Swedish Obesity Study (SOS), a prospective cohort study of surgical cases and matched, medically treated controls, provides the most methodologically rigorous data to date, reporting a 15-year mortality rate of 5.0% in surgical patients and 6.3% in controls (HR 0.71, 95% CI 0.54–0.92).[82] In terms of medical co-morbidity, surgery is associated with resolution or improvement of type 2 diabetes, hypertension, dyslipidemia and sleep apnea in 70–90% of cases.[72] As important, surgery improves psychosocial functioning,[83] quality of life and physical function.[84,85] It should be recognized that, despite the substantial weight losses and improvements in health associated with bariatric surgery, most patients still remain significantly overweight or obese after their operation and, mortality rates in postsurgical patients who survive the immediate postoperative period are still 3–6-fold higher than age- and sex-matched controls in the general population.[86]

Potential complications of surgery can be divided into perioperative and longer term (see Table 19.4).[71,87] The risk of perioperative death is 0.5–1% for combined restrictive/bypass procedures and 0.1–0.4% for restrictive procedures alone.[71,72] Perioperative risks are highest in men, older patients (over 55–65 years), extremely obese patients (BMI >50 kg/m²) and patients with medical co-morbidities.[88,89]

Immediate postoperative complications occur in about 10% of individuals and include anastomotic leaks, venous thromboembolic disease, cardiorespiratory events and wound infections. Anastomotic leaks can present non-specifically with isolated postoperative tachycardia and a high index of suspicion is often required to make the correct diagnosis. Radiologic investigations are not reliably accurate and reoperation is required to confirm the diagnosis and repair the leak.

Longer-term complications may directly result from the weight loss achieved or may be procedure specific. Weight loss can promote gallstone formation, which is often treated prophylactically with ursodiol.[87] Furthermore, as weight is lost, a significant minority of patients will require extensive psychologic counseling and professional rehabilitation, and 30–40% of patients will require plastic surgical removal of excess skin.[90] Malabsorptive procedures increase the risk of nutrient deficiency (particularly iron, vitamin B12, calcium and vitamin D) and may result in dumping syndrome, manifesting as postprandial nausea, vomiting, diarrhea and vasomotor symptoms.[87] Dumping syndrome, commonly precipitated by eating high osmotic loads such as refined sugar, results from the rapid emptying of gastric pouch contents directly into the jejunum.[87,91] This is followed by compensatory insulin release and/or vagal stimulation due to intestinal distension from water following the solute load. Wernicke's encephalopathy due to thiamine deficiency is an uncommon complication of bariatric surgery, particularly in patients with persistent vomiting.[92] Patients undergoing purely restrictive procedures often experience postoperative nausea and vomiting (8–10%). Gastric banding may also be complicated by band slippage (6%) or erosion into surrounding structures (10%), often necessitating reoperation.[93]

Demand for bariatric surgery is increasing at an exponential rate. In the US, the annual number of procedures has risen eightfold over one decade to over 100 000 per year.[94] Despite this large increase, only 1% of eligible patients receive surgery annually in the US because the number of potential candidates is so great (estimated at 15 million in 2002[95]). The population eligible for surgery is disproportionately composed of ethnic minorities and individuals of low socioeconomic status,[96] yet surgery is most commonly performed in middle-aged women of moderate-to-high socioeconomic status and free of pre-existing cardiovascular disease.[72]

Because of the large gap between the potential demand for bariatric surgery and the capacity to perform such procedures, surgery will remain a risk-targeted approach for highly selected individuals. However, it is currently unclear how triaging should be performed. Certain patient subgroups, such as individuals with diabetes, clearly may benefit more from undergoing surgery but also are at higher risk for complications.[97] Surgery should only be performed at experienced, specialized centers, as complication rates are highest when surgeons perform fewer than 25 operations per year and medical centers perform fewer than 50 procedures per year.[88,89,98] Complication rates are lowest for surgeons performing more than 100 operations per year and hospitals performing more than 150 procedures per year.[99] Patients who have undergone surgery require lifelong medical surveillance.

Cardiovascular disease and mortality

Many observational studies of overweight and obese patients have demonstrated that intentional weight loss is associated with a reduction in cardiovascular disease and mortality,[100] but this area is not without controversy (**Class IIa, Level C**).[101] As mentioned above, there is a lack of high-quality RCT data demonstrating that intentional weight loss reduces hard cardiovascular outcomes and mortality. Further complicating matters is the fact that many studies demonstrating a beneficial effect of weight loss involve overweight and obese patients without pre-existing cardiovascular disease. When studies examine patients with pre-existing coronary disease or heart failure, overweight and mild obesity are often associated with a reduction in mortality compared to non-obese individuals.[102,103] Indeed, weight loss (albeit not intentional) in advanced heart failure is associated with increased mortality risk.[104] Whether these latter findings are a result of residual confounding, whether obesity is a marker of other favorable characteristics (e.g. absence of cachexia) or whether obesity is truly a protective factor is currently unknown. Notably, the association of obesity with reduced mortality has been reported in many chronic inflammatory diseases including chronic renal failure and HIV/AIDS.[102]

Overall, the favorable effects of weight loss on cardiovascular risk factors in overweight and obese patients imply that intentional weight loss will ultimately reduce cardiovascular morbidity and mortality. Furthermore, observational studies demonstrating that weight loss in severely obese patients undergoing bariatric surgery is associated with mortality reduction lend further credence to this conclusion. Data from trials such as Look AHEAD, SCOUT and CRESCENDO are urgently needed to provide more definitive evidence. It is our practice to routinely prescribe obesity treatment and weight loss to the vast majority of individuals with overweight and obesity, with the exception of patient populations in which weight loss clearly appears potentially detrimental (e.g. advanced heart failure). Indeed, one of the most important barriers to the treatment of obesity is the therapeutic inertia of healthcare professionals[105] and we do not wish to leave the reader with the impression that weight loss should not be attempted until hard outcome RCTs are available. The importance of obesity as a medical disease and a public health emergency cannot be overemphasized and demands aggressive action on the part of all involved, including all healthcare practitioners.

Conclusion

Obesity is a highly prevalent chronic disease and an important risk factor for cardiovascular morbidity and mortality. Weight loss programs should focus on achieving realistic initial weight loss goals (e.g. 5–10% of initial body weight) and should emphasize the need for weight maintenance. Weight reduction induced by lifestyle, pharmacologic or surgical measures has been shown to improve obesity-related co-morbidities and, in the case of lifestyle modification and surgery, has been associated with reductions in major morbidity and mortality in observational studies. Surgery is the only treatment that results in large amounts of weight loss and has become preferred therapy in medically refractory severely obese patients. Randomized controlled obesity studies with hard morbidity and mortality endpoints are still lacking but several are currently under way.

Key points

- BMI is the means most widely used to classify obesity. Measures of central adiposity, such as waist circumference, are also important predictors of obesity-related health risk.
- Obesity and overweight now affect 40–70% of adults in industrialized nations. Particularly concerning is the disproportionately rapid rise in the prevalence of severe obesity, which substantially increases the risk of obesity-related health complications.
- Important components of a comprehensive obesity treatment plan include assessing and treating co-morbidities, identifying readiness to change and barriers to weight loss, and setting realistic weight loss goals (initially 5–10% of initial body weight, which is sufficient to improve obesity-related co-morbidity).
- Weight loss should be recommended for all patients with a BMI ≥30 kg/m² and for those with a BMI ≥27 kg/m² with two or more obesity-related co-morbidities. Weight loss should be gradual (1–2 lbs/week), achieved through a 500–1000 kcal/d deficit diet.
- A multimodal lifestyle intervention (diet, exercise and behavioral modification) is preferred and reduces weight by approximately 3–5 kg after one year. Unfortunately, nearly 50% of the weight initially lost is typically regained within the first three years, emphasizing the importance of optimizing weight maintenance. Therefore, all treatment should be initiated with the expectation that, if successful, it will be continued over the long term.
- Calorie restriction is the most important component of dietary modification. Varying the proportions of macronutrients within the diet does not lead to materially greater amounts of weight loss.
- Individuals should perform at least 30 minutes of moderate-intensity physical activity 5–7 days per week. Exercise is primarily beneficial in assisting with weight maintenance.
- Lifestyle modification is particularly beneficial in improving blood pressure, glycemic control and lipid profiles. It is the most efficacious means to reduce diabetes incidence.
- Antiobesity drug therapy is indicated as an adjunct to lifestyle modification in patients with BMI levels of 27–29.9 kg/m² and concomitant obesity-related risk factors or BMI levels of 30 kg/m² or greater. Drug therapy should be discontinued if 5% weight loss or improvement in obesity-related comorbidity has not been achieved within the first 3–6 months.
- Orlistat (lipase inhibitor), sibutramine (adrenergic reuptake inhibitor) and rimonabant (endocannabinoid receptor antagonist) are the three antiobesity drugs with efficacy data of one year or greater.
- Compared to placebo, drug therapy significantly reduces weight by 3–5 kg, increases the proportion of patients achieving 5% and 10% weight loss thresholds, and reduces waist circumference. Each drug also has specific effects on cardiovascular risk factors.
- The major side effects are gastrointestinal for orlistat, hypertension for sibutramine and mood disorders for rimonabant.
- Bariatric surgery is currently indicated in patients with BMI levels of ≥40 kg/m² or BMI levels of 35–39.9 kg/m² with a major obesity-related co-morbidity. Surgery is the most efficacious treatment for severe obesity and substantially reduces weight, increases lifespan, reduces co-morbidity and increases quality of life.
- Gastric banding restricts the volume of the stomach to about 15 mL. Gastric bypass restricts stomach capacity to approximately 30 mL and bypasses a portion of the small intestine. Both procedures are preferentially performed laparoscopically to reduce morbidity, pain and lengths of stay.
- Perioperative mortality rates are 0.5–1.0% depending on the procedure. Perioperative morbidity occurs in about 10% of individuals. The major long-term complications are gastrointestinal in nature and vary according to the type of procedure performed. To minimize complications, surgery should be performed by experienced surgical teams and centers.
- Demand for bariatric surgery dramatically outstrips capacity. The optimal approach to selecting and triaging patients for surgery is currently unclear.
- High-quality RCT data demonstrating that intentional weight loss reduces mortality and cardiovascular morbidity are currently lacking but several trials are currently under way. With the exception of specific advanced disease states associated with cachexia and inflammation, the preponderance of evidence suggests that intentional weight loss is beneficial.

19 Ethnicity and cardiovascular disease

Clara K Chow, Sonia S Anand and Salim Yusuf

Hamilton General Hospital, Hamilton, Ontario, Canada

Introduction

Knowledge regarding the major risk factors for cardiovascular disease (CVD), which include elevated blood pressure, elevated cholesterol, cigarette smoking, and diabetes, have been derived from epidemiologic studies conducted primarily in white populations.[1] Globally, non-white populations constitute the majority of the world's population. Ethnicity-related CVD research compares and contrasts levels of known risk factors and new risk factors, effects of risk factors, efficacy of treatments and preventive strategies and healthcare utilization patterns to explore the reasons for differences in CVD rates among ethnic populations.[2] Such research can lead to specifically tailored CVD preventive strategies for different populations and therefore are of major public health importance.

General issues

Defining ethnic groups

The concept of race was based on the belief that members of a race were homogeneous with respect to biologic inheritance.[3] However, over the past 20 years, as our ability to unravel the genetic code has increased, little evidenc has arisen to support the contention that the historical "racial" divisions represent differences in genetic make-up.[3,4]

Ethnicity, on the other hand, is a term used to describe a group of people whose lifestyles are characterized by distinctive social and cultural traditions which are maintained within the group and passed on from generation to generation. Therefore ethnicity has both sociocultural and biologic components.[5] Given that variations in disease rates

between populations may be explained by socio-economic, sociocultural, biologic, and genetic factors, classification by ethnic origin rather than race is desirable.[6]

Interpretation of studies in ethnic populations

The methodologic limitations of studies of ethnic populations must be recognized.[7] Mortality statistics often provide the first clues of differences in CVD rates between ethnic groups. Most developed countries have methods of collecting reliable mortality statistics.[8] However, in developing countries, these systems are less well organized and information on some selected populations may only be available from sample registration systems, community surveys and hospital admissions.

Worldwide patterns of disease

In 2001, 59% of the total global mortality was attributable to non-communicable diseases (NCD) such as CVD, cancer, and diabetes; this was 10% higher than estimates in 1990, and projected to rise to 69% by 2030.[9,10] Approximately 80% of global NCD mortality occurs in developing countries. In 2005 NCD accounted for about 61% of deaths, 50% of disease burden and 46% of premature death (deaths in people less than 70 years) in low- and middle-income countries (LMIC).[11] Coronary heart disease (CHD) and stroke are now the leading causes of deaths in LMIC. More than half of all cardiovascular deaths in LMIC occur among people aged 30 to 69 years, compared to about one-quarter in high-income countries (HIC).[12]

In most HIC, CVD rates are declining due to preventive strategies that target the most potent cardiovascular risk factors (CVRF). For example, tobacco use has declined in many HIC because of legislation and policy,[13] and the proportion of high-risk patients receiving evidence-based secondary prevention therapies has increased.[14] However, in LMIC increasing life expectancy associated with a decline in childhood and adult deaths from infections and coupled

with lifestyle changes secondary to rapid industrialization and urbanization have lead to increasing CVRF and CVD.

Differences in CVD mortality rates across countries are influenced by differences in the physical, social, political and cultural environment.[15] Ethnic variations in disease rates are closely tied to geographic patterns of disease. These geographic differences have provided many of the initial hypotheses of the association between lifestyle factors, which are strongly influenced by culture and ethnicity, and CVD. One of the first epidemiologic studies to highlight the variation in CHD rates between countries was the Seven Countries Study.[16] This study of 16 cohorts of men aged 49–59 years found substantial differences in CHD mortality between countries, for example very low rates in Japan and the Mediterranean countries and very high rates in Finland and the USA. Similarly, the WHO MONICA study in 26 countries[17] documented a more than 14-fold difference in CHD mortality among men and more than 11-fold differences in CHD mortality for women between countries. More recent data indicate that there is still wide variation across both space and time[18] (Table 19.1). The enduring differences in CHD rates across world regions have raised questions as to whether they are due to biologic factors, sociocultural factors, differences in environment or other risk factors.

Migrant groups

Observational studies have found that when members of a given ethnic group migrate to a new environment they often adopt new behaviors and risk factors and lose behaviors common to their native land. This suggests that environmental influences are very powerful factors in CVD causation. Conversely, despite different environments, similarities in disease rates within an ethnic group suggest an inherent propensity towards or protection from CVD that could be related to genetics. Comparing the mortality rates of long-settled migrants to the disease rates in their country of origin helps to establish the relative contribution of genetic and environmental influences to differences in mortality rates. The Ni-Ho-San Study of Japanese migrants to Hawaii and San Francisco revealed that changes in disease rates in this population likely reflected changing environmental influences.[19] The age-adjusted CHD mortality rate rose as the Japanese moved from Japan to Hawaii and California. More than half of the increase in CHD was attributable to different levels of conventional risk factors, as the US cohort had a higher fat diet and higher mean serum cholesterol compared to the Hawaii or Japan cohorts.[19] This suggests that the low rates of CHD mortality in Japan may be retained in Japanese migrants if they kept their risk factors at similar levels to those in Japan, which likely would require maintenance of their traditional lifestyle.

Specific ethnic groups

A major contribution to our understanding of ethnic variation in risk factors for CHD is the findings of the INTERHEART study. INTERHEART was a large case–control study involving about 14 000 cases of first myocardial infarction (MI) and 14 000 matched controls from 52 countries. It was designed to study the importance of conventional and emerging risk factors in different geographic regions and ethnic groups.[20] The principal findings of this study were that nine modifiable risk factors, including abnormal lipids, smoking, hypertension, diabetes, abdomi-

nal obesity, psychosocial factors, consumption of fruits and vegetables, alcohol intake and regular physical activity, account for more than 90% of the risk of MI worldwide, in both sexes, and at all ages, in all regions, and in all major ethnic groups. This study challenged the conventional belief that different ethnic groups had different CVRF and provided evidence that while the frequency of risk factors varied by ethnic group, the strength of association with MI was similar. Thus the differences in CVD rates across different regions and/or ethnic groups are attributable to the difference in distribution of established CVRF (Table 19.2).

The following sections review the CVD profile of seven major ethnic groups. Based on the best available data, we document their disease burden and changes in disease rates over time, and review common/influential CVD risk factors. We then discuss ethnic group-specific preventive strategies that need to be further developed or reinforced.

European origin (including North Americans)

People of European origin include those who originate from Northern Europe such as the Nordic countries and Germany, Western Europe including the United Kingdom and France, Southern Europe including Spain and Italy, and Eastern Europe (which includes the Slavic countries).

Disease burden

Differences in the age-standardized mortality rates (ASMR) vary widely between European populations, with the highest rates observed in Eastern Europe (e.g. Bulgaria, the Russian Federation) and the lowest in France and

ApoB/ApoA ratio(4 v 1)§	19.99	24.22	2.72 (2.38,3.10)	–	2.41 (2.09,2.79)	–
ApoB/ApoA ratio(5 v 1)§	20.00	33.49	3.87 (3.39,4.42)	54.1 (49.6,58.6)	3.25 (2.81,3.76)	49.2 (43.8,54.5)
All above Risk Factors combined¶	–	–	129.20* (90.24,184.99)	90.4 (88.1,92.4)*	129.20* (90.24,184.99)	90.4 (88.1,92.4)*

*The median waist /hip ratio was 0.93 in cases and 0.91 in controls (*P* < 0.0001), and the median ApoB/ApoA1 ratio was 0.85 in cases and 0.80 in controls (*P* < 0.0001). Percentage of controls with four or five factors positive is 2.2% compared with 29.2% in cases.

*PARs for smoking, abdominal obesity, and ApoB/ApoA1 ratio are based on a comparison of all smokers *vs* never, top two tertiles *vs* lowest tertile, and top four quintiles *vs* lowest quintile. For protective factors (diet, exercise, and alcohol), PARs are provided for the group without these factors.

†Top two tertiles *vs* lowest tertile.

‡A model-dependent index combining positive exposure to depression, perceived stress at home or work (general stress), low locus of control, and major life events, all referenced against non-exposure for all five factors.

§Second, third, fourth, or fifth quintiles *vs* lowest quintile.

¶The model is saturated, so adjusted and unadjusted estimates are identical for all risk factors. The odds ratio of 129.20 is derived from combining all risk factors together, including current and former smoking *vs* never smoking, top two tertiles *vs* lowest tertile of abdominal obesity, and top four quintiles *vs* lowest quintile of ApoB/ApoA1. If, however, the model includes only current smoking *vs* never smoking, the top *vs* lowest tertile for abdominal obesity, and the top *vs* lowest quintile for ApoB/ApoA1, the odds ratio for the combined risk factors increases to 333.7 (99% CI 230.2–483.9).

Table 19.3 Age-standardized CVD mortality rates (45–74 years) in selected European countries, 2000[21]

Country	CHD mortality rates (men) SMR (95% CI)	CbVD mortality rates (men) SMR (95% CI)	CHD mortality rates (women) SMR (95% CI)	CbVD mortality rates (women) SMR (95% CI)

Romania	449 (433–465)	302 (289–314)	209 (199–220)	207 (196–217)
Bulgaria	404 (389–419)	361 (347–375)	157 (148–166)	220 (209–230)
Estonia	713 (693–733)	487 (471–504)	260 (248–271)	248 (237–260)

Switzerland (Table 19.3). In a recent update on regional variation in mortality rates across Europe, the rate ratio of dying from CHD between the countries with the highest mortality compared with the lowest mortality is 7.1 (95% confidence interval (CI) 6.6–7.6) for men (Latvia v France) and 9.9 (95% CI 8.5–11.5) for women (Estonia v France). There is still a clear north-east to south-west gradient in mortality from CHD.[21] For cerebrovascular disease (CbVD), the rate ratio is 14.5 (95% CI 12.7–16.4) for men (Estonia v Switzerland) and 12.0 (95% CI 10.2–14.1) for women (Estonia v Switzerland). With regard to CbVD, there appears to be a "green" circle of reduced mortality in the centre of Western Europe (France, northern Italy and Spain). Although in all countries the CVD mortality rates are much lower among women, substantial between-country differences persist. Over the past 30 years most European countries, the United States and Canada have experienced substantial declines in the CVD mortality rates.[22] However, the Eastern European countries, including Ukraine, the Russian Federation, Hungary, and the Czech Republic, continue to have among the highest rates of CHD and CbVD in the world, with a few showing a decline (Poland) and several showing an increase (Ukraine).[23,24]

Common risk factors

Throughout European populations the high rates of CVD are mainly attributable to high rates of a combination of risk factors including elevated serum cholesterol, elevated blood pressure, diabetes, diets high in saturated fat and smoking. More recently, high rates of overweight and obesity are likely to perpetuate the high rates of associated risk factors and disease. The epidemic of CVD in the Eastern European countries is in part related to high levels of smoking, diets high in animal fats, along with excessive alcohol consumption and social disparity.[25,26] Research to explain why the Italian and French populations remain

relatively "protected" from CHD has yielded numerous hypotheses. It is likely that dietary differences may explain the disparity. For example, the high consumption of olive oil and antioxidants may explain low CHD rates in Italy. In France, however, despite similar saturated fat consumption and levels of serum cholesterol, blood pressure and smoking, the CHD mortality rate remains low.[27] This immunity to CHD has been attributed to high consumption of wine which may offer cardioprotection by increasing HDL cholesterol levels, or by inhibiting postprandial hyperlipidemia and platelet aggregation.[28] Others believe the lower rate of CHD mortality may simply be due to a time lag as increases in consumption of animal fat and elevations in serum cholesterol have only occurred recently in France.[29]

Influential factors

CHD, like other epidemics, relates closely to social conditions and its prevalence appears to be more strongly related to the social and cultural conditions of a society than its genetic make-up. This is evidenced by the rapid decline in the rates of CHD in parallel to economic changes in the United States and Japan, and the increase in CHD rates in the Eastern European countries. These changes have occurred too quickly for changes in gene frequencies to have occurred.[26] Therefore, rather than explaining differences in CHD rates between populations largely on genetic differences, rapid changes in CHD rates can occur and are usually explained by changes in diet (including alcohol consumption) and smoking that are influenced by economics.

Special approaches to prevention

It is clear that major lifestyle changes, and vigilant treatment of risk factors, result in declines in CVD rates. In Finland, an impressive 60% reduction in CHD and stroke

mortality was observed between 1972 to 1994, and it is estimated that approximately 75% of this decline can be explained by a substantial lowering of serum cholesterol by 13% (0.88 mmol/L) in men and 18% (1.19 mmol/L) in women, a lowering of diastolic blood pressure by 9% (6.6 mmHg) in men and 13% (12.2 mmHg) in women, and a significant reduction in smoking rates (30% in men) which have occurred as a result of individual and population-targeted interventions.[30]

In the USA, a 34% decline in CHD mortality occurred between 1980 and 1990. One-quarter of this decline is attributed to primary prevention efforts, such as decline in smoking due to effective policies,[13] and 29% is explained by secondary prevention efforts, such as treatments to lower cholesterol and blood pressure. Furthermore, 43% of this decline is attributed to improved medical and surgical management in patients with established CHD.[31] However, it is important to note that despite the general success in reducing CVRF in the US population, not all segments of society are benefiting equally and improvements may have slowed. Smoking and diabetes rates are particularly high among people with a lower socio-economic status. To further reduce CVD in the US, programs need to be targeted at these high-risk groups.

Population health interventions to reduce CVRF levels seem to be very effective in achieving long-term CVD prevention. In Finland the decline in CVRF and CVD was associated with the launch of the national demonstration project in North Karelia in the 1970s and with subsequent major national activities thereafter.[30] More recently in Poland, during the 1990s, a rapid decrease (about 25%) in CHD deaths in early middle age was observed. This sudden decline is attributed to rapid political and economic changes in Poland (and surrounding countries) that made fruit and vegetables more accessible and affordable and oppositely impacted foods of animal origin, which led to improved diets.[32] By contrast, a marked increase in death rates from CVD, accidents, violence, and infectious diseases has been observed in Russia over a relatively short time period, and is thought to be due to socio-economic upheaval.[33] Such examples substantiate the claim that societal factors contribute greatly to CVD burden.

Japanese

Disease burden

Mortality rates from CVD are much lower in Japan than Western countries.[23] Initial data from the Seven Countries study confirmed that the Japanese experience lower rates of CVD compared to Western populations.[16] The pattern of CVD in Japan also differs from Western populations, as they tend to experience relatively higher proportions of stroke (ASMR: M 79, F 41/100 000) and less CHD (ASMR: M 57, F 21/100 000).

Temporal trends

In parallel with a rise in economic prosperity, the CHD rates in Japan have declined like other OECD (Organization for Economic Co-operation and Development) countries. For CHD the ASMR decreased from 47/100 000 in 1995 to 42/100 000 in 1997 among males, and from 25 to 21/100 000 during the same time period among females.[23] Given the low rate of CHD in Japan, the life expectancy in Japan is among the highest in the world.[34] The mortality from stroke in Japan has also declined substantially since 1950.[26] Between 1995 and 1997, ASMR decreased for both men from 82/100 000 in 1995 to 79/100 000, and in women from 54/100 000 to 41/100 000 during the same time period. Low cholesterol levels and declining levels of blood pressure (due to reduction in salt intake and increased use of blood pressure-lowering treatments) and smoking (82.3% among men in 1965 to 45.5% in 2005) in a socially stable environment are probably responsible for the declines in CHD and stroke in Japan.[26,34,35]

Common risk factors

A review of CVRF in the Japanese population suggest that high blood pressure is a major determinant of CVD (particularly high rates of stroke), more so than cholesterol and cigarette smoking.[34] Low serum cholesterol related to a diet low in saturated fats is probably also an important contributing factor. Despite the fact that two-thirds of Japanese men smoke, CHD rates have remained unexpectedly low. Smoking rates and rates of hypertension are declining (prevalence of severe hypertension in men 60–69 years fell from 21% in 1965 to 4% in 1990), but the prevalence of type 2 (non-insulin dependent) diabetes in Japanese males and females is higher than rates in most Western countries. The National Nutrition Survey of 2000 reported that 22.6% (20.7–24.5) of men and 22.3% (20.7–23.9) of women aged 20 years and over had diabetes according to WHO 1999 criteria.[36] The same survey reported the prevalence of overweight (Body Mass Index (BMI) 25–29.9 kg/m^2) to be 24.5% in men and the rates of obesity (30 kg/m^2) as 2.3%. The corresponding rates in females were 17.8% and 3.4% respectively. Rates of obesity have increased in men over the last three decades but have been stable or decreased in women. In the last decade average BMI has increased in men by 0.45 kg/m^2 (0.42–0.47), but decreased in women by 0.08 (0.6–0.11) kg/m^2.[37] Therefore, obesity and type 2 diabetes appear to be emerging and may influence trends in CVD in the future for Japan.

Influential factors

Over the past 30 years blood pressure levels have declined in Japan due to primary prevention efforts.[38] However, "Westernization" of Japanese diets during this period likely explains the two- to threefold increase in glucose intolerance and type 2 diabetes, as well as obesity and more

recently hypercholesterolemia.[34,39] Studies have documented that the average serum cholesterol concentration among Japanese has increased from 1980 to 1989, from age-adjusted total serum cholesterol levels of 4.84 to 5.22 mmol/L in men and from 4.91 to 5.24 mmol/L in women. These concerning trends combined with the substantial use of tobacco among Japanese males (59%) suggest that Japan may soon experience a rise in CVD.[34] Studies of Japanese migrant groups show they are susceptible to changing environments. Brazil-born Japanese had a higher proportion of fat in their diet (similar to the general Brazilian population) compared to Japan-born participants (first-generation migrants) and compared to data from Japan,[40] and this was associated with more adverse lipid profiles[41] and a higher prevalence of diabetes (also higher than the general Brazilian population).[42] Similar patterns have been observed in Japanese migrants to Hawaii and California.[19,43,44]

Special approaches to prevention/treatment

With increasing adoption of Western lifestyles in Japan,[38] the pattern of CVRF may become more and more like that of Western countries. A number of studies have shown the protective benefit of the traditional Japanese diet, particularly the Okinawan diet. People in Okinawa (South Island of Japan) enjoy the longest average life expectancy in Japan. Okinawans have less salt in their diet, low animal fat and marked soy bean and fish consumption.[45] Therefore, maintenance of traditional Japanese low-fat diets, high in soy, seaweed and green vegetables,[45] and control of cigarette smoking may be what Japan needs to focus on to prevent CVD.

Chinese

Disease burden

Although the overall mortality from CVD is less in China than in Western countries, CVD is the most common cause of death in China and Taiwan. When compared to Western populations, Chinese, like Japanese, experience higher stroke rates and lower rates of CHD. In urban China in 1999, the ASMR for CHD in men aged 35–74 was 106/100 000 and for women 71/100 000,[23] fivefold lower than the highest rates documented in the MONICA project from Europe.[23] In contrast, the ASMR for stroke in this period and age group was 217/100 000 in men and 147/100 000 in women.[23] CHD incidence in China is also relatively low (highest incidence reported in Sino-Monica 1987–1989 was 109/100 000 in men 35–64 years) whereas stroke incidence is high (highest incidence of stroke from the same study 553/100 000 for men 35–64 years). Hemorrhagic strokes are about two to three times more common in China compared to the West.[46] Only 6–12% of strokes in whites are reported as hemorrhagic compared to 25–30% of strokes among Chinese.[24]

Temporal trends

In parallel with increasing average life expectancy to 71.4 years in 2000 compared with 68.6 years a decade earlier,[47] death rates from CVD (particularly CHD) are increasing in China.[48] The proportion of all deaths due to CVD in China increased from 86/100 000 (12.8% of total death) in 1957 to 214/100 000 (35.8%) in 1990.[49] A recent study of a large representative cohort from China of 169 871 men and women 40 years and over found that CHD accounted for 22.5% and stroke for 21.3% of all deaths.[50] Although Japan has reported a decline in stroke mortality, the decline in stroke deaths in China has not been as striking. The relatively stable incident stroke levels may be due to the balance of falling rates of hemorrhagic stroke with rising rates of ischemic stroke and there is some evidence for this from Beijing and Shanghai where hemorrhagic stroke rates have fallen by 12.0% and 4.4% but ischemic stroke rates have increased by 5.0% and 7.7% respectively.[51]

Common risk factors

Data from the Sino-MONICA project (a 7-year study monitoring trends and determinants of CVD in geographically defined populations in different parts of China) indicate that mean blood pressure levels are high by international standards but total cholesterol and BMI are low.[52]

The rise in CVD in China is likely attributable to adverse changes in health behaviors such as falling levels of physical activity and dietary change associated with rapid urbanization. Risk factor levels are lower in rural compared to urban areas (Table 19.4). Amongst a representative sample of 15 540 Chinese adults, aged 35–74 years from the International Collaborative Study of Cardiovascular Disease in Asia, 78.1% and 21.8% of rural and urban residents, respectively, were physically active. Cigarette smoking is highly prevalent among Chinese males. Over 60% of men smoke and some evidence suggests rates are increasing.[53] Smoking rates among women are much lower, but about a third of smoking-related deaths in women are due to passive smoking.[54] While underweight is still a problem among some Chinese, the prevalence of overweight is increasing, particularly in urban areas.[55]

The strength of association of established CVRF (e.g. cholesterol, blood pressure, smoking, BMI) and CHD/stroke has been shown to be similar for populations from Chinese and Western populations in the APCSC (Asia Pacific Cohort Studies Collaboration).[56] The INTERHEART study included 3030 cases of first MI and 3056 controls from China and Hong Kong and indicates that the same risk factors that are responsible for CHD in other world regions explain the majority of CHD in China, as the nine INTERHEART risk factors explained 88.8% of the PAR for China and Hong Kong.[20] Thus in a study that modeled the impact of changes in risk factors and medical/surgical treatments on CHD mortality in Beijing between 1984 and 1999, most of the

Table 19.4 Cardiovascular risk factors levels in China from the INTERASIA China Study 2001

Factor	Population	Year	Men	Women
Smoking	National (Urban & rural)	2002	60.2%	6.9%

From references 52, 61–65.

increase (~77% or 1397 additional deaths) was attributable to substantial rises in total cholesterol levels (more than 1 mmol/L), plus increases in diabetes and obesity.[57] Blood pressure decreased slightly, whereas smoking prevalence increased in men but decreased substantially in women. Changing levels of treatments seemed to have less impact; in 1999, medical and surgical treatments together prevented or postponed ~642 deaths, mainly from initial treatments for acute myocardial infarction (41%), hypertension (24%), angina (15%), secondary prevention (11%), and heart failure (10%).

Influential factors

Absolute rates of CVD are still lower in China and Chinese migrant populations. However, the burden of CVD is unlikely to have been fully realized in China. Smoking-related mortality and morbidity are climbing. A large national study in 1990 found that smoking was already causing about 12% of Chinese male mortality in middle age and predicted that this proportion would rise to about 33% by 2030.[58] China has the largest production and consumption of tobacco worldwide. It has witnessed a dramatic increase in tobacco consumption over the past two decades, with more than 34.8 million cartons of cigarettes being produced and 34.7 million sold annually. The continuous, rapid increase in the number of Chinese smokers is largely due to teenagers taking up smoking. The average daily consumption of tobacco per person in China rose from one cigarette in 1952 to 10 cigarettes in 1990.[59] Passive smoking as well as the effects of both indoor and outdoor air pollution are also likely to be important influencing factors for CVD in China in the future. [54] These together with the continuing high rates of hypertension and early evidence of effects of urbanization on health behaviors and subsequent falling levels of physical activity and increasing obesity and diabetes are concerning signs of what may come. In one urban cohort from China, acquisition of a motorized vehicle was associated with 80% higher odds of becoming obese.[60] Higher rates of CHD in Chinese populations with prolonged exposure to urban lifestyles such as in Singapore indicate that Chinese are not immune to the effects of CHD.

Migrant patterns

Data from Chinese migrants to Singapore and Mauritius provide evidence that exposure to urban environments leads to adverse risk factor profiles.[66,67] A comparison of rural Chinese in China to urban Chinese subjects living in Hong Kong and Australia found that despite a slightly better risk factor profile among the urban Chinese (based on HDL cholesterol and lower blood pressure), carotid intima media thickness (a measure associated with cardiovascular risk) was lower among the rural subjects (0.50 + 1.0 mmHg) than among urban subjects

$(0.56 + 0.12 \, \text{mmHg})$.[68] Together with urbanization, increased levels of metabolic risk factors and CHD in Chinese populations outside China may be due to cultural dietary differences such as the higher consumption of coconut and palm oil, mainly containing saturated fat, in Singapore.[69] Diabetes rates and mean serum cholesterol were also higher in Mauritius Chinese (5.5 mmol/L) than in Beijing Chinese (4.4 mmol/L), whereas the prevalence of hypertension and smoking was greater in Beijing.[66] Therefore, although the prevalence of hypertension and smoking may decline for these migrant populations, the rates of obesity, late-onset diabetes, elevated serum cholesterol, and CHD increase. However, Chinese migrants to the United States and Canada have lower rates of CHD relative to other migrant groups, and have low or similar rates of stroke, indicating they may still retain some level of protection from CVD compared to other populations.[44]

Approaches to prevention

Economic modernization in China is resulting in increased rates of CVRF common among Western populations becoming apparent in urban populations of China. This offers a major challenge for future prevention efforts in China as increasing populations are exposed to rapid urbanization. Important prevention strategies for the Chinese will include smoking cessation/prevention, maintenance of traditional Chinese lifestyles including diet (high in leafy green vegetables and fish, low in saturated fat) and regular physical activity to prevent continuing adverse changes in BMI, diabetes, serum cholesterol and blood pressure.

South Asians

South Asians include people who originate from India, Sri Lanka, Bangladesh, and Pakistan.

Disease burden

There are relatively few mortality studies from India as there is no uniform completion of death certificates and no centralized death registry for CVD.[70] However, the WHO and the World Bank data indicate that mortality attributable to CVD has increased in parallel with the expanding population in India, and now accounts for a large proportion of disability-adjusted life years (DALY). Of all deaths in 1990, approximately 25% were attributable to CVD, which is greater than the 10% due to diarrheal diseases, the 13% due to respiratory infections, and the 8% due to tuberculosis.[71] In 2006 the Global Burden of Disease Studies (GBDS) reported detailed cause of death estimates for the South Asian region based on 2001 data.[72] CHD was reported to be the number one cause of death in South Asia, accounting for 13.6% of all deaths, and CbVD was the fourth leading cause of death, accounting for 6.8% of all deaths.[72]

Temporal trends

In South Asia CHD is expected to rise in parallel with increasing life expectancy, increase in per capita income, and decline in infant mortality.[72,73] There are few direct measures of CHD incidence from India, which makes evaluation of trends difficult. However, indirect comparisons of studies in which CHD incidence was defined using ECG indicate that CHD incidence is probably increasing in India.[74]

Common risk factors

Historically most populations from South Asia have documented low levels of CVRF, particularly blood lipid levels, diabetes and hypertension. However, over the past several decades, the prevalence of these risk factors has increased, especially in urban areas.[75] For example, a recent survey of six major cities of India including 11 216 participants ≥20 years reported a diabetes prevalence of 12.1% and impaired glucose tolerance prevalence of 14.1%,[76] in contrast to rates of diabetes reported in urban studies in the 1970s of 1–3%.[77] There is also evidence that diabetes rates are increasing in rural areas. In comparison to the rates reported by the PODIS study (including 41 270 adults ≥25 years conducted between 1999 and 2002) of 1.9% in rural and 4.6% in urban areas, recent rural studies from select states report rates as high as 13%.[78,79] Similarly, rates of hypertension have increased from about 5% in urban areas in the 1960s to 12–15% in the 1990s.[80] Recent studies have also documented high rates of abdominal obesity in select urban and rural areas. In a survey of employees aged 20–59 years in a large industry near Delhi (n = 2935), 43% had central obesity (waist >90 cm) and the metabolic syndrome was present in 28–35% of individuals depending on the diagnostic criteria used.[81] In a survey of rural adults from Andhra Pradesh (n = 4535), the prevalence of central obesity (waist >90 cm in men, >80 cm in women) was 26.0% and the prevalence of metabolic syndrome ranged from 24.6% to 30.2% depending on the definitions used.[82]

Smoking rates are also high in India, particularly amongst men. Rural rates of smoking are higher than urban rates and may reflect socio-economic differences. In a cross-sectional survey (n = 19 973) of Indian industrial employees and family members from urban and peri-urban areas, tobacco use was significantly more prevalent in low versus high education groups (56.6% v 12.5%).[83] While previous evidence has indicated the possible importance of novel risk factors, such as higher levels of lipoprotein (a), homocysteine, fibrinogen, and plasminogen activator inhibitor (PAI-1),[84] in South Asian populations that may be driving the epidemic of CVD in South Asians, recent findings suggest otherwise. The INTERHEART study found protective factors were lower in South Asian controls than in controls from other countries (moderate- or high-intensity exercise, 6.1% v 21.6%; daily intake of fruits and vegetables,

26.5% v 45.2%; alcohol consumption once/wk, 10.7% v 26.9%). However, some harmful factors were more common in South Asians living in India than in individuals from other countries (elevated apoB/apoA-I ratio, 43.8% v 31.8%; history of diabetes, 9.5% v 7.2%). Similar relative associations were found in South Asians compared with individuals from other countries for the risk factors of current and former smoking, apoB/apoA-I ratio for the top versus lowest tertile, abdominal obesity as measured by the WHR for the top versus lowest tertile, history of hypertension, history of diabetes, psychosocial factors such as depression and stress at work or home, regular moderate- or high-intensity exercise, and daily intake of fruits and vegetables. Alcohol consumption was not found to be a risk factor for acute MI in South Asians, likely because the reported use of regular alcohol intake is low. The combined odds ratio (OR) for all nine risk factors was similar in South Asians (123.3, 95% CI 38.7–400.2) to individuals from other countries (125.7, 95% CI 88.5–178.4). The similarities in OR for the risk factors explained a high and similar degree of population attributable risk in both groups (85.8%, 95% CI 78.0–93.7%) versus 88.2% (95% CI 86.3–89.9%), respectively. When stratified by age, South Asians had more risk factors at ages younger than 60 years, which explained the younger mean age of MI in South Asians compared with other countries (Fig. 19.1).[85]

Influential factors

Urbanization of South Asian populations has influenced the rise in glucose intolerance, abdominal obesity, and its associated dyslipidemia (Table 19.5). This clustering of factors is also associated with impaired fibrinolysis, increased C-reactive protein, and enhanced thrombogenesis. Increasingly, data support the idea that elevations of glucose in the non-diabetic range which is prevalent among South Asians is associated with the development of atherosclerosis among South Asians.[86] Tobacco use, particularly indigenous forms, is also an important determinant of CVD in South Asian countries. Smoking rates are higher in rural men and women compared to their urban counterparts (Table 19.5). The INTERHEART study confirms previous indications that indigenous forms of tobacco use are also harmful. Smoking beedies alone was associated with increased risk (OR 2.89, 95% CI 2.11–3.96), similar to that associated with cigarette smoking. Chewing tobacco alone was associated with OR 2.23 (95% 1.41–3.52) and smokers who also chewed tobacco had the highest increase in risk (OR 4.09, 95% CI 2.98–5.61)[87] (Fig. 19.2).

Migrant patterns

Cross-sectional studies of CVRF in South Asians living in North America find a high prevalence of diabetes, impaired glucose tolerance, central obesity, elevated LDL choles-
Figure 19.1 Predicted probability of acute myocardial infarction at a younger age in South Asians compared with individuals from other countries. (From Joshi, *JAMA* 2007;**297**:286–94 with permission.)

terol,[89] elevated triglycerides, and low HDL cholesterol.[90,91] The prevalence of impaired glucose tolerance and type 2 diabetes is four to five times higher in South Asian migrants than in Europeans by the age of 55 (20% v 4%).[90] The prevalence of diabetes in South Asians in the UK was 10–19%, 21% in Trinidad, 25% in Fiji, 22% in South Africa, 25% in Singapore, 20% in Mauritius, and 10% in Canada.[90,92]

Studies of South Asian migrants to countries such as the UK, South Africa, Singapore, and North America indicate that South Asians suffer between 1.5 and 4.0 times higher CHD mortality compared to other ethnic groups (Table 19.6).[89] Although the CHD mortality rate of South Asians compared to other populations remains high, a decline in CHD rates has been observed in most South Asian migrants over the past 10 years, although this decline has been less than that observed in the general population in most countries except Canada.[93,94]

A study which compared the risk profiles of urban South Asians living in the UK with their siblings living in India revealed that the UK cohort had a higher BMI (27 v 23), systolic BP (144 mmHg v 137 mmHg), total cholesterol (6.35 v 5.0 mmol/L), lower HDL cholesterol (1.14 v 1.27 mmol/L), and higher fasting glucose (5.4 v 4.6 mmol/L) compared to their siblings. Lp(a), which is mostly genetically determined, was similarly high in both groups.[103] These studies indicate that South Asians have a propensity for adverse changes in CVRF when they adopt urban and Westernized lifestyles, whether they live in India or abroad (Table 19.7).

Prevention strategies

Changes in the risk factor profiles of South Asians are attributable to changes in health behaviors associated with

Table 19.5 Urban–rural comparisons of CVD risk factors in India[88]

Cardiovascular risk factor comparisons in three age groups					
Factor	**Age (years)**	**Male**		**Female**

urbanization, such as decreased physical activity and increased energy consumption which leads to obesity, abdominal obesity, and its harmful sequelae. The INTER-HEART study found that compared with individuals from other areas, native South Asians had significantly higher PARs associated with waist-to-hip ratio but lower PARs for history of hypertension and psychosocial stress. Therefore efforts to increase physical activity and improve diets are likely to lead to the greatest reduction in CHD.

Arabs

The term Arab refers to Semitic people who originate from the Middle East. Included in this region are the countries of Egypt, Saudi Arabia, Jordan, Iraq, Syria, Bahrain, Lebanon, Kuwait, Qatar, Yemen and the United Arab Emirates. People from Iran originate from the Middle East but are known as Persian and not typically included in the Arab ethnic group classification.
Figure 19.2 Risk of acute myocardial infarction associated with different tobacco use. (From Teo, *Lancet* 2006;**368**:647–58 with permission.)

Disease burden

Cardiovascular disease is the leading cause of death among Arabs living in the Middle East.[72] The high rates are likely secondary to rapid socio-economic development, urbanization, and improved survival in recent decades. The Global Burden of Disease report estimates that the acute MI rate among men and women in the Middle East was 139/100 000 and 124/100 000 respectively in 2000, which is an increase of 12% among men and 5% among women since 1990.[72]

Temporal trends

While national incidence and mortality data are not readily available for many Arab countries, one indication of the increase in CVD is the rise in hospital admission for CVD

Table 19.6 Standardized mortality ratios (SMR) (per 100 000) for CHD in South Asians worldwide

over time. In Egypt the proportion of hospital admissions due to CVD increased from 12% in 1970 to close to 40% in 1990.[104] In Saudi Arabia, CHD represented the leading cause of admissions in 1995.[105] In Oman during 1985–87 CHD and CbVD accounted for 30% of hospital deaths in the age group 15 years and above.[106]

Common risk factors

Cardiovascular risk factors are generally common in this region and are increasing in both urban and rural regions. Overweight (BMI 25–30) and obesity (BMI > 30) are highly prevalent in the Arabian Peninsula, and over half of all adults aged 40–69 years are either overweight or obese.[107] Obesity rates vary from 16% to 25% among men and from 17% to 43% among women. The perception that obesity is symbolic of prosperity may contribute to the higher rates of obesity observed in women.[108] Adverse lifestyles associated with socio-economic improvement and urbanization, such as diminished physical activity (with the availability of domestic help, private cars, popularity of television, etc.) and altered dietary patterns (increased fat and energy intakes), contribute to the high prevalence of obesity.[107] In a nationally representative sample from Bahrain rates of leisure time physical activity were low among all age and sex groups, though higher among men (30–49 years: 19.9%) than among women (30–49 years: 9.9%).[109]

High prevalence of type 2 diabetes is also observed in this region. In 1995 the prevalence of diabetes in the Middle East was approximately 6.3% and this is expected to increase to 8.2% by the year 2025.[110] In 1995, there was approximately twice the number of diabetics in urban compared to rural areas of the Middle East. By 2025 it is expected this ratio will increase dramatically, and there will be approximately 3.5 times the number of diabetics in urban compared to rural areas.[110] In Saudi Arabia in 2001, a national cross-sectional survey reported a diabetes (defined as fasting glucose ≥7.0 mmol/L) prevalence of 26.2% in men and 21.5% in women 30 years and over,[36] with similar levels reported at a similar time period in the United Arab Emirates (UAE) of 21.5% in men and 19.2% in women ≥20 years.[36]

The high prevalence of obesity and sedentary lifestyles may also be associated with high levels of hypertension in this region. National surveys have demonstrated high prevalence of hypertension in Oman (33.1%, up from 27%),[111] Egypt (26%),[112] and the UAE (37%).[113] In the UAE, 26% of hypertensive subjects were aware that they had high blood pressure, 41% were being treated for the disease, and only 19% were under control.[113] This high prevalence, coupled with low awareness and poor control, suggests the need for additional focus on prevention. Some studies also indicate significant levels of dyslipidemia and hypercholesterolemia in Saudi Arabia[114] and Syria.[115]

Smoking is typically more common among men than women for cultural reasons, and the prevalence varies markedly between countries within the region but increasing rates are seen amongst young females in some populations. In Jordan adult smoking rates for men are 50.5% and women 8.3%, but amongst 13–15 year males the rate is 36.5% and females 27.7% (Jordan Global Youth Tobacco Survey 2003).[36] In Saudi Arabia, the prevalence of smoking is 12% among men, compared to only 1% among women.[114] However, the increasing use of the "water pipe" has resulted in increased smoking among women. In Bahrain, approximately 46% of men and 30% of women reported smoking. Smoking is also common amongst youth in Bahrain with 33.5% of 13–15 year old males reporting current smoking in the Global Youth Tobacco Survey in 2001. Furthermore, women more often reported exposure to passive smoke (44%) compared to men (29%).[109] High levels of CVRF have also been observed in Arab migrant communities in the United States, with similar or higher levels of metabolic risk factors (diabetes and overweight) compared with NHANES III survey results.[116]

Influential factors

In comparison with European populations with similar degrees of obesity, Arabs experience more diabetes. This suggests that Arab people may have an increased genetic susceptibility to abdominal obesity (for example, the "thrifty gene"), which is expressed as glucose intolerance and excess abdominal fat in the face of an environment of abundant energy intake and relatively little physical activity.[117] Profound changes associated with rapid economic development and urbanization in much of this region which have occurred during the past 30 years are associated with the emergence of both obesity and diabetes, and this trend is expected to continue.

Approaches to prevention

Increased susceptibility to insulin resistance among Arabs suggests that control of obesity and diabetes is critical. Attention to lifestyle practices that promote obesity, such as sedentary lifestyles and increased energy intake, should be a focus. Cultural beliefs about overweight and obesity for both men and women must be understood in order to develop effective prevention strategies.[108] These directions have already been established in many countries of the Arabian Peninsula, and more recently in collaboration with the World Health Organization. Furthermore, tobacco use is high among some countries and increasing among some segments of society and effective prevention tactics should be introduced and maintained.

Hispanics

The term Hispanic includes Cuban Americans, Mexican Americans, and Puerto Rican Americans. There are approximately 35.3 million Mexican Americans living in the USA,

and they comprise approximately 12.5% of the US population.[118] The majority of information on CVD in Hispanics has been derived from studies conducted among Mexican Americans.

Disease burden

Vital statistic data collected since the 1970s in the USA show that cardiovascular mortality has been lower in Hispanic men and women compared to non-Hispanic whites.[119] In findings from the National Health Interview Survey (NHIS) (1986–1994), Hispanics had ~20% lower all-cause, CHD and CVD mortality compared with whites in the United States. The Hispanic/white mortality ratio for CHD was 0.77 (95% CI 0.64–0.93) for men and 0.83 (95% CI 0.66–1.01) for women. The rate ratio for CVD (CHD and stroke) was 0.79 (95% CI 0.68–0.94) for men and 0.80 (95% CI 0.69–0.94) for women.[120]. However, given the lower all-cause mortality rate in Hispanics, the proportion of total deaths due to CHD or CVD was similar between the two populations for the same gender. For white men the proportion of deaths due to CHD was 29.7% and CVD for 44.7% compared to 28.1% and 43.2% among Hispanic men. Among white women, CHD accounted for 24.9% of deaths, CVD for 43.2% compared to 24.1% and 41% of deaths among Hispanic women.[120] The major weaknesses of vital statistics data to estimate mortality in Hispanics are misclassification (i.e. incorrectly assigning race to decendents) and underregistration. Most misclassified descendents are falsely reported as white Caucasians. Surveys of misclassification indicate that as many as 20% more deaths were Hispanic descendants than documented by death certificate. In contrast, the 1980 census undercounted Hispanics by as much as 8%. The aggregate effects of these errors are not known.

Cohort studies to date have found contradictory findings. The National Longitudinal Mortality Study followed up 700 000 respondents including 40 000 Hispanics from 1979 to 1987. Hispanics (≥25 years) had significantly lower CVD mortality than whites (standardized rate ratios: 0.65 for men, 0.80 for women).[121] However, in contrast the San Antonio Heart Disease Study of 1438 Mexican Americans and 921 non-Hispanic whites aged 45–64 years and followed for an average of 14.5 years found higher rates of CHD or CVD among Hispanics. The age- and gender-adjusted hazard ratio comparing Mexican Americans with non-Hispanic whites for all-cause mortality was 1.5 (95% CI 1.23–1.81), for CVD 1.70 (1.30–2.24) and for CHD 1.60 (1.09–2.36). After adjusting for all possible confounders including age, risk factors and socio-economic variables, the hazard ratios were all attenuated; for example, comparing Mexican Americans with non-Hispanic the hazard ratio for CHD mortality was 1.20 (95% CI 0.63–2.27).[122] The San Luis Valley Diabetes Cohort Study of 1862 Hispanics and non-Hispanic white participants found similar rates of CVD mortality in Hispanics and non-Hispanic whites.

The Corpus Christi Heart Project (CCHP), Texas, reported a greater incidence of MI in Mexican Americans compared to non-Hispanic whites over a 4-year period.[123] This population-based surveillance project conducted between 1988 and 1992 reported that age-adjusted incidence ratios comparing Mexican Americans to non-Hispanic whites were 1.52 (95% CI 1.28–1.80) and 1.25 (95% CI 1.10–1.42) among women and men respectively.[123] Although cross-sectional studies reveal a similar or lower prevalence of MI among Mexican Americans than non-Hispanic whites, the CCHP has reported a greater case-fatality rate following MI among Mexican Americans than non-Hispanic whites. Therefore a lower CHD prevalence in Mexican Americans does not necessarily reflect a lower incidence of CHD.

There are some data to suggest that all-cause mortality rates are higher amongst younger Hispanics. The Hispanic/white mortality ratios in the NHIS were 1.33, 0.92 and 0.76 among men aged 18–44, 45–64 and 65 and older respectively. Among women in the same age groups the Hispanic/white mortality ratios were 1.22, 0.75 and 0.70 respectively.[120] Hispanics under the age of 60 have a significantly elevated CbVD death rate compared to non-Hispanic whites (M 32 v 19, F 23 v 18 per 100 000 respectively). However, in older age categories the CbVD rate in Hispanics is substantially lower than whites (M 589 v 765, F 535 v 847 per 100 000).[23] Therefore, overall the CbVD death rate over 45 years of age in Hispanics is lower when compared to whites (M 115 v 147 and F 110 v 209 per 100 000).[23]

The data on CHD are conflicting but suggest that the burden of CHD is similar or greater compared to whites, and Hispanics have a higher case-fatality rate. For stroke it appears that Hispanics have lower incidence compared to whites.

Temporal trends

Although declines in CHD and CbVD mortality have occurred in Mexican Americans over the past 20 years, this decline has been less than that which has occurred among non-Hispanic whites.[23]

Common risk factors

Mexican Americans suffer a high prevalence of conventional CVRF such as smoking (42.5% in men and 23.8% in women), hypertension (17% men and 14% women), low HDL cholesterol (<0.90 mmol/L: 15.2% men and 5% women), elevated cholesterol (total cholesterol >6.2 mmol/L: 16.5% men and 16.5% women), diabetes (24%), physical inactivity (39%), and obesity (BMI >85th percentile: 30% men and 39% women). The San Antonio Heart Study reported that Mexican Americans had 2.5 times the prevalence of NIDDM compared to non-Hispanic whites as diagnosed by the oral glucose tolerance test.[122] They also observed that a socio-economic gradient within the

Hispanic population existed, with diabetes being more prevalent in the lower socio-economic groups.[124] Furthermore, Mexican Americans have higher blood concentrations of triglycerides and lower HDL cholesterol levels compared to non-Hispanic whites.[125]

Influential factors

A number of explanations have been put forward regarding the paradoxic findings of studies of Hispanic populations in the USA. The early studies which suggested that Hispanics have lower rates of CVD and CHD have been hypothesized to involve a "healthy migrant effect" – a diet that includes more fruits and vegetables, less chronic disease risk factor exposure before leaving their country of birth and health-preserving cultural psychosocial effects. It has also been suggested that some Hispanics may return to their country of birth when they retire or have a potentially fatal illness, especially those with a lower education, lower wages and fewer employment experiences. Selective out-migration would lead to underestimates of mortality, as would misclassification of deaths as discussed above. However, among long-settled Hispanics who adopt Western lifestyles, abdominal obesity and glucose intolerance appear to be the major factors for CHD among Mexican Americans.[119] Lower rates of smoking amongst older Mexican Americans compared with white Americans (11.9% v 15.4%)[126] and lower rates of smoking among Hispanic women compared with white women (12% v 28%) may contribute to lower rates of disease.[127] The greater mortality observed among Mexican Americans following MI in comparison to non-Hispanic whites is attributed in large part to the increased prevalence of diabetes. Findings from the San Antonio Heart Study also show that diabetic Mexican Americans not taking insulin treatment are at higher risk of fatal CVD compared with non-Hispanic white diabetics not using insulin.[122]

Latin America

While the above discussion has focused on Hispanics living in the USA, CVD is a major burden of disease in Latin America. In 2001, 28% of all deaths in Latin America were caused by CVD (GBD2001 http://www.dcp2.org/pubs/GBD/3/Table/3.B4). Latin America (LA) has also experienced major demographic, epidemiologic and nutritional transition in recent decades in an environment of increasing economic prosperity and urbanization. The Latin American region has exhibited a marked increase in the consumption of high-energy density foods (high in fats and sugars) and a decrease in physical activity, with rising trends of sedentary life among the urban population. The INTERHEART study recruited 1237 cases of AMI and 1888 controls from Argentina, Brazil, Colombia, Chile, Guatemala and Mexico. The most prevalent risk factor among controls was abdominal obesity; 48.6% of controls were in the highest tertile compared with 31.2% in other countries participating in INTERHEART. Latin Americans had higher rates of current and former smoking (48.1% v 42%), dyslipidemia (42.0% v 32.0%) and hypertension (29.1% v 20.8%). Fruit and vegetables consumption and physical activity were, however, similar to other countries. Abdominal obesity was the most important risk factor in Latin Americans with an average population attributable risk for the region of 48.5%, followed by abnormal ratio of Apo B/Apo A-1 (40.8%) and smoking (38.4%).[128]

There is some evidence that CHD mortality rates are going down in some sectors of Latin America following the trends in the USA and Canada. CHD mortality fell by ~60% in the US and Canada and also fell by a similar amount in Argentina, but increased for some Latin America countries such as Costa Rica, Mexico and Venezuela for the period 1970 to 2000. The decline versus increase in rates by country and region is likely reflective of their various degrees of socio-economic transition and access to screening and treatment programs. Some of the decline may also be due to falling rates of smoking. Brazil reported smoking rates falling between 1989 and 2003 from 34.8% to 22.4%.[129] The rates of stroke also appear to be declining in most Latin American countries by approximately 30% compared to ~60% in USA and Canada (Table 19.8). The impact of rising obesity and sedentary habits on these regions in the future is, however, uncertain.

Approaches to prevention/treatment

Due to the discrepant data concerning the CHD mortality rates of Mexican Americans, despite their adverse risk factor profile, many researchers believe that they remain "protected" from CHD.[130] Clearly, the burden of CHD among Mexican Americans is considerable, and screening and modification of conventional CHD risk factors are necessary. Furthermore, primary prevention of obesity will be important to reduce the burden of type 2 diabetes in this group.

Aboriginal populations

Aboriginal populations or indigenous people generally refer to an ethnic group who inhabit the geographic region with which they have the earliest historical connections. For example, in Canada, Aboriginal people are the descendants of the original inhabitants of North America. (Indian and Northern Affairs Canada: http://www.ainc-inac.gc.ca/pr/info/info125_e.html) and include Indians (now known as First Nations people), Métis and Inuit. The focus of this next section is on Aboriginal populations of North America, but other indigenous populations such as the Aboriginals from Australia share a similar cardiovascular risk profile.

Disease burden

Cardiovascular disease is the leading cause of death in North American Indian and Alaskan Native males and females. Although research in this ethnic group is limited, the Strong Heart Study,[131] which was initiated in 1988, studied 4549 American Natives aged 45–74 years from 13 tribes in the southern US. The prevalence estimates of definite MI in those aged 45–74 years was 2.8% in men without diabetes and 5.3% in men with diabetes, 0.4% in women without diabetes and 1.4% in women with diabetes. Data from the 2005 Behavioral Risk Factor Surveillance System (BRFSS) indicate that American Indian. Alaskan Natives

report the highest prevalence of CHD (myocardial infarction or angina) of 11.2% compared to non-Hispanic whites (6.2%), African Americans (6.2%), Hispanics (6.9) and Asians (4.7%).[132] Similarly data from Canada indicate that Aboriginal people suffer higher rates of CHD compared to the general population.[92] There is little published information concerning the epidemiology of stroke in native populations. In the USA the stroke mortality rate under the age of 65 years is similar in Native Americans and white Americans, and substantially lower than rates in African Americans.[133] Over the age of 65, the stroke rate in Native Americans is reported to be approximately 40% lower than whites.[133] In Canada, CVD is the leading cause of death among Aboriginal peoples.[134] Although the CHD mortality rates among Aboriginal and Canadian males are similar, the CHD mortality among Aboriginal women is 61% higher compared with Canadian women. In addition, the stroke mortality rate is 44% and 93% higher among Aboriginal men and women respectively, compared with the general Canadian population.[134] However, all of the above data are based on studies conducted more than 10 years ago. More recent data from a prevalence study in Canada indicate a 2.5-fold higher rate of CVD among Aboriginal peoples compared with Canadians of European origin.[135] As more Aboriginal people give up their traditional lifestyles and adopt "urban" lifestyles, the prevalence of CVD and its risk factors is increasing.

Common risk factors

The common CVRF among Aboriginal people include obesity, abdominal obesity, diabetes, elevated blood pressure, low HDL cholesterol, and tobacco use. The prevalence of cigarette smoking is generally high and increasing among Aboriginal people but varies greatly between Aboriginal communities.[135] The prevalence of diabetes in the Strong Heart Study was an astounding 48% in the 45–64 year age group compared to approximately 5.5% in the US general population, and the prevalence of obesity was between 26% and 41%, with an average BMI of 31 and waist–hip ratio of 0.96 in men.[136] Interestingly, the prevalence of hypertension and elevated serum cholesterol among Aboriginal people appears to be lower when compared to the general US population. In Canada, however, the prevalence of hypertension requiring drug treatment, and elevated cholesterol requiring medication, was significantly increased among Aboriginal people compared to a similar sample of non-Aboriginal people.[135] In addition, the prevalence of low HDL cholesterol is greater in this group, as approximately 25% of Aboriginal people have HDL cholesterol values less than 0.90 mmol/L.[135] Canadian Aboriginal people also have a higher prevalence of CVD, atherosclerosis, glucose abnormalities, obesity, abdominal obesity, and tobacco use compared to European-origin Canadians. [135]

Influential risk factors

Obesity, diabetes, and tobacco use among Aboriginal people are the most influential risk factors for future CHD. Aboriginal people who are diabetic are two to four times more likely to suffer CVD than non-diabetic people.[135] In the Strong Heart Study other important risk factors for CHD included hypertension, obesity, and low HDL cholesterol.[136]

Approaches to disease prevention

Control of obesity through increased physical activity and lowering of energy consumption will continue to be the mainstay of prevention amongst Aboriginal people. In addition, provision of strong disincentives to tobacco use are necessary to prevent smoking initiation amongst young Aboriginals. Also the imbalance in socio-economic circumstances between Aboriginal and non-Aboriginal peoples must be addressed, as lower socio-economic status is clearly associated with adverse lifestyle practices, psychosocial stress, and CVD.

Black people of African origin

Disease burden

Cardiovascular disease mortality data from countries in sub-Saharan Africa (SSA) are limited, as only 1.1% of all deaths are registered with a central agency.[12] Data from other sources such as sample registries and small-scale population studies in 1990 indicate that the CHD mortality was 41/100 000.[137] These rates are considerably lower than those of whites and South Asians who live in Africa, as well as rates of most Western countries, which are on average five times higher. Even so, in SSA, the proportional mortality rate from CHD accounts for 26% of all deaths, and in the 60–70 year age group it is responsible for over 80% of all deaths.[12,137] First MI also appears to occur at an earlier age among people from SSA. In the INTERHEART study the mean age of presentation of first MI in SSA participants was 54.3 years (3.8 years earlier than the overall INTERHEART study). Men (53.2 years) presented at a younger age than women (56.4 years). Furthermore, the case-fatality rate of CHD is higher in SSA compared to Western countries, meaning that once an individual develops CHD in SSA, the probability of death in SSA is higher than in Western countries. This probably reflects the limited access to acute and chronic treatment strategies. Absolute numbers of strokes are also relatively low in SSA countries such as Zimbabwe (31/100 000 in 1997) and South Africa (101/100 000 in 1986) compared to the UK Oxford Vascular Study (145/100 000 in 2004) and the US North of Manhattan Stroke Study (223/100 000).[138] In-hospital stroke case fatality is high at 33%, and higher in hemorrhagic stroke (58%) compared to ischemic stroke (22%).[138]

Risk factors

The prevalence of most conventional CVRF is lower among blacks compared to other groups within Africa and the world, with the exception of hypertension and smoking among urban blacks.[139,140] Data from the WHO Inter-Health Program (a substudy of the MONICA project) assessed the risk factor profile of men and women aged 35–64 years from Tanzania.[140] The prevalence of smoking was 37% among men and 4% among women, the mean BMI was 21 in men, and 22 in women, the mean BP was 126/79 mmHg among men compared to 125/79 mmHg in women, the mean serum cholesterol was 4.1 mmol/L in men, and 4.3 mmol/L in women. When compared to the risk factor profile of other developing and developed countries, Tanzania's was more favorable, with the exception of smoking among men. Furthermore, the prevalence of multiple CVRF was low, as 65% of the population had no identifiable risk factors, 30% had a single risk factor, and only 5% had at least two risk factors, compared to 50%, 40%, and 10% in the USA.[140] The INTERHEART study found that the risk of MI increased with higher income and education in the black African group in contrast to findings from other African ethnic groups. Contrasting gradients in socio-economic class suggest that groups are at different stages of epidemiologic transition.[141] Although CHD rates among people of African origin remain relatively low, the data are limited and given the increased migration of blacks to urban centers[142] and a subsequent rise in the number of conventional CVRF, the rates of CHD and stroke are expected to rise.

Approaches to disease prevention

Regional analysis of 578 cases and 785 controls from nine SSA countries (80% from South Africa) in the INTER-HEART study found that known CVRF accounted for approximately 90% of the MI observed in African populations, which was consistent with the overall INTERHEART study. However, a history of hypertension was associated with a higher MI risk in the black African group (OR 6.99, 95% CI 4.23–11.55) compared with the overall INTER-HEART group (OR 2.48, 95% CI 2.30–2.68).[141] Thus prevention strategies to reduce the consumption of saturated fats and salt and control tobacco use and blood pressure ar likely to be effective in these populations.

African Americans

African Americans comprise the largest non-white population in the USA and represent approximately 13% of the population.

Disease burden

Cardiovascular disease is the leading cause of death among African Americans, and the incidence of both CHD and stroke is higher in African Americans compared to white Americans. Mortality from both CHD and stroke has been noted to be higher in black compared to white Americans.[143,144] Sudden cardiac death rates have also been noted to be higher in black patients.[145] Although there has been a decline in mortality rates from CVD in both African Americans and white Americans over the past 30 years, these declines have been less marked in African Americans.[23]

Common risk factors

Compared to whites, African Americans develop high blood pressure at an earlier age, are more likely to develop hypertension over the life course, and appear to have a more severe type of hypertension.[146] The reason for black–white differences in hypertension prevalence likely involves a complex interaction between environmental response to diet and stress, and a potential genetic/physiologic difference such as differences in sodium/potassium excretion, perhaps linked to their origins in Africa. The prevalence of high cholesterol (>5.2 mmo/L) is similar or lower among African Americans compared with white Americans (47% v 54% in males, 51% v 53% in females)[23] and HDL cholesterol levels are generally higher. Smoking is more common among African American men (33% v 27%) compared with white men, but less common among African American women compared to white women.[23] Overweight and obesity are more common especially among African Americans women compared to white women (50% v 33%).[23] Physical activity is lower – 65% of African Americans report a sedentary lifestyle compared to about 56% of whites.[23] Diabetes rates are higher in African Americans compared to whites as demonstrated by NHANES II conducted from 1976 to 1980 in adults 20–74 years of age, which found that 9.9% of African Amercians versus 6% of white Americans had type 2 diabetes.[23] The rate of diabetes is also increasing faster among African Americans, especially in women.[23] Although elevated levels of Lp(a) are found more often in African Americans than whites, whether or not elevated Lp(a) levels are related to an increased CHD risk among African Americans is unclear.[147]

However, even after consideration of these "biomedical" differences, an important determinant of persisting CVD among African Americans is the persisting differences in socio-economic status which translate into poorer access to medical services, less screening for risk factors and lower rates of coronary revascularization procedures.[148]

Influential factors

While hypertension is an important difference between black and white American people, at least 30% of the excess CHD mortality in blacks compared to whites can be accounted for by differences in socio-economic status.[148] In addition to poorer access to care, black Americans have worse outcomes from treatments. Black American CABG

patients have significantly worse in-hospital mortality rates than other ethnic groups.[149]

Approaches to prevention/treatment

The rates of CHD among blacks in Africa are relatively low compared to the rates in most Western countries. However, in populations that have urbanized both within Africa and amongst migrant Africans to the West Indies and the USA, the rates of CVD are comparable to those of Western/European populations. As in other populations, conventional CVRF remain important but the dominant CVRF among people of African origin is hypertension and hence this needs to be specifically targeted for these populations. In the USA, the socio-economic disparity must be addressed to improve health outcomes for black groups. To ensure equal access to healthcare services overall changes in social policy are likely to be required at the national level.

Studies of multiple ethnic groups

Studies of diverse ethnic populations who reside in a single country and hence are exposed to a similar environment indicate that the pattern of CHD mortality in these groups initially resembles that of their home country. However, through the process of acculturation, prolonged exposure to new environmental factors results in similarities in CVRF and trends within multiethnic populations. However, comparative studies of ethnic groups within multiethnic countries (US and UK) suggest that certain ethnic groups are still relatively protected (e.g. Japanese, East Asians) and certain groups are more prone to CVD (e.g. black Africans, South Asians). This is likely due to a complex interaction of environment, sociocultural factors, behaviors and genetics.

Environmental contribution to ethnic and regional differences in cardiovascular disease

It is now apparent that most of the attributable risk for MI within populations from across the world can be ascribed to a limited number of risk factors.[20] What is less clear, however, is what shapes the distribution of risk factors between populations. There is now a growing body of evidence indicating that factors that describe our environment are likely to contribute to these differences.[15] These include: poor access to healthcare, a more toxic physical environment (e.g. less access to healthy food choices,[150] more fast food,[151] fewer opportunities for physical activity[152] more

exposure to air pollution), and less social support for those with disease.[153]

Genetic contribution to ethnic and regional differences in cardiovascular disease

Variation in risk factor levels across populations may also be genetically driven. Genetic factors have been shown to contribute to the development of certain risk factors. For example, many lipid abnormalities have genetic determinants and some have been shown to also predict clinical outcomes in patients with established CHD.[154] A number of possible mechanisms have been postulated, including that genetic variants could contribute to population differences in risk factors through:

* differences in allele frequency
* variation in gene expression
* epigenetic influences
* environmental interactions resulting in differences in gene expression.

Studies of different ethnic groups are ideally suited to understanding gene–environment interactions because they increase the range of allele frequencies and environmental exposures.[155]

Conclusion

Cardiovascular disease accounts for the largest percentage of deaths worldwide. To date, recognition and modification of the major CVRFs have led to declines in CVD rates in many OECD countries, although within many of these countries there remain high-risk groups as both ethnic and socio-economic disparities exist. Socio-economic development, urbanization, and increasing life expectancy have led to a progressive rise in CVD rates in developing countries such as India and China.

It is clear from the INTERHEART study that smoking, cholesterol and blood pressure are the major determinants of CVD globally, across all regions and across all ethnic groups. As populations urbanize, increasing levels of CVRF lead to an increasing burden of CVD for these populations. It seems that environment/social influences are implicated in these changing levels of CVRF. However, it is less clear what particular factors about our changing environment impact on population risk factors and how these interact with individual biologic and genetic factors. In the future a more detailed understanding of the interaction of environmental/social factors, human behaviors, individual risk factors and genetics will be needed to develop appropriate prevention strategies to decrease the global burden of cardiovascular disease.

20 Fetal origins of coronary artery disease

Katherine M Morrison, Stephanie Atkinson and Koon K Teo
McMaster University and Hamilton Health Sciences, Hamilton, Ontario, Canada

Introduction

Although cardiovascular (CV) disease presents most commonly in middle-aged adults, it takes many years for the morphologic changes of atherosclerosis to develop and become manifest as clinical CV disease.[1,2] Several lines of evidence implicate exposures in fetal life as important determinants of obesity, type 2 diabetes, other CV risk factors and early development of the atherogenic process leading to CV disease. Maternal adiposity, particularly central body fat, and metabolic status at conception, maternal nutritional deprivation and smoking, and exposure of the fetus to an environment of maternal hyperglycemia, hypercholesterolemia, and diabetes, as well as size of the infant at birth, may be key initiating factors for later risk of CV disease (Fig. 20.1). Emerging evidence supports the concept that metabolic programming changes invoked during fetal development may be modified by exposures at other developmental stages in infancy and early childhood.

This chapter will focus on an evaluation of the evidence linking fetal factors to early risk indicators of CV disease to improve insight into the origins of CV disease and to explore how the risk factors at early stages of development can be amenable to modification. This knowledge can lead to effective prevention strategies throughout the life course.

Atherosclerosis development in youth

The earliest morphologic atherosclerotic change, the fatty streak, has been identified in the fetus and is present in many children by three years of age.[1] Progression of this collection of lipid-laden macrophages to an intermediate state (raised fatty streak), and eventually to fibrous plaques, occurs in the aorta of many youth by the second decade of life.[2–4] This development has been linked to the presence of established risk factors (elevated glucose and blood pressure, excessive weight, dyslipidemia and cigarette smoking) during childhood and adolescence. The prevalence of these risk factors is rising in youth, in part because of the sharp worldwide increases in childhood obesity. In the Pathobiological Determinants of Atherosclerosis in Youth (PDAY) Study and in a similar study in Japan, glycohemoglobin (a marker of dysglycemia), dyslipidemia, cigarette smoking and obesity were related to the extent of atherosclerosis found on postmortem examinations.[2,5,6] In the Bogalusa longitudinal study of CV risk factors in youth, the extent of atherosclerosis was also related to blood pressure, and to the clustering of CV risk factors by the second decade of life.[7] In addition to the traditional CV risk factors, maternal hypercholesterolemia also influences the development of atherosclerosis in children, independent of the child's blood cholesterol. This suggests that fetal exposure to hypercholesterolemia can influence atherosclerosis development in the offspring.[8] The evidence presented in this chapter highlights the fetal influences on the development of these CV risk factors in youth.

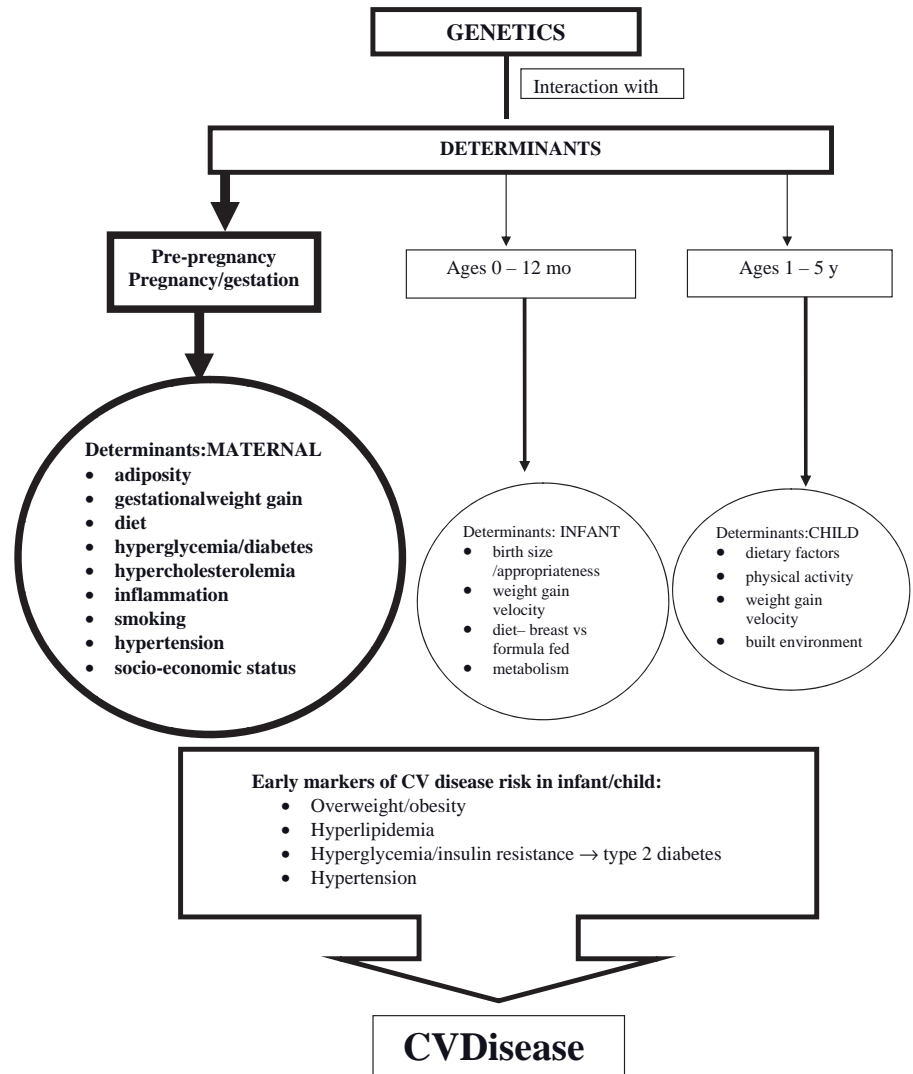
Non-invasive measures of vascular structure (carotid intima-media thickness or cIMT) and function (brachial flow-mediated dilation or FMD), employing ultrasound technology, are used in adults to delineate the extent of atherosclerosis[9–11] and predict future coronary artery disease risk.[12,13] In young adults followed since early life, childhood low-density lipoprotein (LDL) cholesterol level is an important determinant of cIMT, highlighting the importance of childhood risk factors in the development of adult CV disease. The potential of cIMT as a tool to non-invasively assess atherosclerosis in youth is supported by observations that cIMT is increased in adolescents with markedly elevated LDL cholesterol, and can be reduced by pharmacologic LDL cholesterol lowering in these subjects.[14] In addition, cIMT is also greater in adolescents with obesity


Figure 20.1 Determinants of risk of cardiovascular (CV) disease: focus on early life factors.

and type 1 diabetes.[15,16] cIMT and FMD have not yet been assessed in younger children in studying the effects of fetal influences, but may be potentially important tools. However, the clinical usefulness of cIMT is dependent on the resolution of the ultrasound equipment in imaging the thinner IMT in children and detection of excess thickness may not be reliable until after puberty.[17,18]

Fetal health and cardiovascular risk factors and disease: evidence from retrospective studies

The association between fetal health and adult CV disease was shown in early epidemiologic studies linking early childhood data (particularly birth weight) and adult mortality outcomes decades later. These studies provide the epidemiologic evidence that supports the hypothesis that fetal life is important in the development of atherosclerosis and CV disease in adulthood. For the most part, low birth weight was used as a surrogate marker of untoward fetal exposures, but as birth weight is linked to socioeconomic status (which may be reflected in maternal smoking, inadequate healthcare and suboptimal nutrition during pregnancy and which may also influence the child's health postnatally), the causal linkages between fetal health, birth outcome and later CV disease are difficult to clearly delineate.

Development of CV disease

The link between low birth weight and increased CV disease events in adults, first described in men in the United Kingdom,[19] has been reconfirmed in numerous studies,

including a study of 15 000 Swedish men and women[20] in which 97% of the cohort was tracked at follow-up. Of the 7000 men born in 1915–29 and followed to 1995, risk of CV disease death was highest in those with a birth weight in the lowest quartile compared to the second, third and fourth quartiles (odds ratio (OR), 95% confidence interval (CI): 0.85, 0.71–1.02; 0.67, 0.53–0.84; 0.72, 0.51–1.02, respectively), even when corrected for gestational age and socioeconomic status at birth and in adulthood. This relationship was not evident in women in this study. In another study of US women, low birth weight was associated with lower self-reported CV disease events.[21] While suggestive, a wide gap in knowledge and information exists between low weight at birth and the subsequent development of CV disease many years later. One problem with these studies is that since CVD presents in mid to late adulthood, assessment of CV disease outcomes requires very long-term follow-up. Adequate follow-up of these cohorts is difficult and uncertainties can arise as to the validity of these findings.

Non-invasive assessment of vascular structure using B-mode ultrasound measuring the cIMT has been useful in identifying markers of atherosclerosis[9–11] which serve as surrogates for clinical CV disease in adults.[12,13] In a follow-up study of 347 adults aged 49–51 years, multiple health determinants at birth and throughout childhood and traditional CV risk factors in adulthood have been assessed. Although birth weight was inversely related to cIMT, this relationship was no longer significant when adult lifestyle was considered. Early childhood events explained only a small proportion of the variance in cIMT (2.2% in men, 2.0% in women) compared to adult lifestyle (3.4% in men and 7.6% in women) and biologic risk factors in adulthood (9.5% in men and 4.9% in women).[22]

The causality of the relationship between birth weight and CV disease has also been difficult to establish, as many retrospective historic cohorts were unable to correct for confounding factors including maternal smoking, maternal health and socioeconomic status. Conditions such as preeclampsia that result in lower birth weight are themselves associated with CV disease development in the mother, suggesting that conditions that influence the health of both the mother and baby may also confound the relationship of low birth weight[23,24] to subsequent CV risk in the fetus. Furthermore, the relative importance of fetal growth restriction relative to other postnatal factors in CV disease development has not been established. Offspring of mothers exposed to extreme undernutrition in the first trimester of pregnancy as a result of food restriction during extreme social upheaval had increased risk of coronary artery disease.[25] Suggested potential mechanisms for the influence of reduced fetal growth on adult CV disease include reduced or modified growth and development of the kidneys, vascular smooth muscle, endothelium, heart, pancreas, liver or increased activity of the hypothalamus-pituitary-adrenal axis leading to the development of hypertension, dysglycemia and obesity.

Development of CV risk factors

The observation of a possible relationship between birth weight and risk of subsequent adult CV disease has led to investigations of the relationship between CV risk factors and fetal environmental health. Exposures during the prenatal period of development are also associated with the development of obesity, CV risk factors and dysglycemia in childhood. The accumulation of these risk factors may underlie the increased CV disease risk identified in epidemiologic studies of historic cohorts. Aspects of maternal health including maternal obesity, glycemic environment, nutrition, cigarette smoking and hypercholesterolemia have been related to CV risk factors in the offspring. Furthermore, as with the development of CV disease, fetal growth patterns are also associated with metabolic disturbances. Although not a direct measure of CV disease, long-term follow-up of traditional CV risk factors from childhood to young adulthood affords an opportunity to examine CV risk in established cohorts who are now young adults, and in contemporary pediatric cohorts.

Effect of early growth patterns

In adults, both high and low birth weight have been linked to risk markers for chronic disease from early childhood. Fetal growth restraint, followed by rapid postnatal weight gain and early obesity, is thought to prime the metabolic and endocrine milieu for premature pathology, leading to early onset of chronic diseases such as obesity, hypertension and CV disease. Population and clinical studies demonstrate associations between low birth weight and risk for hypertension,[26,27] dysglycemia, insulin resistance[28–31] and central obesity in adulthood. Extreme maternal undernutrition during pregnancy has been linked with an increased risk of obesity, hypertension and dysglycemia in the adult offspring of exposed families during the Dutch famine during the Second World War.[25,32,33] In contrast, in a recent report, exposure to the Dutch famine was not associated with clustering of CV risk factors or metabolic syndrome,[34] and the offspring of mothers exposed to undernutrition during the WWII Leningrad siege showed no such predilection for increased CV risk factor development.[35]

The relationship between birth weight and adult blood pressure has been explored in several systematic reviews[36–38] and despite more than 80 published studies addressing this issue, the conclusions remain controversial. Though an inverse relationship between birth weight and adult blood pressure has been frequently reported, the magnitude of effect is smaller in larger studies (–1.9 mmHg/kg birth weight for studies with <1000 subjects compared to –0.6 mmHg/kg for studies with >3000 subjects). The

discrepancy is in part related to the controversial practice of adjusting adult blood pressure for a factor along its causal pathway, adult body size, resulting in exaggerated findings.[39]

The relationship between birth weight and adult dysglycemia is more complex – described as J-shaped,[40] U-shaped[41] or inverse.[42] Thus, although highest risk is found in those with low and high birth weights in some studies, there is an inverse relation in others.[43] Interestingly, in the US Nurses' Study which initially reported a J-shaped relation, correction for adult BMI resulted in an inverse relationship, which was stronger in those with no family history of type 2 diabetes.[40] Type 2 diabetes results from both beta-cell dysfunction and insulin resistance, but the relative importance of these variables in individuals with low birth weight remains unclear. No consistent relationship between birth weight and insulin secretion has been identified[43] although it has been vigorously assessed in most studies. Animal studies suggest that nutritional compromise *in utero*, and low birth weight, may be associated with reduced pancreatic cell mass[44] but that reduced insulin sensitivity in muscle or adipocytes[45] may only be present concomitantly with accelerated postnatal growth.[46]

The influences of early programming on body composition in adulthood remain controversial. Low birth weight has been associated with central adiposity in some studies[47] but not others.[48] Most historic cohorts have relied on height, weight and body circumference measurements; few have assessed body fat directly. In several studies that have characterized body composition in adults with dual energy X-ray absorptiometry, a direct relationship between birth weight and lean mass was consistently shown, but inconsistent relationships to body fat were identified.[49]

Birth weight reflects the responses of the fetus to *in utero* conditions including maternal health, nutrition and placental function. Conditions that result in low birth weight, e.g. maternal smoking and pre-eclampsia, are associated with adiposity[50] and hypertension[51] respectively, in the adult offspring. Support for this comes from observations in animal studies of a relationship between low birth weight (due to nutrient restriction in the mother or restricted uteroplacental circulation) and increased adiposity and CV risk factor prevalence in the offspring.[52] It remains unclear, however, if the influence of cigarette smoking on adiposity and glucose homeostasis is a result of reduced growth or direct influence of the toxins in cigarette smoke. In an animal model, the offspring of animals exposed to nicotine during pregnancy showed evidence of impaired glucose tolerance[53] and loss of pancreatic beta-cell mass.[54] Critical windows of effect range from preimplantation to late pregnancy and proposed mechanisms include disturbances in the size and phenotype of organ systems, changes in biochemical thresholds for activity and changes in angiogenesis.[55]

Interestingly, patterns of accelerated fetal growth as seen in adolescent and adult offspring of mothers with diabetes or overweight are also associated with increased central adiposity, dysglycemia[56] and clustering of CV risk factors.[57]

Effect of glycemic status *in utero*

Maternal diabetes during pregnancy is consistently associated with greater adiposity and central deposition of body fat in the offspring.[28-30] Recently, impaired glucose tolerance (IGT) of pregnancy (often referred to as prediabetes) was also noted to increase risk of greater weight in the offspring.[58] Maternal diabetes also enhances the risk of dysglycemia in the offspring,[28-30,56] commencing as early as 1–4 years of age. This risk is enhanced in the offspring of mothers with diabetes during the pregnancy but not related to fathers with diabetes, suggesting that a glycemic environment during fetal life has a greater influence than genetic predisposition alone.[59] In the Pima Indian population who are at very high risk for the development of type 2 diabetes, prospective, longitudinal studies of offspring of mothers who eventually develop type 2 diabetes suggest a higher risk of dysglycemia if the mother developed type 2 diabetes prior to her pregnancy, i.e. if the offspring were exposed to a diabetic environment *in utero*.[60] Underscoring the importance of the glycemic environment is the finding that diabetes risk is greater in offspring of Pima mothers with a glycemic response to a glucose load in the upper "normal" range.[61] Although diagnostic cut-offs for dysglycemia are applied clinically, the glycemic response to a glucose load is a continuous relationship, which may have important implications in considering levels of risk. Outside the Pima population, the relationship of offspring health to maternal glycemic status in mothers without diabetes or prediabetes has not been reported.

In utero influence on cardiovascular risk factor development in childhood: evidence from contemporary prospective birth cohorts

In contrast to epidemiologic studies in historic cohorts which have provided important insights and generated hypotheses now being explored in studies, prospective assessment of the determinants for development of excess adiposity and CV risk factors allows consideration of potential confounding variables, and can reflect *in utero* effects in children reared in our current obesogenic environment. Fewer prospective studies are available as many are ongoing and the available data remain inconclusive. These contemporary birth cohorts exist or are being established in both developed (Australia, UK, Denmark, United States, Canada) and developing countries (India) (summarized in Table 20.1). Although adult CV disease cannot be

assessed directly in childhood in these studies, markers of future CV disease including excess adiposity, dyslipidemia, dysglycemia and hypertension can be measured in childhood. Thus, examining the impact of fetal exposures on these CV risk factors in contemporary, prospective cohorts will assist in clarifying both pre- and postnatal influences on CV disease development.

Influence on body composition

Fetal influences on body size, adiposity and body composition have been assessed in several ongoing, prospective cohorts (see Table 20.1). In these cohorts, multiple determinants of body size in early childhood have emerged.[62] Important elements of maternal health including maternal gestational weight gain, maternal obesity and maternal cigarette exposure have emerged as determinants of body size in several studies. Paternal obesity is recognized as an important determinant in one study.[62] Postnatal factors including rapid weight gain in infancy, early childhood growth patterns, nutritional intake, sedentary activity levels and sleep patterns have been identified as important determinants of body size. In the single study that has reported body composition, rather than just body size, birth weight was directly related to lean mass and to total fat mass, but was unrelated to the ratio of lean mass to fat mass, raising questions about the role of the fetal environment in excess adiposity.[63] Thus, although birth weight and, by inference, fetal nutrition may have an influence on lean mass accretion, with smaller babies having less lean mass, the influence on fat mass development is less clear.

Although maternal diabetes during pregnancy is associated with greater risk of overweight or obesity in most studies identified in a recent review[64] and in a modern retrospective cohort,[65] a number of studies prospectively examining the development of adiposity have not reported on maternal glycemic status. In fact, few prospective cohorts have considered many identified confounding variables in examining the fetal and early childhood determinants of increased adiposity (see Table 20.1).

Influence on glycemia status

The influence of birth weight on dysglycemia in children has been investigated in three prospective cohort studies (see Table 20.1). Most studies investigated the influence of fetal exposures on insulin resistance although insulin secretion was estimated in one study. In a population of children followed from birth in Pune, India, insulin resistance was highest in those in the lowest quartile for birth weight and the upper quartile for BMI at eight years of age.[66] In the ALSPAC study, insulin resistance at eight years of age (n = 800) was most closely related to BMI at that age, and birth weight was related to insulin resistance only in the

heaviest group.[67] Among infants studied in New Zealand, reduced insulin sensitivity was identified in children 4–10 years of age who were born prematurely (both small for gestational age and appropriate for gestational age) compared to term born controls.[68]

Maternal diabetes (type 1 and 2) during pregnancy has consistently been related to increased prevalence of prediabetes and diabetes in the offspring, suggesting a role of *in utero* glycemia and not genetic predisposition to type 2 diabetes as the most important etiologic factor.[56,69,70] However, this relationship remains underinvestigated in contemporary prospective birth cohort studies.

Influence on blood pressure

Although body size during childhood is an important determinant of hypertension in youth, fetal factors including maternal gestational weight gain and cigarette smoke exposure *in utero* have also been identified as determinants. In longitudinal studies, elevated systolic blood pressure associated with maternal smoking persists until at least six years of age.[71]

Influence on clustering of metabolic risk factors

Clustering of risk factors including body mass index, blood pressure, dyslipidemia and glycemic status in childhood has been associated with fetal influences in prospective studies, though it remains underinvestigated (see Table 20.1). In one study, maternal smoking and postinfancy weight gain were identified as the most important predictors of multiple CV risk factors, and breast feeding for longer than four months (OR 0.6, 95% CI 0.37–0.97) was protective. In that study, heavy newborns born to mothers who smoked during pregnancy had a 14-fold increased risk of clustering of the CV risk factors at eight years of age. Unfortunately, this study was unable to account for the influence of maternal glycemic status, a factor shown to increase clustering of CV risk factors at 11 years of age in a smaller study.[57] In the latter study, those born with high birth weights to mothers with diabetes had a 3.6-fold greater risk of clustering of CV risk factors, while heavier babies born to mothers without diabetes had risk levels similar to offspring with normal birth weights.

Review of ongoing contemporary cohorts has identified several important fetal influences on increased adiposity and CV risk factor development in the offspring. Maternal weight gain, obesity, cigarette smoking and diabetes all appear to negatively influence the future CV and metabolic health of the offspring. While these outcomes are preliminary and need confirmation in future studies, they are all potentially preventable fetal exposures, and as such offer hope of future prevention interventions directed at early life.

Table 20.1 Fetal and early childhood influences on CV risk factor development in children: key findings from contemporary cohorts

Cohort (country)	N	Outcome	Age	Maternal factors			Birth weight	Infancy factors		Childhood factors

'+ #', identified effect and OR where reported; '−', no significant effect; Conf, reported confounder; blank, variable not reported.

NOTES: Ong et al also reported significant effect of gestational weight gain; Dubois also reported effect of socioeconomic status; Boney et al reported OR of 3.6 for maternal diabetes + large for gestational age birth weight.

*Cluster of increased BMI, BP, serum triglyceride, serum glucose.

**BMI > 85th, increased BP, dyslipidemia, glucose intolerance.

~ U-shaped relation with birth weight – highest risk at lowest and highest birth weights.

Development of risk due to postnatal factors

The relative importance of prenatal versus postnatal growth on the development of CV disease and risk factors in adults has been controversial. The argument has been made that correction for adult weight has resulted in erroneous magnification of the influence of low birth weight on adult disease, and has minimized the potential role of postnatal factors. A systematic review of 21 studies confirmed the significant positive association between rapid infancy weight gain up to two years and obesity risk.[72] Further, as discussed above, numerous studies in youth suggest that low birth weight followed by accelerated growth in early life is closely related to the development of CV risk factors.[73] Many of the studies discussed conclude that postnatal growth is an important determinant of the development of CV risk factors, strongly suggesting that fetal effects are modulated in postnatal life. It is hypothesized that undernutrition *in utero* results in developmental changes in organ systems that are maladapted to an environment of plenty postnatally. For example, undernutrition *in utero* results in reduced pancreatic beta-cell number. In these offspring, in the face of increasing obesity postnatally, greater insulin requirements secondary to insulin resistance cannot be met, resulting in beta-cell failure and ultimately dysglycemia. Similar developmental changes in other organ systems including the renin-angiotensin system and liver are proposed to be maladapted to the current obesogenic environment.

Underlying mechanisms

As summarized in Figure 20.1, converging evidence from human and animal studies substantiate that a number of factors occurring before birth and in early childhood can profoundly alter subsequent CV disease risk. These factors interact with genetic predisposition. Interpretation of the relative influence of each of the fetal and early life factors on later CV disease risk must take into account adult health status and are modifiable by postnatal exposure to other factors.

While the mechanisms of programming in fetal life are not clear, the postulates center on the impact of the maternal nutritional and hormonal milieu on programming in the developing fetus and infant. Programming of organ growth (as discussed above) and of hypothalamic modification of appetite control, energy balance, altered metabolic rate and/or physical activity in the offspring[52,74] are emerging as important potential mechanisms. Several molecular mechanisms related to methylation status, sympathetic innervations and selective leptin resistance or program-

ming of the mitochondrial and related genome have been proposed as the underlying processes involved in developmental programming.

Implications for primary prevention of cardiovascular disease

Evidence to date suggests that fetal life and early childhood are periods of increased sensitivity to exposures that may result in the development of CV risk factors in childhood, and CV disease in adulthood. Prenatal exposures, especially to maternal metabolic disturbances including malnutrition, cigarette smoking, dysglycemia and hypercholesterolemia, increase the risk of ill health in the offspring. Accelerated growth postnatally modifies these exposures. Although our current obesogenic environment appears to adversely influence these prenatal exposures, postnatal modification also affords an opportunity for primordial prevention efforts if introduced in children at high risk as identified by their prenatal exposures. Continued efforts are required to define the exposures and clarify our understanding of potential modifiable determinants of ill health in the offspring. While we await sufficient human data to develop evidence-based practice guidelines for intervention in women and their offspring at increased CV risk, messages regarding the risks of maternal ill health on pregnancy outcome and future health of the offspring are emerging.[75,76] These developments may afford new opportunities for primary prevention of CVD, such as that initiated by the NIH.[77] Although we should start thinking about preventive strategies based on our current understanding, we must recognize that, in spite of the promise, we do not yet have interventions that are proven effective in influencing these very early determinants of CV disease development.

21 Genetics of coronary heart disease

Michael S Cunnington and Bernard D Keavney

Institute of Human Genetics, Newcastle University, Newcastle upon Tyne, UK

Evidence for genetic susceptibility to coronary heart disease

Coronary heart disease is a complex phenotype which arises from the interaction of a number of risk factors including smoking, hyperlipidemia, hypertension, obesity, and diabetes. Epidemiologic studies have consistently indicated the importance of a family history of coronary heart disease (CHD) as an independent risk factor for disease. Perhaps the most frequently cited study in this regard is the 1994 report from the Swedish Twin Study.[1] That report included 21 004 individuals, of whom 2810 had fatal CHD. Among male twin pairs in which the first twin had died of CHD before the age of 55, the relative risk of fatal CHD in the second twin was 8.1 (95% confidence interval (CI) 2.7–24.5) for monozygotic (i.e. genetically identical) twins and 3.8 (95% CI 1.4–10.5) for dizygotic twins. Among female twin pairs in which the first twin had died of CHD before the age of 65, the relative risk of fatal CHD in the second twin was 15.0 (95% CI 7.1–31.9) for monozygotic twins and 2.6 (95% CI 1.0–7.1) for dizygotic twins. These results clearly indicate a significant genetic contribution to the risk of CHD death. A 2002 analysis of the same cohort, which at that time included 4007 CHD deaths and a follow-up time of up to 36 years, used more sophisticated statistical modeling approaches to conclude that the heritability of fatal CHD events was 57% for males and 38% for females.[2] By contrast with the earlier report from this study, it was suggested that there was persistence of the excess genetic risk of CHD death even into old age. A similar analysis among 7955 Danish twin pairs including 2476 CHD deaths reported a heritability of fatal CHD events of 53% for males and 58% for females, which is broadly concordant with the Swedish data.[3] Studies in the offspring of the original

Framingham Heart Study participants have shown strong evidence for association of parental cardiovascular disease with the risk of offspring cardiovascular disease, and for sibling–sibling association of cardiovascular disease even after multivariable adjustment for other measured risk factors. In these studies, the relative risk associated with parental or sibling cardiovascular disease was between 1.45 and 2.0.[4,5]

The INTERHEART case–control study identified nine modifiable risk factors (smoking, dyslipidemia, hypertension, diabetes, abdominal obesity, psychosocial factors, daily consumption of fruit and vegetables, regular alcohol consumption, and regular physical activity) which together predicted a very substantial proportion of the risk of a first myocardial infarction (MI) in populations derived from every inhabited continent.[6] Family history was also assessed as a risk factor in that study. After adjustment for age, sex, smoking and region of recruitment, a positive family history conferred an odds ratio (OR) for MI of 1.55 (95% CI 1.44–1.67). After additional adjustment for all of the nine most significant factors, the risk was reduced to 1.45 (95% CI 1.31–1.60), remaining significant.

Some studies have examined the heritability of quantitative phenotypes related to atherosclerotic disease, such as carotid intima-media thickness and arterial calcification in various sites;[7–9] substantial heritabilities have been found for these phenotypes (30–60%). These findings further substantiate the assertion that genes play a significant role in susceptibility to atherosclerosis and its consequences.

Genetic architecture of coronary heart disease susceptibility

While it is clear that there is a substantial genetic component to CHD susceptibility, the architecture of that component – in terms of the number of effects and their sizes – remains uncertain. Population genetic theory would predict that the
Figure 21.1 Effect size and allele frequency in populations. Both population genetic theory and empiric evidence suggest that the frequency of an allele will be inversely related to the size of its biologic effect (curve). Three general classes of detectable variants (boxes) can be distinguished; different approaches are needed to detect members of the different classes. GWA, genome-wide association.

size of the effect of an allele on a phenotype should vary inversely with its frequency: that is, alleles that are common in the population should have small biologic effects, while large effects should be confined to rare alleles. With relatively few exceptions, this prediction has been found to hold true both in humans and in experimental animals. Figure 21.1 illustrates this concept. Most of the successes in CHD genetics before 2007 were confined to the upper left-hand portion of the curve shown in Figure 21.1, where studies in families with Mendelian (single-gene) forms of CHD had revealed large-displacement alleles which substantially affected the function of particular genes and which were sufficient alone to confer very markedly increased risks of CHD (for example, LDL-receptor mutations which cause familial hypercholesterolemia). However, because these alleles are rare, each one possibly existing in only a handful of families worldwide, their individual contribution to the population burden of disease is modest. Common alleles which had only small effects on disease risk (conferring odds ratios of 1.2–1.5) would contribute far more significantly to the impact of disease in the population. Conversely, however, such alleles would not be expected to have great predictive value for individual patients.

CHD is, in evolutionary terms, a very recent disease. Moreover, even at the peak of the CHD epidemic that is now waning in most Western countries, deaths from CHD tended to occur at ages older than the best estimates of the average life expectancy throughout human history.[10,11] Therefore CHD, in common with many other degenerative diseases of later life, has almost certainly been invisible to

natural selection throughout our evolutionary history, as it would not have affected our ancestors' reproductive fitness. This implies that common variants (which tend to be evolutionarily ancient) with effects on CHD could have arisen and persisted by chance alone, although the effects of such variants would be expected to be small. It is an attractive hypothesis that variants with beneficial effects on conditions of greater evolutionary impact (for example, infectious disease or the ability to survive trauma) could have been selected for in our evolutionary history but have now "outlived their usefulness" in the toxic environmental setting of caloric abundance and limited physical activity. However, this has yet to be convincingly demonstrated for any variant.

In the last year, studies which have characterized common variation throughout the human genome in large numbers of CHD cases and controls have considerably clarified our understanding of the situation with respect to the contribution of such common variation to disease risk. One locus has been convincingly replicated in multiple studies thus far (even in relatively small studies), and it seems likely that this is the principal susceptibility locus existing in the genome. It is, however, clear that there remains a substantial "heritability gap" – that is, the fraction of the heritability of CHD that is accounted for by the existing confirmed candidate genes (such as variants in the apolipoprotein E gene) and the newly discovered alleles is far below the total calculated heritability of the condition. Among the possible explanations are that the rest of the heritability is due to very small effects of common alleles

which lie beyond the resolution of even the largest association studies. Alternatively, the remaining heritability may be due to "low-frequency intermediate penetrance" variants, which would not have been captured by the existing genome-wide association studies but could nonetheless have significant effects on risk for those individuals who carry them. Some evidence in favor of the existence of such variants from systematic resequencing studies is described below; recent technologic innovations which have dramatically increased the speed and cost effectiveness of genome sequencing will enable systematic genome-wide evaluation of rare variants in the near future.

Mendelian disorders associated with coronary artery disease

A number of Mendelian disorders associated with premature CHD have been recognized, as summarized in Table 21.1. Such disorders explain only a very small proportion of CHD cases, but knowledge of them is important for a number of reasons. First, it allows the development of effective strategies for the detection, treatment and prevention of disease in affected individuals and families, which is particularly important as disease in these individuals often presents at a young age and follows an aggressive clinical course. Second, certain genes causing Mendelian forms of CHD have also been implicated in the risk of non-Mendelian CHD in the general population (see Table 21.1). Third, novel insights into the pathophysiologic mechanisms of disease gained through the study of Mendelian disorders may allow the identification of new biomarkers or targets for therapeutic intervention. Insights from investigations of familial hypercholesterolemia were important in the development of statins, and studies of apolipoprotein A-I (Apo A-I) deficiency have resulted in recent clinical trials of recombinant Apo A-I Milano for the treatment of CHD, as discussed below.

Familial hypercholesterolemia (FH) is the most common Mendelian disorder conferring CHD risk. It is an autosomal dominant condition caused by mutations in the low-density lipoprotein receptor (LDLR) gene, which disrupt the ability of the receptor to bind LDL at the cell membrane. Cellular uptake of LDL cholesterol is impaired, resulting in increased circulating levels of LDL cholesterol and stimulation of intracellular cholesterol synthesis.[12–15] Over 1000 mutations in the LDLR gene have been reported to be associated with the syndrome. Point mutations account for 91% of mutations (missenses, deletions, nonsenses, insertions and splice variants have all been described), and 9% are major rearrangements.[16] The heterozygote frequency of familial forms of hypercholesterolemia is around 1 in 500 in Western populations. The term familial hypercholesterolemia is usually used specifically for the syndrome associ-

ated with mutations in the LDLR gene, but similar phenotypes are associated with abnormalities of the APOB and PCSK9 genes. Detailed investigation of patients with "familial hypercholesterolemia" phenotypes demonstrated that 79.1% were due to LDLR mutations, with 5.5% due to APOB mutations, and 1.5% due to mutations in PCSK9.[17] Involvement of other genes may account for some of the remaining proportion.

FH heterozygotes have elevated circulating LDL cholesterol levels, typically in the range 190–465 mg/dL, and develop tendon xanthomas, corneal arcus and premature coronary artery disease often before the age of 50 years. Affected homozygotes are more severely affected, often with LDL cholesterol above 465 mg/dL, cutaneous xanthomas, and coronary disease which may present below the age of 30 years. Untreated, the risk of CHD in affected heterozygotes by age 60 years is approximately 50–85% for men and 30–55% for women.[18,19] The key elements of the clinical diagnostic criteria for FH are raised serum cholesterol, tendon xanthomas in the patient or a first-degree relative, and a dominant inheritance pattern of premature CHD or elevated cholesterol.[20] Opportunistic and cascade screening for relatives of affected individuals may be used in routine practice, as discussed below.

Apo A-I is the major protein constituent of high-density lipoprotein (HDL). Mutations in the APOA1 gene cause Apo A-I deficiency, which is an autosomal dominant disorder. Numerous mutations in the APOA1 gene have been reported, some of which lead to very low circulating HDL levels and increased risk of atherosclerosis.[21–23] However, a variant of Apo A-I (named Apo A-I Milano) identified in an Italian family in 1980 did not seem to be associated with increased CHD risk.[24] The pedigree carrying this mutation was traced to a village in northern Italy, revealing 33 heterozygous carriers of the mutation who had markedly reduced HDL (10–30 mg/dL), raised triglycerides but a lower, rather than higher, risk of atherosclerosis compared to the general population.[25,26] The Apo A-I Milano protein differs from native Apo A-I by the substitution of cysteine for arginine at position 173, which changes its properties and allows the formation of disulfide-linked homodimers and heterodimers with apoA-II.[27] Recombinant Apo A-I Milano complexed with a naturally occurring phospholipid has been manufactured to mimic the properties of nascent HDL, and studies in animal models of atherosclerosis showed that infusions of this complex rapidly reduced the lipid and macrophage content of atherosclerotic plaques.[28–31] A randomized double-blinded controlled trial of recombinant Apo A-I Milano therapy on coronary atherosclerosis in human subjects with acute coronary syndromes showed that intravenous infusion of the recombinant Apo A-I Milano complex at weekly intervals for five weeks significantly reduced coronary atheroma volume measured using intravascular ultrasound.[32] The

Table 21.1 Mendelian disorders involving coronary artery disease

Disorder	Inheritance	Affected genes	Consequences of gene mutation	Prevalence and clinical features
Familial hypercholesterolemia (OMIM# 143890)	Autosomal dominant	LDLR*	LDLR encodes the cell membrane LDL receptor. More than 1000 mutations have been reported in the LDLR gene, which disrupt the ability of the LDL receptor to bind and endocytose LDL.[16] This results in accumulation of LDL cholesterol in the circulation.	Heterozygote frequency 1/500. Heterozygotes have elevated circulating LDL levels, tendon xanthomas, corneal arcus, and premature CHD. Homozygotes more severely affected with higher LDL levels, cutaneous xanthomas, and CHD may present below the age of 30 years.
Familial defective Apo B (OMIM# 144010)	Autosomal dominant	APOB*	APOB encodes apolipoprotein B-100, which is the protein component of LDL. Apo B-100 is the major ligand for the LDL receptor and mediates binding of LDL to the receptor. 10 mutations reported in APOB, which reduce the binding affinity of Apo B-100 to the LDL receptor, resulting in impaired cellular uptake and processing of LDL.	Heterozygote frequency 1/1000. Elevated circulating LDL with phenotype very similar to FH, but slightly milder in some studies. Risk of premature CHD is lower than with FH, but remains substantially elevated.
Autosomal dominant hypercholesterolemia 3 (OMIM# 603776)	Autosomal dominant	PCSK9*	PCSK9 encodes proprotein convertase subtilisin/kexin type 9. The exact function of this glycoprotein is not well understood, but several gain-of-function mutations seem to be associated with a reduction in the number of LDL receptors at the cell surface.	Studied in several pedigrees. Phenotype similar to FH, but prevalence and variations in phenotype not yet well defined.
Autosomal recessive hypercholesterolemia (OMIM# 603813)	Autosomal recessive	ARH	ARH encodes LDL receptor adaptor protein 1 (LDLRRAP1). This interacts with the cytoplasmic domain of the LDL receptor and components of the clathrin endocytic machinery. Mutations lead to defective endocytosis of the LDL receptor.	Rare. Raised circulating LDL levels with phenotype similar to FH.
Apolipoprotein A-I (Apo A-I) deficiency (OMIM# 107680)	Autosomal dominant	APOA1*	APOA1 encodes Apo A-I, which is the major protein constituent of HDL. It mediates the interaction of HDL with cell surface receptors and other pathways. Mutations lead to very low circulating HDL levels.	Rare. Heterozygotes have low circulating HDL levels and some variants are associated with premature CHD risk[22,23] whilst others are not.[25] Homozygotes with certain mutations may have xanthomas or corneal opacities and early CHD.
Tangier disease (OMIM# 205400)	Autosomal recessive	ABCA1*	ABCA1 encodes ATP-binding cassette A1. This acts as a cholesterol efflux pump, involved in cellular cholesterol homeostasis and HDL formation. Mutations lead to lipid accumulation within cells, including macrophages, which produces characteristic clinical and histologic features.	Rare. Affected homozygotes usually have pathognomonic enlarged orange tonsils. HDL levels very low, with increased CHD risk. Other features include: hepatosplenomegaly, lymphadenopathy, thrombocytopenia, anemia, GI disturbance, neuropathy, corneal opacities. Heterozygotes have low HDL and increased CHD risk without the other clinical features.[117]

Table 21.1 *Continued*

Disorder	Inheritance	Affected genes	Consequences of gene mutation	Prevalence and clinical features
Homocystinuria (OMIM# 236200)	Autosomal recessive	Cystathionine beta-synthase	Cystathionine beta-synthase is an enzyme in the methionine metabolism pathway. It catalyzes conversion of homocysteine and serine to cystathionine. Multiple loss-of-function mutations have been reported, producing high circulating homocysteine levels. The mechanisms leading to CHD are incompletely defined.	Worldwide 1/300 000, in Ireland 1/65 000.[118] Affected homozygotes have "marfanoid" skeletal abnormalities, developmental delay/mental retardation, ectopia lentis, osteoporosis, and thromboembolism. Untreated, 50% risk of thromboembolic vascular events (including CHD) by age 30 years.[119]
Autosomal dominant coronary artery disease 2 (OMIM# 610947)	Autosomal dominant	LRP6	LRP6 encodes LDL receptor related protein 6, which is related to the LDLR gene and acts as a co-receptor in the Wnt signaling pathway. Missense mutation associated with reduced Wnt signaling, raised LDL, and premature CHD.	Single Iranian pedigree. Elevated LDL, premature CHD and metabolic syndrome described in homozygotes and heterozygotes.[120]
Autosomal dominant coronary artery disease 1 (OMIM# 608320)	Autosomal dominant	Uncertain ?MEF2A	Genome-wide linkage analysis in a family with an autosomal dominant pattern of premature CHD identified chromosome 15q26 as a possible susceptibility locus.[121] Sequencing revealed a 21bp deletion in the MEF2A gene at this locus in affected individuals in that family, but analysis in other populations demonstrated that the 21bp MEF2A deletion did not co-segregate with CHD, suggesting it is not causative.[122] Other MEF2A mutations do not appear to be a common cause of CHD in Caucasians. The gene and mechanism remain to be elucidated.	Reported in isolated pedigrees. Premature CHD and MI.
Sitosterolemia (OMIM# 210250)	Autosomal recessive	ABCG5 ABCG8	ABCG5/8 encode ATP-binding cassette G5/G8. These limit intestinal absorption, and promote biliary excretion, of non-cholesterol sterols. Inactivating mutations lead to high levels of plasma sterols.	Rare. Affected homozygotes have high plasma sterol levels, xanthomas, and premature CHD.

OMIM#, National Center for Biotechnology Information Online Mendelian Inheritance in Man identifier (www.ncbi.nlm.nih.gov/sites/entrez?db=OMIM). *, genes for which variants have been shown to contribute to lipid/cardiovascular phenotypes in the general population. FH, familial hypercholesterolemia.

mechanism is uncertain, but may relate to an increase in reverse cholesterol transport from atheromatous lesions to the serum with subsequent hepatic removal. These investigations suggest that recombinant Apo A-I Milano, or drugs mimicking the effect of the mutation on lipoprotein trafficking, could be useful for the stabilization, and possibly even regression, of atheromatous plaque in the wider population with CHD.

Family-based studies of non-Mendelian coronary heart disease: genome-wide linkage analysis

Family-based linkage studies, which had delivered the identity of over 2000 genes for Mendelian conditions by 2005, have also been performed in many complex

diseases, including CHD. In this approach, the inheritance of chromosomal segments is tracked through families which have multiple members affected with disease by typing markers spaced throughout the genome. Because the individuals involved in a family study are separated by few meioses, comparatively few markers are required to accurately identify the inheritance of each chromosomal segment genome-wide within a family (several hundred rather than the hundreds of thousands of markers required in genome-wide association studies). Segments that are shared more often than expected by chance among family members affected with disease can thus be identified; these segments may harbor genes which are involved in disease etiology. Most such studies in CHD were conceived in the early to mid 1990s, predating the vast expansion (by three orders of magnitude) in knowledge of genetic markers that made genome-wide association studies possible. Such studies were dogged by two intrinsic problems. First, although linkage is a very efficient approach to detect alleles of large effect (such as in the context of Mendelian disease), the power to detect alleles with small effects (odds ratios below about 2.0) is very low.[33] Second, even when a replicated linkage "hit" is obtained in a complex disease, the genomic region requiring investigation before a gene is identified remains very large, possibly containing hundreds of genes. As a result, there are relatively few examples where complex disease loci have been identified using this approach.

Several genome-wide linkage studies in CHD have been published,[34–40] but cross-study replication of identified loci has in general been lacking. Of these linkage studies, only one produced evidence in favor of a specific positional candidate gene, ALOX5AP, which encodes 5-lipoxygenase activating protein (FLAP).[38] FLAP is a necessary co-activator of the enzyme arachidonate 5-lipoxygenase (ALOX5) which synthesizes leukotriene A4 (LTA4), a short-lived mediator of inflammation. Variants in ALOX5AP were associated with a relative risk of MI of 1.8, and a relative risk of stroke of 1.67, in that study. These genetic findings have, however, not been consistently replicated in other studies, and the summary of the evidence to date suggests that the effect of the haplotypes studied, if it exists, is of a much smaller size than originally estimated.[41–46] Based on the initial genetic findings, a clinical trial was conducted to examine the effect of FLAP inhibition on levels of biomarkers associated with MI risk in 191 patients who had already suffered an MI and carried at-risk variants in FLAP.[47] The FLAP inhibitor led to suppression of plasma levels of leukotriene B4, myeloperoxidase, and C-reactive protein without any adverse events. This result suggests that clinical trials of agents inhibiting FLAP that are powered to detect differences in CHD endpoints would be of interest.

Single nucleotide polymorphisms and the human haplotype map

In the last 18 months genome-wide association (GWA) studies have delivered over a hundred new loci for upwards of 40 common diseases and continuous traits with a "complex" (that is, made up of multiple genetic effects) genetic architecture. The majority of such studies have been conducted in large numbers of unrelated cases of disease and controls, and at its simplest, the analysis consists of comparing the frequency of genotypes at a large number of genetic polymorphisms spaced throughout the human genome one by one in the cases and controls. The polymorphisms used in these analyses consist of single base alternatives in the genetic sequence, called single nucleotide polymorphisms (SNPs, usually pronounced "snips"). The large-scale sequencing studies conducted to complete the Human Genome Project established that SNPs were the most common type of human genetic variant, and that SNPs with a minor allele frequency of greater than 1% occurred on average every 300 bases throughout the human genome.

Consider an autosomal SNP which has as alternative alleles the nucleotides thymine (T) or adenine (A). A diploid individual has three possible genotypes: thymine/thymine (T/T), thymine/adenine (T/A) or adenine/adenine (A/A). If the frequency of these two alleles in the population were 80% T alleles and 20% A alleles, then the three genotype frequencies would be expected to be around 64%, 32%, and 4% respectively (since the frequency of each homozygote genotype would be expected to be the square of the frequency of the corresponding allele, and the heterozygote frequency twice the product of the two allele frequencies). Such a SNP would qualify as a "common variant" – though the cut-off is somewhat arbitrary, SNPs with minor allele frequencies greater than 5% are generally considered to be common. Common SNPs tend to be evolutionarily ancient, because rare variants have a much higher likelihood of being eliminated over time by the random selection of gametes that occurs from generation to generation. Alleles conferring susceptibility to common degenerative diseases of later life such as CHD may have persisted throughout evolution because they do not commonly affect fitness in the reproductive years and are therefore invisible to natural selection. Thus, genetic susceptibility to common disease might arise from a relatively small number of common variants in a particular susceptibility gene, as opposed to a large number of individually rare variants. This theory is known as the "common disease–common variant hypothesis". It is the main theoretical argument in favor of studying common SNPs for association with disease. From a practical point of view, rare SNPs with small effects on disease would be essentially impossible to detect in studies

of a feasible size (see Fig. 21.1), and the technology to systematically investigate genes for rare SNPs, even of large effect, has until very recently been far behind that available for the investigation of common SNPs. Recent GWA studies of many diseases have convincingly shown that the common disease–common variant hypothesis is to an extent true, although even for diseases such as type 2 diabetes, in which a large number of susceptibility variants have been found, these together do not explain the bulk of the inherited propensity to disease.

A systematic discovery program for SNPs was implemented by the SNP Consortium, a public–private partnership formed in 1999. The consortium released 1.4 million SNPs into the public domain by 2001, and there are presently more than 7 million validated SNPs in public databases. This constitutes a fairly complete picture of human common SNP variation. However, simple knowledge of the SNPs did not make the task of assessing variation across the genome possible, since no platform exists that could type 7 million SNPs in each of a large number of cases and controls in a cost-effective manner. It was therefore necessary to additionally determine the relationships between the SNPs that had been discovered, in order to establish which SNPs gave redundant or substantially overlapping information about genetic variation in different regions of the genome, and establish a minimal set of SNPs that could be feasibly typed in case–control studies while retaining relatively full information. Such data were provided by the collaborative International Haplotype Map (HapMap) Project, which aimed to obtain detailed genome-wide information on patterns of common genetic variation in multiple world populations, suitable for association studies (www.hapmap.org).

Chromosomes in the present-day population are essentially mosaics which reflect the results of new mutations and genetic recombination on ancestral haplotypes (Fig. 21.2). When a SNP arises on a chromosome (since the per-base mutation rate at SNPs is low, most SNPs are thought to have arisen only once during evolution), initially the alleles present at all the surrounding pre-existing SNPs are strong predictors of genotype at the new SNP. As meiotic recombination occurs throughout the generations, the initially lengthy chromosomal segment containing strongly predictive genotypes will break down. Note that although in general terms more closely neighboring SNPs will be better predictors of each other's genotypes, the relationships cannot simply be derived mathematically; they must be empirically observed for each pair of SNPs of interest. The degree to which genotype at one SNP predicts genotype at a neighboring SNP is called "linkage disequilibrium", abbreviated "LD". For the purposes of association mapping it is most usefully measured by the correlation coefficient r^2 which varies between 0 in the case of two SNPs whose genotypes have no predictive value for each other, and 1 in the case of two SNPs that are perfect proxies
Figure 21.2 Decay of allelic association over time: chromosomes are mosaics. Consider a new disease susceptibility allele D arising on an ancestral chromosome (bar). In that generation, all the markers in the region including markers M1 and M2 will be correlated with D. Genetic recombination will break down the region of association over time, introducing new haplotypes into the region. If the mosaic is "coarse" (which is the case with the human genome) fewer markers are needed to tag each piece (or "haplotype block") of the mosaic: thus, M1 and M2 are both still good markers for D when the mosaic is coarse, but only M2 is a good marker after further time has elapsed and the mosaic is finer.

for each other (and therefore one of them is entirely redundant for association study purposes). r^2 is a useful measure because the power of an association study where the disease-causing variant is not directly observed varies inversely with r^2. Thus, if a study of 2000 cases and controls were required to have adequate power to detect an odds ratio of a particular size should the causative variant be directly typed, a study of 4000 would be required if the most closely correlated SNP that was typed had an r^2 of 0.5 with the untyped causative SNP.

The "grain" of the human genomic mosaic was a key factor in determining the feasibility of GWA studies (Fig. 21.2). If it had been very "fine", it might have been necessary to type most of the 10 million common SNPs to represent them all satisfactorily, and if relatively "coarse", typing of only a few hundred thousand SNPs might be sufficient. Some early studies[48] provided encouraging information that at the level of single genes, the mosaic was indeed quite coarse; subsequent studies in large genomic segments confirmed that this was more generally true,[49] and showed that the mean size of regions of strongly associated SNPs (also known as "haplotype blocks") is around 22 kb in populations of European or Asian ancestry, and 11 kb in populations of African ancestry.[50] These findings, among others, suggested that a substantial proportion of common variation genome-wide could indeed be characterized with several hundred thousand SNPs that were sufficiently well correlated with all the remaining untyped

SNPs that they could be considered to "tag" the untyped SNPs. In 2005 the Phase I HapMap reported data from around 1 million SNPs; in 2007, the Phase II HapMap containing data on 3 million SNPs covering most common variations in most of the human genome was made available.[51–53] This provided the necessary information to design experiments in which common variation either within candidate genes or genome-wide could be thoroughly assessed using a subset of "tag" SNPs. An excellent recent review provides more detailed information on the achievements of the HapMap.[54]

The key technologic advance required for the success of genome-wide association studies has been the development of "gene chips" able to assay up to 1 million SNPs chosen on the basis of the genomic knowledge from the HapMap. Currently such chips are available for less than 750 US dollars per sample, and the price is constantly falling even as the genomic coverage improves, in a situation analogous to that for computer microprocessors in recent years. The current "top of the range" products from the major manufacturers Illumina and Affymetrix tag 80–90% of genome-wide SNPs in non-African origin population at an r^2 of 0.8 or greater, although only around 66% of genome-wide SNPs are tagged at r^2 of 0.8 or greater in African origin populations in whom there is greater haplotype diversity.

Finally, large samples of well-characterized cases and controls have been required to render both reliable candidate–gene association studies and GWA studies feasible. Early work on CHD genetics in the 1990s clearly showed the potential for false-positive results in small samples; at that stage the problem was one of overoptimism, as investigators hoped to discover genetic effects much larger than those that (with the benefit of hindsight) appear to be present. In the initial stage of a GWA study, where up to 1 million SNPs may be typed, around 50 000 SNPs would be expected to show statistical significance at the $P < 0.05$ level, most of these purely by chance. To avoid these false positives, extremely stringent levels of significance must be adopted (typically 5×10^{-7} or thereabouts). In order to obtain this level of significance for a SNP with a minor allele frequency of around 0.1, that confers an odds ratio of disease of about 1.3, 2000 cases and a similar number of controls are required. Within-study replication of associated SNPs in additional cohorts is considered an additional requirement to rule out the play of chance as a cause for the initial finding.

Candidate–gene association studies in coronary heart disease

In common with many other diseases, CHD has been the subject of large numbers of candidate–gene association studies that have examined many different genes. Nearly 1000 such published studies are currently in the Genetic Association Database, an archive of association studies in human complex diseases (http://geneticassociationdb.nih. gov). Conclusive identification of associated variants has been very rarely achieved. Several factors are likely to contribute to this. The prior probability of association of any particular SNP in any one of 20 000 genes with a given disease is vanishingly small. Relevant pathophysiologic information that has led to the selection of a gene as a candidate (for example, its involvement in determining plasma levels of cholesterol) may increase the prior probability, but even so, it is certain that in this context $P < 0.05$, the conventionally accepted significance level for result reporting, does not represent secure evidence in favor of the involvement of that gene. Thus, most genetic associations initially reported with significance levels $0.01 < P < 0.05$ can reasonably be expected to be false. The majority of reported studies to date have been of insufficient size to robustly identify (i.e. with appropriately small P-values) the effects of small magnitude that would usually be expected for common SNPs. In a 2007 paper, Morgan and colleagues highlighted the replication problems in the field by typing 85 variants in 70 genes previously claimed to be associated with the risk of acute coronary syndrome, finding just one borderline significant ($P = 0.03$) association that was most likely due to the play of chance.[43] Although meta-analyses may, as in traditional epidemiology, assist in identifying true associations, a number of meta-analyses of genetic association studies have shown evidence for publication bias – the preferential reporting in the literature of small positive studies, whereas equally sized negative studies go unreported. This greatly complicates the interpretation of quantitative overviews of the published literature; statistical tests for publication bias are relatively insensitive, and the regular detection of publication bias in the field tends to undermine confidence that it is not present for a particular association even in the absence of statistical evidence. Results of several large-scale (that is, involving greater than 5000 cases of disease) meta-analyses are shown in Table 21.2. Of these, the most convincing evidence in favor of association is with the Apo E epsilon-2/epsilon-3/epsilon-4 isoform polymorphism. Apolipoprotein E is a ligand for receptors that clear remnants of chylomicrons and very low density lipoproteins; the three isoforms bind with different affinities and are associated with differences in levels of LDL-cholesterol. The recent GWA studies (see below) have not provided a great deal of additional evidence pertinent to this association because the two polymorphisms (Cys112Arg and Arg158Cys) that together define the isoform are not well "tagged" by the SNPs present on the genotyping chips used in studies to date.

Table 21.2 Candidate gene polymorphisms associated with CHD in large-scale meta-analyses (>5000 CHDcases)

Gene	Variant (rs number) and risk allele	Number of studies included	Number of CHD cases/controls	Relative risk (95% CI)	References
Cholesteryl ester transfer protein (CETP)	TaqIB (rs708272) –A allele	38	19035/32368	0.95 (0.92–0.99) per allele	123
	I405V (rs5882) –G allele	18	10313/32244	0.94 (0.89–1.00) per allele	123
	–629C>A (rs1800775) –A allele	17	11599/23185	0.95 (0.91–1.00) per allele	123
Apolipoprotein E (APOE)	ε2 isoform carrier	17	21331/47467	0.80 (0.70–0.90)	124
	ε4 isoform carrier	17	21331/47467	1.06 (0.99–1.13)	124
	ε4/ε4 homozygote	17	21331/47467	1.22 (1.08–1.38)	124
Angiotensin type 1 receptor (AGTR1)	+1166A/C (rs5186) –C allele	27	10180/17129	1.13 (1.04–1.23) per allele	125
Factor V	G1691A (rs6025) –A [Factor V Leiden]	60	15704/26686	1.17 (1.08–1.28) per allele	126
Prothrombin (factor II)	G20210A –A allele	40	11625/14462	1.31 (1.12–1.52) per allele	126
Plasminogen activator inhibitor (PAI-1)	[–675]4G/5G –4G allele	37	11763/13905	1.06 (1.02–1.10) per allele	126
Paraoxonase (PON1)	Q192R (rs662) –R allele	43	10106/11786	1.12 (1.07–1.16) per allele	127
Endothelial nitric oxide synthase (eNOS)	Glu298Asp –Asp/Asp homozygote	14	6036/6106	1.31 (1.13–1.51)	128
	Intron-4a –a/a homozygote	16	6212/6737	1.34 (1.03–1.75)	128
Apolipoprotein B (APOB)	SpIns/Del –DD homozygote	22	6007/5609	1.19 (1.05–1.35)	129
Methylene tetrahydrofolate reductase (MTHFR)	677C>T (rs1801133) –TT homozygote	40	11162/12758	1.16 (1.05–1.28)	130

Identification of lymphotoxin-alpha and galectin 2 by association study of 93 000 single nucleotide polymorphisms

The first report from an association study of CHD that typed many thousands of SNPs (although providing insufficient coverage to be classified as a true genome-wide association study) was published in 2002. Ozaki and colleagues examined almost 93 000 gene-based SNPs (mainly in exons, introns and flanking regions surrounding genes) in 14 000 genes, in 94 cases of MI and 658 controls.[55] Those SNPs showing a P-value for association of <0.01 were genotyped in a larger panel consisting of a total of 1133 cases with MI and 1006 controls. A susceptibility locus on chromosome 6p21 was identified, with maximal association found between MI and a five-SNP haplotype in the lymphotoxin-alpha (LTA) gene, which encodes a member of the tumor necrosis factor ligand family. Ozaki and colleagues then used molecular biologic techniques to identify novel proteins interacting with LTA, among which were galectin 2 (LGALS2), a sugar-binding lectin molecule of unknown function.[56] They identified SNPs in LGALS2 and tested them for association with CHD in a study of 2302 MI cases and 2038 controls. They found an odds ratio of 1.23 (95% CI 1.13–1.35; $Pp = 4.5 \times 10^{-6}$) for MI associated with genotype at a SNP in intron 1 (C3279T). The rare T allele appeared protective, and it was associated with a

halving of the transcriptional activity of the gene compared to the common allele. These studies identifying LTA and LGALS2 were large, rigorously conducted and included highly plausible functional data. It is therefore somewhat perplexing that the promising early results have not been successfully replicated in most other large studies.[44,57–63]

Genome-wide association studies of coronary heart disease endpoints

Four genome-wide association studies of CHD reported in 2007 demonstrated conclusive evidence for association between common SNPs in the same ~100 kb region on chromosome 9p21 and CHD risk.[64–67] Results of these studies are summarized in Table 21.3. The Wellcome Trust Case–Control Consortium (WTCCC) study examined around 400 000 SNPs in 1988 British Caucasians with a validated history of MI or coronary revascularization before the age of 66 years, and 3004 controls.[66] Associations were seen for SNPs across >100 kb in the 9p21 region, with the strongest association demonstrated for rs1333049 ($P = 1.8 \times 10^{-14}$). For this SNP the heterozygote odds ratio was 1.47 (95% CI 1.27–1.70) and the homozygote odds ratio was 1.90 (95% CI 1.61–2.24). 'Moderate' associations, defined as SNPs with a P-value greater than 5×10^{-7} but less than 1×10^{-5}, were reported for six other loci. Replication of the chromosome 9 locus was achieved in a subsequent paper which added

Table 21.3 Susceptibility loci identified in genome-wide association studies of CHD that have been successfully replicated in a separate cohort

| Study | Phenotype | Total patients/ controls | SNPs on array | Locus/SNP.risk allele | Allele frequency | | Relative risk (95% CI) heterozygote/ homozygote | P-value |
					Controls	Cases		
WTCCC[66] and Samani[67]	CHD/MI	2863/4648	500 000	9p21/rs1333049/C	0.47	0.55	1.36 (1.27–1.46) per copy of risk allele	2.9×10^{-19}
				6q25.1/rs6922269/A	0.25	0.29	1.23 (1.15–1.33) per copy of risk allele	2.9×10^{-8}
				2q36.1/rs2943634/C	0.34	0.30	1.21 (1.13–1.30) per copy of risk allele	1.6×10^{-7}
Helgadottir[65]	MI/CHD	4587/12 767	305 000	9p21/rs2383207/G	0.492	0.548	1.25 (1.18–1.31) per copy of risk allele	2.0×10^{-16}
				9p21/rs10757278/G	0.453	0.517	1.28 (1.22–1.35) per copy of risk allele	1.2×10^{-20}
McPherson[64]	CHD	4306/20 119	100 000	9p21/rs10757274/G	0.487*	0.525*	1.18 (1.02–1.37)/1.29 (1.09–1.52)*	4×10^{-3}*

*Data from ARIC cohort only.

data from a cohort comprising 875 German Caucasians with MI before the age of 60 years and at least one family member with premature CHD, and 1644 controls, which had been genotyped using the same chip.[67] As shown in Table 21.3, two loci on chromosome 6 and chromosome 2 were also replicated in the German cohort. The combined analysis identified four additional loci potentially associated with CHD, one of which (chromosome 1p13.3) has subsequently been shown to be strongly associated with plasma LDL cholesterol. An analysis of 55 candidate genes previously reported to show association with CHD only confirmed association for two SNPs tagging a variant in the lipoprotein lipase gene in these cohorts.

Helgadottir and colleagues performed a similar study in 1607 Icelandic patients with MI (before age 70 years in males and 75 years in females) and 6728 controls, typed for around 300 000 genome-wide SNPs using the Illumina Hap300 chip.[65] The strongest association was found for three correlated SNPs in the same chromosome 9p21 region that was identified in the WTCCC study, each with P-values of approximately 1×10^{-6}. The association was replicated in four additional case–control cohorts. Combining data from all groups, allele G of the SNP rs10757278 showed the strongest association with MI, with an odds ratio of 1.28 (95% CI 1.22–1.35, $P = 1.2 \times 10^{-20}$) per allele.

In the third GWA study, McPherson and colleagues typed 100 000 SNPs in 322 cases of premature CHD and 312 controls, confirming positive results in a further 1658 cases and 9380 controls.[64] Two SNPs located within 20 kb of each other in the same region of chromosome 9p21 were signifi-

cantly associated with CHD. These two SNPs were validated in three additional independent cohorts (with varying inclusion parameters for defining CHD).

The chromosome 9p21 locus has thus shown a remarkably consistent association with CHD in GWA studies involving multiple Caucasian populations (Fig. 21.3). Subsequent reports have replicated the association in Japanese and Korean populations,[68] and in multiple additional Caucasian case–control series, confirmed by meta-analysis.[69–71] Fine mapping and detailed characterization of the locus were performed in a large case–control study of 4251 CHD cases and 4443 controls from four European populations by Broadbent and colleagues.[69] Analysis of 62 SNPs in the region identified a region of strong LD containing 14 SNPs that form four common haplotypes (cumulative frequency 89%), with the association of the linked SNPs at this locus a consequence of a perfect "yin–yang" pair of haplotypes spanning 53 kb.

At the time of writing, this field is rapidly evolving. As of February 2009, a number of subsequent GWA studies have provided strong evidence for several further loci, all of which have smaller effects than the chromosome 9p21 locus.[72–75]

The chromosome 9p21 region: mechanistic clues and candidate genes

The mechanism for the 9p21 association with CHD remains unclear at present; relationships between risk genotypes and other phenotypes have been explored to search for
Figure 21.3 Position of the CHD risk SNPs/haplotypes and nearby genes at the chromosome 9p21 locus. Arrows denote genes or transcripts in the region, with the arrowhead pointing in the direction of transcription. Numbers designate base pairs along chromosome 9. The positions of lead SNPs/haplotypes associated with cardiovascular disease and diabetes at the chromosome 9p21 locus in GWA studies are represented by the bars in the top half of the figure. Figure adapted from www.hapmap.org.

mechanistic clues. Subgroup analyses in case–control studies have not demonstrated significant heterogeneity in the risk associated with genotype between patients who had presented with or without MI, suggesting that the genetic effect is not on plaque rupture but rather on atherosclerosis susceptibility. Nor has heterogeneity been demonstrated with regard to sex, age, and traditional risk factor status. Furthermore, no association between genotype and known risk factors for atherosclerosis has been demonstrated, suggesting the mechanism of the association is independent of any of these factors.[65,67,69,76]

GWA studies for type 2 diabetes mellitus published around the same time showed an association between diabetes and a chromosome 9p21 locus in some populations,[77–79] although this was not reported in other groups.[80,81] Diabetes is a major risk factor for CHD, associated with features such as vascular endothelial dysfunction and hyperlipidemia that are also important in atherogenesis, raising the prospect of a shared pathophysiologic mechanism for the two diseases. However, the most strongly associated SNP for type 2 diabetes in the region (rs10811661) lies beyond the linkage disequilibrium block that is strongly associated with CHD risk (see Fig. 22.3) and does not show association with CHD.[69,82] A second SNP (rs564398), associated with diabetes in a meta-analysis of 14 586 cases,[79] which is not correlated with rs10811661, lies within the CHD-associated region described in the WTCCC study,

and shows moderate correlation ($0.28 < r^2 < 0.42$) with CHD-associated SNPs (see Fig. 21.3). rs564398 showed association with CHD in the study by Broadbent *et al* ($P = 4 \times 10^{-8}$), but once a marker of the CHD risk haplotype was included in the statistical model, this became non-significant ($P = 0.08$).[69] There is therefore no evidence for an effect of rs564398 on CHD risk independent of its association with the risk haplotype at the present time. However, insufficient numbers of people with and without CHD that are concordant and discordant for diabetes have been studied so far to enable a possible effect of rs564398 on both diabetes and CHD to be entirely ruled out.

A CHD risk SNP (rs10757278) from the chromosome 9p21 region has also been found to be significantly associated with abdominal aortic aneurysm (OR 1.31, $P = 1.2 \times 10^{-12}$) and intracranial aneurysm (OR 1.29, $P = 2.5 \times 10^{-6}$), although after excluding potentially confounding cases of known CHD, it was not significantly associated with peripheral arterial disease, ischemic stroke or diabetes in a study involving patients with multiple cardiovascular phenotypes.[82] This report showed that the effect of 9p21 variants on arterial disease is not solely confined to atherosclerotic conditions. Intracranial aneurysms typically present at a younger age than CHD, are commoner in females, and have non-atherosclerotic pathology. The identification of an association between the same variants and two different pathologic types of arterial disease

suggests that the risk locus may be having its effect via a defect in the arterial ability to remodel in response to different types of stress, though this remains a conjecture at present. With respect to 9p21 variants and intermediate phenotypes related to coronary and cerebral atherosclerosis, two separate reports also found no association between CHD risk variants and carotid artery intima-media thickness, a marker of carotid vascular disease that is associated with both MI and stroke risk.[76,83]

A number of candidate genes potentially influencing the risk of CHD lie adjacent to the associated region (see Fig. 21.3). Functional studies to establish the influence of risk-associated SNPs on the transcription and activity of genes in the immediate region may enable one gene to be selected as the strongest candidate. The cell cycle checkpoint kinase genes CDKN2A and CDKN2B lie some 50 kb from the SNPs most associated with CHD (see Fig. 21.3). These tumor suppressor genes are involved in regulation of the cell cycle, aging, senescence and apoptosis, which are important factors in atherogenesis.[84,85] Resequencing of these genes in cases of MI has not identified variants explaining the genetic association in the region, though effects of the risk SNPs on regulation of these genes remain a plausible mechanism requiring further investigation.

The CHD risk haplotype overlaps with ANRIL, a gene first characterized in 2007 by investigators examining a deletion in a large melanoma-neural tumor syndrome family.[86] ANRIL encodes a large antisense non-coding RNA of presently unknown function. Such non-coding RNAs are believed to be involved in regulation of gene expression, through transcriptional and translational control mechanisms.[87] ANRIL has been shown to be widely expressed in different tissues, including heart, coronary smooth muscle, human monocyte-derived macrophages, carotid endarterectomy specimens, and abdominal aortic aneurysm samples.[69,86] The SNPs most strongly associated with CHD map to ANRIL introns and downstream sequences which could influence its expression, although no relationship between ANRIL expression and CHD risk has as yet been demonstrated.[69]

Somewhat more distant from the risk haplotype, the MTAP gene encodes methylthioadenosine phosphorylase, an enzyme that is involved in polyamine metabolism. It has been suggested that variants may influence plasma levels of homocysteine and folate, although a recent study reported no variation in these related to genotype of the CHD risk SNP rs10757274.[71]

It seems likely that the studies to date have identified on chromosome 9p21 the most important single association between common genetic variation and CHD present in the genome. However, individual GWA studies have only had adequate power (80%) to detect relative risks greater than about 1.5 at the stringent significance levels required for these analyses, and it is likely that further loci with smaller effects will be identified through larger studies or meta-analyses of existing datasets.[88,89] The potential health importance of particular loci, particularly with regard to drug discovery, is not predictable from the magnitude of the odds ratio: for example, variants of the KCNJ11 gene confer an odds ratio of only 1.2 for diabetes in genome-wide studies but this gene is the target for the sulfonyl-ureas, which have been a cornerstone of diabetes therapy for many years.[54,90,91] Meta-analyses should be facilitated by the recent development of genotype imputation algorithms which use the patterns of intermarker association in a set of common samples genotyped on two platforms to enable the combination of datasets typed on one or other platform.[92] It should also be noted that the genotyping chips used in studies so far do not have complete coverage of all common variants. The Affymetrix 500K chip used in the WTCCC and German studies tags only about 68% of HapMap SNPs in Caucasian populations at $r^2 > 0.8$; the Illumina HumanHap300 is somewhat better at about 77% but still incomplete.[51] Thus, additional genotyping to complete the representation of common genome-wide SNPs may yield additional loci in due course.

Genome-wide association studies of plasma lipids: new loci

Recent GWA studies investigating plasma lipoprotein concentrations as quantitative traits have produced convincing associations at a number of loci, many of which have been replicated in separate analyses.[92–97] These recent studies have confirmed over a dozen previously implicated loci and identified seven newly associated genes associated with HDL cholesterol, LDL cholesterol and triglyceride levels (Table 21.4). One of these studies examined the relationship between lipoprotein-associated SNPs and CHD risk in a combined cohort comprising the WTCCC sample and an expanded panel of British individuals. All of the alleles associated with LDL metabolism were more common in CHD cases than controls, with modest odds ratios of 1.04–1.29 per allele; the association was significant ($P < 0.05$) for eight of the 11 SNPs. These findings suggest that the newly identified loci are potential targets for novel therapies affecting lipoprotein levels and CHD risk.

"Mendelian randomization" studies: using genetics to identify causal emerging risk factors

As illustrated in the GWA studies of lipoproteins discussed above, it is now relatively straightforward to conduct GWA studies of intermediate traits potentially relevant to CHD

Table 21.4 Loci associated with lipid levels in genomewide association studies ($P < 10^{-6}$)

Trait	Locus	Nearest gene(s)	Largest effect size (mg/dL)
HDL cholesterol	16q13	CETP	4.12
	8p21	LPL	2.09

*Estimated effect size in mg/dL obtained by multiplying the proportion of 1 standard deviation change reported by Kathiresan and colleagues[93] by the standard deviation of the lipid value from the MDC-CC cohort of that study.

susceptibility, and to test whether the association between genotype and intermediate trait translates to an association between genotype and disease. In the case of LDL cholesterol above, the disease–trait association is securely established through epidemiologic and randomized clinical trial data, so the disease–genotype association serves to validate the trait–genotype association. For emerging risk factors where the epidemiologically observed disease–trait association is not supported by randomized clinical trials (possibly because suitably specific agents are not available), the question can be posed somewhat differently to address the causality or otherwise of the intermediate trait in the disease process – an approach termed "Mendelian randomization".[98,99] The first large-scale application of this approach investigated the association between genotypes at the fibrinogen locus influencing plasma fibrinogen levels and the risk of MI.[100,101] In that study of around 5000 cases of MI and a similar number of controls, association between plasma fibrinogen level and MI risk was observed, as in many previous studies. Association was also found between polymorphisms in the promoter region of the beta-fibrinogen gene and plasma fibrinogen levels. The authors reasoned that if the relationship between plasma fibrinogen and MI were causal, the polymorphisms associated with fibrinogen level should show an association with MI risk that was commensurate with the associations between the polymorphisms on plasma fibrinogen, and between plasma fibrinogen and MI risk. No association between the SNPs typed and MI risk was observed, either in primary data or a literature-based meta-analysis of beta-fibrinogen SNPs and MI. This suggested that plasma fibrinogen did not play an important causal role in the risk of MI, but rather that the association observed was due to confounding or reverse causality.

Plasma levels of lipoprotein(a) have been known for many years to be highly genetically determined, with the major effect being due to a kringle IV type 2 size polymorphism in the Apo(a) gene. Plasma lipoprotein(a) levels are associated with MI risk, but the causal nature of the association has remained unclear. Recently, a "Mendelian randomization" approach involving 2800 cases and 37000 controls showed consistent association between lipoprotein(a) levels and MI risk, and between kringle IV repeats and MI risk, suggesting the association is causal.[102] By contrast, a similar study involving 6500 MI cases, 2800 ischemic cerebrovascular disease cases, and over 35000 controls did not suggest a causal association of C reactive protein with ischemic vascular disease.[103]

Genetic testing in coronary heart disease: ready for "prime time"?

The potential utility of genetic testing in predicting the risk of CHD and other serious conditions of later life is easily appreciated by scientists and the public alike. CHD, however, is a condition in which known and modifiable lifestyle factors play key roles. It could be argued that public health measures such as tobacco control, promotion of physical activity and healthy diet, and reducing salt consumption are likely to yield much more substantial reductions in CHD morbidity and mortality than genetic testing. Since there have not, as yet, been any loci discov-

ered which modify the risk of non-Mendelian CHD to an extent that they would be considered useful in risk prediction, it remains unknown whether the reactions of patients at risk of CHD for genetic reasons would be to avoid lifestyle factors that further increased their risk or to take an attitude of "genetic determinism" that might if anything lead to adverse changes in their lifestyles.

For some of the monogenic disorders increasing CHD risk referred to above, genetic testing is already being applied in the clinical setting. In familial hypercholesterolemia, the most common such disorder with a population prevalence of 0.2%, there has been recent debate regarding the optimal strategy to deliver this service. Many patients with FH go untreated: only around 15% of the estimated 110 000 patients with FH in the UK are thought to be receiving treatment in lipid clinics[104] and up to 75% of patients with FH may be unrecognized prior to their first coronary event.[105] In The Netherlands and Iceland, both small countries with concentrated populations and well-supported government-funded programs, cascade screening for FH has proved very successful. The Dutch program is estimated to have found over a third of all cases to date, and is expected to achieve almost complete identification of cases by 2013.[106] The cascade screening strategy involves identification and mutation testing of all first-degree relatives of known cases in whom a mutation has been detected; of these relatives, 50% will be carriers of the same mutation. This optimizes the cost effectiveness of the approach by reserving the relatively costly genetic test for a group in which the prior probability of a positive result is substantial. Testing is then "cascaded" to the first-degree relatives of mutation-positive family members, and so on through the family. Cascade screening can also be carried out in families without identified FH mutations using gender- and age-specific LDL cholesterol criteria to diagnose FH, but in this situation there is a range of LDL-C concentration where the diagnosis remains unclear.

Recently, Wald and colleagues proposed an alternative approach based upon opportunistic screening of children for hypercholesterolemia at the time of their routine immunizations, arguing that in order for cascade screening to be optimally implemented, more index cases had to be identified.[107] Subsequent measurement of cholesterol in parents of hypercholesterolemic children was estimated by these authors to have power to detect around 96% of parents with FH, and thus potentially reduce the impact of FH in both generations of families where it was discovered. Such an approach raises many contentious issues including obtaining valid consent from the child, potential psychologic damage from screening, and the impact of false positives. However, in many healthcare settings it is unlikely that cascade screening will identify more than 50% of cases,

so novel approaches to case finding such as opportunistic childhood screening, screening of family practitioner records, and targeted screening of patients presenting with first MI or acute coronary syndrome will need to be considered and piloted. It is unlikely that a "one size fits all" approach will be effective across multiple healthcare systems.

Present knowledge about the genetic contribution to non-Mendelian CHD susceptibility does not argue in favor of genetic testing. Although population attributable fractions of up to 0.22 for genotype at SNPs in the chromosome 9p21 region have been claimed, it should be remembered that the case–control cohorts which have been used in studies to date have been specifically collected to be "genetically loaded" – that is, in general early-onset cases have been studied, with a preference for inclusion of families in whom there is an affected relative-pair. The generalizability of results regarding the relative magnitude of a genetic contribution to risk in such selected cohorts to the entire population at risk of CHD is questionable. From a practical point of view, the contribution of genotype at associated SNPs to the capacity to predict CHD in a representative population assessed for the "classic" CHD risk factors is perhaps the most important question. In a recent report, the chromosome 9p21 CHD risk SNP rs10757274 was typed in a prospective study of 2742 men aged 50–64 years old, who were free of CHD at baseline.[71] The report included 270 CHD events that had occurred during a 15-year follow-up period. Even in this relatively small number of cases, an effect of the SNP could be demonstrated ($P = 0.04$) with a per-allele effect size congruent with previous studies. The contribution of rs10757274 genotype to prediction of CHD risk was assessed using receiver operating characteristic (ROC) curves. The area under the ROC curve for the "classic" risk factors was 0.62 (95% CI 0.58–0.66), and this did not increase significantly when rs10757274 genotype was included. Simulations suggested that if 10 additional SNP genotypes of similar effect to rs10757274 could be identified, the area under the ROC curve could be increased to 0.76, a gain in predictive capacity which the authors judged to be potentially useful. However, it was noted that the proportion of individuals segregating multiple independently associated SNPs in any population would be low, limiting the likely clinical utility of such SNPs as predictors even if discovered. Moreover, the chromosome 9p21 locus is clearly the strongest common genetic risk factor for CHD that has been discovered so far, and it seems unlikely from currently available data that many further loci will be discovered that confer a similar level of risk.

In this context, perhaps the best hope for "personalized medicine" with regard to CHD risk prediction lies with the potential for discovery of low-frequency intermediate

penetrance (LFIP) variants which, although contributing a small amount to the population attributable risk of disease, significantly impact an individual's personal risk.

Low-frequency intermediate penetrance variants: still largely unknown territory

Until recently, few studies had attempted to undertake systematic discovery of low-frequency variants (which we consider as those with allele frequencies 0.005–0.05 in the population) that may be involved in disease susceptibility. This is because such variants require gene sequencing to identify them directly; they cannot be indirectly inferred through association, as is possible with common variants. Sequencing using the Sanger method was too slow and costly to permit any but very limited studies of a handful of genes, which were conducted in major sequencing centers. Low-frequency variants might be expected to confer substantially higher disease odds ratios per allele than the 1.2–1.5 range generally observed in studies of common variation, as both theory and available data suggest that an inverse relationship between allele frequency and effect size will usually be the case (see Fig. 21.1). Depending on the size of the effect on risk and the allele frequency, variants with frequencies 0.005–0.05 could make significant contributions to familial risk. A hypothetical variant present in 1% of the population conferring an odds ratio of 3 for a disease with 5% population prevalence would have an insufficiently strong effect to result in Mendelian segregation in carrier families, but would also be too uncommon to have much chance of being detected in a GWA study despite its large effect size. Such a variant would, however, have a larger effect on familial risk than most of the risk alleles for any complex disease that have emerged from GWA studies to date.[84]

The PCSK9 gene provides the best example to date of the potential importance of LFIP variants in CHD risk. PCSK9 is a member of the proprotein convertase gene family and regulates the availability of LDL receptors on the cell surface; activating mutations reduce the number of receptors, while inactivating mutations result in a higher number (and thus a higher internalization of LDL cholesterol).[108] Activating mutations in PCSK9 give rise to autosomal dominant hypercholesterolemia.[109] Nonsense mutations which inactivate PCSK9 result in 30–40% lower plasma LDL levels, and are present in 3% of African Americans. Missense mutations with smaller effects on LDL (~15% lower) are present in a similar percentage of Caucasians. African American carriers of nonsense mutations have an 88% lower long-term CHD risk while European American carriers of missense mutations have a 47% lower CHD risk.[110] These differences in risk are larger than would have been predicted from trials that used statins to lower LDL,

presumably reflecting the additional benefit of lifelong lower LDL compared with LDL reduction initiated in middle life. These genetic results suggest that pharmacologic inhibition of PCSK9 may be a promising therapeutic strategy to achieve or enhance LDL lowering.

Most importantly for this discussion, the effects on risk conferred by the LFIP variants in PCSK9 are much larger than those associated with any common variant likely to be identified for CHD. If present for other genes, such substantial effects on risk would, by contrast with currently known common alleles, potentially be of interest in risk stratification. This would be true particularly if the intermediate trait affected by the gene were either unknown or not readily measurable (that is, unlike LDL cholesterol in the case of PCSK9), and if the rare allele effect were to increase, rather than to decrease risk. Novel resequencing technologies available within the last two years are now able to generate sequence data at over 200 times the speed of Sanger sequencing and a fraction of the cost, rendering systematic approaches to LFIP variants feasible.[111] Resequencing of several hundred individuals will be necessary to identify LFIP variants with security; in the first instance, such studies are likely to be targeted to those genes implicated in disease susceptibility either by GWA studies or findings in novel Mendelian families.

Pharmacogenetic studies in cardiovascular disease

Pharmacogenetic studies investigating the effect of common genetic variants on drug response or side effects are in general at an early stage, although robust information is available in the case of warfarin and statins. Warfarin dosage requirement is influenced by common variants in the vitamin K epoxide reductase (VKORC1) gene, which is a target of warfarin, and in the cytochrome P450-2C9 (CYP2C9) gene, which metabolizes warfarin. VKORC1 genotype has been estimated to explain around 30% of the variation in warfarin dose, and CYP2C9 genotype around 12% of the variation.[112] A recent GWA study confirmed the importance of these two genes, and found no additional large effects in a test sample of 181 patients and a replication cohort of 374 patients.[113] In August 2007, the US Food and Drug Administration decided that the labeling of warfarin should be modified to highlight the potential role of genetic information at the CYP2C9 and VKORC1 genes in prescribing decisions. However, it is as yet unclear whether routine incorporation of genotype data into dosing protocols when warfarin is commenced would be of substantial clinical benefit, particularly in relation to its cost.[114]

A recent genome-wide pharmacogenetic study of statin-induced myopathy typed around 300 000 SNPs in 85 subjects with myopathy and 90 controls, all taking

80 mg of simvastatin per day as part of a clinical trial (SEARCH) involving 12 000 participants.[115] A SNP in the SLCO1B1 gene, which encodes the hepatic transporter protein OATPB1, was strongly associated with myopathy ($P = 4 \times 10^{-9}$). The odds ratio among heterozygotes for the risk allele was 4.5 (95% CI 2.6–7.7) and in homozygotes it was 16.9 (95% CI 4.7–61.1). The frequency of the risk allele was 15%, and genotype was estimated to account for more than 60% of the risk of myopathy. The findings were confirmed in a second population drawn from a trial of 40 mg of simvastatin daily ($P = 0.004$). Variants in the SLCO1B1 gene have previously been shown to affect the blood levels of several different statins, so it is likely that the genetic effect will be present for other drugs within the class.[116] Among people taking 40 mg of simvastatin (or equivalent doses of other statins) or less, the incidence of myopathy is only around 1 in 10 000 cases per year, but it may be substantially increased at higher statin doses – for example, definite or incipient myopathy occurred in just under 1 in 60 patients taking 80 mg of simvastatin in the SEARCH study. These findings suggest that genotyping SLCO1B1 polymorphisms could be clinically useful in safety monitoring and tailoring of statin dosages, particularly among patients in whom high-dose statins are being considered.

Conclusion

The last 12 months have seen the emergence of robust results regarding the magnitude and nature of the contribution of common genetic variants to coronary heart disease risk. Four studies which systematically searched for variants associated with CHD risk throughout the human genome in large numbers of cases and controls all identified the same novel region of chromosome 9p. The association has been replicated in many follow-up studies and can be considered definite. The consensus estimate from these studies is that CHD risk is increased by between 20% and 30% per copy of the most strongly associated allele in the region that an individual carries, and the population attributable risk of CHD from this region has been estimated to be as high as 20%. The mechanism of the association is as yet unclear. Pooled analyses of multiple datasets may identify additional common alleles, which are likely to have smaller effects on risk than the chromosome 9p locus. In parallel with analyses of coronary disease endpoints, genome-wide association studies of plasma lipids in healthy populations have identified seven new loci with significant effects on HDL cholesterol, LDL cholesterol or triglycerides. New insights into the pathogenesis of CHD and the mechanisms of plasma lipoprotein metabolism are anticipated as a consequence of these recent discoveries. In addition to the technologic and knowledge advances that have rendered systematic studies of common genetic variants feasible, novel ultra-high throughput technologies will shortly render it possible to screen all coding genetic sequence in an individual at relatively low cost. This will enable the systematic investigation of lower frequency variants which may have higher odds ratios for disease than common alleles, and thus be of greater importance in delivering a useful genetic input to personalized assessments of CHD risk.

The challenges in this field are rapidly moving from identifying association signals to elucidating the mechanisms whereby the genes identified affect the risk of CHD. This will be a time-consuming endeavor, but a necessary prerequisite for the design of new therapeutic agents based on these genetic insights.

Glossary of genetic terms used

Alleles: Alternative variants of genetic sequence that can be found at the same chromosomal locus. Because human cells are diploid (having two copies of each chromosome), individuals have two alleles at each locus (which may be the same or different).

Autosomal: Pertaining to a non-sex chromosome (i.e. chromosomes 1–22 in humans, but not chromosomes X and Y).

Complex trait: Phenotype influenced by multiple genetic and environmental effects.

Dominant condition: Genetic disease where the presence of one abnormal allele is sufficient to cause the condition.

Exon: Part of a gene whose sequence appears in mature RNA and may encode a protein (i.e. the "coding" part of the gene).

Gene: A functional region of DNA, including sequence that is transcribed into RNA, regulatory elements, and also non-coding sequence that is removed during the formation of mature RNA (introns).

Genome: The total genetic information encoded by the DNA in a set of chromosomes.

Genotype: The combination of two alleles that represent an individual's genetic sequence at an individual locus.

Haplotype: The arrangement of alleles at a series of sites where variants exist along a chromosome.

Heterozygote: Individual with different alleles on the maternally and paternally inherited chromosomes at a particular chromosomal locus.

Homozygote: Individual with the same allele on the maternally and paternally inherited chromosomes at a particular chromosomal locus.

Intron: Part of a gene that is removed during the formation of mature RNA and which does not encode a protein (i.e. the "non-coding" part of the gene).

Linkage disequilibrium (LD): The association between alleles at two genetic markers. High LD means that geno-

type at one marker predicts genotype at the other marker (and therefore, only one may need to be typed in association studies).

Low-frequency intermediate penetrance variant: A genetic variant that is relatively uncommon (somewhat arbitrarily, the less frequent allele present on less than 5% of chromosomes in the population), but which has a moderate to large phenotypic effect.

Meiotic recombination: Exchange of genetic sequence between homologous chromosomes that occurs during gamete formation (meiosis).

Mendelian disease: A disease due to a single gene whose effects are sufficiently large that the disease and the abnormal allele co-segregate within carrier families.

Nucleotides: Purine and pyrimidine bases that make up the DNA sequence. There are four different nucleotides in DNA: adenine (A), cytosine (C), guanine (G), and thymine (T).

Polymorphism: Naturally occurring variation in the genetic sequence. Typically used for variants where the less frequent allele is present on at least 1% of chromosomes in the population.

Recessive condition: Genetic disease where the presence of two abnormal allele is required to cause the condition.

RNA: Ribonucleic acid. The nucleic acid into which DNA is transcribed; messenger RNA is subsequently translated into proteins, while other types of RNA have roles in regulating gene expression.

Single nucleotide polymorphism (SNP): A single base variation at a particular locus in the genetic sequence, where the less frequent allele is present on at least 1% of chromosomes in the population. Mostly biallelic, that is, two alternative nucleotides may be present at any given SNP. There are estimated to be approximately 10 million SNPs in the human genome, and they are the most common form of human genetic variation.

22 Molecular genetics of cardiovascular disorders

Ali J Marian[1] and Robert Roberts[2]

[1]Center for Cardiovascular Genetics, University of Texas Health Science Center, Houston, TX, USA
[2]University of Ottawa Heart Institute, Ottawa, Ontario, Canada

Introduction

The sequencing of the human genome is likely to be a landmark study of millennium proportions. The implications for cardiology from knowing the sequence of the human genome are many, but probably the most obvious is identifying the genes responsible for familial disorders. Abnormalities of the heart and blood vessels are number one among human birth defects occurring at about 1% of live births.[1,2] Genetic diagnosis and management are expected to be incorporated into the practice of a cardiologist by the end of this decade.[3] Knowing the etiology and understanding the pathogenesis of genetic disorders are most likely to improve the diagnosis, prevention and treatment of those disorders and in addition, provide fundamental insights into acquired disorders that simulate the phenotype. A good example is that of familial hypercholesterolemia in which there is a defective receptor for cell uptake of cholesterol.[4] The findings confirmed that the plasma cholesterol was a major factor in coronary artery disease and subsequently led to unraveling of the synthesis, transport and degradation of cholesterol.

The standard treatment today for coronary artery disease, both familial and acquired, includes the use of statins to lower plasma levels of low-density lipoprotein (LDL) cholesterol. It must be emphasized that practically all genetic disorders have an environmental component and the resulting phenotype is due to an interplay between the gene (genotype) and the environment (phenotype). Furthermore, for single gene disorders it is now recognized that some of the variability in the phenotype is also due to interplay between the causal mutations, environmental factors and the modifier genes.[5] An obvious example of the importance of environmental factors is that of familial hypertrophic cardiomyopathy (FHCM). FHCM is a single gene disorder that is transmitted in an autosomal dominant pattern, giving rise to a phenotype of left ventricular hypertrophy.[6] The same genetic defect is present in the same abundance in the right and left ventricles yet the disease is seldom manifested in the right ventricle. This would imply that the high pressure of the left ventricle is an important stimulus in the pathogenesis of the phenotype of hypertrophy.

Genetic disorders are considered in three categories: chromosomal abnormalities, single gene disorders, and polygenic disorders. Chromosomal abnormalities are usually detected by the pediatric cardiologist in children while they are still very young. An example of an adult form of chromosomal abnormality would be Turner syndrome. In the last edition, we stated that the multigene disorders (e.g. coronary artery disease) are where the future must be but the technology had not yet arrived. The technology has now arrived and remarkable progress has been made in the past year.[7–9]

Mutations responsible for single gene disorders

Diseases due to an abnormality in a single gene are inherited in a predictable pattern termed Mendelian transmission. In single gene disorders, the responsible gene is both necessary and sufficient to induce the phenotype. Each individual has two copies of the gene, referred to as alleles, one from each parent. The odds of which of the two alleles from each parent is inherited are by chance alone, namely 50%. Genes are units of heredity that are transmitted independently to the next generation. Two genes separated on different chromosomes sort themselves independently through the process of cross-over between the chromosomes. The greater the distance between two loci, the more

likely they are to be separated during genetic transmission. A given disease may be due to multiple mutations in the same gene (allele heterogeneity) or to a single or multiple mutations in two or more genes (locus heterogeneity). It is important to keep in mind, however, that within any one family the gene and the mutation responsible for the disease are the same and only rarely would two genes be transmitted for the same disease. Mutations involving only a single nucleotide are known as point mutations and are responsible for 70% or more of all adult single gene disorders (Table 22.1). A point mutation may be due to substitution of one nucleotide for another (missense mutation) or it may change the amino acid to a stop signal (nonsense), which will truncate the protein (truncated mutant); or it may eliminate a stop signal so the protein is elongated (elongated mutant). Nucleotides may be deleted or added which will result in a different reading from left to right and the gene may be read entirely differently, resulting in a non-functioning product (frameshift).

Table 22.1 Cardiac diseases with an identified genetic locus or gene

Cardiomyopathies	Chromosomal locus
Hypertrophic cardiomyopathy	1q32, 3p21, 11q11, 12q23, 14q12, 15q22, 19p13, 15q11, 14q1, 4q26–27
Dilated cardiomyopathy without conduction defects	1q32, 6q1, 9q12, 10q24, 15q1, 2q31
Dilated cardiomyopathy with conduction defects	1q1, 3p22, 6q23
Arrhythmogenic right ventricular cardiomyopathy	1q12, 2q32, 14q12, 14q23, 3p23, 1q42
Mitochondrial cardiomyopathies	Mitochondrial DNA
Cardiac septal defects	
Holt–Oram syndrome	12q2
Di George syndrome	22q
Noonan syndrome	12q
Aortic diseases	
Aneurysms	11q23–24
Supravalvular aortic disease	9q
Marfan syndrome	15q
Conduction disorder	
Familial heart block	19q13, 1q32
Ventricular arrhythmias	
Long QT syndrome	3p21, 4q25, 7q35, 11p15, 21q22, 17q23
Brugada syndrome	3p21
Idiopathic VT	3p21

Patterns of inheritance of single gene disorders

Autosomal dominant disorders are so named because the disease occurs despite a mutation in only one of the alleles. Males and females are equally affected with about 50% of the offspring expected to have the defective gene (Fig. 22.1). The following features are characteristic of autosomal dominant inheritance:
• each affected individual has at least one affected parent
• 50% of the offspring will have the defective gene
• normal children of an affected individual bear only normal offspring
• males and females are equally affected
• both sexes are equally likely to transmit the abnormal allele to male and female offspring and therefore, male-to-male transmission occurs
• vertical transmission through successive generations occurs
• it is typical for autosomal dominant disorders to have delayed age of onset and variable clinical expression.
Autosomal dominance is the predominant form of inheritance in adult cardiovascular disorders and examples would be FHCM and long QT syndrome.

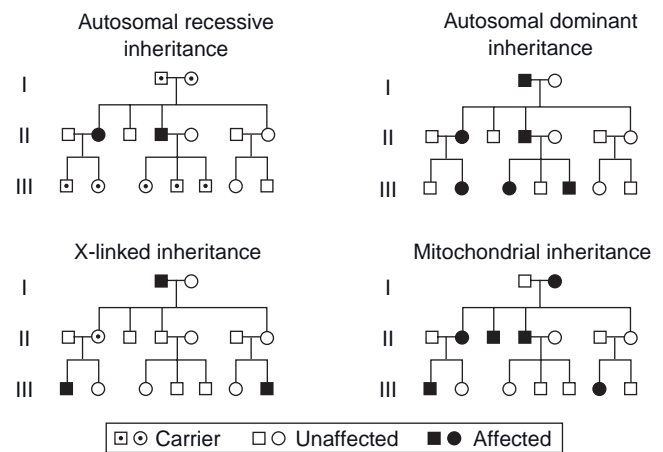
Autosomal recessive inheritance, in contrast, requires both alleles to be defective and thus both parents must have the defective gene. The following features are characteristic of autosomal recessive inheritance:
• generally the parents are clinically normal heterozygotes
• alternate generations are affected with no vertical transmission
• both sexes are affected with equal frequency
• each offspring of heterozygous carriers has a 25% chance of being affected, a 50% chance of being an unaffected carrier and a 25% chance of inheriting only normal alleles.


Figure 22.1 Mendellian patterns of inheritance. Indicates carrier, unaffected and affected patterns of inheritance.

If one parent is homozygous and the other is heterozygous, the pattern is changed, with 50% being affected and 50% being carriers.

Examples of autosomal recessive disorders affecting the heart include Jervell and Lang-Nielson long QT syndrome and Pompe's disease.

X-linked inherited disorders are caused by genes located on the X chromosome. Since a female has two X chromosomes, she may carry either one mutant allele or two mutant alleles; the trait may therefore display dominant or recessive expression. Since males have only a single X chromosome, they are likely to display the full syndrome whenever they inherit the abnormal gene from their mother. Hence, the terms *X-linked dominant* and *X-linked recessive* apply only to the expression of the gene in females. Since males must pass on their Y chromosome to all male offspring, they cannot pass on mutant X alleles to their sons; therefore, no male-to-male transmission of X-linked disorders can occur. All females receiving a mutant X chromosome are thus carriers and those who become affected clinically are usually homozygous for the defective gene. The characteristic features of X-linked inheritance are as follows:

• no male-to-male transmission
• all daughters of affected males are carriers
• sons of carrier females have a 50% risk of being affected and daughters have a 50% chance of being carriers
• affected homozygous females occur only when an affected male and a carrier female have children
• the pedigree pattern in X-linked recessive traits tends to be oblique because of the occurrence of the trait in the sons of normal carrier sisters of affected males.

Examples of X-linked disorders of the heart include X-linked cardiomyopathy, Barth's syndrome and muscular dystrophy.

Another uncommon inheritance pattern is that of mitochondrial abnormalities. The mitochondrion has its own genome of about 37 genes contained in 16 K of DNA in a single circular chromosome. Most of the disorders involve oxidative phosphorylation and are usually evident very early in life. Phenotypes due to mitochondrial DNA mutations are transmitted by maternal inheritance only since the ovum has mitochondria but the sperm does not. The characteristic features of mitochondrial inheritance of disease include:

• equal frequency and severity of disease for each sex
• transmission through females only, with offspring of affected males being unaffected
• all offspring of affected females may be affected
• extreme variability of expression of disease within a family
• phenotypes may be age dependent
• organ mosaicism is common.

An example of mitochondrial inherited cardiac disease is the cardiomyopathy of Kearns–Sayre syndrome.

Family history and inherited cardiovascular disorders

Identification of a disease segregating in a particular family is determined from the family history. Obtaining a careful family history has not hitherto been an emphasis for the cardiologist. Recognizing the importance of family history in single gene disorders and also in family cluster disorders such as atherosclerosis and hypertension must be a foremost part of the history and physical examination. Certain ethnic groups may direct specific testing such as for hemoglobinopathies in populations from the Mediterranean or sickle cell disease in the African American. The first individual to be recognized to have the disease is usually referred to as the proband. Once a proband is recognized, information should be collected on all first-, second- or third-degree relatives. The information should include medical problems, pregnancies and information on those individuals related to the family who are deceased. Frequently, it is important to pursue miscarriages, birth defects and other factors that may appear to be unrelated. A pedigree should be constructed analogous to those shown in Figure 23.1, to determine the pattern of inheritance.

Genetic counseling

Once it has been established that there is a familial disease, it is important to provide information to the individual or parents appropriate to the education of the individual. Every attempt must be made to explain the disease so that important issues are understood by the individual. An attempt must be made to outline the diagnosis, prognosis if known, and mode of transmission together with a discussion of the psychologic and social issues. It is also important in young couples to emphasize the mode of transmission and their chances of passing on the disease as well as the availability of prenatal diagnosis if appropriate. The information must be provided in a non-judgmental and unbiased manner. The family must be able to make a decision with respect to their religion, social and cultural backgrounds. It is sometimes frustrating for the counselor but personal bias must be avoided. Sometimes the issues are extremely sensitive and the options must be presented with concern and compassion but still remaining non-directional.

Single gene cardiovascular disorders

These diseases cover a wide spectrum from structural defects such as familial atrial septum to functional defects such as long QT syndrome (see Table 22.1). For most of

these diseases, the chromosomal location (locus) has been mapped but the gene has not yet been identified. However, diseases such as the cardiomyopathies, particularly FHCM, have undergone major investigations with elucidation of the pathogenesis. Animal models of human FHCM have been developed and therapies have been evaluated. There is considerable progress in the identification of genes responsible for ventricular arrhythmias, particularly the long QT and Brugada syndromes. It is still premature to manage these disorders based on their genetic etiology. This is in part because genetic screening is not available and the populations studied are not yet adequately characterized to provide generalized approaches to treatment. A few of these disorders will be discussed to indicate our progress in improving diagnosis, prevention and treatment. The discussion also indicates the trends for the future when most of these genes will be identified and data become available on the pathogenesis and prognosis as they relate to the specific molecular defects.

Long QT syndrome

Several mutations have been identified in cardiac ion channels (sodium, potassium and calcium channel genes) responsible for long QT syndrome (LQT) which predisposes to ventricular arrhythmias and sudden death. Since the initial locus identified was on chromosome 11, seven loci have been mapped and six genes identified (see Table 22.1). Several mutations have been identified in the sodium channel gene *SCN5A*.[10–12] The long QT-associated mutations in *SCN5A* are associated with increased sodium flux and prolonged depolarization. The mechanism for the arrhythmias is believed to be an imbalance between the inward and outward currents during the plateau of the action potential. Most of the mutations in the sodium channel appear to be gain of function. The pattern of inheritance is most frequently autosomal dominant although a rare recessive form has also been identified.

Several mutations have also been noted in potassium channels, which decrease potassium flux through a loss of function.[11,12] These mutations appear to have a dominant negative effect. Rarely, the QT syndrome is inherited in an autosomal recessive manner and may be associated with deafness (e.g. the Jervell and Lang–Nielsen syndromes). This observation led to the recognition that the inward potassium current is necessary for endolymph production in the inner ear.[13] There is extensive phenotypic variability among these various genes and mutations and within the same family there are many modifiers yet to be recognized to properly interpret genotype/phenotype correlations.

Mutations are claimed to have some prognostic significance. In general, patients with LQT1 due to the *KVLQT1* gene and LQT2 due to *HERG* have a higher risk of cardiac events than patients with LQT3 due to *SCN5A*.[14] The latter,

despite causing fewer events, has a relatively higher mortality, which indicates higher lethality of the events. The first line of therapy in patients with LQT1 is beta-blockers. Preliminary data suggest LQT3 patients might benefit from Na^{+1} channel blockers, such as mexiletine, but long-term data are not available yet (**Class IIb**).

A new syndrome has been described associated with shortening of the QT interval on the ECG and clinically with syncope and sudden death. This syndrome, referred to as the short QT syndrome, is due to mutations in the *SCN5A* gene.[15]

Another form of cardiac channelopathy is idiopathic ventricular fibrillation. The ECG may be normal although some individuals have an associated electrocardiographic abnormality, including ST segment elevation in V1–3 together with right bundle branch block, referred to as Brugada syndrome.[16–18] Mutations responsible for this disease have been linked to *SCN5A* with dominant inheritance. There is at present no proven mechanism for the ventricular arrhythmia but it is believed to be due to heterogeneity between the epicardium and endocardium during repolarization which leads to re-entry.

Brugada syndrome

The ECG pattern is characteristic of this syndrome, consisting of right bundle branch block and ST segment elevation in V1–3 and sudden death at a young age.[19]

SCN5A was identified as the first and, thus far, the only causal gene for Brugada syndrome in 1998.[20] Over 60 different mutations in SCN5A have been identified that collectively account for approximately 25% of all cases with Brugada syndrome. As in many other genetic disorders, Brugada syndrome also exhibits locus heterogeneity, and a second locus on chromosome 3 has been mapped.[21] However, the causal gene has not yet been identified. The only treatment is an implantable cardioverter-defibrillator (ICD). Once a case is identified, it is recommended the family be screened for the mutation. *SCN5A* mutations induce a large spectrum of phenotypes, including Brugada syndrome, long QT syndrome (LQT3), isolated progressive cardiac conduction defect, idiopathic ventricular fibrillation, and sudden unexpected death syndrome (SUDS).[22]

Familial atrial fibrillation

Atrial fibrillation is the most common cardiac arrhythmia with a prevalence of 6% over the age of 65 years.[23] The chance of developing atrial fibrillation over age 40 years is about 25% in men and women.[24] Atrial fibrillation accounts for about one-third of all strokes and 30% of all patients with atrial fibrillation have a family history of the disease.[25] In 1997, Brugada *et al* identified the first locus on chromosome 10q22–24 in a Spanish family.[26] Since that time, seven

Table 22.2 Genetic loci responsible for atrial fibrillation

Locus	Gene	Mode of inheritance	Effect on function
10q22	–	AD	
11p15	KCNQ1	AD	Gain of function
21q22	KCNE2	AD	Gain of function
11q13	KCNE3	AD	
17q23	KCNJ2	AD	Gain of function
12p13	KCNA5	AD	
1q21	GJA5	AD	
6q14–16	–	AD	
5p13	–	AR	

loci have been mapped and five genes identified: *KCNQ1*, *KCNE2*, *KCNE3*, *KCNJ2*, *KCNA5* (Table 22.2). All of the genes identified encode a potassium channel subunit. The mechanism of action by which these genes induce atrial fibrillation is shortening of the action potential duration and shortening of the atrial effective refractory period. The consistency of the mechanism of action suggests the development of therapy specifically targeted to prevent these molecular events.

The most recent finding is that of somatic mutations in the connexin 40 gene.[27] This gene (*CJA5*) encodes for the gap junction protein connexin 40, which is involved in electrical conduction in the myocardium. The mutation was identified through genetic screening of human atrial samples obtained from patients with atrial fibrillation undergoing cardiac surgery for valvular or other diseases. In addition to monogenic diseases, there is the observation that patients with structural heart disease are predisposed to atrial fibrillation by inherited DNA polymorphisms.[28] The recent development of chips with hundreds of thousands of SNPs, enabling genome-wide scans will, over the next few years, elucidate those SNPs that predispose to atrial fibrillation. Within the next decade, one can expect most of the genes responsible for atrial fibrillation and those SNPs that confer predisposition to be identified and therapies will be developed based on an individual's genomic profile.

Wolf–Parkinson-White syndrome

A gene responsible for an uncommon form of Wolff–Parkinson-White syndrome (WPW) was shown to be *AMPK*.[29,30] Several mutations in *AMPK* have since been identified[31–33] as inducing WPW which is associated with hypertrophic cardiomyopathy and conduction disorders along with a high incidence of atrial fibrillation. It appears that *AMPK* induces abnormalities in glycogen which leads to all three phenotypes: WPW, conduction disturbance and hypertrophic cardiomyopathy. A genetic animal model of

WPW expressing the *AMPK* gene has been developed which should elucidate pathogenesis and suggest potential therapies.[34]

Familial hypertrophic cardiomyopathy (HCM)

Clinical and pathologic features of HCM

HCM is an autosomal dominant disease defined by cardiac hypertrophy in the absence of an increased external load (primary hypertrophy). Patients with HCM exhibit protean clinical manifestations ranging from minimal or no symptoms to severe heart failure and sudden cardiac death (SCD). The majority of patients with HCM are asymptomatic or mildly symptomatic. The clinical manifestations often do not develop until the third or fourth decades of life. HCM is a relatively benign disease with an estimated annual mortality rate of <0.7% in the adult population.[35] However, SCD is often the first and tragic manifestation of HCM in the young.[36] HCM is the most common cause of SCD in young competitive athletes, accounting for approximately one-third of all SCD.[36]

The main pathologic features of HCM include myocyte hypertrophy and disarray, interstitial fibrosis and, to a lesser extent, thickening of the media of intramural coronary arteries. While hypertrophy and fibrosis are the common responses of the heart to all forms of injury, myocyte disarray is considered the pathologic hallmark of HCM.[37] Cardiac hypertrophy and interstitial fibrosis are the major determinants of mortality and morbidity in HCM.[38–40] In those with mild or no cardiac hypertrophy, myocyte disarray is associated with the risk of SCD.[41]

Molecular genetics

HCM is a genetic disease with an autosomal dominant mode of inheritance. Family history of HCM is present in approximately half of all index cases (familial HCM) and the remainder are sporadic. *Sporadic* means offspring of parents of whom neither has the mutant gene or the disease. Presumably, the mother was exposed shortly after conception (12–24 hours) to a mutagen (EG radiation) that induced in the embryo a mutation that causes HCM. The mutation, albeit *de novo*, in the affected offspring will transmit the mutation and disease to their offspring in the same pattern as familial. HCM usually is due to mutations in any of at least 12 contractile sarcomeric proteins (Table 22.3). Recently, a new gene (*MY0Z2* or myozenin 2) was identified as being responsible for HCM.[42] The gene encodes a Z disk protein and thus expands the spectrum of the causal genes to include those encoding the Z disk proteins. Over 500 mutations in 12 genes have been identified.[9]

Genotype/phenotype correlations

Genotype/phenotype correlation studies suggest that causal mutations affect the magnitude of cardiac hypertrophy and

Table 22.3 Causal genes for HCM: genes coding for sarcomeric proteins

Gene	Symbol	Locus	Frequency	Predominant mutations
β-Myosin heavy chain	MYH7	14q12	~30%	Missenses
Myosin binding protein-C	MYBPC3	11p11.2	~30%	Splice junction and insertion/deletion
Cardiac troponin T	TNNT2	1q32	~5%	Missenses
Cardiac troponin I	TNNI3	19p13.2	~5%	Missense and deletion
α-Tropomyosin	TPM1	15q22.1	<5%	Missenses
Essential myosin light chain	MYL3	3p21.3	<5%	Missenses
Regulatory myosin light chain	MYL2	12q23–24.3	<5%	Missense and 1 truncation
Cardiac α-actin	ACTC	15q11	<5%	Missense mutations
Titin	TTN	2q24.1	<5%	Missense mutations
Telethonin (Tcap)	TCAP	17q2	Rare	Missense mutations
Myozenin 2	MYOZ2	4q26	1:250	Missense mutations
α-Myosin heavy chain	MYH6	14q1	Rare	Missense and rearrangement mutations, (association)
Cardiac troponin C	TNNC1	3p21.3–3p14.3	Rare	Missense mutations (association)
Cardiac myosin light peptide kinase	MYLK2	20q13.3	Rare	Point mutations (association)
Caveolin 3	CAV3	3p25	Rare	Point mutations (association)
Phospholamban	PLN	6p22.1	Rare	Point mutations (association)
Figure 22.2 Stratification of risk according to mutation. Shown here are two different mutations in the βMHC gene. The mutation in Family 152 is associated with essentially normal lifespan while Family 2 has a mean lifespan of about 28 years. This emphasizes the potential prognostic significance of individual mutations.

the risk of SCD (Fig. 22.2). Mutations in the beta-myosin heavy chain (MyHC) are generally associated with an early onset and more extensive hypertrophy and a higher incidence of SCD.[43,44] In contrast, mutations in the myosin-binding protein C (MyBP-C) are associated with a low penetrance, relatively mild hypertrophy, late onset of clinical manifestations and a low incidence of SCD.[44–46] Mutations in cTnT are usually associated with a mild degree of hypertrophy but more extensive disarray and a high incidence of SCD.[41,47,48] Mutations in alpha-tropomyosin are generally associated with a benign phenotype and mild left ventricular hypertrophy. However, a phenotype of mild hypertrophy and high incidence of SCD also has been described.[49] Mutations

in essential and regulatory myosin light chains have been associated with mid-cavity obstruction in HCM and skeletal myopathy in some[50] but not in others.[51] Mutations in titin[52] and alpha-actin[53–55] have been observed in a small number of families.

Despite the observed associations between severity of the phenotype and the causal mutations, there is considerable variability in phenotypic expression of HCM among affected members, even among those who have identical causal mutations. Overall, the results of genotype/phenotype correlation studies have been subject to a large number of confounding factors, such as the small size of the families, small number of families with identical mutations due to low frequency of each mutation, influence of modifier genes,[56] influence of non-genetic factors and rarely homozygosity for causal mutations and compound mutations.[20,57,58] Correlations in the small number of patients studied suggest prognostic stratification by the mutations but caution must be exercised until larger studies are performed (see Fig. 22.2).

Pathogenesis of HCM

The initial defects induced by the mutant sarcomeric proteins are diverse. They comprise impaired acto-myosin interaction and cardiac myocyte contractile performance, altered Ca^{+2} sensitivity, reduced ATPase activity, sarcomere dysgenesis, altered subcellular localization and altered stoichiometry of the sarcomeric protein.[59] However, despite the diversity of the initial defects, the final phenotype is hypertrophy, fibrosis, and disarray. We have proposed that

a common link between the initial defect and the final phenotype is impaired cardiac myocyte contractile function,[60] which increases myocyte stress and leads to activation of stress-responsive intracellular signaling kinases and trophic factors. Release of trophic factors activates the transcription machinery, leading to cardiac hypertrophy, interstitial fibrosis and other histologic and clinical phenotypes of HCM.[60] Accordingly, myocyte hypertrophy and disarray, interstitial fibrosis and thickening of the media of intramural coronary arteries are considered "secondary" phenotypes and thus, potentially reversible. In addition, the severity of the phenotype is affected by factors other than the causal genes, i.e. the environmental factors and the modifier genes. In support of this hypothesis, we have shown that stress-responsive signaling kinases ERK1/2 are activated in the heart of transgenic animal models of HCM and that cardiac hypertrophy and interstitial fibrosis could be reversed or attenuated by pharmacologic interventions, discussed later.

Dilated cardiomyopathy (DCM)

Genetics of DCM

Dilated cardiomyopathy (DCM) is a primary disease of the myocardium diagnosed by a decreased left ventricular ejection fraction (<0.45) and an increased left ventricular cavity size (end-diastolic diameter >2.7 cm/m^2). Clinical features of DCM are those of heart failure, including syncope, cardiac arrhythmias and SCD. The etiology of DCM is diverse and a family history of DCM is present in approximately half of all index cases.[61–63] Thus, in such cases DCM is considered a familial disease. The remainder have no family history of DCM and thus DCM is considered sporadic. A significant number of patients with DCM and their affected relatives are asymptomatic and are mistakenly considered as normal unless subjected to clinical and genetic investigation.[60] Familial DCM is commonly inherited as an autosomal dominant disease,[61] which clinically manifests during the third and fourth decades of life. X-linked and autosomal recessive patterns of inheritance also occur, which may manifest early, often during the second decade of life. The mode of transmission is matrilineal when DCM occurs because of mutations in the mitochondrial DNA. DCM also occurs in conjunction with the triplet repeat syndromes and follows their pattern of inheritance.

DCM is an extremely heterogeneous disease (Table 22.4). Despite the diversity of the causal genes and mutations, the vast majority of them encode for proteins that are either components of the myocardial cytoskeleton or support it. Therefore, DCM is considered a disease of cytoskeletal proteins. Given the diversity of causal genes and mutations, it is not surprising that each causal gene accounts for a very small fraction of familial DCM and none predominates.

Collectively, the mapped genes account for approximately half of all familial DCM cases and in a significant number of families, while the chromosomal loci have been mapped, the causal genes remain unidentified. The gene encoding cardiac alpha-actin (*ACTC1*) was the first causal gene identified for familial DCM with an autosomal dominant mode of inheritance.[64] The authors proposed that defects in the cytoskeletal proteins could cause DCM by impairing the transmission of contractile force.[64] Mutations in two additional components of the sarcomere, namely the beta-myosin heavy chain and cardiac troponin T, were found in patients with DCM.[65] As discussed earlier, mutations in *ACTC1*, *MYH7* and *TNNT2* are also known to cause HCM. These findings suggest that the topography of the mutations within the sarcomeric proteins and the modifier genes plays a significant role in determining the ensuing clinical phenotype. Mutations in the cytoskeletal proteins delta sarcoglycan,[66] metavinculin and dystrophin[45] are also known to cause DCM. Mutations in alpha-sarcoglycan (adhalin) cause an autosomal recessive form of DCM that occurs in conjunction with limb-girdle muscular dystrophy. An intriguing causal gene for familial DCM is the lamin A/C gene,[67–69] which encodes a nuclear envelope protein. The observed phenotype resulting from mutations in the rod domain of lamin A/C is progressive conduction disease, atrial arrhythmias, heart failure and SCD. Finally, mutations in the intermediary filament desmin and its associated protein alpha/B-crystallin have been identified in patients with DCM.[70–72] Often such mutations lead to a phenotype of cardiac and skeletal myopathy, referred to as desmin-related myopathy.[71] Collectively, these findings suggest that mutations affecting the integrity of the cytoskeleton can cause DCM. Genotype/phenotype correlations are not yet available in a systematic study.

Pathogenesis of DCM

Mutations in cardiac alpha-actin, beta-myosin heavy chain, cardiac troponin T and other cytoskeletal proteins impart a dominant-negative effect on transmission of the contractile force to the extracellular matrix proteins.[64] Mutations in the dystrophin gene lead to decreased expression level of dystrophin, a major cytoskeletal protein in skeletal and cardiac muscles. Decreased expression of dystrophin impairs efficient mechanical coupling and myocyte shortening. In X-linked DCM, the severity of the clinical phenotype correlates inversely with the expression level of dystrophin. The pathogenesis of DCM resulting from mutations in desmin and alpha/B-crystallin involves deposition of desmin and alpha/B-crystallin aggregates in the myocardium. The molecular pathogenesis of DCM caused by mutations in lamin A/C or emerin remains largely unknown. It is likely that lamin A/C is also involved in maintaining the integrity of the cytoskeleton. The pathogenesis of cardiomyopathies in patients with the triplet

Table 22.4 Genetic causes of dilated cardiomyopathy

Gene	Symbol	Locus	Frequency	Phenotypes
Cardiac α actin	ACTC	15q11–14	Low	DCM or HCM based on topography of the mutation and probably genetic background
β-myosin heavy chain	MYH7	14q11–13	Low	DCM or HCM based on topography of the mutation and probably genetic background
Cardiac troponin T	TNNT2	1q32	Low	DCM or HCM based on topography of the mutation and probably genetic background
δ Sarcoglycan	SGCD	5q33–34	Low	DCM
β-Sarcoglycan	SGCB	4q12	Autosomal dominant	
Dystrophin	DMD	Xp21	Low	X-linked DCM

repeats syndrome is also unclear. Expansion of the CTG (CUG in mRNA) repeats in the 3′ untranslated region of the myotonin protein kinase gene could lead to unstable mRNA and decreased expression of the protein. It is also possible that proteins that bind to CUG repeats may be necessary for proper transcription, splicing, translation, and nuclear transport of mRNAs of cardiac genes.

Arrhythmogenic right ventricular cardiomyopathy (ARVC)

ARVC is the primary abnormality of the myocardium characterized by a progressive loss of myocytes, fatty infiltration and replacement fibrosis, which occur predominantly in the right ventricle.[73] ARVC, also referred to as arrhythmogenic right ventricular dysplasia, often manifests as ventricular arrhythmias originating from the right ventricle. A characteristic electrocardiographic pattern is the presence of an epsilon wave and less characteristic findings are depolarization/repolarization abnormalities in the right precordial leads. The age of onset of the disease is variable but commonly ARVC manifests with minor arrhythmias during adolescence, which progress to serious ventricular arrhythmias during the third and fourth decades of life, leading to SCD. In Italy, ARVC is a relatively common cause of SCD in the young.[74] Gradual fibro-fatty infiltration of the myocardium leads to regional and global right ventricular dysfunction and, less frequently, left ventricle failure. In advanced stages, both ventricles are involved and heart failure is the predominant manifestation.

Several loci for ARVC have been mapped, including loci on 14q23-q24 (ARVD1),[75] 1q42-q43 (ARVD2),[76] 14q12-q22 (ARVD3),[77] 2q32-q32.3 (ARVD4),[78] 3p23 (ARVD5),[79] and 10p14-p12 (ARVD6).[80] The causal gene for ARVC2 with its locus on chromosome 1q42-q43 has been identified as the cardiac ryanodine receptor gene (RYR2).[81] Mutations in the RYR2 gene in four independent families with ARVC have been identified.[81] However, the phenotype may be a phenocopy of catecholaminergic polymorphic ventricular tachycardia and not true ARVC. Mutations in DSP, JUP, PKP2 and DSG2, encoding the desmosomal proteins desmoplakin (DP), plakoglobin (PG), plakophilin 2 (PKP2)

and desmoglein 2 (DSG2), have been identified.[82–86] Mutations in *PKP2* appear to be the most common, accounting for approximately 20% of the cases.[83,86] Mutations in *DSG2* and *DSP* each account for approximately 10–15% of the cases of ARVC.[86] Most mutations cause a frameshift and hence are expected to lead to premature termination of the proteins. The only treatment is an ICD to prevent sudden cardiac death. Mechanistic studies suggest suppression of the canonical Wnt signaling through beta-catenin by nuclear plakoglobin or plakophilin 2 as the mechanism responsible for myocyte apoptosis and fibro-fatty replacement of the myocardium.[87]

The causal gene for an autosomal recessive form of ARVC, palmoplantar keratoderma, and peculiar woolly hairs (Naxos syndrome), is *JUP*, which encodes plakoglobin.[88] Plakoglobin is also a desmosome protein and, along with desmoplakin, anchors intermediate filaments to desmosomes. The phenotype was described first in a family from the island Naxos in Greece and was mapped to 17q21.

Integration of genetics into routine clinical management

Single gene disorders, many of which are already known, could theoretically be tested for multiple mutations. However, such testing has not yet been incorporated into clinical management. This is due to many reasons: medical insurance is not available to offset the cost; certain ethical, social and legal issues await federal policies; and for many disorders, the screening technology is not yet available. There are also other issues (e.g. penetrance and expressivity) that confound the interpretation of genetic data even when a mutation is known. Penetrance refers to the percentage of individuals with the mutant gene who will develop the disease. Most genes are not 100% penetrant and the onset of the disease further confounds the diagnosis since it is often age dependent. These problems are of greater concern when the pattern of inheritance is dominant. Expressivity refers to the variability of clinical manifestations. In some individuals with the mutant gene, the phenotype is only partially represented which poses the problem of a causal relationship.

Despite the lack of availability of clinical genetic testing, screening of first-degree relatives and other family members should be encouraged.[89] Once a DNA-based diagnosis of HCM is known within a family, clinical screening including history, physical examination, 12-lead ECG and two-dimensional echocardiography should be performed on individuals who are 12 years of age or older. In general, individuals do not develop hypertrophy until puberty when there is a significant growth spurt. Individuals affected should be re-evaluated every 12–18 months. Individuals within the family who do not have evidence of

HCM should be screened every five years. There is some debate as to whether at age 25 or 30, if there is no evidence of the disease, screening should be discontinued; however, since certain genes do not have onset until middle age or later, until genetic testing has been performed, clinical assessment should continue. In the meantime, it is suggested that individuals of suspected HCM families undergo genetic testing through either a research laboratory or one of the independent private laboratories. In addition, genetic testing is sometimes necessary to exclude other causes of hypertrophy such as lysosomal enzyme abnormalities.

Polygenic or complex disorders

There is ample evidence from dizygotic and monozygotic twins as well as endemic populations to indicate that diseases such as coronary artery disease (CAD) and hypertension have a significant genetic predisposition.[90] It is estimated that genetic predisposition accounts for over 50% of risk in patients with coronary artery disease and an even greater component in those with premature heart disease.[91] Despite the success with single gene disorders, there has been very little progress with the common chronic diseases such as coronary artery disease and hypertension. In single gene disorders, a single gene responsible for the disease is inherited in a Mendelian pattern (i.e. passed from parents to their children). Families with these diseases can be analyzed for the genetic anomaly using a few hundred DNA markers (spanning the genome at 10 million base pair intervals). Using a process referred to as genetic linkage analysis, researchers can determine which markers are present in affected individuals versus normals and map the location of the gene. While genetic linkage analysis is useful for single gene disorders within an affected family, this approach cannot be used for complex common diseases such as CAD and hypertension.

Twenty diseases account for about 89% of all deaths in the world, with cardiovascular disease accounting for over 40%.[92] In contrast to single gene disorders, genetic predisposition contributing to these diseases is due to multiple genes, with some contributing as little as 5% risk. The more appropriate and sensitive method to detect genes and other genomic alterations responsible for multigene disorders is referred to as a case–control association study.[93] In this type of study, the genomes of large populations of unrelated individuals with a chronic disease are compared to another large population without the disease, and the pool of genetic differences between the two is identified. These genetic differences are then assessed in independent populations to determine whether the association remains significant (referred to as replication). This method is best performed with a genome-wide scan that uses hundreds of thousands of DNA markers that span the entire human

genome. While the need for these genome-wide scans has been recognized for some time, they have not been feasible because of the availability of too few DNA markers and the prohibitive cost of genotyping large populations.[93] In the meantime researchers pursued a less expensive and less time-consuming method referred to as the candidate gene approach. This consisted of selecting one gene at a time and determining whether one or more forms of that gene are more common in diseased versus normal individuals. Several genes were claimed to be associated with disease, but recent studies[94] indicate that essentially none have been confirmed in independent populations.

New technology

The DNA of the human genome consists of 3.3 billion bases, the sequence of which was determined in 2003 by the Human Genome Project. This sequence is 99.9% identical in all humans, meaning the DNA sequence which carries the genetic differences varies by only one-tenth of 1% or about 3 million bases. Most of these variations are referred to as single nucleotide polymorphisms (SNPs) since ≥80% are due to substitutions of single bases (nucleotides) scattered throughout the genome. On average, each genome has one SNP per 1000 base pairs. The remaining 15–20% of variation is due to differing patterns of repetitive sequences, and deletion or addition of nucleotides, referred to as copy number variation (CNV). These SNPs and CNVs account for all human variation such as height, weight and susceptibility for, or protection against, disease.[95] Utilizing the SNPs as DNA markers, it was possible to generate platform arrays of millions of markers that could be used to search the entire genome for genes that predispose to chronic disease. This makes it possible to perform what are now referred to as genome-wide association (GWA) studies. Commercial platforms utilizing millions of DNA markers are currently available. With markers spaced across the genome at intervals averaging 1000 to 6000 base pairs, it is possible to detect genes that contribute even modestly to the disease. This is the newest technology evolving to map the location of the genes predisposing to chronic disease.[96]

Success is already evident from genome-wide case–control association studies. Results from these studies are beginning to appear, with promising implications. Recently, three independent groups using the GWA approach discovered the same genetic variation at chromosome 9p21 that results in a significantly increased risk of heart disease in Caucasians.[96] The risk of this genetic variation is independent of all known risk factors such as cholesterol, high blood pressure and diabetes. Several genes have also been identified in other chronic diseases including diabetes, Crohn's disease and prostate cancer.[97]

Coronary artery disease

Identifying the genes responsible for several single gene disorders affecting cholesterol metabolism has contributed significantly to our understanding of the pathogenesis and treatment of CAD (e.g familial hypercholesterolemia). However, as indicated previously, progress until recently has been minimal. Most of the research utilized the candidate gene approach and none of these genes have been replicated in independent populations and so remain suspect.[94] The list of candidate genes in Table 22.5 may be discarded as the results of the GWA studies become available. Two examples, namely *ABCA1* and *CYBA*, are discussed briefly. Plasma levels of high-density lipoprotein (HDL) cholesterol and its apolipoprotein A1 (apo-A1) are under tight control of genetic factors, which are largely unknown. Mutations in the ATP binding cassette transporter (*ABCA1*) gene in patients with Tangier disease[98] have very low plasma levels of HDL-C and apo-A1 and an increased risk of coronary atherosclerosis. This suggests a major role for the ABCA1 protein in regulating plasma HDL-C and apo-A1 levels and thus the risk of atherosclerosis.[99] Several studies have reported an association between plasma HDL-C levels and SNPs in *ABCA1*.[100–102]

A second example is the *CYBA* gene located on 16q24, which is involved in maintaining the delicate balance between oxidation and reduction (redox) in the vessel wall. *CYBA* codes for p22^{phox} protein, which is a component of the plasma membrane-associated enzyme NADPH oxidase. NADPH oxidase is the most important source of superoxide anion, the precursor to a variety of potent oxidants, in intact vessel walls. p22^{phox} in conjunction with gp91 forms a membrane-bound heterodimeric protein referred to as flavocytochrome b$_{558}$. The latter is considered the redox center of the NADPH oxidase. The p22^{phox} protein is essential for the assembly and activation of the NADPH oxidase and plays a major role in NADPH-dependent O_2^- production in the vessel wall. There are several genetic variants of p22^{phox} including a 242C/T transition that results in replacement of histidine by tyrosine at amino acid position 72 (H72Y), a potential heme-binding site. We determined the association of the 242C/T variants with severity and progression of coronary atherosclerosis and response to treatment with a statin in a well-characterized cohort of Lipoprotein Coronary Atherosclerosis Study population.[103] In the placebo group, subjects with the mutation had 3–5-fold greater loss in mean minimum lumen diameter (MLD) and lesion-specific MLD than those without. Progression was also more and regression less common in those with the mutation.

As indicated previously, GWA studies are likely to identify many genes predisposing to CAD in the very near future. The first major locus has been identified on chromosome 9p21.[96] The mechanism whereby this DNA region of 58 K base pairs predisposes to CAD remains to be

Table 22.5 Selected candidate genes for coronary atherosclerosis and myocardial infarction

Gene	Locus	Polymorphism	Allele	Function
Vascular homeostasis

ACE, angiotensin-converting enzyme; AGT, angiotensinogen; AT1, angiotensin II receptor 1; PAI-1, plasminogen activator inhibitor-1; GpIIb-IIIa, glycoprotein IIb-IIIa; eNOS, endothelial nitric oxide synthase; LPL, lipoprotein lipase; MTHFR, methylenetetrahydrofolate reductase; LCAT, lecithin cholesteryl acyltransferase; CETP, cholesteryl ester transfer protein; LDLr, low-density lipoprotein receptor; CBS, cysthathionine β synthase; HDL, high-density cholesterol; VLDL, very low-density cholesterol.

determined. Nevertheless, in the Ottawa Heart Genome Study, 23 000 Caucasians were genotyped and the heterozygous form was present in 50% and the homozygous form in about 25%. The relative risk for CAD is increased 40% by the homozygous form and 15–20% by the heterozygous form. The overall population risk is estimated to be about 10%. The 9p21 region was independently confirmed for increased risk of myocardial infarction by the Icelandic group in over 17 000 Caucasians with a similar gene frequency.[104] This was followed by further confirmation in a population of 5000 by the Wellcome Trust Case Control Consortium.[105] Thus, the 9p21 region has been confirmed as a significant risk factor for CAD, in over 45 000

Caucasians, and appears to be statistically independent of known risk factors. It does not appear to be a risk factor in African Americans and remains to be determined in other ethnic groups such as the Indian and Chinese populations.

Hypertension

Hypertension is among the top three or four most common diseases throughout the world. It is an independent risk factor for cardiac morbidity and mortality. It is a major stimulus for cardiac hypertrophy, which in itself significantly increases susceptibility for SCD. Hypertension, as

indicated previously, is primarily a polygenic disease. There are likely to be multiple genes that increase susceptibility for developing hypertension. These genes interact with the environment and the onset of hypertension is usually age dependent with 20–30% of the population being hypertensive in their elderly years. The susceptibility genes remain elusive but with the new ability to perform GWA studies, it is expected that many of these genes predisposing to hypertension will be identified in the next 5–10 years.

Geller and his associates recently identified a family with early onset of hypertension.[106] The disease segregates as a dominant Mendelian disorder. A mutation was identified in the mineralocorticoid receptor. The patient had severe hypertension, decreased plasma renin activity, serum aldosterone and no other underlying cause for hypertension. The mutation was a missense mutation in which leucine was substituted for serine at codon 810. The mutation is in the domain of the receptor that binds to the hormone. Normally, 21-hydroxyl group steroids are necessary to activate this receptor. In contrast, the receptor with the mutation seems to activate itself and does not require 21-hydroxyl stimulation. The potent antagonist spironolactone, which would block mineralocorticoid activity in normal individuals, acts as an agonist in individuals with this mutation, causing hypertension and further activating mineralcorticoid activity. This is quite a drastic and unexpected change for the mutation to not only have a positive effect but change the receptor to respond to hormones and drugs opposite to its normal response. Another important observation occurred in pregnancy, in which about 6% of individuals develop hypertension and may proceed to pre-eclampsia. It was noted that progesterone, which normally does not activate the mineralcorticoid receptor, does so in individuals with the mutation. This has significant implications in pregnancy since progesterone levels are normally increased 100-fold and thus, women with this mutation would be expected to develop hypertension. Furthermore, treatment with spironolactone would increase the hypertension and may precipitate pre-eclampsia. Two of the carriers in this family had undergone pregnancies all complicated by hypertension. It is also of note that while pregnant, these women had decreased serum potassium and aldosterone levels in keeping with the expected abnormal response induced by the mutation. While this is not part of the polygenic causes for hypertension, it emphasizes the pathogenetic mechanism involved with hypertension and clearly has improved the treatment of this condition which is particularly important in pregnancy. It is hoped that other Mendelian disorders causing hypertension will be identified since although they form a very small percentage of the etiology of hypertension, compared to polygenic forms, they could have significant implications for prevention and treatment.[106]

Genetics and future therapy

Once the gene responsible for a disease is identified, it is usually possible through genetic animal models to determine the function as well as the pathogenesis of the disease. Genetic animal models of human FHCM have been developed both in mice and in the rabbit.[107–109] In the mouse, expression of Arg 403, known to cause human FHCM, exhibits myocyte and myofibrillar disarray, impaired cardiac function and extensive fibrosis. However, there is very little hypertrophy. Expression of this same mutation, Arg 403, in the rabbit is associated with a phenotype that is virtually identical to that observed in human FHCM.[109] This may be because the rabbit has beta-MHC as the predominant myosin in the heart, as is found in human myocardium, whereas the mouse heart has alpha-MHC. In the transgenic rabbit, there is myocyte disarray, impaired systolic and diastolic function, extensive interstitial fibrosis and extensive septal and posterior wall hypertrophy. There is also a significant incidence of sudden death. Utilizing these two models, the pathogenesis of FHCM has been considerably elucidated. It does appear that impaired contractility due to the inherited defect in the beta-MHC leads to impaired contractility,[60] which in turn is associated with disarray and upregulation of several growth factors that stimulate fibroblast proliferation with increased matrix formation, myocyte hypertrophy and further disarray.[60] It has been shown in human FHCM that several growth factors are upregulated[60] and the pathology is that of fibrosis and hypertrophy. Recognizing that fibrosis and hypertrophy are secondary phenotypes would imply that, with appropriate therapy, there could be attenuation, prevention or even regression of these phenotypes.

A randomized placebo-controlled study was performed in the mouse model with 12 transgenic mice receiving placebo, 12 receiving losartan and 12 controls.[110] This study showed that despite a fully developed phenotype of disarray and fibrosis, there was essentially a reversal of the phenotype to normal after about six weeks of therapy. TGF-beta, which is known to be a stimulus of fibroblastic activity and collagen deposition, also returned to control levels. It is thus likely that TGF-beta is a major mediator of fibrosis in the mouse. In the rabbit model, a similar randomized placebo-controlled study[111] was performed with simvastatin. After 12 weeks of therapy, this model showed a 37% reduction in hypertrophy and fibrosis with significant improvement in ventricular function. The mechanism whereby simvastatin induces regression of hypertrophy and fibrosis is most likely due to the inhibition of isoprenylation of signaling proteins. This process is necessary to induce growth of the cardiac myocytes and/or fibroblasts. In similar studies spironolactone was also shown to reverse the HCM phenotype in the mouse.[112] Most recently, in

similar placebo-controlled studies, atorvastatin was shown to prevent the development of the HCM phenotype, when given prior to puberty in the transgenic rabbit.[113]

These studies are very exciting and provide compelling evidence for an appropriate clinical study in humans. We are even more excited about these results since all of these drugs have been shown to be safe as they have been taken by millions of patients for other reasons. These animal models provide the potential to identify other targets for development of new therapies but clearly losartan, simvastatin, atorvastatin and spironolactone can be evaluated in the near future. It is of note that FHCM in humans usually does not present prior to puberty and thus, there is at least a 10–12 year window in those positive for the mutation in which appropriate therapy could prevent or modulate the rate of development of the phenotype of fibrosis and hypertrophy. There is also, of course, the possibility that one can inhibit the fibrosis separately, which would lead to more specific therapy for the treatment of the disease in humans. It is an example of how one can work from the bedside to the bench in identifying the gene and then back to the bedside, having developed therapies in animal models that can be evaluated in clinical trials.

We are also interested in a novel diagnostic means for the preclinical diagnosis of FHCM. In the transgenic rabbit model of human FHCM induced by expression of the Arg 403 mutation, tissue Doppler velocities of the myocardium were assessed. It was observed that rabbits positive for the mutation, despite having no hypertrophy, exhibited impaired tissue Doppler velocities. These animals developed hypertrophy and the full phenotype but not until several months later.[114] Tissue Doppler velocities were evaluated in patients with FHCM, those positive for a mutation but without any clinical features and controls.[115] Thirteen patients positive for mutations but without hypertrophy or any other clinical phenotype exhibited decreased myocardial tissue velocity. We compared these findings with controls and patients with a clinical phenotype of FHCM. Tissue Doppler imaging had a sensitivity of 85% and specificity of 90% in individuals without other clinical findings. These findings have been confirmed by other investigators[116] and hopefully will be used to initiate therapy for prevention and possibly for screening athletes. The combination of effective therapy in animal models and a non-invasive test for preclinical diagnosis in patients offers great promise for the future. It is hoped clinical trials will be initiated in the near future for HCM, the most common cause of sudden cardiac death in the young.

23 Diet and cardiovascular disease

K Srinath Reddy

All India Institute of Medical Sciences, New Dehli, India

Introduction

Diet, as regularly consumed, and the nutrients supplied by it are major determinants which initiate and influence the course of atherothrombotic vascular disease.[1] It is estimated that up to 30% of deaths from coronary heart disease (CHD), a major form of cardiovascular disease (CVD), are due to unhealthy diets.[2] Identification of increased or decreased risk associated with dietary patterns or specific nutrients, in a methodologically rigorous manner, should lay the scientific foundation for general dietary recommendations to populations as well as specific nutritional interventions in individuals at high risk of CVD.

Methodologic issues in the study of causal associations

Issues related to study design

Studies investigating the influence of diet on CVD or cardiovascular risk factors have employed a wide variety of study designs: ecologic studies within and across populations, cross-sectional surveys, case–control studies (*de novo* or nested), cohort studies, community-based demonstration projects, randomized clinical trials and before/after type of metabolic studies. These differ widely in terms of their ability to (a) identify, avoid and adjust for confounding, (b) establish a temporal relationship of cause preceding the effect, (c) minimize bias, (d) provide a wide range of exposure, (e) ascertain composite endpoints, including fatal outcomes, (f) evaluate population-attributable risk, and (g) yield generalizable results.

Clinical trials, if well designed, provide the best framework for studying associations, as the results are relatively free from bias and confounding. However, they often evaluate interventions which are relatively short term and introduced late in the natural history of disease and may not reflect the effects of long-term differences in dietary exposures. Genetics now offers an alternative approach through "Mendelian randomization". This approach takes into account that genotypic differences in the metabolism of food ingredients may cause lifelong differences in exposure to food components and their metabolites or to purported risk factors, and may thus establish causality without the need for prolonged follow-up.[3,4]

A related issue is the use of experimental animals. Although these are often referred to as "animal models", their validity in predicting outcomes in humans is unclear. Lipid metabolism especially is species specific, as exemplified by the lack of efficacy of cholesterol-lowering statin drugs in many animal species, including monkeys.[5] Experiments in animals are therefore best reserved for elucidating mechanisms, and cannot be used to argue that a particular food will have a particular effect on cardiovascular disease in humans.

Issues involving outcome variables

These principally relate to a choice between disease endpoints and intermediate variables and the type of variables which are selected for study. Ideally, disease-related endpoints are preferable since they clearly demonstrate the benefits or risks of dietary exposures. With an exposure such as diet, effects may extend beyond cardiovascular outcomes. The need to evaluate impact of diet on total mortality and major co-morbidities, therefore, becomes important. Dietary exposures which influence thrombotic pathways may have opposite effects on the risk of hemorrhagic stroke and thrombotic stroke. The need to differentiate the types of stroke in outcome evaluation is, therefore, clear and has important implications for populations which differ in their stroke profiles.

Intermediate variables have been frequently utilized in studies evaluating the association of dietary constituents or

dietary patterns to CVD. Most often, these are risk factors like blood pressure or plasma lipids. However, similar changes in total plasma cholesterol may be associated with variable effects on levels of LDL cholesterol and HDL cholesterol and on the ratio of total to HDL cholesterol. The impact on risk of atherosclerotic CVD may thus vary. The 25-year follow-up experience of the Seven Countries Study revealed that while the increase in relative risk of CHD for comparable levels of plasma cholesterol elevation was similar across diverse populations, the absolute risk of CHD varied widely at the same level of plasma cholesterol, possibly due to other dietary and non-dietary influences.[6] Dietary changes may also influence LDL particle size differentially, and also the level of plasma triglycerides, with variable net effects on the atherogenicity of the plasma lipid pool. Such limitations were clearly illustrated in a study by Rudel *et al*[7] in which monkeys fed monounsaturated fat had similar lowering of LDL cholesterol as monkeys fed polyunsaturated fat but developed atherosclerosis equivalent to those fed saturated fat. In monkeys fed monounsaturated fatty acids, there was an enrichment of cholesteryl oleate in plasma cholesteryl esters, which correlated with coronary artery cholesteryl ester concentration.[8] Plasma lipids, as intermediate variables, could not also explain the degree of cardiovascular protection conferred by the Mediterranean diet in the Lyon Diet Heart Study.[9] While studies of intermediate variables (e.g. cholesterol levels) are useful in identifying mechanistic pathways of diet, there is a need for methodologically strong studies which relate dietary patterns or dietary interventions to hard endpoints such as total mortality and combined fatal and non-fatal cardiovascular events.

Issues involving exposure variables

These involve the type of exposure selected for study, the methods of measurement employed as well as the duration and dose of exposure. First, the types of dietary exposure assessed for associations with CVD have varied from specific nutrients (such as saturated fat) to dietary items (such as fish) to food groups (such as fruit and vegetables) to dietary patterns (such as the Mediterranean diet or Adventist diet) and composite dietary interventions (e.g. the

DASH diet). A reductionist approach has inherent limitations in the area of diet, because multiple interactions among many nutrients are likely to determine the physiologic effects and pathologic outcomes much more than the individual effects of an isolated nutrient. Multicomponent dietary exposures, however, render identification of mechanistic causal pathways difficult to elucidate. While this frustrates efforts to develop and market specific food supplements or nutriceuticals, interests of public health are likely to be better served by a causal enquiry exploring the connections of food patterns and food components to cardiovascular health.

Second, the strengths and limitations of various methods of collecting accurate food consumption data are well recognized.[10] Questionnaire methods of ascertaining information related to habitual food intake pose problems of validity and reproducibility even within well-defined populations but these problems are likely to be magnified when such instruments are applied across different cultures. Even if the nutrient composition of self-reported diets is accurately estimated, different cooking methods may alter the final bio-availability of those nutrients as actually consumed. The need for valid and reproducible biomarkers is, therefore, important when studies of specific nutrients are proposed. For example, adipose tissue fatty acid composition is a suitable biomarker for habitual type of dietary fat intake.[11] There may, however, be technical and financial constraints which limit the use of such biomarkers in large epidemiologic studies.

Third, a causal enquiry needs to recognize the lag time effect, wherein a long period of exposure to dietary variables is required before effect is evident on outcome variables Short-term studies may be incapable of identifying true effects even when they exist. This is clearly illustrated by trials evaluating the effect of sodium restriction on blood pressure, where benefit was demonstrated only in trials in which the duration of exposure was at least 5 weeks.[12] The dose of exposure is another critical variable, where many of the nutrients are physiologic requirements at a certain level but may pose risk of cardiovascular dysfunction and disease at other levels. The relationships may vary from linear to J-shaped or threshold, for different variables.
Figure 23.1 Change in CHD risk associated with replacement of saturates by other fats (Nurses' Health Study). (Reproduced with permission from Hu *et al*[21].)

Issues related to diet as an independent variable

Unhealthy dietary behaviors often occur in association with other unhealthy behaviors such as physical inactivity and smoking. Furthermore, unhealthy dietary practices such as high consumption of saturated fats, salt and refined carbohydrates as well as low consumption of fruit and vegetables tend to cluster together. In contrast, persons who habitually adopt one healthy dietary practice are more likely to adopt other healthy dietary habits as well as practice regular physical activity and abstinence from smoking. Dietary behaviors may also reflect patterns influenced by social class and may be influenced by stress levels. Dissociating the specific effects of individual dietary components from other dietary components, physical activity levels and other behaviors becomes difficult outside the setting of a randomized controlled clinical trial. In observational studies, the question arises whether some dietary practices are merely a surrogate for other dietary practices or lifestyles such as physical activity, or for a composite of multiple health behaviors.

The effects of diet on multiple cardiovascular risk factors, ranging from body weight to blood lipids and blood pressure to thrombotic mechanisms, also pose the question of when and how far to adjust for these variables in evaluating the relationship of diet to CVD. Since many of these are intermediate variables linking diet to CVD, adjustment to exclude their effect would underestimate the effect of diet. However, such variables are also influenced by factors other than diet.

Nutrients and cardiovascular disease

Willett defined a good diet by using a score based on low trans fat, high polyunsaturated fat, low glycemic load, high cereal fiber, fish twice a week or more, and high folic acid.[13]

Dietary fats

The relationship between dietary fats and CVD, especially CHD, has been extensively investigated, with strong and consistent associations emerging from a wide body of evidence accrued from animal experiments, as well as observational studies, clinical trials and metabolic studies conducted in diverse human populations. The relationship of dietary fat to CVD was initially considered to be mediated mainly through the atherogenic effects of plasma lipids (total cholesterol, lipoprotein fractions and triglycerides). The effects of dietary fats on thrombosis and endothelial function as well as the relationship of plasma and tissue lipids to the pathways of inflammation have been more recently understood.[11,14] Similarly the effects of dietary fats on blood pressure have also become more evident through observational and experimental research.

Cholesterol in the blood and tissues is derived from two sources: diet and endogenous synthesis. Dairy fat and meat are major sources. Egg yolk is particularly rich in cholesterol but, unlike dairy and meat, does not provide saturated fatty acids. Dietary cholesterol raises plasma cholesterol levels.[15] Although both HDL and LDL increase, the effect on the total/HDL ratio is still unfavorable, but small.[16] Observational evidence on an association of dietary cholesterol intake with cardiovascular disease is contradictory.[17,18] The upper limit for dietary cholesterol intake has been prescribed, in most guidelines, to be 300 mg/day. However, since there is no requirement for dietary cholesterol, it is advisable to keep the intake as low as possible.[14] If intake of dairy fat and meat is controlled, there would be no need for a severe restriction of additional egg yolk intake.

Fatty acids are grouped into three classes – saturated fatty acids (SFA), monounsaturated fatty acids (MUFA) and polyunsaturated fatty acids (PUFA). SFA and MUFA can be synthesized in the body and hence are not dietary essentials. PUFA are essential fatty acids, since they cannot be synthesized in the body.

Saturated fatty acids (SFAs) as a group raise total and LDL cholesterol, but individual SFAs have different effects.[11,19] Myristic and lauric acids have greater effect than palmitic acid, but the latter is more abundant in food supply. The plasma cholesterol-raising effects of these three SFAs is higher when combined with high-cholesterol diets. Stearic acid has not been shown to elevate blood cholesterol and is rapidly converted to oleic acid (OA) *in vivo*. Metabolic (feeding) studies demonstrate a marked elevation of both HDL and LDL cholesterol induced by SFA diets.[20,21] Replacement of saturated fatty acids by polyunsaturated fat reduces the total to HDL cholesterol ratio but replacement by carbohydrates does not. Also, tropical fats rich in lauric acid (C-12) raise total cholesterol strongly, but because of their specific effect on HDL, the ratio of total to HDL cholesterol falls. Thus effects on blood lipids can be variable, depending on which blood lipids are studied, and we need data on actual outcomes to determine the true effects of fats on coronary heart disease.[22]

The relationship of dietary saturated fat to plasma cholesterol levels and to CHD was graphically demonstrated by the Seven Countries Study involving 16 cohorts, in which saturated fat intake explained 73% of the total variance in CHD across these cohorts.[23] In the Nurses' Health Study,[21] the effect of saturated fatty acids was much more modest, especially if saturates were replaced by carbohydrates. The most effective replacement for saturated fatty acids in terms of CHD outcome is by polyunsaturated fatty acids, i.e. linoleic acid. This agrees with the outcome of large randomized clinical trials, in which replacement of

saturated and trans fats by polyunsaturated vegetable oils effectively lowered coronary heart disease risk.[24]

Trans fatty acids (t-FAs) are geometric isomers of unsaturated fatty acids that assume a saturated fatty acid-like configuration. Partial hydrogenation, the process used to create t-FAs, also removes essential fatty acids such as linoleic acid and alpha-linolenic acid. Metabolic studies have demonstrated that t-FAs render the plasma lipid profile even more atherogenic than SFAs, by not only elevating LDL cholesterol to similar levels but also decreasing HDL cholesterol.[25] As a result, the ratio of LDL cholesterol to HDL cholesterol is significantly higher with a t-FA diet (2.58) than with a SFA diet (2.34) or an oleic acid diet (2.02). Evidence that intake of t-FAs increases the risk of CHD initially became available from large population-based cohort studies in the US[26,27] and was corroborated in an elderly Dutch population.[28] Levels of t-FAs in a biochemical analysis of replicated baseline food composites correlated with the risk of coronary death in the cohorts of the Seven Countries Study. Most trans fatty acids are contributed by industrially hardened oils, but the dairy and meat fats of ruminants are also a source. Eliminating t-FAs from the diet would be an important public health strategy to prevent cardiovascular disease. Since these agents are commercially introduced into the diet, policy measures related to the food industry would be required along with public education. Trans fatty acids have been eliminated from retail fats and spreads in a large part of the world, but deep-fat fried fast foods and baked goods are a major and increasing source.[29]

The only nutritionally important *monounsaturated fatty acid* (MUFA) is oleic acid, which is abundant in olive and canola oils and also in nuts. The epidemiologic evidence related to MUFAs and CHD is derived from studies on the Mediterranean diet, as well as from the Nurses' Health Study and other similar studies, which investigated the association and controlled for confounding factors.[30] MUFAs have been shown to lower blood glucose and triglycerides in type 2 diabetics and may decrease susceptibility of LDL to oxidative modification.

Polyunsaturated fatty acids (PUFAs) are derived from dietary linoleic acid (LA) (n-6 PUFAs) and dietary alpha linolenic acid (ALNA) (n-3 PUFAs). The important n-6 PUFAs are arachidonic acid (AA) and dihomogammalino-lenic acid (DHGLA), while the important n-3 PUFAs are eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). Eicasanoids derived from AA have opposing metabolic properties to those derived from DHA. A balanced intake of n-6 and n-3 PUFAs is, therefore, essential for health.

The biologic effects of n-3 PUFAs are wide ranging, involving lipids and lipoproteins, blood pressure, cardiac function, arterial compliance, endothelial function, vascular reactivity and cardiac electrophysiology as well as potent antiplatelet and anti-inflammatory effects, includ-ing reduced neutrophil and monocyte cytokine production.[11,31] DHA appears to be more responsible for the beneficial effects of fish and fish oils on lipids and lipoproteins, blood pressure, heart rate variability, and glycemic control, in comparison to EPA, while a mixture of DHA and EPA significantly reduced platelet aggregation in comparison to ALNA *in vitro*.[11,32] The very-long chain n-3 polyunsaturated fatty acids powerfully lower serum triglycerides, but they raise LDL cholesterol.[33] Therefore, their effect on coronary heart disease is probably mediated through pathways other than cholesterol.

Much of the epidemiologic evidence related to n-3 PUFAs is derived from the study of fish consumption in populations or interventions involving fish diets in clinical trials. Fish oils were, however, used in the GISSI study of 11 300 survivors of myocardial infarction.[34] In this factorial design, fish oil (1 g/day) and vitamin E (300 mg/day) were compared, alone and in combination, to placebo. After 3.5 years of follow-up, the fish oil group had a statistically significant 20% reduction in total mortality, 30% reduction in cardiovascular death and 45% decrease in sudden death. While most published studies do not indicate that dietary n-3 PUFAs prevent restenosis after percutaneous coronary angioplasty or induce regression of coronary atherosclerosis, one study reported that occlusion of aortocoronary venous bypass grafts was reduced after 1 year by daily ingestion of 4 g fish oil concentrate.[35]

The Lyon Diet Heart Study incorporated an n-3 fatty acid (alpha-linolenic acid) into a diet altered to develop a Mediterranean diet intervention.[9] In the experimental group plasma ALNA and EPA increased significantly and the trial reported a 70% reduction in cardiovascular mortality at 5 years in its initial report. Total cholesterol and LDL cholesterol were identical in the experimental and control groups, suggesting that thrombotic and perhaps arrhythmic events may have been favorably influenced by n-3 PUFAs. Since the diet altered many other variables, such as fiber and antioxidants (by increasing fruit and vegetable consumption), direct attribution of benefits to n-3 PUFAs becomes difficult to establish.

The effect of different fatty acids on cardiac arhythmias has been an area of great interest. Diets rich in saturated fatty acids increase the risk of ventricular fibrillation and sudden cardiac death in primates. A population-based case–control study, using biomarkers, revealed a modest association of trans fatty acids in general and a strong association of trans isomers of linoleic acid in particular with primary cardiac arrest in humans.[36] Several studies in different animal models, primate and rodent, have shown that n-3 PUFAs are protective against cardiac arrhythmias, especially ventricular fibrillation.[37] It has been suggested that the fall in CHD mortality in the USA and Australia since 1967 is probably attributable to an increase in polyunsaturate fat consumption in both countries since 1960.[38]

The decline in CHD mortality in the Zutphen cohort has similarly been attributed to a decreased consumption, over time, of trans fatty acids.[28]

The proportions of SFAs, MUFAs and PFAs as constituents of total fat intake and total energy consumption have engaged active attention, in view of the strong relationship of these fatty acids to the risk of CVD, especially CHD. The reduction of SFAs in the diet has been widely recommended, but its replacement remains an area of debate as to whether the place of reduced SFAs should be taken by MUFAs, PUFAs or carbohydrate. In a meta-analysis of studies on the effect of various dietary fats on blood lipids, the negative effect of dietary trans fat was about twice that of saturated fat on a calorie-for-calorie basis.[39] Dietary trans fats have additional adverse effects, including increased serum triglyceride and lipoprotein (a) levels and adverse effects on endothelial function.[40,41] Both MUFA and PUFA improve the lipoproteins profile, although polyunsaturated fatty acids are somewhat more effective. In view of this, recent US dietary recommendations suggested that SFAs should be reduced to 7–8%, MUFAs should be increased to 13–15% and PUFAs raised to 7–10% of daily energy, with the total fat contributing no more than 30% of all calories consumed.[30,42] These may need to be adjusted for populations who consume lower quantities of total fat, so as to ensure an adequate intake of MUFAs and PUFAs even under those circumstances.

The total quantity of fat consumed, as a proportion of daily energy intake, has not shown a relation to CVD that is independent of the SFAs content. It has been argued that the type of fats consumed is far more important than the total amount of fat consumed.[43] The compatibility of high-fat Mediterranean diets (with total fat contributing >30% of calories) with coronary protection has also been cited as supportive evidence. While the emphasis on the type of fat is well placed, it must be recognized that high-fat diets are also high in energy. Whether this contributes substantially to overweight is a subject of much debate.[44] The Strong Heart Study examined the association between dietary fat

intake and CHD incidence in American Indians.[45] Participants (n = 2938) were followed for a mean (±SD) of 7.2 ± 2.3 years. In the age group of 47–59 years, those in the highest quartile of intake of total fat, saturated fatty acids or mono-unsaturated fatty acids had higher CHD mortality than did those in the lowest quartile (hazard ratio (95% CI): 3.57 (1.21–10.49), 5.17 (1.64–16.36), and 3.43 (1.17–10.04), respectively) after confounders were controlled for. These associations were not observed for those aged 60–79 years. Based on these strong independent risk associations, it would be prudent to reduce fat intake early in life to reduce the risk of dying from CHD.

Enhancing the nutritional quality of dietary fat consumption, to provide greater cardiovascular protection, may be attempted by decreasing the sources of saturated fats and eliminating trans fatty acids in the diet, increasing the consumption of foods containing unsaturated fatty acids (both MUFAs and PUFAs) and decreasing dietary cholesterol consumption. Figure 23.2 provides a breakdown of different types of fats in the commonly consumed edible fats/oils.[46]

Carbohydrates

The relationship of dietary carbohydrates to CVD appears to be mediated through indirect mechanisms: contribution to total energy and its effect on overweight and obesity; influence on central obesity; effects on plasma lipids, especially triglycerides, and effects on glycemic control. The balance between carbohydrates and fat as sources of energy as well as the fiber component of the diet are also areas of interest when considering this relationship. In feeding experiments, an increase in dietary energy from carbohydrates is usually associated with a moderate increase in fasting plasma triglyceride levels in the first few weeks but these return to near original levels eventually. Epidemiologically, high carbohydrate intakes are associated with low plasma cholesterol and variable plasma triglyceride concentrations.[47]
Figure 23.2 Breakdown of fat types in various fats and oils. (Reproduced with permission from Steckel[46].)

High-carbohydrate diets appear to reduce HDL cholesterol levels and increase the fraction of small dense LDL, both of which may impact adversely on vascular disease. This dyslipidemic pattern is consistent with the elevation of plasma triglycerides. There is as yet no clear evidence that the risk of CVD is altered independently by the carbohydrate levels in the diet. The glycemic index of foods might also be a determinant of the extent to which carbohydrates can influence the glycemic status. Carbohydrate diets with high glycemic index might adversely impact on glucose control, with associated changes in plasma lipids.[48,49]

Liu et al[50] first reported a positive association between a higher dietary glycemic load (GL) and risk of CHD in the Nurses' Health Study (NHS). Buelens et al[51] report a similar association between GL and risk of CVD in the EPIC (European Prospective Investigation into Cancer and Nutrition) cohort. The analysis included 15 714 women aged 49–70 years without diabetes or CVD at baseline. During 9 years of follow-up, 556 incident cases of major CVD events were documented. After adjusting for CVD risk factors and dietary fat and fiber, the investigators found a significant association between dietary GL and increased risk of CVD (risk ratio comparing extreme quartiles = 1.47, 95% confidence interval (CI) 1.04–2.09, P for trend = 0.03). In both the NHS and EPIC cohorts, the increased risk was more pronounced among overweight and obese women compared with normal-weight women.

It is mainly the amount and the type of carbohydrate consumed that will increase a person's risk of developing cardiovascular disease, increased weight or type 2 diabetes. Non-refined carbohydrates, rich in dietary fiber, like wholegrains, fruit, vegetables and legumes, reduce the risk of heart disease. The greater risk of heart disease is associated with eating patterns high in refined carbohydrates, such as confectionery, cakes, biscuits, pastries and high-sugar drinks and fruit juice drinks. Limiting the amount of carbohydrate from foods containing refined carbohydrates is important for weight management and thus lowering the risk for heart disease.

Dietary fiber

Dietary fiber is a heterogeneous mixture of polysaccharides and lignin that cannot be degraded by the endogenous enzymes of vertebrate animals.[53] Water-soluble fibers include pectins, gums, mucilages and some hemicelluloses. Insoluble fibers include cellulose and other hemicelluloses. Most soluble fibers reduce plasma total and LDL cholesterol concentrations, as reported by several trials.[54] Pectins, psyllium, gums, mucilages, algal polysaccharides and some hemicelluloses lower total and LDL cholesterol levels without affecting HDL cholesterol, the reductions in total cholesterol being usually in the range of 5–10%. Human

BOX 23.1 Recommendations by the National Heart Foundation, Australia[52]

There is good evidence in the scientific literature to indicate that:
- there is no significant association between the total carbohydrate intake and the risk of developing cardiovascular disease
- eating patterns with a high glycemic load raise blood triglyceride levels, increasing the risk of cardiovascular disease
- eating patterns high in soluble fiber lower blood LDL cholesterol levels, reducing the risk of CVD
- total carbohydrate intake has no effect on insulin sensitivity or the risk of developing type 2 diabetes

There is moderate evidence in the scientific literature to indicate that:
- consuming dietary fiber from cereals (particularly wholegrains) and fruit is associated with a lower risk of cardiovascular disease
- eating patterns low in refined carbohydrates are associated with a lower risk of developing type 2 diabetes

experiments have clearly shown that oat fiber tends to lower plasma total and LDL cholesterol but wheat fiber does not. Rice bran and barley may also lower cholesterol.[55] Fiber consumption predicted insulin levels, weight gain and cardiovascular risk factors like blood pressure, plasma triglycerides, LDL and HDL cholesterol and fibrinogen more strongly than other dietary components in the CARDIA cohort study of young adults.[56] However, fiber intake may be confounded with many other determinants of cardiovascular health.

Between 1996 and 2001, five very large cohort studies in the USA, Finland and Norway all reported that subjects consuming relatively large amounts of wholegrain cereals have significantly lower rates of CHD.[55,57] High intake of fiber from cereal sources was associated with a reduced risk of CHD in the Nurses' Health Study[57] and was inversely associated with the risk of hypertension in the Health Professionals Follow-up Study.[58]

There are no randomized controlled trials evaluating the effects of wholegrain consumption on CHD events. However, numerous reviews have examined wholegrain intakes and the risk of CHD.[59–62] Others have linked wholegrain consumption to lowered risk of diabetes and obesity in men[63] and women.[64] Both diabetes and overweight are risk factors for early-onset CHD and there is the possibility that modifying their risk could mediate some of the protective effects of wholegrains.[60] Lowering of plasma total and LDL cholesterol has been shown in male and female

Hispanic Americans.[65] In contrast, Davy et al[66] did not find a significant reduction in total or LDL cholesterol but demonstrated a lowering of more atherogenic small, dense LDL particles by oat bran relative to wheat cereal in sedentary, overweight American men.

Thus, the large body of prospective data provides convincing evidence for a protective effect of wholegrains against CHD. Available evidence supports a recommendation for consumption of about 15 g /1000 kcal of fiber.[54] Since some of the reported benefits may have arisen from other dietary components occurring in association with fiber in natural foods, dietary consumption of high-fiber foods should be recommended rather than isolated fiber. Addition of oat bran may be considered, where necessary, to supplement natural foods in order to attain the recommended dietary intake.

Antioxidants

The oxidation of LDL by oxygen free radicals results in the unregulated uptake of modified LDL by macrophages in arterial walls, accelerating the atherosclerotic process. Antioxidant nutrients, which can directly scavenge free radicals, include alpha-tocopherol (vitamin E isomer) and ascorbic acid (vitamin C), which have shown antioxidant activity both *in vitro* and *in vivo*, as well as beta-carotene (a provitamin A carotenoid) which has displayed antioxidant activity *in vitro*.[67] These mechanisms suggested that increased dietary intake or supplementation of these nutrients would be protective against atheroslerotic vascular disorders. This was supported by evidence from observational studies for vitamin E and beta-carotene, but results of clinical trials employing supplements have been disappointing.

Observational cohort data suggest a protective role for carotenoids. The randomized trials, in contrast, reported a moderate adverse effect of beta-carotene supplementation, with a relative increase in the risk of cardiovascular death of 12% in a meta-analysis of four trials.[68] Cancer risk was also increased.

Several large cohort studies showed significant reductions in the incidence of cardiac events in men and women taking high-dose vitamin E supplements.[67] However, the HOPE trial, a definitive clinical trial relating vitamin E supplementation to cardiovascular outcomes, revealed no effect of vitamin E supplementation (at 400 IU/day, for a mean follow-up of 4.5 years) on MI, stroke or death from cardiovascular causes in men or women.[69] Other trials also failed to demonstrate a cardioprotective effect of vitamin E supplements.[70] A recent meta-analysis also showed no evidence of a protective effect of antioxidant or B vitamin supplements on the progression of atherosclerosis.[71]

Flavonoids are polyphenolic antioxidants which occur in a variety of foods of vegetable origin, such as tea, onions and apples. Data from several prospective studies indicate an inverse association of dietary flavonoids with coronary heart disease.[65] A benefit on stroke risk has also been reported.[66] However, confounding may be a major problem and may explain conflicting results of observational studies on flavonoids and coronary heart disease. Fruits and vegetables also contain other phytochemicals that may have protective properties, including isothiocyanates and indoles (found in cruciferous vegetables), sulfides (found in onions and garlic), terpenes (found in citrus oils) and phytoestrogens.[54] The overall health benefit of flavonoid consumption is unproven, and their intake in the form of fortified foods or supplements should not be encouraged.[72]

Systematic reviews[73,74] appraising large amounts of epidemiologic and observational evidence suggest that flavonoids in chocolates may lower the risk of CHD mortality. Crude approximations suggest that eating 50 g of dark chocolate per day may reduce one's risk of CVD by 10.5% (95% CI 7.0–13.5%). However, these estimates were based on results from studies of short duration, extrapolated to long-term CVD outcomes. Long-term randomized feeding trials, beyond short-term studies of CVD risk factor intermediates, are warranted to investigate the impact of chocolate consumption on cardiovascular outcomes.

Phenolics in red wine were shown to be able to inhibit the oxidation of LDL *in vitro* and this was suggested as an explanation of the "French paradox".[75] The Zutphen study, an epidemiologic study in The Netherlands, suggested an inverse correlation between the incidence of CHD and stroke and the dietary intake of flavonoids, especially quercetin.[76]

Green tea polyphenols have been studied extensively as CVD chemopreventive agents. A population-based prospective cohort study (the Ohsaki Study) examined the association between green tea consumption and mortality from CVD, cancer and all causes with 40 530 persons in Miyagi Prefecture, in northern Japan.[77] Green tea consumption was inversely associated with mortality from CVD and this inverse association was more pronounced in women ($P = 0.08$ for interaction with sex). Kuriyama[78] reviewed the association between green tea or green tea extracts and CVD risk profiles and reported that more than half of the trials have demonstrated the beneficial effects of green tea on CVD risk profiles. These results suggest a plausible mechanism for the beneficial effects of green tea.

Sesso et al[79] determined whether the intake of lycopene or tomato-based foods is associated with the risk of CVD in a prospective cohort of 39 876 middle-aged and older women initially free of CVD and cancer. They found that the dietary lycopene was not strongly associated with the risk of CVD. However, some inverse associations for CVD, noted for higher levels of tomato-based products, particularly tomato sauce and pizza, suggested that dietary

lycopene or other phytochemicals consumed as oil-based tomato products could confer cardiovascular benefits.

The conflict between diet-based observational studies and clinical trials employing supplements may arise because of one or more explanatory factors: confounding, interactions/synergistic activity (among antioxidants; with other nutrients), isomers with differing activity in food compared to supplements, other associated protective elements in natural foods (e.g. flavonoids, phytoestrogens) and/or temporal dissociation of antioxidant blood levels from fat intake in meals, when administered as once-daily pills. While the failure of pill supplementation does not necessarily exclude protective effects of dietary antioxidants, current evidence does not support supplementation of any of these antioxidant vitamins for prevention of CHD. However, intake of their primary food resources, especially fruit and vegetables, may be encouraged.

Folate

The relationship of folate to CVD has been mostly explored through its effect on homocysteine (HCY), which has been incriminated as an independent risk factor for CHD and probably stroke.[80–83] Folic acid is required for the methylation of homocysteine to methionine. Reduced plasma folate has been strongly associated with elevated plasma homocysteine levels and folate supplementation has been demonstrated to decrease those levels.[84] However, the role of homocysteine as an independent risk factor for CVD has been subject to debate, in view of the data from several prospective studies which did not find this association to be independent of other risk factors.[85] Furthermore, clinical trials such as the Norwegian Vitamin Trial (NORVIT),[86] Vitamin Intervention for Stroke Prevention (VISP)[87] and HOPE-2[88] showed that, even though vitamin supplementation reduced HCY levels, there was no significant effect on cardiovascular risk. It has also been suggested that elevation of plasma HCY is a consequence and not a cause of atherosclerosis, wherein impaired renal function due to atherosclerosis raises plasma HCY levels.[89] At present, we cannot recommend the use of vitamin supplementation to reduce CVD risk.

Minerals: blood pressure and cardiovascular disease

Sodium

High blood pressure (HBP) is a major risk factor for CHD and both forms of stroke (ischemic and hemorrhagic). The relative risk of CVD for both systolic and diastolic blood pressures operates in a continuum of increasing risk for rising pressure but the absolute risk of CVD is considerably modified by co-existing risk factors.[90] Of the many risk factors associated with high blood pressure, the dietary exposure most investigated has been daily sodium consumption. It has been studied extensively in animal experimental models, in epidemiologic studies, controlled clinical trials and in population studies on restricted sodium intake.[90] Salt or sodium intake has been directly correlated with mean blood pressure levels and prevalence of hypertension in many populations. Comprehensive epidemiologic evidence was provided by the INTERSALT Study[91,92] which investigated the relationship of 24-hour urinary electrolyte excretion to blood pressure in 52 population groups across 32 countries, using standardized methodology to provide comparable data. In adults aged 20–59 years, there was a significant positive relationship between urinary sodium excretion and blood pressure across the 52 population samples. Further, it was also observed that in four of these populations in whom the mean 24-hour urinary sodium excretion was lower than 100 mmol/day, systolic blood pressure did not rise with age.[93]

The effects on blood pressure levels of increased sodium consumption accompanying urbanization were demonstrated in the Kenyan Luo Migration Study wherein rural farmers who traditionally consumed a low-salt diet were observed to have an elevation of blood pressure when they migrated to an urban environment. These migrants exhibited blood pressure levels higher than rural controls and comparable to levels observed in Western populations.[94] This rise in blood pressure was related to an increase in salt consumption and a reduced dietary intake of potassium. An overview of observational data in populations suggested that a difference in sodium intake of 100 mmol/day could be associated with average differences in systolic blood pressure of 5 mmHg at age 15–19 years and 10 mmHg at 60–69 years.[95] Diastolic blood pressures are reduced by about half as much, but the association increases with age and the magnitude of the initial blood pressure. It was estimated that a universal reduction in dietary intake of salt by 50 mmol/day would lead to a 50% reduction in the number of people requiring antihypertensive therapy, a 22% reduction in number of deaths due to strokes and a 16% reduction in number of deaths from coronary heart disease.[95]

A cohort study in Finland prospectively followed 1173 men and 1263 women aged 25–64 years, with complete data on 24-hour urinary sodium excretion and cardiovascular risk factors.[96] The hazard ratios for CHD, CVD and all-cause mortality, associated with a 100 mmol increase in 24-hour urinary sodium excretion, were 1.51 (95% CI 1.14–2.00), 1.45 (1.14–1.84) and 1.26 (1.06–1.50) respectively, in both men and women. The frequency of acute coronary events, but not acute stroke events, rose significantly with increasing sodium excretion. Disaggregated analyses revealed significant risk ratios in men only and revealed

that sodium predicted mortality in men who were over-weight. Despite the limitations of such subgroup analyses, the overall association of increasing sodium excretion with CVD and all-cause mortality further supports the evidence linking increased sodium intake to adverse cardiovascular health outcomes.

Several clinical intervention trials, conducted to evaluate the effects of dietary salt reduction on blood pressure levels in hypertensive and normotensive individuals, have been systematically reviewed.[12,97] Many of the earlier trials were of limited size and short duration and were deficient in statistical power. Based on an overview of 32 methodologically adequate trials (22 in hypertensive subjects and 12 in normotensive persons), Cutler *et al*[12] concluded that a daily reduction in intake of sodium by 70–80 mmol was associated with a lowering of blood pressure in both hypertensive and normotensive individuals, with systolic and diastolic blood pressure reductions of 4.8/1.9 mmHg in the former and 2.5/1.1 mmHg in the latter. Clinical trials have also demonstrated the sustained blood pressure lowering effects of sodium restriction in infancy,[98] as well as in the elderly in whom it provides a useful non-pharmacologic therapy.[99] In a 3-year study of salt restriction by Cook *et al*,[100] the Trials of Hypertension Prevention (TOHP), Phase II, participants had a decrease in systolic blood pressure (1.3 mmHg, $P = 0.02$) that corresponded with a significant dose-dependent reduction in sodium excretion. The Trial of Nonpharmacologic Interventions in the Elderly (TONE) was the first multicenter clinical trial of sufficient size and duration to show that lifestyle modifications can be used to control high blood pressure in older people. In elderly participants, sodium restriction resulted in mean reductions of 4.3 mmHg ($P < 0.001$) and 2.0 mmHg ($P = 0.001$) in systolic and diastolic blood pressure, respectively.[101]

The effect of a multi-component lifestyle intervention that includes the combination of sodium restriction, the DASH diet, weight loss and regular aerobic exercise was evaluated in the Diet, Exercise, and Weight Loss Intervention Trial (DEW-IT).[102] After 9 weeks, systolic and diastolic blood pressures were decreased by 12.1 mmHg ($P < 0.001$) and 6.6 mmHg ($P < 0.001$) respectively in the intervention participants compared with those in the control group. In subjects with above optimal blood pressure, the PREMIER trial showed that those in the "established recommendations" or "established + DASH diet" intervention groups had significant weight loss and reduction in sodium intake; both groups achieved greater reductions in systolic and diastolic blood pressure than did patients in the "advice only" group.[103]

The results of the low sodium – DASH diet trial[104] further strengthen the conclusion that reduction of daily sodium intake, through salt-restricted diets, lowers blood pressure effectively and is additive to the benefits conferred by the DASH diet. This trial revealed that low-sodium diets, with 24-hour sodium excretion levels around 70 mmol/day, are effective and safe. Sodium consumption has also been linked to the presence of left ventricular hypertrophy and restricted sodium intake has been demonstrated to result in regression of this important indicator of cardiovascular risk.[105,106] Of three population studies on restriction of salt, two (the Portuguese Salt Trial and the Tianjin trial in China) revealed significant reductions in blood pressure in the intervention group, while the third (the Belgian Salt Intervention Trial) did not reveal success because of difficulties in reducing salt consumption.[107–109] Animal models as well as ecologic associations derived from the INTERSALT study suggest a direct relationship between sodium consumption and the risk of stroke, though the methodology employed in these studies is not strong.[109,110]

Based on the observational and trial data so far available, it would be justified to recommend a salt intake of less than 5 g/day.[104] Such advice would be appropriate even in tropical climates, as sodium homeostasis regulates sodium excretion in sweat and urine without adverse effects under such conditions.

Potassium

Cardioprotective effects of dietary potassium have been hypothesized as the basis for low CVD rates in populations consuming "primitive" diets and in vegetarians in industrialized cultures.[111] The INTERSALT study provided evidence of an inverse association between urinary potassium excretion and blood pressure levels, across diverse populations.[91] Migrant studies also revealed a rise in blood pressure when diets changed to a lower potassium and higher sodium intake.[94]

A protective effect of potassium on blood pressure was suggested by clinical studies reporting that severe short-term potassium restriction induces salt sensitivity in normotensive humans,[112] as well as the blood pressure lowering effect of potassium supplements to the diet (ranging from 24 to 104 mmol/day) in hypertensive subjects.[111] Whelton *et al* concluded, from a meta-analysis of randomized controlled trials, that potassium supplements reduced mean blood pressures (systolic/diastolic) by 1.8/1.0 mmHg in normotensive subjects and 4.4/2.5 mmHg in hypertensive subjects.[113] An increase in dietary intake of potassium, from approximately 60 to 80 mmol/day, was shown to be inversely and significantly related to the incidence of stroke mortality in women.[114]

While dietary potassium has been shown to have protective effects on blood pressure and CVD, there is no evidence to suggest that long-term potassium supplements should be administered for cardiovascular protection. Supplemental potassium has the potential for toxicity and adequate dietary intake of potassium, though foods rather than supplements should be the preferred pathway for

For sodium

Reducing dietary sodium is associated with a fall in blood pressure in hypertensive and normotensive individuals. This is supported by good evidence in the scientific literature to indicate that:

- a reduction in dietary sodium from 140 to 100 mmol/day is associated with a fall in systolic blood pressure of 2 mmHg from an average systolic blood pressure of 135 mmHg
- a reduction in dietary sodium from 140 to 65 mmol/day is associated with a fall in systolic blood pressure of 7 mmHg from an average systolic blood pressure of 135 mmHg
- a reduction in dietary sodium of approximately 75 mmol/day is associated with a fall in systolic blood pressure of 4–5 mmHg in hypertensive individuals (baseline systolic blood pressure = 140 mmHg) and a fall in systolic blood pressure of 2 mmHg in normotensive individuals (baseline systolic blood pressure <120 mmHg).

There is moderate evidence in the scientific literature to indicate that:

- high dietary sodium intake is associated with increased stroke incidence, and mortality from coronary heart disease and cardiovascular disease.

For potassium

Increasing dietary potassium is associated with a fall in blood pressure in hypertensive and normotensive individuals. This is supported by good evidence in the scientific literature to indicate that:

- an increase in dietary potassium intake of approximately 54 mmol/day is associated with a fall in systolic blood pressure of 4–8 mmHg in hypertensive individuals (baseline systolic blood pressure = 140 mmHg) and a fall in systolic blood pressure of 2 mmHg in normotensive individuals (baseline systolic blood pressure <120 mmHg).

There is moderate evidence in the scientific literature to indicate that:

- High potassium intake is associated with decreased stroke mortality.

For Sodium/Potassium ratio

There is weak evidence in the scientific literature to indicate that:

- Blood pressure responsiveness to increased dietary potassium intake is greater in subjects with high sodium intake
- Blood pressure responsiveness to decreased sodium intake is greater in subjects with low potassium intake

cardiovascular potential. The beneficial effects of fruit and vegetables recommend their regular use in daily diets at a level that should assure an adequate intake of dietary potassium.

Calcium and magnesium

A meta-analysis of studies involving calcium supplements reveals modest effects on blood pressure. The estimated blood pressure reduction was 2.1 mmHg for systolic blood pressure and 1.1 mmHg for diastolic blood pressure.[116] There is weak evidence in the scientific literature to indicate that an increase in calcium intake reduces the risk of ischemic stroke.[115]

A review of 29 studies of magnesium was inconclusive due to methodologic problems but suggested that there was no negative association of blood pressure with magnesium.[117] There is presently no evidence to recommend public health or clinical interventions involving the use of these minerals for cardiovascular protection in populations or individuals, other than in the form of a balanced diet providing an adequate daily intake.

Food items and food groups

Fruits and vegetables

While the consumption of fruit and vegetables has been widely believed to promote good health, evidence related to their protective effect has only been presented in recent years.[118–120] A systematic review reported that nine of 10 ecologic studies, two of three case–control studies and six of 16 cohort studies found a significant protective association for coronary heart disease with consumption of fruit and vegetables or surrogate nutrients.[120] For stroke, three of five ecologic studies and six of eight cohort studies found a significant protective association.[120]

A 5-year follow-up study of 39876 female health professionals[121] observed a significant inverse association between fruit and vegetable intake and CVD risk. For increasing quintiles of total fruit and vegetable intake, the relative risks were 1.0, 0.78, 0.72, 0.68 and 0.68. After excluding participants with a self-reported history of diabetes, hypertension or high cholesterol at baseline, the multivariate adjusted relative risk was 0.45 when extreme quintiles were compared (95% CI 0.22–0.91). In a 12-year follow-up of 15220 male physicians in United States,[122] men who consumed at least 2.5 servings of vegetables/day were observed to have an adjusted relative risk of 0.77 for coronary heart disease, compared with men in the lowest category (<1 serving per day). Combining analyses of data from two large prospective cohort studies of women and men respectively, Joshipura et al[123] reported that overall fruit and vegetable consumption were inversely related to the risk of ischemic stroke after adjusting for confounders. Assessed as a continuous trend, an increment of one serving/day was associated with 6% lower risk of ischemic stroke among men and women combined. When analyzed

separately for the type of fruit and vegetables, the lowest risks were observed for high consumption of cruciferous vegetables such as Brussels sprouts, cabbage and cauliflower, green leafy vegetables, citrus fruits, vitamin C-rich fruits and vegetables.

The effects of increased fruit and vegetable consumption on blood pressure, alone or in combination with a low-fat diet, were assessed in the DASH trial.[124] While the combination diet was more effective in lowering blood pressure, the fruit and vegetable diet also lowered the blood pressure in comparison to the control diet (2.8 mmHg systolic and 1.1 mmHg diastolic). Such reductions, while seeming modest at the individual level, would result in a substantial reduction in population-wide risk of CVD by shifting the blood pressure distribution.

As per a recent review by Winkler,[125] the nature of the relationship does not appear to follow a strict dose–response pattern, but generally does show additional risk reduction with increases in fruit and vegetable intake (Table 23.1).

The bulk of evidence supports an inverse association between fruit and/or vegetable consumption and CHD. Fruits and vegetables, being low in energy, sodium, saturated fat and total fats, bring about a reduction in obesity, blood pressure and serum lipids as a result of replacing "less healthy" alternative foods in the diet. Thus the benefits of a plant-based diet, rich in fruit and vegetables, may derive from protective phytonutrients, high fiber content and replacement value of substitution for atherogenic or obesogenic foods, all contributing in concert.

Fish

Most, but not all, population studies have shown that fish consumption in populations is associated with a reduced risk of CHD.[126–128] A systematic review concluded that the discrepancy in the studies may be due to differences in the populations studied, with only high-risk individuals benefiting from increasing their fish consumption.[128] It was estimated that, in high-risk populations, an optimum fish intake estimated at 40–60 g/day would lead to approximately a 50% reduction in death from coronary heart disease. In the Diet and Reinfarction Trial, 2-year mortality was reduced by 29% in survivors of a first myocardial infarction receiving advice to consume fatty fish at least twice a week.[129] While the protective effects of fish on CHD are principally mediated by n-3 PUFAs, the contribution of other constituents of fish cannot be ruled out. The effect of dietary fish on the risk of stroke has been investigated in cohort studies, with conflicting results on the risk of ischemic stroke.[130,131] An ecologic study reported that fish consumption is associated with a reduced risk of death from all causes as well as CHD and stroke mortality, using data from 36 countries.[132]

In addition to the Nurses' Health Study[133] and the Health Professionals Follow-up Study,[134] other prospective cohort studies[135,136] also exhibited an inverse association between increasing omega-3 consumption and the risk of stroke. In multivariate analyses, tuna, broiled or baked fish consumption was inversely associated with total stroke ($P = 0.04$) and ischemic stroke ($P = 0.02$). There was a 13% lower risk of ischemic stroke with an intake of 1–3 times per week (relative risk (RR) 0.87), a 27% lower risk with an intake of 1–4 times per week (RR 0.73) and 30% lower risk with intake of five or more times per week (RR 0.70), compared with an intake of less than once per month.[135]

Omega-3 can reduce the incidence of atrial fibrillation (AF) in the elderly[137] and in patients undergoing coronary bypass surgery.[138] In a randomized, double-blind, placebo-controlled study of 65 patients with cardiac arrhythmias without coronary heart disease or heart failure, Singer et al[139] supplemented patients with 3 g daily fish oil or olive oil over 6 months. In the fish oil group, the incidence of atrial and ventricular premature complexes was reduced by 47% and 68% respectively; couplets were reduced by 72% and triplets entirely disappeared. Other studies[140–142] also support a preventive role of omega-3s in arrhythmias and sudden death.

Two meta-analyses[143,144] further support an inverse association between omega-3 and CHD. He et al[143] assessed 222 364 individuals with an average 11.8 years of follow-up. The pooled multivariate RRs for CHD mortality were 0.89 for fish intake 1–3 times per month, 0.85 for once per week, 0.77 for 2–4 times per week and 0.62 for five or more times per week. Each 20 g/day increase in fish intake corroborated to a 7% lower risk of CHD mortality (P for trend = 0.03). Whelton et al[144] conducted a meta-analysis of 19 observational studies (14 cohort and five case–control). Fish consumption versus little to no fish consumption was associated with a RR of 0.83 ($P < 0.005$) for fatal CHD and 0.86 ($P < 0.005$) for total CHD.

Hooper et al[145] reported no benefit of omega-3 in relation to total or CV mortality in a meta-analysis. The inclusion of the Diet and Reinfarction Trial-2,[146] which reported an increase in sudden death with fish and fish oil intake, contributed substantial heterogeneity to the meta-analysis. The results are also at variance with DART-1, in which fish or fish oil supplementation decreased mortality by 29% over a 2-year period.[147] The omission of the DART-2 trial from the analysis provided an overall RR of death of 0.83 (CI 0.75–0.91) with no significant heterogeneity.

Thus, convincing evidence exists that supplemental omega-3 fatty acids in relatively high doses of about 1 g per day modestly reduce blood pressure and triglycerides but, to date, this has not resulted in a consistent reduction in CVD risk in well-designed randomized controlled trials.[148–150]

Table 23.1 Summary of findings related to association between consumption of fruits and vegetables and oucomes related to coronary heart disease

Nuts

Five large epidemiologic studies have, thus far, demonstrated that frequent consumption of nuts was associated with decreased risk of CHD, the best known among them being the Adventist Health Study.[151–154] The RR ranged from 0.43 to 0.82 for subjects who consumed nuts more than five times/week compared to those who never consumed nuts. An inverse dose–response relationship was demonstrated between the frequency of nut consumption and the risk of CHD, in men and women. Most of these studies considered nuts as a group, combining many types of nuts.

The effect of specific nuts on lipid and lipoprotein endpoints was evaluated in several clinical studies. The nuts studied to date include walnuts, almonds, legume peanuts, macadamia nuts, pecans and pistachio nuts.[151] Collectively, these clinical studies indicate that inclusion of nuts in a lipid-lowering diet has favorable effects, but do not provide unequivocal evidence of an additive effect of nuts to the effects of a low saturated fat diet *per se*. The fatty acid profile of nuts (high in unsaturated fatty acids and low in saturated fatty acids) contributes to cholesterol lowering by altering the fatty acid composition of the diet as a whole. Nuts are also a rich source of dietary fiber. It must, however, be recognized that the high fat content of nuts makes them high in calorie content and advice to include nuts in the diet must be tempered in accordance with the desired energy balance. While further research is needed to characterize the independent protective effects of nuts against CVD and identify the mechanisms of such protection, available evidence suggests that nuts should be recommended as part of an energy-appropriate healthy diet which is intended to reduce the risk of CHD.

In 2003, the FDA approved two qualified health claims for nuts, one for nuts in general and another for walnuts.[155] The approved language is as follows: "'Scientific evidence suggests but does not prove that eating 1.5 oz (42 g) per day of most nuts, as part of a diet low in saturated fat and cholesterol, may reduce the risk of heart disease". This health claim language was consumer tested and found to be ranked significantly higher than the FDA generic claim for clarity and understandability. In order for a food to qualify for the health claim, the product must contain 11 g or more of whole or chopped nuts per reference amount customarily consumed (a standardized serving size). Any nuts labeled with the claim must contain no more than 4 g saturated fat per 50 g. Eligible nuts for the claim include almonds, hazelnuts, peanuts, pecans, some pine nuts, pistachio nuts, and walnuts.[156,157]

Soy

Several trials indicate that intake of soy has a beneficial effect on plasma lipids.[158,159] A composite analysis of 38 clinical trials found that an average consumption of 47 g of soy protein a day led to a 9% decline in total cholesterol and a 13% decline in LDL cholesterol in subjects free of CHD.[158] The benefit of soy consumption was associated with baseline cholesterol levels, such that those with the highest cholesterol levels derived the maximum benefit (subjects with total cholesterol >335 mg/dL showed a 19% reduction in total and 24% reduction in LDL cholesterol). Cholesterol lowering of this magnitude could potentially reduce the risk for CHD by 20–40%.

Soy is rich in isoflavones, compounds that are structurally and functionally similar to estrogen. Several animal experiments suggest that intake of these isoflavones may provide protection against CHD[160] but human data on efficacy and safety are still awaited. Naturally occurring isoflavones, isolated with soy protein, reduced the plasma concentrations of total and LDL cholesterol without affecting the concentrations of triglycerides or HDL cholesterol in mildly hypercholesterolemic individuals, in a casein-controlled clinical trial.[161]

A very large amount of soy protein, more than half the daily protein intake, may lower LDL cholesterol by a few percentage points when it replaces dairy protein or a mixture of animal proteins.[162] The evidence favors soy protein rather than soy isoflavones as the responsible nutrient. No benefit is evident on HDL cholesterol, triglycerides, lipoprotein (a) or blood pressure. Thus, the direct cardiovascular health benefit of soy protein or isoflavone supplements is minimal at best. For this reason, use of isoflavone supplements in food or pills is not recommended. In contrast, soy products such as tofu, soy butter, soy nuts or some soy burgers should be beneficial to cardiovascular and overall health because of their high content of polyunsaturated fats, fiber, vitamins, and minerals, and low content of saturated fat. Using these and other soy foods to replace foods high in animal protein that contain saturated fat and cholesterol may confer benefits to cardiovascular health.[163] Soy protein also may be used to increase total dietary protein intake and to reduce carbohydrate or fat intake.

Garlic

Zhang *et al*[164] reported that gender might affect the action of garlic on plasma cholesterol and glucose levels of normal subjects. A systematic review of the effectiveness of garlic as an antihyperlipidemic agent included 10 studies and found that in six studies garlic was effective in reducing serum cholesterol levels. The average drop in total cholesterol was 9.9%, LDL 11.4%, and triglycerides 9.9%.[165] Other direct cardioprotective effects of garlic in humans have also been reported, such as a decrease in unstable angina,[166] an increase in the elastic property of blood vessels,[167] and a decrease in peripheral arterial occlusive disease.[168] In

addition, garlic has been shown to increase peripheral blood flow in healthy subjects[169] while inhibiting the progression of coronary calcification in patients receiving statin therapy.[170] Rahman and Lowe[171] concluded in their review that although garlic appears to hold promise in reducing parameters associated with cardiovascular disease, more in-depth and well-designed studies are required.

Dairy products

Milk and milk products are important contributors to dietary fat and can be high in saturated fat and cholesterol. They are also sources of minerals like potassium, magnesium and calcium. Milk protein has been implicated in a study reporting elevated levels of antibodies to milk protein in patients with myocardial infarction in comparison with healthy controls.[172] Dairy consumption has been correlated positively, in an ecologic study, with blood cholesterol as well as coronary mortality. Milk consumption correlates positively with coronary mortality rates in 43 countries and with myocardial infarction in 19 regions of Europe.[173,174] In contrast, a population-based study in men of Japanese ancestry in Honolulu reported a reduced risk of ischemic stroke in older middle-aged men, which could not be explained by the intake of dietary calcium.[175]

On the basis of presently available evidence, reduced intake of high-fat dairy foods should be recommended for cardiovascular protection. Whether milk or milk products modified to substantially lower the content of saturated fat are associated with an increase or decrease in cardiovascular risk cannot be commented upon at present. They formed a component of the DASH diet which significantly lowered blood pressure and may be considered as part of a composite dietary advice.

Alcohol

Alcohol is both a nutrient supplying 29 kJ/g and a drug that is a central nervous system depressant.[176] The relationship of alcohol to overall mortality and cardiovascular mortality has generally been J-shaped, when studied in Western populations in whom the rates of atherothrombotic vascular disorders are high.[177–181] The protective effect of moderate ethanol consumption is primarily mediated through its effect on the risk of CHD, as supported by more than 60 prospective studies.[178] A consistent coronary protective effect has been observed for consumption of 1–2 drinks per day of an alcohol-containing beverage but heavy drinkers have higher total mortality than moderate drinkers or abstainers, as do binge drinkers. Moderate alcohol consumption (up to two drinks per day) has also been associated with a reduced risk of ischemic stroke in men and women.[182] Long-term heavy alcohol consumption (>60 g/day) increases an individual's risk for all stroke subtypes.

Several mechanisms for the cardioprotective effects of alcohol have been proposed: increase in plasma HDL cholesterol; reduced platelet aggregation or clotting; enhanced fibrinolysis; phenolic constituents of some alcoholic beverages acting as antioxidants or platelet inhibitors.[183] Genetic variations which slow alcohol metabolism have been shown to increase HDL cholesterol and reduce the risk of myocardial infarction.[4] Based on current evidence, the benefit of moderate alcohol consumption seems to be a generic effect regardless of the type of beverage.[184] While the specific advantages of red wine over other alcoholic beverages are unproven, the claimed beneficial effects of flavonoids on lipoprotein oxidation are available from grape juice as from wine.[185]

Certain subgroups have a lower risk of coronary heart disease associated with alcohol intake. These include postmenopausal women and men over the age of 45 years.[186] In these groups, light and moderate drinking of alcohol has consistently been associated with lower risk of coronary heart disease.[187–189]

A systematic review of ecologic, case–control and prospective studies concluded that all alcoholic drinks were linked with a lower risk of coronary heart disease.[190] However, beyond three drinks per day for men and two per day for women, the disadvantages of alcohol consumption rapidly outweigh the advantages.[191] This is especially true for those at low risk of death from coronary heart disease. In younger populations, drinking larger amounts of alcohol in one session is associated with injuries and cardiovascular heart disease mortality.[192]

The possible beneficial effects of moderate ethanol consumption must be weighed against the deleterious effects of high intake, including increased risk of hypertension, cardiomyopathy and hemorrhagic stroke. Alcohol consumption, in excess of three drinks per day, is associated with a rise in blood pressure and plasma triglyceride levels. Reduction or cessation of alcohol consumption is a widely recommended measure for non-pharmacologic therapy of hypertension, in many international guidelines. The recommendations related to alcohol should be made in accordance with the cultural practices of the populations and the clinical profile of individuals, with advice to avoid excess in all cases. The optimal intake, for cardiovascular protection, depends on age, gender, presence of other risk factors or associated diseases and on the intake of folic acid. However, it is generally recommended to be about two drinks a day for men and one a day for women.

Eggs

Eggs are unique because of their high cholesterol content. Major effects on atherosclerosis are observed in experimental animals but extrapolation to humans is doubtful. A large

observational study suggested that there was no increase in the risk of CHD up to one egg per day (except in a diabetic subgroup), in the US population.[193] In terms of global recommendations, it may still be prudent to limit the intake to 3–4 eggs/week. With all the trimmings, a three-white egg omelet is almost indistinguishable by taste from an omelet enriched with 600 mg cholesterol, and the whites-only omelet also remains a very good source of protein, riboflavin, and selenium.[194]

Djoussé and Gaziano[195] have calculated an adjusted hazard ratio of 1.41 for all-cause mortality over a 20-year span in 21 327 Harvard-educated male physicians who ate ≥1 egg/day. It is important that a pattern of less frequent intake did not influence risk. However, if diabetes was co-existent in these healthcare professionals, a trend existed across a broader range of egg consumption. The egg intake pattern in this study population was extremely low: only 8% of participants were eating ≥1 egg/day. For comparison, 36% of the men in the Framingham Study[196] and 37% of men in a Japanese study[197] with similar outcome assessments ate ≥1 egg/day. However, in both these cohorts, there was no association between egg consumption and myocardial infarction, CVD death or all-cause mortality. Yet, this much higher consumption pattern may has confounded a graded effect that occurred at lower egg intakes.

Data from the most recent National Health and Nutritional Examination Survey (NHANES III, 1988–94) were utilized by Song and Kerver[198] to compare the nutritional quality indicators of diets that contained eggs (USDA food grouping system) with those that did not. In this cross-sectional and population-based study, egg consumption made important nutritional contributions to the American diet and was not associated with high serum cholesterol concentrations.

Dietary patterns and composite dietary interventions

The Mediterranean diet

The traditional Mediterranean diet has been described to have eight components:
1 high monounsaturated-to-saturated fat ratio
2 moderate ethanol consumption
3 high consumption of legumes
4 high consumption of cereals (including bread)
5 high consumption of fruits
6 high consumption of vegetables
7 low consumption of meat and meat products
8 moderate consumption of milk and dairy products.[118]
Most of these are found in many diets. The characteristic component is olive oil, and many equate a Mediterranean diet with consumption of olive oil.

Based on ecologic comparisons, Keys *et al*[199] hypothesized that a traditional Mediterranean diet conferred protection against CVD and several other disorders, principally because of a low saturated fat content. Three prospective population studies in Greece, Denmark and Australia provided supportive evidence of protective effects on overall mortality.[200] However, this traditional form of Mediterranean diet has not been tested in controlled clinical trials.

A secondary prevention trial of dietary intervention in survivors of a first recent myocardial infarction, which aimed to study the cardioprotective effects of a Mediterranean type of diet, actually left out its most characteristic component, olive oil.[201] This diet was designed to supply <35% of energy as fat, <10% of energy as saturated fat, <4% of energy as linoleic acid (n-6) and >0.6% of energy as alpha-linolenic acid (n-3). The main fat source was rapeseed oil. Vegetables and fruits were also increased in the diet. Two major biologic factors were modified by the intervention: plasma levels of alpha-tocopherol and ascorbic acid were elevated and plasma n-3 fatty acids increased, along with a decrease in n-6 fatty acids. Other biologic mediators of altered risk, like flavonoids, folate and minerals like potassium, were probably altered but not measured. While the initial publication reported a 70% reduction in recurrence of myocardial infarction and cardiac death, the 4-year follow-up study reported a 72% reduction in cardiac death and non-fatal myocardial infarction. The risk of overall mortality was lowered by 56%.[9]

In the Mediterranean Diet, Cardiovascular Risks and Gene Polymorphisms (Medi-RIVAGE) study, the effects of a Mediterranean-type diet (Med group) or a low-fat diet (low-fat group) on risk factors were evaluated in 212 volunteers (men and women) with moderate risk factors for cardiovascular disease. After a 3-month intervention, both diets significantly reduced cardiovascular disease risk factors to an overall comparable extent.[202]

Vegetarian diets

A reduced risk of CVD has been reported in populations of vegetarians living in affluent countries[203–205] and in case–control comparisons in developing countries.[206] Reduced consumption of animal fat and increased consumption of fruit, vegetables, nuts and cereals may underlie such a protective effect. However, vegetarian diets *per se* need not be healthful.[205] If not well planned, they can contain a large amount of refined carbohydrates and trans fatty acids while being deficient in the levels of vegetable and fruit consumption. The composition of the vegetarian diet should, therefore, be defined in terms of its cardioprotective constituents rather than endorsing the "vegetarian" label as an omnibus category.

"Prudent" versus "Western" patterns

Using factor analysis on a 131-item food frequency questionnaire, Hu *et al* identified two major dietary patterns at baseline in 44 875 men followed up for 8 years in the Health Professionals Follow-up Study.[207] The "prudent" pattern was characterized by higher intake of vegetables, fruit, legumes, wholegrains, fish and poultry whereas the "Western" pattern was characterized by higher intake of red meat, processed meat, refined grains, sweets and dessert, French fries and high-fat dairy products. After adjustment for age and other coronary risk factors, relative risks, from the lowest to the highest quintiles of the prudent pattern score, were 1.0, 0.87, 0.79, 0.75 and 0.70. In contrast, the relative risks across increasing quintiles of the Western pattern were 1.0, 1.21, 1.36, 1.40 and 1.64. These associations persisted in subgroup analyses according to cigarette smoking, Body Mass Index and parental history of myocardial infarction.

Japanese diet

The traditional Japanese diet has attracted much attention because of the highest life expectancy and low CHD mortality rates among the Japanese.[208] This diet is low in fat and sugar and includes soy, seaweeds, raw fish and a predominant use of rice. It has been high in salt, but salt consumption has recently been declining in response to Japanese Health Ministry guidelines. There is also a recent trend towards increased fat consumption and plasma cholesterol levels have risen, and their effects on CHD and CVD mortality rates need to be watched.

DASH diets

The effects of composite dietary interventions on blood pressure levels, in "normotensive" and "hypertensive" individuals, were studied in well-designed clinical trials.[104,124] The initial dietary intervention, used in the Dietary Approaches to Stop Hypertension (DASH) trial, involved a diet that emphasized fruits, vegetables and low-fat dairy products and included wholegrains, poultry, fish and nuts while reducing the amounts of red meat, sweets and sugar-containing beverages. Two variants of the intervention diet were used: a fruit and vegetables (F-V) diet and a low fat F-V (DASH) diet. The latter was designed to lower the intake of total and saturated fat as well as dietary cholesterol. In comparison with a "typical" diet in the United States, both intervention diets lowered blood pressure but the DASH diet was more effective in substantially reducing systolic and diastolic blood pressures, both in people with and those without hypertension.[104] The DASH diet was also demonstrated to be effective as first-line therapy in individuals with stage I isolated systolic hyper-

tension (i.e. with a systolic blood pressure of 140–159 mmHg and a diastolic blood pressure below 90 mmHg), with 78% of those on the DASH diet reducing their systolic blood pressure to <140 mmHg, in comparison to 24% in the control group.[209] The DASH diet resulted in lowering plasma levels of total cholesterol and LDL cholesterol but these changes were also accompanied by a reduction in HDL cholesterol levels.[210] While the Framingham risk score improved as a result of the impact on total and LDL cholesterol as well as blood pressure, the impact of the associated reduction in HDL cholesterol needs to be assessed.

The DASH trial was followed by a well-designed factorial trial combining the DASH diet with high, intermediate and low levels of sodium consumption and measuring the effects on blood pressure, in comparison to a control diet typical of the United States, administered with similar graded variations in the sodium content.[124] Within each assigned group (DASH v typical), participants ate foods with high, intermediate and low levels of sodium for 30 consecutive days each, in random order. Reduction in sodium intake, at each level, resulted in significant lowering of systolic and diastolic blood pressures in both DASH and control groups. The fall was, however, maximal when the DASH diet was modified to reduce the sodium content. As compared with the control diet with a high sodium level, the DASH diet with a low sodium level led to a mean systolic blood pressure that was 7.1 mmHg lower in participants without hypertension and 11.5 mmHg lower in participants with hypertension (Fig. 23.3). There was also a −4.5 mmHg difference in the mean diastolic pressure level, between the low sodium-DASH diet phase and the high sodium-control diet phase of the trial.

The effects of the low sodium-DASH diet have great potential for application in both population-based and individual focused strategies for prevention and control of high blood pressure and associated CVD. Adoption of the low sodium-DASH diet, by populations at large, is
Figure 23.3 Effect of the low sodium DASH diet on systolic blood pressure.

likely to be safe and beneficial in shifting the population distributions of blood pressure (and plasma cholesterol) towards lower levels of cumulative risk of CVD in those populations. Similarly, this diet will also provide an effective non-pharmacologic therapeutic intervention in the clinical management of individuals identified to be at increased risk of CVD because of high blood pressure and associated risk factors.

Implications for policy

Diet and nutrition play a critical role in the causation of major CVDs and, along with physical activity, influence many of the biologic variables that mediate the risk of those diseases. There is, therefore, an opportunity to alter the direction and dimensions of the global CVD epidemic through policy interventions (at the local, national and global levels), which promote the availability, affordability and acceptability of health-promoting diets and restrain the marketing and consumption of unhealthy foods.

Currently available evidence strongly indicates that cardiovascular health is heavily influenced by the quality of dietary fat and the quantity of fruits and vegetables as well as salt consumed daily. While several other food items also contribute to enhanced or decreased risk of CVD, these remain the principal determinants of diet-related CVD risk. Whether derived from controlled clinical trials or an ecologic study of reasons for the sharp decline in coronary mortality in Poland since 1991, the evidence suggests that dietary changes can substantially alter the risk of CVD.[211,212] Policies must, therefore, address these directly and decisively.

These measures must encompass a wide range of educational as well as regulatory measures, acting through price and non-price mechanisms. That success in reducing CVD risk factor levels as well as CVD mortality is achievable through such measures that influence usual diet patterns is clear from the experience of developed countries.[213] Developing countries like Mauritius too have shown that population levels of CVD risk factors can be altered by a combination of community education and regulatory inter-

---

BOX 23.3 Dietary recommendations for cardiovascular health

- A low intake of saturated fatty acids (SFAs): less than 7% of daily energy intake (within these limits, intake of foods rich in myristic and palmitic acids should be especially reduced). Edible fat intake need not exceed 40 g and total fat intake should be limited to levels at which fat will provide no more than 20% of total energy. The use of ghee (clarified butter) should be restricted to special occasions and should not be a regular daily feature.
- A very low intake of trans fatty acids (hydrogenated oils and fats): less than 1% of daily energy intake.
- Adequate intake of polyunsaturated fatty acids (PUFAs): 6–10% of daily energy intake, with an optimal balance of n-6 PUFAs and n-3 PUFAs at 5–8% and 1–2% levels of daily energy intake, respectively.
- Intake of monounsaturated fatty acids (MUFAs) to make up the rest of daily energy intake from fats, with daily total fat intake ranging between 15% and 30% of daily energy intake (this may be based on current levels of population consumption in different regions and modified in accordance with age, activity and goals of body weight).
- While there is no evidence that links the quantity of dietary fat to CVD, independent of the effects of fat composition and unhealthy weight gain, there are concerns over potential excess energy consumption associated with an unrestricted fat intake. These support a recommendation that fat intake should not exceed 30% of daily energy intake. However, in very active groups with healthy dietary practices and stable healthy weight, fat intake may go up to 35% of energy.
- Dietary cholesterol consumption should be restricted to less than 300 mg per day, mainly through the restriction of dairy fats.
- Daily intake of fresh fruit and vegetables (including berries, green leafy and cruciferous vegetables and legumes), in an adequate quantity (400–500 g per day), is recommended to reduce the risk of CHD, stroke and high blood pressure.
- Restrict daily salt (sodium chloride) intake to less than 5 g per day. This should take into account total sodium intake from all dietary sources. Minimize other forms of sodium consumption such as as through food additives or preservatives, such as monosodium glutamate (MSG). Potassium intake should be at a level which will keep the sodium:potassium ratio close to 1, i.e. at daily potassium intake levels of 70–80 mmol per day. This may be achieved through adequate daily consumption of fruits and vegetables. Such a balance may also be obtained through use of potassium-enriched low-sodium salt substitutes.
- The consumption of fish and other marine foods should provide over 200 mg per day of docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA).
- Regular low to moderate consumption of alcohol (that is 1–2 drinks per day) is protective against CHD. Concerns about other cardiovascular and health risks associated with alcohol consumption (including stroke, hypertension and some cancers) do not favor a general recommendation for its use.

ventions related to the price of edible oils.[214] Measures to influence the quality of dietary fat (as well as the total quantity) consumed must address the elimination of trans fats and reduction of saturated fats from the daily diet. Governments must work with the food industry to influence production, processing, pricing and labeling of food products so that these goals can be met. Consumer education must be enhanced so that informed choices can be made, even as the availability of healthier foods is promoted through such measures. As market economy becomes a globally pervasive economic model, it must be recognized that markets are not autonomous entities and should be molded, for public good, by consumer consciousness as well as enlightened regulatory measures.

Recent initiatives in different regions of the world offer models for such policy interventions. The agreement between the food industry and the food standard authorities of UK, to progressively reduce the salt content in processed foods, is yielding results in terms of reduced salt consumption by the population.[215] The ban on trans fats in the restaurants of New York and for processed foods in Denmark exemplifies nutrition regulation in the interests of public health.[216] Food labeling, ranging from display of nutrient composition to "traffic lights" signals indicating the health-related nutrient profile of food products, is being practiced or proposed by an increasing number of countries. Voluntary or legally imposed restrictions on advertising of high-energy/low-nutrient beverages and foods to young people ("advertising code") are also on the anvil in the European Union. The WHO's Global Strategy on Diet and Physical Activity and Health (DPAS) provides guidelines for multisectoral policies which countries should implement to prevent CVD and other chronic diseases.[217] Policy interventions such as these do not as yet have the evidence of evaluated implementation to support them. However, the weight of scientific evidence which links salt, trans fats and refined sugars to high risk of CVD and other health disorders should be adequate to initiate such policies.

As these policies are progressively implemented, rigorous evaluation must be conducted to assess their impact. As Louis Pasteur exhorted his research students, "Keep your enthusiasm but let strict verification be its constant companion".

24 Integrating approaches to prevention of cardiovascular disease

David A Wood and Kornelia Kotseva

Cardiovascular Medicine, National Heart and Lung Institute, Imperial College, London, UK

Introduction and historical perspective

Cardiovascular diseases (CVD), of which coronary heart disease (CHD) is the most common, are the major causes of death in middle-aged and older people in most developed countries and in many developing countries.[1–3] Cardiovascular diseases result in substantial disability worldwide and contribute in large part to the escalating costs of healthcare, especially with an increasing aging population,[4] and are predicted to be the leading cause of death and disability-adjusted life-years by 2020.[5] A significant proportion of cardiovascular morbidity and mortality could be prevented through population strategies, and by making cost-effective clinical interventions accessible and affordable, both for people with established disease and for those at high risk of developing cardiovascular disease.[6,7]

This chapter is about integrating clinical approaches to prevention of cardiovascular disease for those with established atherosclerotic disease (secondary prevention) and those who are asymptomatic but at high risk of developing the disease (primary prevention).

The World Heart and Stroke Forum (WHSF) Guidelines Task Force of the World Heart Federation (WHF) recommends that every country develop a national policy on CVD prevention.[8] This national policy should set priorities for public health and clinical interventions appropriate to the country, and be the foundation for developing national evidence-based clinical guidelines on CVD prevention.

While the causes of CVD are common to all parts of the world, the approaches to cardiovascular prevention at a societal or individual level will differ between countries for cultural, social, medical, and economic reasons. Although national guidelines will share common principles of CVD prevention – the need for patient priorities, absolute risk

thresholds for treatment and treatment targets – they may differ in terms of the organization of preventive cardiology, risk factor treatment thresholds and targets, and the availability and use of cardioprotective medications.

Nomenclature and definitions

The World Health Organization report on prevention of coronary heart disease describes three strategies for prevention,[1] which still apply today but for all atherosclerotic cardiovascular disease. These three strategies complement each other:
- a 'population' strategy – for altering, in the entire population, the lifestyle and environmental factors, and their social and economic determinants, that are the underlying causes of the mass occurrence of CVD
- a 'high-risk' strategy – identification of individuals at high risk of developing the disease, and action to reduce their risk factor levels
- secondary prevention – prevention of disease progression and recurrent cardiovascular events in patients with clinically established coronary or other atherosclerotic disease.

The *secondary prevention* strategy addresses those who have survived the development of symptomatic atherosclerotic disease – acute coronary syndromes, angina, transient cerebral ischemia, stroke, peripheral arterial disease – with the object of reducing the risk of recurrent cardiovascular events, improving quality of life and life expectancy. However, it is necessarily limited to survivors. The first manifestation of CVD can be sudden collapse and death, e.g. ventricular fibrillation in the context of acute myocardial infarction. In addition, among those who survive the initial ischemic insult, the resulting tissue damage may be so great that secondary prevention offers little gain. This is because prognosis is largely determined by the extent of cardiac or cerebral damage. Therefore, a high-risk primary prevention strategy is required.

The *high-risk* strategy identifies those asymptomatic individuals in the population who are apparently well but at high multifactorial risk of developing CVD, with the object of reducing their total CVD risk through lifestyle, risk factor and therapeutic management. However, its overall impact on the burden of disease in the population is limited because it only targets those at highest risk whereas the burden of CVD arises in those at modest risk where medical interventions are not appropriate.

Therefore, a *population* strategy, which tackles the major determinants of cardiovascular diseases at a societal level, is paramount and without such a strategy, these diseases will remain a major cause of ill health and premature death, regardless of the fact that secondary prevention and high-risk strategies do reduce cardiovascular morbidity and mortality for individuals.

Incidence, natural history, and prognosis

Secondary prevention

The first clinical presentation of atherosclerotic disease is with sudden death or, more commonly, a non-fatal event, principally of the coronary arteries, cerebral arteries or peripheral arteries. Whatever the affected arterial territory, the pathology of the disease is the same and is usually ubiquitous. Although the acute management will differ according to the affected arterial territory, the ways of preventing a recurrence are common to all manifestations of atherosclerosis – lifestyle (smoking cessation, eating a healthy diet and being physically active), the management of other risk factors (blood pressure, lipids and glucose) and the use of cardioprotective drugs, some of which have specific clinical indications, e.g. beta-blockers following myocardial infarction, based on evidence from randomized controlled trials.

All patients with atherosclerotic cardiovascular disease should be eligible for a comprehensive prevention program. Traditionally, such programs have focused on patients with coronary disease, especially those following myocardial infarction or revascularization, usually by cardiac surgery. Yet the benefits of prevention demonstrated in those who have had a myocardial infarction are as likely to be achieved in patients with angina pectoris, stroke or other atherosclerotic disease. So the new challenge is to provide preventive cardiology programs for all atherosclerotic disease patients.

High-risk strategy

Primary prevention of CVD in individuals has traditionally focused on single risk factors, such as "hypertension", rather than multiple risk factors or the total risk approach and as a consequence, the potential benefits of total CVD

risk reduction have not been achieved. Although there is a continuous relationship between blood pressure and the risk of developing CVD, the higher the blood pressure, the higher the risk. The term "hypertension" dichotomizes this distribution into those with a blood pressure consistently greater than a specified level, e.g. 140/90 mmHg, and those with a blood pressure less than this level which is commonly referred to as "normal". The level of blood pressure defining "hypertension" is not based on the epidemiology of blood pressure and cardiovascular risk, but is rather deduced from randomized controlled trials which have shown evidence of benefit through reducing blood pressure in those with levels above, say, 140/90 mmHg. The consequence of this approach is that someone with a blood pressure of 142/92 mmHg is considered to be "hypertensive" and therefore receives blood pressure-lowering therapy, but another person of the same age and sex with a blood pressure of 138/88 mmHg is considered to be "normotensive" and therefore requires no treatment. Yet the total risk of developing CVD is not just a function of blood pressure but of all the cardiovascular risk factors taken together which are associated with a given level of blood pressure. This is called total cardiovascular risk. This term is used to describe the probability of a person developing an atherosclerotic cardiovascular event over a defined period of time.

The concept of total CVD risk assessment and management was first advanced by Jackson in 1993 in the context of treating "hypertension"; namely, the indication for treating blood pressure was not just a function of the blood pressure level but rather the absolute CVD risk, based on a combination of all risk factors, of which blood pressure was just one component.[9] This was followed in 1994 and 1998 by the Joint European Societies' recommendations which applied this principle of total coronary risk assessment to the management of all risk factors: blood pressure, lipids and diabetes.[10,11] The European CHD risk charts, developed from a concept pioneered by Anderson,[12] used age, sex, smoking status, blood cholesterol and SBP to estimate the 10 year risk of a first fatal or non-fatal coronary heart disease event. There were separate European charts for those with and without diabetes.

The importance of estimating total CVD risk before making a decision to intervene medically is illustrated in Figure 24.1. The figure illustrates that in a middle-aged man who is a non-smoker with a blood pressure of 120 mmHg, the absolute risk of developing fatal CVD progressively increases as the total cholesterol to HDL-cholesterol ratio rises from 3.0 to 7.0. However, at every level of this lipid ratio the absolute risk for a man of the same age who smokes cigarettes and has raised blood pressure is substantially higher. In fact, the chances of such a man developing CVD with a lipid ratio of 3.0 is actually higher than a lipid ratio of 7.0 in a non-smoking man with lower

blood pressure. Although women are usually, age for age, at lower absolute risk of CVD than men, this advantage is lost at any level of the lipid ratio if the woman is a smoker with raised blood pressure.

The third and fourth editions of the Joint European Societies Guidelines published in 2003 and 2007[13,14] introduced
Figure 24.1 The relationship of total cholesterol/HDL cholesterol ratio to 10-year fatal CVD events in men and women aged 60 years with and without risk factors, based on a risk function derived from the SCORE project. (Reproduced with permission from Graham et al.[2])

a new system for cardiovascular risk estimation called SCORE (Systematic Coronary Risk Estimation), based on data from 12 European prospective cohort studies: 205,178 subjects with 2.7 million years of follow-up and 7934 cardiovascular deaths.[15] Two charts were produced: one for high-risk regions and the other for low-risk regions of Europe (Figs 24.2, 24.3). SCORE estimates the 10-year risk of a first fatal atherosclerotic event, whether heart attack, stroke, aneurysm of the aorta or other fatal manifestation of atherosclerotic disease. All ICD (International Classification of Diseases) codes that could be due to atherosclerosis are included. One advantage of a risk score based on mortality is that it can be recalibrated if good-quality, up-to-date mortality and risk factor prevalence data are available for a country. The SCORE CVD mortality charts have been recalibrated for a number of European countries: Germany, Greece, Poland, Spain, Sweden, Cyprus, Bosnia/ Herzegovina and Russia. The electronic, interactive version of SCORE, called HEARTSCORE, is available from the European Society of Cardiology (www.escardio org/ heartscore).

A 10-year CVD risk of 5% or more (red zone) for fatal events was defined in the 2003 Joint European Societies guidelines as high risk, and people at this level of risk should receive a professional lifestyle intervention and, if appropriate, drug therapies to reduce total CVD risk. Although an individual's treatment should be guided by their total CVD risk, the physician also needs to

take account of other factors, e.g. co-morbidity and life expectancy, before committing a person to lifelong therapies.

In 2007 the WHO developed CVD risk prediction charts because equations derived from Caucasian populations are not necessarily valid to predict CVD risk in low- and middle-income countries.[1] The Comparative Risk Assessment (CRA) Project, conducted by the WHO and described in the 2002 World Health Report, determined the burden of disease attributable to selected major risk factors, including smoking, Body Mass Index, high blood pressure, and high blood cholesterol.[16] This project involved the standardized collection and assessment of risk factor prevalences by WHO epidemiologic subregion. Estimates of relative risk per unit increase in continuous risk factors, i.e. per mmHg for systolic blood pressure, were determined from the CRA project largely from prospective cohort studies. Absolute risk of a cardiovascular event was determined by scaling individual relative risk to population incidence rates of cardiovascular disease (coronary heart disease and stroke), estimated from the Global Burden of Disease Study. The probability of a cardiovascular event was extrapolated to a 10-year period. The new WHO/International Society of Hypertension (ISH) risk prediction charts are based on these data and there are charts with and without cholesterol, and for patients with and without diabetes.

In summary, the great strength of the total risk approach is that it provides a rational means of making decisions about intervening in a targeted way, thereby making best use of resources available to reduce cardiovascular risk. The traditional approach focused on single risk factors as if they were "diseases" and this way of thinking is still being promoted with the use of terms such as "pre-hypertension" or "pre-diabetes". Many in the medical profession are reluctant to change from a unifactorial to a total risk approach because of their traditional medical training. The total risk approach also runs counter to the special interests of some professional societies, which focus on single risk factors, and the pharmaceutical industry and regulatory authorities which license drugs for single clinical indications. This unifactorial approach leads to people being labelled as "high risk" and for many this will be incorrect, leading to inappropriate use of drug therapies. In contrast, the total risk approach identifies that section of the population at highest risk of developing CVD. Such individuals have the most to gain from lifestyle and medical interventions to reduce their cardiovascular risk. So CVD risk scoring moves the focus of identification and treatment from individual risk factors to multiple risk factors. The intensity of interventions can then be matched to the level of total CVD risk. Research is required to validate the WHO regional risk prediction charts for each national population, and to confirm that using risk stratification methods in low- and middle-income countries results in benefits for both patients and the population as a whole.

Management

Secondary prevention

Cardiac rehabilitation traditionally focused on physical rehabilitation but this specialty has gradually evolved into more comprehensive professional lifestyle programs – smoking cessation, making healthy food choices and becoming physically active – based on behavioral models of change. Risk factor management in terms of controling blood pressure, lipids and glucose to defined targets, and the use of cardioprotective drug therapies, is also now integral to this approach. Finally, the psychosocial and vocational support required to help patients lead as full a life as possible is also provided. This evolution in cardiac rehabilitation is reflected in the current WHO definition.[17]

> "The rehabilitation of cardiac patients is the sum of activities required to influence favorably the underlying cause of the disease, as well as the best possible physical, mental and social conditions, so that they may, by their own efforts, preserve or resume when lost, as normal a place as possible in the community. Rehabilitation cannot be regarded as an isolated form of therapy but must be integrated with the whole treatment of which it forms only one facet."

The original definition[18] was changed in 1993 with the addition of the following words: "to influence favorably the underlying cause of the disease"– in short, all aspects of CVD prevention.

The overall preventive objective for patients who present with symptoms of coronary artery disease – stable angina, unstable angina or acute MI – is to reduce the risk of a further non-fatal event or death from cardiovascular disease. Cardiac rehabilitation was originally provided only for patients recovering from a myocardial infarction (MI) and those who had coronary artery bypass graft (CABG) surgery (or other forms of cardiac surgery). With the more recent emphasis on influencing the underlying causes of atherosclerotic disease, patients presenting with all forms of coronary artery disease, including unstable and stable angina, are now being included together with those who have other forms of atherosclerotic disease (e.g. transient cerebral ischemia or peripheral arterial disease) in cardiovascular prevention and rehabilitation programs. By addressing all aspects of lifestyle and risk factor management, and prescribing cardioprotective drug therapies, the risk of future cardiovascular events can be reduced in all these patients as evidenced by the meta-analyses.

The scientific evidence from randomized controlled trials shows that exercise-based cardiac rehabilitation of coronary patients reduces both total and cardiac mortality.

The main objective of the Cochrane systematic reviews and meta-analyses,[19] last updated in 2004,[20] was to determine the effectiveness of exercise only, or exercise as part of a comprehensive cardiac rehabilitation programme, on total and CHD mortality, morbidity, health-related quality of life (HRQoL) and modifiable cardiac risk factors of patients with coronary heart disease. The last review also addressed previous concerns regarding the applicability of this evidence to routine clinical practice. Trials with 6 or more months of follow-up were included if they assessed the effects of exercise training alone or in combination with psychologic or educational interventions. Altogether, 48 trials with a total of 8940 patients were included. Cardiac rehabilitation compared with usual care was associated with reduced all-cause mortality (odds ratio (OR) 0.80; 95% confidence interval (CI) 0.68–0.93) and cardiac mortality (OR 0.74; 95% CI 0.61–0.96) (**Class I, Level A**). There was no difference in recurrent myocardial infarction, CABG or PTCA (**Class IIb, Level B**) (Table 24.1).

At follow-up the proportion of patients who reported smoking was significantly reduced with cardiac rehabilitation (OR 0.64; 95% CI 0.50–0.83) (**Class IIa, Level B**). There was a significantly greater reduction in systolic blood pressure for those in cardiac rehabilitation (weighted mean difference, −3.2 mmHg; 95% CI −5.4 to −0.9 mmHg) but no difference in diastolic blood pressure (**Class IIa, Level B**). There was also a significantly greater reduction in total cholesterol concentration (weighted mean difference, −0.37 mmol/L (−14.3 mg/dL); 95% CI −0.63 to −0.11 mmol/L (−24.3 to −4.2 mg/dL)) and triglyceride concentration (weighted mean difference, −0.23 mmol/L (−20.4 mg/dL); 95% CI −0.39 to −0.07 mmol/L (−34.5 to −6.2 mg/dL)) for those in cardiac rehabilitation, but no difference in low-density or high-density lipoprotein concentrations (**Class IIa, Level B**). With the exception of smoking, the other risk factor changes in favor of intervention were rather small, and therefore would have had a limited impact on clinical events. So the reduction in total and cardiac mortality

Table 24.1 Pooled odds ratios (OR) and 95% confidence intervals (CI) for total and cardiac mortality, recurrent myocardial infarction, CABG and PTCA in patients with CHD randomly assigned to evidence-based cardiac rehabilitation versus usual care[20]

Clinical outcomes	Treatment n/N	Control n/N	OR (95% CI)
Total mortality	326/4295	381/4137	0.80 (0.68–0.93)
Cardiac mortality	211/2706	267/2665	0.74 (0.61–0.90)
Recurrent myocardial infarction	203/2416	214/2331	0.79 (0.57–1.09)
CABG	101/1556	120/1581	0.87 (0.65–1.16)

observed in this meta-analysis can be largely attributed to lifestyle changes: increased physical activity, healthier diets and smoking cessation.

Importantly, this meta-analysis showed no difference in mortality between exercise-only cardiac rehabilitation and comprehensive cardiac rehabilitation. The effect of cardiac rehabilitation on total mortality was independent of coronary heart disease diagnosis, type of cardiac rehabilitation, dose of exercise intervention or duration of follow-up. Health-related quality of life improved to similar levels with cardiac rehabilitation and usual care.

The contribution of secondary prevention programs, with or without exercise, was evaluated in two related systematic reviews and meta-analyses,[21,22] the most recent in 2005.[22] This meta-analysis included 63 randomized trials (21 295 patients with coronary disease), including 51 trials that were not included in the first review (limited to literature published before 1999 and excluding any studies with exercise components) and 26 trials that were not included in Taylor's review of cardiac rehabilitation (limited to literature published before 2003 and including few "individual counseling" programs). The summary risk ratio was 0.85 (95% CI 0.77–0.94) for all-cause mortality (Table 24.2), but this result improved over time from a risk ratio of 0.97 (95% CI 0.82–1.14) at 12 months to 0.53 (95% CI 0.35–0.81) at 24 months (**Class I, Level A**). The summary risk ratio was 0.83 (95% CI 0.74–0.94) for recurrent myocardial infarction over a median follow-up of 12 months (**Class I, Level A**). The effects on mortality and myocardial infarction were similar for programs that included both exercise and risk factor education, or risk factor education without exercise, or for exercise alone. Thirty-five trials reported effects on cardiovascular risk factors and although summary effects are not reported in this review, the effect sizes were generally considered to be small to moderate (**Class IIb, Level B**). Of the 27 trials that assessed the use of cardioprotective medications, eight demonstrated statistically significantly better application of at least one therapy in the intervention patients, three demonstrated better prescribing in intervention but not achieving statistical significance, and 11 did not demonstrate any appreciable difference between intervention and control patients (**Class IIb, Level B**). Quality of life was not formally evaluated overall but effect sizes in the individual trials were reported to be generally small.

Importantly, this distinction between "cardiac rehabilitation" and "secondary prevention" is artificial and any comparisons based on these rather arbitrary classifications will usually be confounded. In "exercise-only" trials people are free to adopt a healthier diet and stop smoking. In "secondary prevention" trials, without a supervised exercise component, people are free to exercise. What these meta-analyses really demonstrate, from different perspectives depending on trials included, are the overall benefits of an integrated multidisciplinary and multifactorial approach to reducing

Table 24.2 Risk ratios (RR) and 95% confidence intervals (CI) for total mortality and recurrent myocardial infarction for secondary prevention programs without exercise, with exercise and exercise only[22]

	Treatment n/N	Control n/N	RR (95% CI)
All-cause mortality			
Program without exercise	364/4598	417/4604	0.87 (0.76–0.99)
Program with exercise	223/2404	242/2251	0.88 (0.74–1.04)
Exercise-only program	72/1165	101/1120	0.72 (0.54–0.95)
Overall	659/8167	760/7975	0.85 (0.77–0.94)
Recurrent myocardial infarction			
Program without exercise	194/2787	221/2742	0.86 (0.72–1.03)
Program with exercise	198/2075	230/1922	0.62 (0.44–0.87)
Exercise-only program	77/1124	99/1073	0.76 (0.57–1.01)
Overall	469/5986	550/5737	0.83 (0.74–0.94)

cardiovascular risk and cardiovascular and all-cause mortality. The relative and absolute contributions in such comprehensive programs of their individual components – smoking cessation, diet, physical activity, lowering blood pressure, cholesterol and glucose – to reducing cardiovascular and total mortality are not known from these meta-analyses, and data quality from many trials is either incomplete or inadequate for such analyses to be performed. As many of the postmyocardial cardiac rehabilitation trials were undertaken before the modern management of acute coronary disease, e.g. primary PTCA and thrombolysis, and the introduction of cardioprotective medications such as antiplatelet therapies, beta-blockers, ACE inhibitors and ARBs, some calcium channel blockers and statins, the added value of such programs to current practice is also not known. However, it is likely that relative reductions in risk achieved by cardiovascular prevention and rehabilitation, principally through lifestyle changes from these early randomized controlled trials, will still apply to coronary and other atherosclerotic disease patients even though they are now, because of modern treatments, at lower absolute risk of recurrent disease and death.

Unfortunately, risk factor management in patients with CHD in Europe is far from optimal. Surveys of preventive cardiology practice such as EUROASPIRE I, II and III show a considerable gap between evidence-based guidelines and the lifestyle, risk factor and therapeutic management of patients with coronary disease.[23–27] Over a period of 12 years there are adverse time trends in smoking (higher rates in younger patients <50 years, especially among women), in the prevalence of obesity and central obesity which are both increasing, no change in the prevalence of raised blood pressure, and an increasing prevalence of diabetes. Only lipid management has improved, and improved

Table 24.3 Time trends in the prevalence (%) of risk factors in patients with CHD in Europe: comparison between EUROASPIREI, II and III in eight countries by survey, country, diagnosis and gender[26]

[1] Self-reported and/or CO in breath >10 ppm; [2] BMI ≥30 kg/m^2; [3] Waist circumference ≥102 cm for men and ≥88 cm for women; [4] Systolic blood pressure ≥140 mmHg and/or diastolic blood pressure ≥90 mmHg (systolic blood pressure ≥130 mmHg and/or diastolic blood pressure ≥80 mmHg in patients with diabetes); [5] Serum total cholesterol ≥4.5 mmol/L; [6] Self-reported and/or fasting plasma glucose ≥7.0 mmol/L.

substantially, due to the huge increase in prescriptions of statins[26] (Table 24.3). In the most recent EUROASPIRE III survey of 13,935 coronary patients from 22 countries, there is evidence of considerable potential to further reduce cardiovascular risk in this patient population, as many are still not achieving the recommended lifestyle and risk factor targets defined in the European guidelines[27] (Table 24.4). In Europe only about a third of coronary patients receive any form of cardiac rehabilitation, with considerable variation between European regions.[28] Patients with other clinical manifestations of atherosclerotic CVD receive little or no systematic preventive and rehabilitative care. The majority of coronary patients in the EUROASPIRE II survey were not advised to follow a cardiac rehabilitation program, and less than a third of all patients attended such a program.[28] The traditions and practice of cardiac rehabilitation in Europe differ substantially between countries, ranging from intensive residential rehabilitation through to ambulatory hospital, community- and home-based programs. They also differ in their patient populations, staffing, management protocols, duration and follow-up. According to EUROASPIRE II, whatever form of cardiac rehabilitation was provided for the coronary patients who reported

attending such programs, the majority still did not achieve the lifestyle, risk factor and therapeutic goals[28] (Table 24.5). In addition, the families of patients with premature CHD are not systematically followed up, with fewer than one in 10 first-degree relatives having a cardiovascular risk assessment as a consequence of premature disease developing in their family[29] (Table 24.6).

Primary prevention

In primary prevention the evidence for multiple risk factor interventions is less strong. Primary prevention programs in many countries attempt to reduce mortality and morbidity due to CHD through risk factor modification. It is widely believed that multiple risk factor intervention using counseling and educational methods is efficacious and cost-effective and should be expanded. The effects of multiple risk factor intervention for reducing cardiovascular risk factors, mortality from CHD and total mortality among adults without clinical evidence of established cardiovascular disease have been assessed in Cochrane reviews and meta-analyses on two occasions, in 1997[30] and 2006.[31] Intervention studies using counseling or education to modify

more than one cardiovascular risk factor in adults from general populations, occupational groups, or high-risk groups were identified. Trials of less than 6 months duration were excluded. A total of 39 trials were found in the 2006 meta-analysis, more than double the 18 trials identified for the original review. Ten out of the 39 trials reported total mortality or coronary heart disease mortality as outcomes. However, only four of these trials were sufficiently large to have meaningful power to address these disease endpoints. In the 10 trials with clinical event endpoints, the pooled effects suggest that multiple risk factor intervention has no effect on mortality (Table 24.7). The pooled OR for total and CHD mortality were 0.96 (95% CI 0.92–1.01) and 0.96 (95% CI 0.89–1.04) respectively (**Class IIb, Level B**). However, there was evidence of statistical heterogeneity in the pooled OR for total mortality, but not for CHD mortality. Three hypertension trials (Hypertension, Detection and Follow-up Program, Johns Hopkins Hypertension Trial and Swedish RIS) reported significant reductions in total mortality, and this is most likely due to the benefits of effective antihypertensive therapy in these trials. Removal of these three trials reduced the heterogeneity for total mortality. Importantly, there was a significant interaction between

intervention and level of CHD risk at baseline, which indicated that trials recruiting higher risk patients were more likely to demonstrate clinical benefits. An important caveat to these results is that a small, but potentially important, benefit of treatment (about a 10% reduction in CHD mortality) may have been missed.

This apparent lack of effect on coronary and total mortality overall reflects a modest reduction in smoking and small changes in blood pressure and lipids, the latter due to limited drug treatment in these trials. The odds of reduction in smoking prevalence was 20% (95% CI 8–31%) with substantial heterogeneity (**Class IIb, Level B**). Validation of reported smoking habit with biochemical measures suggests that this improvement may be overestimated. Changes in systolic (SBP) and diastolic (DBP) blood pressure were small. The weighted mean differences between intervention and control were –3.6 mmHg (95% CI –3.9 to –3.3 mmHg) for SBP and for DBP –2.8 mmHg (95% CI –2.9 to –2.6 mmHg) (**Class IIb, Level B**). Exclusion of those trials in which a high proportion of subjects were on pharmacologic treatment resulted in smaller but still statistically significant net reductions in blood pressure: SBP –2.7 mmHg (95% CI –3.9 to –3.3) and DBP – 1.7 mmHg

(95% CI −2.0 to −1.5). Blood cholesterol concentrations showed a small but highly significant fall of −0.07 mMol/L (95% CI −0.8 to −0.06 mMol/L) between intervention and control (**Class IIb, Level B**). There was also substantial heterogeneity in this analysis. Several trials made substantial use of lipid-lowering drugs but exclusion of these trials did not make any difference to the overall pooled difference observed. Risk factor net changes were strongly correlated with initial level of smoking, diastolic (but not systolic) blood pressure and blood cholesterol. Those studies with the highest baseline smoking prevalence, diastolic blood pressure and blood cholesterol levels demonstrated larger intervention-associated falls in these risk factors. In some studies, outcomes may have been overestimated because of regression to the mean effects, lack of intention-to-treat analyses, habituation to blood pressure measurement, and use of self-reports of smoking. One important observation from this meta-analysis was that interventions using personal or family counseling and education, with or without pharmacologic treatments, appear to be more effective at achieving risk factor reduction and consequent reductions in mortality.

In contrast, numerous single risk factor trials using drug therapies to lower blood pressure and lipids have shown comparable reductions in CVD risk that would be predicted from the epidemiologic relationships.[32–38] Therefore, if multifactorial interventions were to achieve the same treatment effects as those demonstrated in unifactorial trials, a substantial reduction in total CVD risk would be expected. The challenge is to integrate management through a multidisciplinary multifactorial program.

In primary prevention the gap between evidence-based guidelines and clinical practice is even greater than that seen for coronary patients. The EUROASPIRE III survey of primary prevention in 12 countries showed that in 5687 patients being treated for blood pressure, dyslipidemia or diabetes there is even greater potential to further reduce cardiovascular risk. (www.escardio.org/congresses/esc2008/congress-reports/Pages/4480-4481-wood-ryden.

aspx). A large majority of such patients are not achieving the recommended lifestyle and risk factor targets defined in the European guidelines (Table 24.8).

Yet it is possible to further reduce this gap between guidelines and practice by providing a comprehensive program of preventive care, as demonstrated by the European Society of Cardiology EUROACTION project (www.escardio.org/euroaction). This cluster randomized controlled trial of a nurse-managed preventive cardiology program for coronary (hospital) and high-risk (primary care) patients showed that they, and their families, were more likely to make healthy changes to their diet and physical activity levels, and to have their blood pressure and other risk factors managed more effectively compared to usual care.[39,40]

The EUROACTION Preventive Cardiology Program in hospital and general practice

The object of EUROACTION was to demonstrate whether a professional multidisciplinary preventive cardiology program could help more patients and their families achieve the lifestyle, risk factor and therapeutic goals defined in the European prevention guidelines. The EUROACTION program was set up in eight countries and 24 hospital and general practice centers in the context of a matched pair cluster randomized controlled trial.[39]

In the hospitals, cardiologists and nurses recruited eligible patients and their families. After a multidisciplinary assessment of lifestyle, risk factors, and drug treatment by a nurse, dietitian and physiotherapist, couples attended at least eight sessions, one every week, in which they were individually assessed by each member of the team. The patients and their partners then attended a group workshop and a supervised exercise class. The cardiologists initiated and uptitrated the cardioprotective drugs and nurses monitored risk factors and adherence to drug treatments at each session. At 16 weeks, patients and their partners were reassessed by the whole team and a report was sent to their family doctors.

In the general practice centers, family doctors and nurses recruited patients and their families. The program started with the same nurse assessment of lifestyle, risk factors, and drug treatment as for the hospital patients but was then open ended. At each visit (one every week), couples were assessed by the nurse, who led the group workshops, and by the family doctors responsible for drug treatment. Patients and partners did not have supervised exercise classes.

Patients and partners in hospital and general practice were provided with a personal record card for lifestyle and risk factor targets, together with family support packs (www.escardio.org/euroaction).

The EUROACTION preventive cardiology program reduced the risk of cardiovascular disease compared with usual care mainly through lifestyle changes by families, who together made healthier food choices and became more physically active (**Class I, Level A**) (Table 24.9). These lifestyle changes led to some weight loss in both groups of patients and, for high-risk patients, there was also a significant reduction in central obesity. Blood pressure control was improved in both groups of patients and for those with coronary heart disease this was achieved without the use of additional antihypertensive drugs. Control of blood cholesterol concentrations improved in both groups of patients and significantly so in high-risk patients because of increased use of statins. Overall, the use of all cardioprotective drugs was substantially higher in the hospital compared to the primary care program. However, for high-risk patients in the EUROACTION program, ACE inhibitors and statins were both prescribed more frequently compared to usual care.

Although these results are encouraging for the multidisciplinary approach, there is still scope for further improvement. The smoking cessation intervention based on advice reduced relapse in patients with coronary heart disease, but had no impact on smoking high-risk patients. Despite protocol recommendation to use smoking cessation therapies, these were hardly used at all because of cost. Although the same protocol for risk factor management was used in hospital and general practice, use of blood pressure and lipid-lowering drugs was more conservative in general practice. As a consequence, most of the high-risk patients did not achieve lipid targets. Diabetes care could have been improved if the intervention nurses had taken responsibility for diabetes management.

EUROACTION is a contemporary example of an integrated approach to cardiovascular disease prevention which incorporated several important principles. By setting up this program in busy general hospitals and general practices, it is possible to generalize the results to the management of all coronary and high-risk patients in everyday clinical practice. Integrating initial diagnosis and management with continued preventive care in the same healthcare facility is likely to increase and maintain participation

in the program. In the EUROASPIRE survey only a third of coronary patients attended cardiac rehabilitation, whereas two-thirds joined the EUROACTION hospital program and nine out of 10 eligible high-risk patients participated in primary care. EUROACTION addressed all the priority patient groups for cardiovascular prevention and made no distinction between symptomatic coronary disease (secondary prevention) and those at high risk (primary prevention). All these patients are at high risk of cardiovascular disease and need professional lifestyle support and risk factor management. It was a family-centered program involving patients' partners and other family members because of the evidence of concordant lifestyle within families and concordance for change.[41,42] Patients making the greatest changes had partners making similar changes. In addition, first-degree relatives of patients with premature atherosclerotic disease are at increased CVD risk so it is appropriate to offer lifestyle and risk factor management to the whole family, not just the patient.

In summary, the EUROACTION demonstration project in preventive cardiology showed that standards of preventive care in general hospitals and general practices across Europe can be improved. This nurse-managed, multidisciplinary, family-based, ambulatory program achieved healthier lifestyles and improvements in other risk factors for patients with coronary heart disease, those at high risk of developing cardiovascular disease, and their partners by comparison with those in usual care. EUROACTION is a model of preventive cardiology, successfully implemented and objectively assessed, which can be used in routine clinical practice. To achieve the beneficial effects of the EUROACTION program, we need to go beyond specialized cardiac rehabilitation services and provide local preventive cardiology programs, appropriately adapted to the medical, cultural, and economic setting of a country.

The Polypill concept

The concept of combining drugs (aspirin, beta-blocker, angiotensin converting enzyme inhibitors and statins) that have been proven to reduce major vascular events in secondary prevention into a combination tablet was suggested by Yusuf.[43] Such a combination pill could theoretically lead to a 75% relative risk reduction in vascular events. Combining these drugs into a single pill could enhance adherence (both physician and patient), reduce costs and increase affordability, and thereby assist in reducing the treatment gap. Wald and Law[44] expanded this concept to primary prevention (all >55 years) irrespective of the levels of risk factors on the grounds that most individuals in urban societies have elevated risk factors and that age alone is a sufficiently important risk factor. They hypothesized that use of a polypill which includes half doses of three antihyper-

*The difference in percentages were calculated by combining the country-specific differences using a random effect meta-analysis (REML estimation); **Hospital: patients at goal as a proportion of the target population (self-reported smoking in the month prior to the index event); Primary care: proportion of patients not smoking at final assessment; ***Random subsample only; NA: not available; INT, intervention; UC; usual care.

tensive agents, a statin and folic acid (to lower homocysteine levels) could reduce coronary heart disease by 80% and stroke by 88%, with few adverse effects. While the use of a polypill in secondary prevention is likely to be more readily acceptable as each component is already recommended in this population, the use of the polypill in individuals with no CVD and selected solely on age is controversial. At present there is only one trial of the polypill that has been published.[45] The Indian Polypill Study (TIPS)[45] evaluated 8 different drug (combination) regimens and demonstrated that the polypill was well tolerated, but that the degree of reduction of BP and LDL was substantially lower (by about half) than the projections of Wald and Law. Using the observed decreases in risk factors, the TIPS investigators projected that a polypill could reduce the risk of myocardial infarction by about 50%, and that of stroke by about 60%. These estimates require validation in large and long term randomized trials, and at least two such trials in primary prevention are underway.

Summary

An integrated approach to prevention of cardiovascular disease is required for all eligible patients in everyday clinical practice. The WHO describes strategies for secondary and primary prevention of atherosclerotic disease in order to reduce the risk of cardiovascular events, improve quality of life and life expectancy.

In a meta-analysis of cardiac rehabilitation compared with usual care, all-cause mortality was reduced (OR 0.80; 95% CI 0.68–0.93), as was cardiac mortality (OR 0.74; 95% CI 0.61–0.96) (**Class I, Level A**). There was no difference in recurrent myocardial infarction, CABG or PTCA (**Class IIb, Level B**). At follow-up, the number of patients who reported smoking was also reduced in the cardiac rehabilitation group (OR 0.64; 95% CI 0.50–0.83) (**Class IIa, Level B**) and there were significant reductions in systolic blood pressure, total cholesterol and triglyceride concentration (**Class IIa, Level B**). With the exception of smoking, other risk factor changes were rather small so the observed reduction in total and cardiac mortality can be largely attributed to lifestyle changes. The contribution of secondary prevention programs, with or without exercise, was also evaluated in a separate meta-analysis. All-cause mortality was reduced with a risk ratio (RR) of 0.85 (95% CI 0.77–0.94) and this benefit improved over time with a RR of 0.53 (95% CI 0.35–0.81) at 24 months (**Class I, Level A**). Recurrent myocardial infarction was also reduced with a RR of 0.83 (95% CI 0.74–0.94) over a median follow-up of 12 months (**Class I, Level A**). The effects of these programs on other cardiovascular risk factors were also considered to be moderate to small (**Class IIb, Level B**). Importantly, total mortality and myocardial infarction reductions were similar for programs

Table 24.10 Integrated approach to lifestyle, risk factor and therapeutic management for secondary and primary prevention of cardiovascular disease

	Patients with atherosclerotic cardiovascular disease	Asymptomatic patients at high multifactorial risk of developing CVD
Lifestyle		
Smoking habit	All smokers should be advised and supported by a physician or other health professional to stop smoking completely (**Class I, Level A**)	
	Therapeutic support with (i) nicotine replacement therapies or (ii) buproprion or (iii) nicotine receptor antagonist, should be offered to all smokers (**Class I, Level B**)	
Diet	A dietitian or trained health professional should formally assess nutrient intake of patients and their partners and then advise on healthy food choices which achieve the following:	
	Total intake of fat ≤30% of total daily energy intake (**Class I, Level A**)	
	Intake of saturated fats to ≤10% of total daily energy intake (**Class I, Level A**)	
	Replacement of saturated fats with monounsaturated or polyunsaturated fats (**Class I, Level A**)	
	Reduction of daily salt intake to less than 5 g per day (**Class I, Level A**)	
	Daily intake of fresh fruit and vegetables, as well as wholegrains and pulses, to at least 400 g per day (**Class IIa, Level C**)	
	Consumption of fish and other marine foods to provide >200 mg per day of eicosapentaenoic (EPA) and docosahexanaenoic (DHA) fatty acids (**Class I, Level A**)	
	Reduction of the intake of dietary cholesterol to <300 mg per day (**Class IIa, Level C**)	
	Reduction of alcohol to <14 units/week (in women) and <21 units/week (in men) (**Class IIa, Level C**)	
Physical activity	An exercise specialist or trained health professional should formally assess physical activity of patients and their partners and then advise on specific activities which achieve the following: regular moderate-intensity activity (e.g. brisk walking) lasting at least 30 minutes per day on at least 5 days of the week (**Class I, Level A**)	

Table 24.10 *Continued*

	Patients with atherosclerotic cardiovascular disease	Asymptomatic patients at high multifactorial risk of developing CVD
Other risk factors		
Body weight and distribution	A dietitian or other health professional should measure height, weight and waist circumference. All individuals who are overweight or obese should be encouraged to lose weight through a combination of a reduced-energy diet and increased physical activity (**Class I, Level B**) The targets for BMI and waist circumference are: BMI: <25 kg/m² (Caucasians); <23 kg/m² (Asians) Waist circumference: Caucasians: men <94 cm; women <80 cm Asians: men <90 cm; women <80 cm	
Blood pressure	Blood pressure should be measured regularly by a health professional The decision to start blood pressure-lowering medication depends not only on the blood pressure levels but also on total CVD risk Lifestyle advice should be given to all patients with elevated blood pressure Individuals with established CVD, people at high multifactorial risk and individuals with particularly elevated blood pressure, or lesser degree of raised blood pressure with target organ damage, should be given blood pressure-lowering therapy (**Class I, Level A**)	
Lipids Total cholesterol LDL cholesterol	Fasting lipids (total cholesterol, HDL cholesterol and triglycerides) should be measured regularly by a health professional The decision to start lipid-lowering medication depends not only on the lipid levels but also on total CVD risk Lifestyle advice should be given to all patients with dyslipidemia Individuals with established CVD, people at high multifactorial risk, individuals with particularly elevated total and LDL cholesterol should be given a statin or other LLD (if statin is contraindicated) (**Class I, Level A**)	
Glucose Fasting plasma glucose	Fasting plasma glucose should be measured on at least three separate occasions and if the FPG is >6.0 mmol/L (>110 mg/dL) an oral glucose tolerance test (OGTT) should be performed. Glycated hemoglobin (HbA1c) should be checked in all patients with DM Patients with dysglycemia or DM require professional dietary advice and oral hypoglycemic +/– insulin medication (**Class I, Level A**) ACE inhibitors/ARBs and statins are recommended to reduce cardiovascular risk (**Class I, Level A**)	
Cardioprotective drug therapies		
Antiplatelet drugs	Aspirin 75 mg/daily (**Class I, Level A**)	Aspirin 75 mg/daily (**Class IIa, Level B**)
Beta-blockers	All people following myocardial infarction (**Class I, Level A**) People with heart failure or LV dysfunction (**Class I, Level A**) For angina to relieve the symptom of myocardial ischemia (**Class I, Level A**)	As an antihypertensive therapy (ACE inhibitors, calcium channel blockers and diuretics are preferred as the first- and second-line antihypertensive therapies) (**Class IIa, Level A**)
ACE inhibitors/ARBs	Treatment of heart failure or left ventricular dysfunction (**Class I, Level A**) To reduce blood pressure for secondary prevention (**Class IIa, Level B**)	To reduce blood pressure for primary prevention (**Class I, Level A**)
Statins	All patients with established CVD to reduce TC and LDL cholesterol to target (**Class I, Level A**)	All high-risk people for primary prevention (**Class I, Level A**)
Anticoagulants	Consider in: large anterior MI, left ventricular aneurysm, paroxysmal tachyarrhythmia, severe heart failure to reduce the risk of thromboembolic event (**Class II, Level B**)	
Blood relatives	First-degree relatives of patients with premature atherosclerotic disease (men <55 years and women <65 years) should be screened for cardiovascular risk factors, including fasting lipids. The genetic disorder of familial hypercholesterolemia (FH) should be considered when interpreting lipid results in these family members (**Class IIa, Level C**)	If total cholesterol is > or equal to 8.0 mmol/L consider screening first-degree relatives for FH (**Class IIa, Level C**)

that included exercise and risk factor education, or risk factor education without exercise, or exercise alone. So the distinction between "cardiac rehabilitation" and "secondary prevention" is artificial and comparisons based on crude program definitions are usually confounded. What these meta-analyses really demonstrate are the overall benefits of an integrated multidisciplinary and comprehensive multifactorial approach to reducing cardiovascular risk, cardiovascular events and all-cause mortality.

In primary prevention those programs undertaking multifactorial interventions have not achieved the same clinical outcomes as those seen for single risk factor interventions. In a meta-analysis the pooled OR for total and CHD mortality were 0.96 (95% CI 0.92–1.01) and 0.96 (95% CI 0.89–1.04) respectively (**Class IIb, Level B**). A small but potentially important treatment benefit (about a 10% reduction in CHD mortality) may have been missed. There was a modest reduction in smoking (the odds of reduction in smoking prevalence was 20% (95% CI 8–31%)) (**Class IIb, Level B**) with only small changes in blood pressure and lipids. Importantly, it is the use of drugs or not which largely explains differences in treatment effect between unifactorial (almost entirely drugs) and multifactorial (lifestyle and limited drugs) trials in primary prevention. A multidisciplinary and comprehensive multifactorial approach to primary prevention, combining a professional lifestyle intervention and appropriate drug management of other major risk factors, will have a greater beneficial impact on clinical outcomes.

A nurse-managed multidisciplinary, comprehensive multifactorial, preventive cardiology program (EUROACTION) for coronary and high-risk patients and their families across Europe achieved healthier lifestyles and better control of blood pressure and other risk factors, with more effective use of cardioprotective drug therapies (**Class I, Level A**). EUROACTION is only one model of preventive cardiology, successfully implemented and objectively assessed, which is generalizable to everyday clinical practice. At present, lifestyle and risk factor standards set by prevention guidelines are not achieved by a majority of patients, as evidenced by EUROASPIRE and other surveys, and only a minority access professional preventive cardiology programs. To achieve the clinical benefits of a multidisciplinary, comprehensive multifactorial, prevention program, we need to integrate professional lifestyle interventions with effective risk factor management and evidence-based drug therapies, appropriately adapted to the medical, cultural, and economic setting of a country.

IIIa Stable coronary artery disease

John A Cairns and Bernard J Gersh, Editors

25 Medical management of stable coronary artery disease

William E Boden

Division of Cardiovascular Medicine, State University of New York at Buffalo; Buffalo General Hospital, Buffalo, NY, USA

Introduction

Angina pectoris accounts for approximately 6.5 million of the 13 million cases of coronary heart disease (CHD) prevalence in the United States. The economic burden of symptomatic angina and CHD is great, with aggregate direct and indirect costs approximating $150 billion per year.[1] Stable angina refers to discomfort in the chest, neck, arms, and jaws that is precipitated typically by physical activity or emotional stress and is relieved by rest or nitroglycerin. It usually occurs in patients with obstruction of one or more of the coronary arteries though some patients presenting with angina may have normal coronary arteries. Impaired microvascular perfusion related in part to obstructive plaque formation causes a mismatch between myocardial oxygen demand and supply which contributes to development and progression of angina.[2,3]

Despite the unabated growth in percutaneous coronary intervention (PCI) and coronary artery bypass graft (CABG) surgery for treating symptomatic CHD, the prevalence of angina pectoris in the US continues to increase. Inability to tolerate full doses of antianginal agents, limitations due to adverse effects from combinations of medications, intolerance or tachyphylaxis to various antianginal agents, such as nitrates, and persistent ischemia despite revascularization[4] have emphasized a need for more aggressive approaches to management of persistent as well as recurring angina. Drug therapy for stable angina includes antianginal and anti-ischemic agents that improve the "quality" of life and vasculoprotective agents that increase the "quantity" of life.[5] Aspirin, beta-blockers, angiotensin-converting enzyme (ACE) inhibitors and statins are recognized as vasculoprotective agents while beta-blockers also prevent or reduce ischemia. By contrast, long-acting nitrates, calcium channel blockers (CCBs) and newer agents such as ranolazine are anti-ischemic, but have not been shown to provide vasculoprotection.[3]

Epidemiology

Chronic stable angina is the major symptomatic presentation in about 50% of CHD patients.[5,6] There is a growing prevalence of chronic ischemia and angina due to residual coronary artery disease (CAD) after PCI and CABG. Of the 1620 consecutive NHLBI dynamic registry patients who underwent PCI, 26% continued to report angina despite more than one antianginal medication.[7] In the ARTS trial, patients were randomized to PCI or CABG for symptom relief. Despite optimal revascularization nearly 80% of the patients in the PCI group and 60% in the CABG group continued to experience angina and required antianginal medications.[4] Thus increased revascularization has led to increasing residual ischemia, and an increasing need for medical therapy.

Patients continue to experience persistent ischemia and angina despite traditional drug therapy. A significant percentage of patients have relative intolerance to full doses of nitrates, CCB and beta-blockers, and despite use of traditional agents, patients reported having two anginal episodes per week on average.[3] Combinations of beta-blockers and CCBs have similar depressive effects on blood pressue (BP), heart rate (HR) and AV nodal conduction, thus limiting maximal dosage of each of the medications. Thus improved treatment of recurring ischemia and angina remains an important therapeutic goal.

Definition and classification

Chronic stable angina pectoris is often predictable and is classically manifest as substernal or precordial chest discomfort that typically occurs after physical activity,

> **BOX 25.1** Classification and severity of angina
>
> - Class I No angina with ordinary physical activity. Angina with prolonged and more than usual exertion
> - Class II Early onset – limitation of ordinary activity
> - Class III Marked limitation of ordinary activity
> - Class IV Angina at rest/inability to carry out physical activity without chest discomfort

emotional stress or both. The site of discomfort is usually retrosternal but may radiate to neck, arms or jaw. Classic (typical) angina presents as a sensation in the chest of squeezing, heaviness or pressure, which usually lasts up to 15 minutes and abates when the stressor is gone, the patient rests or uses sublingual nitroglycerin. Chest discomfort that occurs during rest or at night has been described in patients with chronic stable angina, although this is generally more typical of unstable angina or acute coronary syndrome. Anginal equivalents such as exertional dyspnea, sweating, excessive fatigue, and fainting are common in women and in the elderly. Atypical presentations are more common in women who may report variable pain thresholds, inframammary pain, palpitations or sharp stabbing pain. Patient with diabetes and dysautonomia may present with atypical pain, dyspnea or no symptoms ("silent myocardial ischemia"). Classification of the severity of the angina is useful in management of chronic angina (Box 25.1).[3,8]

Pathophysiology

A disparity between the metabolic demands of the myocardium during exertion (as a consequence of increasing contractility, heart rate and systolic wall stress) and the inability to supply incremental coronary blood flow (CBF) due to narrowed epicardial coronary arteries in the face of increased myocardial oxygen demand is the principal factor in developing angina pectoris in CHD.[9] Increases in heart rate precipitated by adrenergic stresses, such as physical or emotional stress, sexual activity, or physiologic stresses such as arrhythmias, thyrotoxicosis or infection may precipitate so-called "demand angina".[9] CBF is the most important determinant of myocardial oxygen supply. Numerous factors influence the epicardial and subendocardial blood flow. Limitations of CBF may be due to atherosclerosis in either the epicardial or coronary microvasculature. In the epicardial coronary arteries, as coronary atherosclerosis progresses, there is progressive plaque deposition in the wall of the artery. As atherosclerosis worsens, the plaque may cause hemodynamic obstruction to CBF and may result in angina.[3] Typically, coronary luminal narrowings less than 70% of cross-sectional area

may not elicit either spontaneous or exercise-induced angina or ischemia, since the microvasculature (coronary resistance vessels) has the capacity to dilate and increase subendocardial perfusion in response to increasing demand. Such dilation, however, generally becomes maximized when coronary stenoses exceed 70% which, in turn, will trigger either spontaneous or exercise-induced anginal episodes. Symptomatic angina usually occurs about 25–30 seconds after onset of the ischemic cascade.[10] Approximately one-half of all stable CAD patients experience episodes of silent myocardial ischemia.

Endothelial dysfunction and coronary vasomotor control are important determinants of myocardial oxygen supply. Impaired smooth muscle relaxation has been suggested as a marker for atherosclerosis. In the WISE study, attenuation of coronary flow reserve was observed with intracoronary adenosine, suggesting impaired vascular smooth muscle relaxation.[11] In patients with CAD, there is loss of endothelium-dependent vasodilation and increased sensitivity to catecholamine-induced vasoconstriction.[12] This may become manifest in patients as "variable threshold angina" due to superimposed dynamic obstruction secondary to vasoconstriction of narrowed atherosclerotic vessels.

There is accumulating evidence that implicates coronary microcirculatory dysfunction in CHD patients with angina pectoris, including wide variability in effort tolerance over time, a large scatter or overlap between stenosis severity and coronary flow reserve, and variability in clinical outcomes after initial successful PCI. Approximately 25% of biomarker-positive ACS patients exhibit no flow-limiting stenosis at coronary angiography, but may display plaque fissuring or erosion with microvascular embolization.[13]

Medical management of myocardial ischemia

Comprehensive management of myocardial ischemia involves antianginal (anti-ischemic) agents and vasculoprotective agents. Antianginal therapies with nitrates, betablockers and CCBs are useful for symptom management. Vasculoprotective therapy includes lifestyle changes and pharmacologic therapy with antiplatelet therapy, ACE inhibitors (ACE-I), and statins which, in the aggregate, reduce progression of atherosclerosis, stabilize atherosclerotic plaque, and decrease the risk of thrombosis in patients with chronic stable angina.

Lifestyle changes

Intensive multifactorial risk reduction has been shown to reduce the rate of coronary luminal narrowing and decrease hospitalizations for cardiac events.[14] Patients with chronic stable angina who are receiving medical therapy should be

encouraged to exercise as tolerated by their symptoms. Regular exercise may promote "ischemic preconditioning" and provide protection during recurring bouts of ischemia. A trial comparing PCI with graded, regular aerobic exercise in patients with single-vessel CAD showed that 20 minutes of daily exercise was associated with improved maximal myocardial O_2 uptake, lower costs, and fewer rehospitalizations for angina pectoris as compared with PCI during a 1-year follow-up.[15] All patients should be encouraged to enroll in a comprehensive cardiac rehabilitation program. A diet low in saturated fat, and with appropriate restriction of excessive carbohydrate consumption (especially in patients with diabetes mellitus (DM) or insulin resistance) is encouraged.[5] Epidemiologic studies have also consistently demonstrated the benefits associated with modest alcohol intake, which may reduce progression of CAD and lower the likelihood of developing coronary events.[5] Vigorous efforts at smoking cessation and weight control should be encouraged in all patients.[5] In patients with DM, strict control of blood sugar (with a target HbA1C less than 7%) and control of blood pressure (target less than 120–130/80 mmHg) may reduce the rate of secondary events.[5]

Adjunctive pharmacologic therapy

Antiplatelet agents

Aspirin and clopidogrel are the common antiplatelet agents that have been used in the secondary prevention of cardiovascular disease. In high-risk patients with CHD, the use of aspirin was associated with a significantly reduced risk of non-fatal MI, non-fatal stroke and vascular death by 22%.[16] In patients with chronic stable angina, use of aspirin was associated with significant reduction in proinflammatory markers and high-sensitivity C-reactive protein (hs-CRP) levels.[17] Long-term aspirin at a dose of 81–325 mg is recommended in all patients with stable angina who do not exhibit aspirin allergy or evidence of aspirin resistance,[5] in which cases clopidogrel may be substituted. The use of clopidogrel alone was slightly superior to aspirin, and associated with 8.7% relative reduction in vascular death, ischemic stroke and myocardial infarction in the large CAPRIE study.[18]

Dual antiplatelet therapy has been well studied in patients with acute coronary syndrome (ACS) and those undergoing PCI. In the CHARISMA trial,[19] over 15 000 patients with clinically evident cardiovascular disease or multiple risk factors were randomized to receive clopidogrel (75 mg) with low-dose aspirin (75–162 mg daily) or placebo plus low-dose aspirin. The combination of clopidogrel plus aspirin was not significantly more effective than aspirin alone in reducing the composite primary endpoint of MI, stroke or death from cardiovascular causes among patients with stable CHD or multiple cardiovascu-

lar risk factors. There was a strong suggestion of benefit in patients with established vascular disease and symptomatic atherothrombosis (prespecified secondary endpoint), but alternatively, a suggestion of harm in asymptomatic patients with multiple risk factors and no demonstrable heart or vascular disease.

ACE inhibitors

The role of ACE-I in patients with left ventricular dysfunction has been well documented.[20–22] ACE-I improve survival in patients with symptomatic and asymptomatic heart failure, improve heart function after MI, and have provided renal protection in patients with renal insufficiency, especially diabetics. The use of ACE-I is a **Class I, Level A** recommendation in stable angina patients with diabetes, previous MI and those with evidence of left ventricular systolic dysfunction, generally defined as an ejection fraction <40%.[5] Treatment with quinapril improved endothelial function in patients who did not have severe hyperlipidemia or heart failure.[23] The Heart Outcomes Prevention and Evaluation (HOPE) trial showed that ramipril reduced cardiovascular death, MI and stroke in patients with vascular disease in the absence of heart failure.[22] However, the Prevention of Events with Angiotensin Converting Enzyme Inhibition (PEACE) trial showed that in patients with stable heart disease and preserved left ventricular function receiving standard therapy, trandolapril did not add any incremental mortality benefit.[24]

Controversy exists over the best ACE-I to use in patients with CAD. Tissue-specific agents such as quinapril, ramipril, perindopril and trandolapril may have high lipophilicity and better ACE binding capability. It is postulated that these tissue-specific ACE-I are able to penetrate the endothelial wall better and achieve better degrees of ACE inhibition that may impede atherogenesis, although this remains an unsettled question clinically. In patients who are unable to tolerate ACE-I, angiotensin receptor-blocking agents (ARBs) may be used. ARBs have been shown to be as effective as ACE-I in high-risk patients.[25–27]

Statins

Multiple randomized controlled trials of both primary and secondary prevention have convincingly demonstrated the clinical benefit of statins in reducing death, MI and stroke. The role of statins in patients with cardiovascular disease continues to evolve, with more and more aggressive efforts to lower low-density lipoprotein (LDL) cholesterol to levels <70 mg/d (1.82 mmol/L) in high-risk CHD patients (those who are post-MI, ACS patients, diabetics, and those with prior stroke or peripheral arterial disease). Epidemiologic studies have shown a consistent and positive relationship between LDL cholesterol and the risk of coronary heart disease.[28] Statins have emerged as the most widely

prescribed medication for lowering LDL cholesterol. The reduction in LDL cholesterol with statins ranges from 30% to 60%. The benefits of statins may at least partly be explained by the reduction in LDL cholesterol. Statins generally do not cause a significant increase in high-density lipoprotein (HDL) cholesterol or a reduction in serum triglyceride levels, with the possible exception of rosuvastatin. They have been shown to promote plaque stabilization in ACS patients,[29] improve endothelial dysfunction, and elicit regression of atherosclerotic plaques.[30] The anti-inflammatory effects of statins are reflected in the reduction seen in C-reactive protein levels.[31] These benefits have translated clinically into significant reductions in total mortality, rates of fatal and non-fatal MI, stroke, and the need for myocardial revascularization procedures in patients with stable CAD.[32,33] Lipid reduction with statins has been shown to reduce the progression of atherosclerosis not only in native vessels, but also in graft vessels after CABG surgery.[34] Intensive lowering of lipids (LDL <70 mg/dL) as compared to moderate lipid reduction (LDL <100 mg/dL) has been demonstrated to result in less progression of atheroma burden in the coronary arteries.[35] Trials of lower LDL cholesterol levels in patients with stable CAD and angina have demonstrated the benefits of statins and the need to lower the targets for LDL cholesterol for secondary prevention. These trials form the basis of the NCEP guidelines for LDL cholesterol to less than 100 mg/dL in high-risk patients and less than 70 mg/dL for very high-risk patients (e.g. diabetes).[36] Higher doses of statins may increase the incidence of adverse effects. Intensive lipid lowering with 80 mg of atorvastatin daily is associated with greater incidence of elevated serum aminotransferases as compared to 10 mg of atorvastatin daily.[37] The risk of muscle injury is increased with higher doses of statins as well as with the concomitant use of fibrates, which may be used in CAD patients with mixed dyslipidemia (high LDL-C and triglyceride levels).

The role of HDL-C is being increasingly recognized because of the strong inverse relationship between low levels of HDL-C and the risk of developing cardiac events. There are abundant epidemiologic data to support the observation that a low HDL-C level is a strong, independent predictor of CHD risk, with levels less than 35 mg/dL associated with an eightfold higher risk than HDL-C levels above 65 mg/dL.[38] Raising the level of HDL-C has been shown to reduce coronary event rates in primary and secondary prevention. Based on growing clinical evidence, patients should be treated to achieve HDL-C of 40 mg/dL in men and 50 mg/dL in women.[39] Combination therapy with a statin and extended-release niacin may offer the best strategy for controling mixed dyslipidemia characterized by increased LDL-C and reduced HDL-C levels, and may optimize cardiovascular rate reduction in patients with CHD.[40,41]

Inhibition of cholesterol absorption

Ezetimibe is the first member of a class of agents that inhibits the absorption of cholesterol from the intestine.[42,43] Ezetimibe co-administered with statins produces inhibition of both cholesterol synthesis and intestinal cholesterol absorption, resulting in complementary effects that lower LDL-C.[44,45] Co-administration of ezetimibe with a statin results in approximately a 18–24% greater reduction of LDL-C, beyond the LDL-C reduction attributable to the statin alone.[46,47] Accordingly, the percentage of patients who can reach their risk-appropriate NCEP goal is considerably higher when ezetimibe is added to LDL-C-reducing therapy, especially statins.[42,47]

Recent data have shown that ezetimibe also leads to significantly greater reductions in CRP in combination with statins; in one study, reductions on CRP ranged from 26% to 44% across background simvastatin doses of 10–80 mg as compared with 4–20% reductions with simvastatin alone at the same doses. Thus, with both greater LDL-C and CRP reductions, the percentage of patients who reach LDL-C <70 mg/dL in conjunction with CRP <2 mg/dL[17] is nearly doubled when ezetimibe is added. In the recent Vytorin Versus Atorvastatin (VYVA) trial, the combination ezetimibe/simvastatin approximately doubled the rates of achieving this degree of lowering of LDL-C and CRP across the approved dose ranges.[44] This promises to be an important component of combination dyslipidemic therapy, although definitive clinical outcomes data are presently lacking until the ongoing IMPROVE-IT Trial is completed and published.

Anti-ischemic/antianginal therapy

Beta-blockers

Beta-blockers have a **Class 1, Level A** recommendation for the initial therapy of patients with prior MI.[5] However, there is a paucity of prospectively acquired data in patients without prior MI and, in such patients, the ACC/AHA recommendation for chronic stable angina is **Class I, Level B**. Beta-blockers reduce heart rate and contractility and reduce myocardial oxygen demand. Reduction in heart rate increases the diastolic filling time during which nutritive coronary flow occurs, enhancing myocardial tissue perfusion. Beta-blockers limit increases in heart rate during exercise and are particularly effective in exercise-induced angina. Beta-blockers may be non-selective (e.g. propranolol), cardioselective (e.g. atenolol, metoprolol),[48] with intrinsic sympathomimetic effect (e.g. pindolol, acebutolol) or with alpha-blocking activity (e.g. labetolol, carvedilol).[49,50] All of the beta-blockers, including those with combined alpha and beta receptor blockade, have been studied for treatment of stable angina.[51,52] Beta-blockers have been shown to improve survival in patients with previous MI, primary angioplasty for acute ST segment

Table 25.1 Dosage of beta-blockers

Beta-blockers	Dosage	Conditions that may limit use
Propranolol	80–240 mg	Asthma
Metoprolol short acting	50–150 mg twice daily	Severe bradycardia AV block
Metoprolol long acting	100–300 mg once daily	Severe depression Raynaud's syndrome
Atenolol	25–100 mg once daily	Sick sinus syndrome

Table 25.2 Dosage of calcium channel blockers

Calcium channel blockers	Dose	Conditions that limit use
Nifedipine, sustained release	30–90 mg once daily	AV block
Amlodipine	2.5–10 mg once daily	Bradycardia
Verapamil, short acting	40–120 mg 2–3 times/ day	Heart failure
Verapamil, sustained release	180–240 mg once/ twice daily	Left ventricular dysfunction
Diltiazem, sustained release	120–480 mg once daily	Sinus node dysfunction

elevation MI, and patients with heart failure secondary to left ventricular systolic dysfunction. There have been no randomized trials showing survival benefit or reduction in rates of coronary events in patients with only stable angina. Hence, the doses of beta-blockers must be titrated so as to increase exercise tolerance and reduce symptoms of angina while avoiding unwanted side effects (Table 25.1). All beta-blockers are equally effective in alleviating angina pectoris, although optimal doses may vary. Prominent side effects of beta-blockers include bradycardia, bronchoconstriction, fatigue, depression, impotence, and worsening of peripheral vascular disease. Despite concerns about their side effects, beta-blockers can be safely used in many patients with chronic obstructive pulmonary disease or peripheral arterial disease. Beta-blockers may be combined with nitrates and CCBs. The combination of beta-blockers and nitrates is more effective than either agent alone.[53,54] Caution should be used when combining beta-blockers with verapamil and diltiazem due to additive negative inotropic and chronotropic effects and the risk of AV block.

Calcium channel blockers

A variety of calcium channel blockers have been studied in the long-term treatment of chronic stable angina. Calcium channel blockers block the entry of calcium into the myocardial and vascular smooth muscle cells and promote both coronary and peripheral vasodilation. Dihydropyridines (e.g. nifedipine, amlodipine, nicardipine) have a proportionately greater effect on vascular smooth muscle and are particularly effective in reducing systemic arterial blood pressure. Results of a meta-analysis indicated that the use of these drugs for hypertension does not increase morbidity and mortality.[55] Verapamil and diltiazem affect conduction through the AV node and have a negative chronotropic action.

All calcium channel blockers have been shown to be effective in the treatment of chronic stable angina.[56,57] Dihydropyridines reduce the frequency of anginal episodes, improve exercise duration and reduce the need for nitroglycerin. Verapamil, diltiazem and short-acting nifedipine

are effective in vasospastic (Prinzmetal's) angina.[58] Short-acting nifedipine is associated with an increased incidence of cardiovascular events and is not recommended for patients with unstable angina or ACS.[59] On the other hand, verapamil, diltiazem and long-acting dihydropyridines (e.g. amlodipine, extended-release nifedipine) have been shown to be safe and effective in treating stable angina.

Nitrates

Nitroglycerin was the first medication to be used for angina more than 150 years ago. Nitrates reduce myocardial oxygen demand by increasing venous capacitance, thus decreasing LV volume (preload). Nitrates dilate coronary arteries and favorably enhance subendocardial perfusion.[60] Sublingual nitroglycerin has been used to treat the acute onset of anginal symptoms as well as prophylactically to minimize or prevent anginal symptoms when these agents are administered in advance of the known offending activity. Isosorbide dinitrate and its active metabolite, isosorbide mononitrate, are used as an oral preparation for the treatment of angina.[61] Extended-release preparations like isosorbide mononitrate and transdermal nitrate patches offer the convenience of once-daily regimens. None of the nitrate regimens provides 24-hours antianginal prophylaxis due to the development of nitrate tolerance.[62] Prevention of tolerance requires an intermittent dosing strategy with a nitrate-free interval of 8–12 hours. A combination of nitrates with hydralazine, folic acid and antioxidants like vitamin E may reduce the development of nitrate tolerance.[63,64] Carvedilol, with its antioxidant, alpha- and beta-blocking effect, may be a useful combination with nitrates.[65] Nitrates are generally well tolerated, with facial flushing and headache being the most common side effects. Severe hypotension may occur if nitrates are used within 24 hours of phosphodiesterase inhibitors (sildenafil, tadalafil, vardenafil).

Table 25.3 Dosage of nitrates

Nitrates	Dosage	Conditions that limit use
Isosorbide dinitrate, short acting	20–60 mg once daily	Severe aortic stenosis
Isosorbide dinitrate, sustained release	60–120 mg once daily	Hypertrophic obstructive cardiomyopathy
Isosorbide mononitrate, short acting	20 mg twice daily	Caution in patients using medications for erectile dysfunction
Isosorbide mononitrate, sustained release	60–120 mg once daily	
Nitroglycerin patch	0.4–0.6 mg	

Combination of antianginal medications

Combinations of antianginal drugs may be used if symptoms persist. Beta-blockers and nitrates may be more effective than nitrates or beta-blockers alone.[53] Similarly, the combination of beta-blockers with dihydropyridines was more effective for improving exercise duration and was better tolerated than either alone.[66] No data exist on the efficacy of using more than two drugs. Certain drug combinations should be avoided because of the potential for adverse effects including hypotension or bradycardia. Newer agents may offer additional pharmacologic benefit in combination with traditional antianginal medications without the risk of adverse effects.

Newer agents in angina and myocardial ischemia management

Despite intensive escalation of antianginal therapy, including combinations of beta-blockers, long-acting nitrates and calcium channel blockers, some patients continue to experience persistent or refractory angina, and there are now newer mechanistic approaches to optimize pharmacologic management of myocardial ischemia. Additionally, an improved understanding of ischemia mechanisms has prompted new therapeutic approaches towards the treatment of stable angina. The mechanisms of action of these newer drugs are complementary to those of the traditional antianginal medications.

Ranolazine

First approved by the FDA in early 2006, ranolazine is a late sodium (Na^+) current inhibitor that has an antianginal and anti-ischemic effect without eliciting any change in the heart rate, blood pressure or rate-pressure (double) product.[67,68]

Myocardial ischemia causes an exaggerated, enhanced late inward Na^+ current, which leads to intracellular sodium overload which, in turn, leads to intracellular calcium overload, resulting in increased diastolic LV stiffness as well as electrical instability. The ischemia-associated diastolic stiffness compresses the intramyocardial vessels, leading to reduced coronary blood flow and the exacerbation of myocardial ischemia. Ranolazine prevents the abnormal increase in the late inward sodium current, and thereby prevents the "downstream" consequences of ischemic left ventricular stiffness and compression of intramyocardial blood vessels which, in turn, reduces myocardial ischemia.[67]

In chronic stable angina patients, ranolazine monotherapy significantly improved total exercise duration, time to angina onset and time to ST depression as compared to placebo.[69] There was no significant increase in the heart rate or blood pressure at rest or with exercise. Ranolazine significantly improved exercise duration and anginal symptoms when added to standard antianginal therapy, which included beta-blockers, diltiazem or amlodipine.[70] Added to maximum-dose amlodipine (10 mg daily), ranolazine reduced anginal frequency and nitroglycerine consumption.[71] Of note, those patients with the most frequent angina (>4.5 episodes/week) experienced the greatest benefit from the addition of ranolazine, suggesting that these patients may have more severe or prolonged ischemia-associated myocardial dysfunction and consequent hypoperfusion, a pathophysiologic state most likely to benefit from the unique mechanism of action of ranolazine.

Ranolazine also appears to be effective in patients with and without diabetes. A *post hoc* analysis of diabetic patients in the CARISA trial reported not only a reduction in the mean number of anginal episodes per week, but also a reduction in the HbA1c levels by 0.72 from the baseline.[72]

As a result of its multiple effects on transmembrane ion currents (both late inward Na^+ current and the inward potassium (K^+) rectifier current), ranolazine slightly prolongs the QT (~6 ms on average) with no clinical sequelae and no reported instances to date of torsades de pointes.[73] There was also no associated effect of QT dispersion. The use of ranolazine was not associated with early after depolarization (EAD) or increased dispersion of ventricular repolarization. Ranolazine can be used in combination with all CCBs, beta-blockers or nitrates. Dosing should be initiated at 500 mg bid and increased to maximum dose of 1000 mg bid based on clinical symptoms. Dizziness and nausea were the most common side effects, mostly at high doses.

Potent inhibitors of CYP3A (e.g. macrolides, protease inhibitors) increase levels of ranolazine and prolong the QTc interval, and thus should not be co-administered with ranolazine. Ranolazine can be used as add-on therapy in patients with chronic stable angina who have not achieved an adequate response with other antianginal agents but is now approved as first-line therapy for chronic angina.

The recently published MERLIN trial[74] demonstrated in over 6500 patients that ranolazine therapy was safe and well tolerated, even in high-risk patients following an acute coronary syndrome treated with a wide variety of concomitant anti-ischemic therapies. While this study did not show that ranolazine was superior to placebo in reducing the composite primary endpoint of death, MI or recurrent myocardial ischemia, ranolazine was shown to significantly reduce the secondary endpoint of recurrent myocardial ischemia in this population of ACS patients.

Fasudil

Rho kinase in the myocardial cell triggers vasoconstriction through accumulation of phosphorylated myosin. Animal models of coronary artery spasm have shown that Rho kinase inhibitors effectively suppress vasoconstriction. Fasudil, an orally available Rho kinase inhibitor, increased the time to >1 mm ST segment depression and improved exercise duration.[75] Fasudil did not affect the heart rate or blood pressure and was well tolerated.

Trimetazidine

Trimetazidine is a metabolic modulator and partial fatty acid oxidation inhibitor that has proven to be beneficial for combination therapy in patients with stable angina. Oxygen requirements of glucose pathways are lower than the free fatty acid (FFA) pathway. During ischemia, oxidized FFA levels rise which, in turn, blunt the glucose pathway. Trimetazidine inhibits beta-oxidation and shifts the equilibrium towards increased use of glucose, thus improving oxygen utilization. Trimetazidine in combination with long-acting nitrates or beta-blockers has been shown to decrease the number of anginal attacks per week.[76]

Ivabradine

The I_f current is an inward Na^+/K^+ current that activates pacemaker cells of the sinoatrial (SA) node. Ivabradine is a novel, specific heart rate-lowering agent that acts on SA node cells by selectively inhibiting pacemaker I_f current in a dose-dependent manner. It slows the diastolic depolarization slope of the SA node cells and reduces HR during rest and exercise in animals and human volunteers. Ivabradine at 7.5 mg bid and 10 mg bid was non-inferior to atenolol 100 mg daily for all exercise parameters. Sinus bradycardia occurred in 2.2% (ivabradine 7.5 mg), 5.4% (ivabradine 10 mg) and 4.3% in the atenolol group. Results from the INITIATIVE study suggest that I_f current inhibition with ivabradine may be as effective as beta-blockade in the treatment of stable angina.[77] A recent placebo-controlled multicenter trial of ivabradine in stable ischemic heart disease (BEAUTIFUL trial) did not show long-term clinical event reduction but improved angina.

Nicorandil

This drug activates the ATP-sensitive K^+ channels, which play an important role in ischemic preconditioning and promote dilation of the coronary resistance arterioles. Its nitrate moiety dilates epicardial coronary vessels and systemic veins. The addition of nicorandil to standard antianginal therapy was associated with a significant improvement in CAD death, non-fatal MI or unplanned hospital admission for cardiac chest pain.[78]

Non-pharmacologic antianginal approaches

Non-pharmacologic antianginal strategies include enhanced external counterpulsation (EECP), transmyocardial laser revascularization (TMR) and spinal cord stimulation (SCS). EECP promotes coronary collateral formation and may improve endothelial function. EECP has been shown to reduce the frequency and severity of angina in randomized trials.[79] TMR involves making laser channels into the myocardium and promotes angiogenesis. TMR improves angina class in patients with class IV anginal symptoms.[80] Both EECP and TMR are FDA approved for the treatment of chronic stable angina. In addition, SCS improves release of endogenous opiates, redistributes myocardial blood flow and decreases neurotransmission of painful stimuli. In patients with class III and IV angina, SCS may provide equivalent symptom relief to CABG.[81]

Role of myocardial revascularization

Revascularization includes PCI (i.e. balloon angioplasty and stenting) and CABG surgery which have both been shown to improve symptoms in patients with angina. Revascularization has not been shown to improve survival in patients with chronic angina and normal left ventricular function, except for those with left main coronary disease.[82–84] Several trials have compared cardioprotective medical therapy with PCI. In patients with Canadian Cardiovascular Society (CCS) class I or II stable angina, aggressive medical therapy, including lifestyle modification, vasculoprotective agents and revascularization (if symptoms worsen), results in similar rates of death and MI as with PCI.[85,86]

The Clinical Outcomes Utilizing Revascularization and Aggressive Drug Evaluation (COURAGE) trial was a multicenter study of patients with documented myocardial ischemia and angiographically confirmed single- or multi-vessel coronary artery disease who were randomized to a strategy of PCI plus intensive medical therapy or intensive medical therapy alone.[87] Lifestyle modification included smoking cessation, moderately intensive exercise five times per week and dietary fat less than 30% of daily calories. Aggressive medical therapy goals included target BP of less than 130/85 mmHg, LDL 60–85 mg/dL and HDL >40 mg/dL. The primary outcome during long-term follow-up included all-cause mortality and non-fatal MI. A

total of 2287 patients with objective evidence of myocardial ischemia and significant CAD from 50 US and Canadian centers were enrolled between 1999 and 2004; 1149 patients were assigned to PCI with optimal medical therapy and 1138 to optimal medical therapy alone.

The baseline characteristics of the patients were similar in the two groups, the median duration of angina prior to randomization was 26 months (mean six episodes per week), 58% of patients had CCS class II or III angina and 2168 patients (95%) had objective evidence of myocardial ischemia. Among patients who underwent myocardial perfusion imaging at baseline, 90% had either single (23%) or multiple (67%) reversible defects from inducible ischemia. There was a high usage rate of multiple, evidence-based therapies post randomization and during follow-up, which was comparable in both study arms. At the 5-year follow-up visit, 70% of subjects achieved an LDL <85 mg/dL (2.21 mmol/L: (median 71 ± 1.3 mg/dL; 1.84 ± 0.03 mmol/L), 65% and 94% achieved systolic and diastolic blood pressure targets of <130 mmHg and <85 mmHg, respectively, and 45% of diabetics achieved a HgbA1C ≤7.0%.

The primary outcome (death from any cause or non-fatal MI) occurred in 19.0% of the PCI group and 18.5% of the medical therapy group (unadjusted hazard ratio 1.05; 95% confidence interval (CI) 0.87–1.27; $P = 0.62$). For the pre-specified secondary outcome of death, non-fatal MI or stroke, the event rate was 20.0% in the PCI group and 19.5% in the medical therapy group (hazard ratio 1.05; 95% CI 0.87–1.27; $P = 0.62$). The rates of hospitalization for ACS were 12.4% in the PCI group and 11.8% in the medical therapy group (hazard ratio 1.07; 95% CI 0.84–1.37; $P = 0.56$), and adjudicated MI rates were 13.2% and 12.3%, respectively (hazard ratio 1.13; 95% CI 0.89–1.43; $P = 0.33$). For death alone, the rates were 7.7% and 8.3% (hazard ratio 0.87; 95% CI 0.65–1.16). For stroke alone, the rate was 2.1% in the PCI group and 1.8% in the medical therapy group (hazard ratio 1.56; 95% CI 0.80–3.04; $P = 0.19$).

Over the 7 years of follow-up, 21% of the PCI patients had additional revascularization as compared with 33% of the medical therapy patients (hazard ratio 0.61; 95% CI 0.51–0.72; $P < 0.001$). The median time to first (or repeat) revascularization was approximately 11 months; in the first year 10.5% and 16.5% of patients in the PCI and optimal medical therapy groups, respectively, required revascularization. In the initial PCI group, 77 patients subsequently underwent CABG, as compared with 81 patients in the medical therapy group. At 5 years, 74% of the PCI patients and 72% of the medical therapy patients were free of angina ($P = $ ns).

There was no significant interaction ($P < 0.01$) between treatment effect and any predefined subgroup variable. When subgroup variables were included in a multivariate analysis, the hazard ratio for treatment was essentially unchanged (1.09; 95% CI 0.90–1.33; $P = 0.77$).

Recommended initial management approach in stable coronary artery disease patients with angina

The COURAGE trial demonstrated the profound impact of intensive medical therapy and lifestyle intervention on mitigating clinical events in both randomized arms of the trial during long-term follow-up. A recent meta-analysis[88] which evaluated 4 trials (including COURAGE) of bare metal stent vs. optimal medical therapy in patients with stable coronary artery disease, was entirely consistent with the findings in COURAGE. Among stable CAD patients with chronic angina, *optimal medical therapy as an initial management strategy is both safe and effective*. Simply stated, CAD is a systemic problem that requires systemic treatment. Flow-limiting lesions cause angina and ischemia but may not necessarily be the lesions predisposing to death, MI, and ACS. Optimal medical therapy (OMT) is directed toward stabilizing so-called vulnerable plaques that are frequently mild angiographically and non-obstructive, such that OMT should rightfully be regarded as the preferred therapeutic approach to reducing clinical events in patients with chronic coronary syndromes and as complementary to focal revascularization approaches directed toward angina and ischemia relief, if needed. Achieving and maintaining multiple treatment targets may be a difficult challenge, but is well worth the effort.

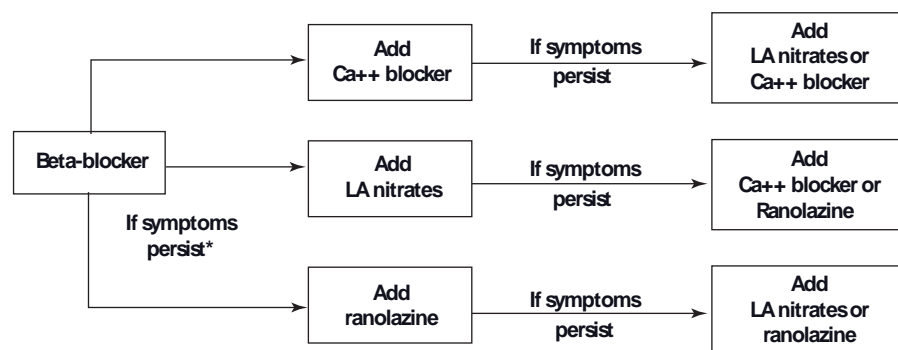
Lifestyle changes of regular aerobic exercise, smoking cessation, dietary intervention, and weight maintenance should be instituted (**Class I, Level B**). Control of blood pressure (**Class I, Level A**), elevated blood sugar in diabetics (**Class I, Level B**), and secondary goals of lipid control (**Class I, Level A**) should be achieved. Antiplatelet agents are to be used in all patients (**Class I, Level A**). Vasculoprotective agents including ACE-I and statins should also be prescribed to all patients with chronic angina (**Class I, Level A**). Beta-blockers are recommended as the initial therapy for patients with prior MI (**Class I, Level A**) and, despite the absence of randomized trials demonstrating clinical event reduction in CAD patients without MI, are widely prescribed for chronic stable angina patients and are effective for relieving angina and abolishing or attenuating ischemia (**Class I, Level B**). Short-acting nitrates are used for acute anginal episodes (**Class I, Level C**). Calcium channel blockers and long-acting nitrates can be used if beta-blockers are not tolerated or contraindicated (**Class I, Level B**). Combinations of anti-anginal drugs may be used if symptoms of angina persist (**Class I, Level B**) (Figure 25.1). Beta-blockers plus nitrates may be more effective than either alone. Similarly, the combination of beta-blockers with dihydropyridines was more effective for improving exercise duration and was better tolerated than either alone. Newer agents like ranolazine


Figure 25.1 Algorithm for treatment of stable coronary artery disease.

*Depending on clinical characteristics and absence of a contraindication

offer additional antianginal effect without additive side effects.

Coronary angiography and the possibility of revascularization should be considered in patients with impaired left ventricular function, angina refractory to maximal medical therapy, symptomatic multivessel disease or high-risk features on stress testing[82–84] (**Class I, Level A**). Advanced age, diffuse disease, poor distal targets, lack of suitable conduits and co-morbid conditions that increase perioperative complications may be barriers to revascularization necessitating medical therapy.[89] In addition, CAD progression is a major reason for postrevascularization angina.[90]

Conclusion

Evidence-based OMT has been shown to significantly reduce the rates of anginal symptoms, death or MI in stable CAD patients, and should be considered the foundation of contemporary management. CAD is fundamentally a systemic vascular disease process that may ultimately lead to ACS when non-flow limiting vulnerable plaques rupture. Revascularization is a "focal" approach to stenotic coronary segments that alleviates angina but does not reduce the overall burden of vascular disease. PCI has not been shown, to date, to reduce the rates of death or MI in non-ACS patients, whether drug-eluting or bare metal stents are employed. A "focal" approach to CAD management, as well as a "systemic" approach with intensive, multifaceted medical therapy and lifestyle intervention, should be viewed as complementary and additive treatment strategies, and should be regarded as the optimal overall approach to contemporary CAD management.

26 Percutaneous intervention

David A Wood, Rohit Khurana and Christopher E Buller
University of British Columbia, Vancouver, British Columbia, Canada

Introduction

Percutaneous coronary intervention (PCI) has been the most commonly employed coronary revascularization strategy for almost 20 years. In patients with chronic stable angina, the goals of PCI include the relief of angina and ischemia as well as preventing the progression and complications of coronary artery disease (CAD). This chapter describes the principles and evidence basis for coronary intervention technologies and reviews historic and contemporary trials that have compared PCI with medical therapy in stable CAD.

Principles and historic overview

Myocardial ischemia arises principally from an imbalance between myocardial oxygen requirements and supply. Coronary flow reserve (CFR) describes the normal physiologic capacity to increase coronary blood flow (hyperemia) in response to heightened downstream demand through dilation of coronary resistance vessels (principally precapillary arterioles). By definition, hemodynamically significant stenoses in upstream epicardial coronary arteries are those that diminish CFR by preventing physiologic hyperemia, leading to the potential for regional myocardial ischemia. The threshold for ischemia is determined substantially by the severity of the epicardial stenosis, but is also modulated by factors such as collateral flow, myocardial viability and blood oxygen content. Successful PCI alleviates the offending epicardial stenosis, thereby preventing ischemia through partial or complete normalization of CFR.

Dotter and Judkins first proposed the concept of transluminal angioplasty in peripheral arteries in 1964.[1]

Thirteen years later, Gruntzig performed the first balloon angioplasty of a stenotic coronary artery in a conscious human.[2,3] The ability of balloon angioplasty to enlarge the vessel lumen and relieve stenosis was originally attributed to compression of the atheromatous plaque.[3] However, luminal improvement immediately following balloon or stent-based PCI is actually the result of plaque displacement. Luminal stretching (barotrauma) leads to fracture of the intimal plaque and partial disruption of the media and adventitia, allowing enlargement of the lumen by increasing overall vessel diameter.[4] Elastic vessel recoil, post-traumatic neointimal proliferation, and positive (favorable) or negative remodeling of the treated segment determine the final healed result which stabilizes 4–6 months following intervention.

Balloon-based percutaneous transluminal coronary angioplasty (PTCA) became widely disseminated in the 1980s. As equipment design and operator experience improved, PTCA was progressively employed in higher risk patients and in more challenging anatomy, including longer lesions, bifurcations, total occlusions and multivessel disease.[5] The technique remained limited, however, by dissection and thrombosis of the treated vessel (threatened or actual abrupt closure) requiring emergency CABG in 3–5% of patients, and by restenosis of the treated segment in 20–30% of patients. A variety of novel devices were developed to solve these problems; however, only coronary stenting has demonstrated improved procedural safety and late clinical outcomes when rigorously compared to balloon angioplasty alone (see below).

Compared to balloon angioplasty alone, modern metallic stents nearly eliminate elastic recoil and compress or seal planes of barotrauma-induced disruption, thereby preventing propagation of dissection and reducing the stimuli for thrombosis that lead to abrupt vessel closure. While metallic stents prevent negative vessel remodeling, they also prevent positive remodeling and have no beneficial effect on neointimal proliferation. Thus bare metal stents have reduced, but by no means eliminated, restenosis. Active antiproliferative drug coatings employed on drug-eluting

stents substantially prevent neointimal proliferation and have reduced restenosis rates to below 10%. Bare metal or drug-eluting stents are now used in more than 95% of PCI cases, with procedural success rates greater than 98% and emergency CABG rates less than 1% in most institutions.[6] Balloon angioplasty is now most often used to dilate a vessel prior to stent deployment in order to enhance visualization of the target segment, improve stent deliverability, and ensure calcified vessels yield to dilation forces. Balloon angioplasty, often at high pressures (14–24 atmospheres), is also employed to further expand the stent and vessel following initial stent deployment. This technique is intended to ensure optimum lumen dimensions and complete apposition of stent struts to the vessel wall, and is associated with a reduced incidence of restenosis and stent thrombosis.[6] Stand-alone balloon angioplasty (no stent) is now reserved for specific circumstances: small-caliber vessels (<2.5 mm), side branch treatment at bifurcations, distal bypass graft anastomotic lesions, select cases of focal in-stent restenosis, and in patients unable to tolerate dual antiplatelet therapy.

Percutaneous coronary intervention technology

PCI systems share three basic components: a guiding catheter that provides stable access to the coronary ostium; a steerable guidewire that is advanced distal to the stenosis and acts as a rail for delivering a variety of therapeutic devices; and a non-elastomeric balloon (with or without a mounted stent) for dilating the physiologically significant epicardial stenosis (Fig. 26.1).

A number of diagnostic and guiding catheters have been developed for coronary arteriography. To allow passage of balloons and other devices, early thick-walled guiding catheters were constructed from large 10 and 11 F tubes that demanded correspondingly large-caliber arterial sheaths with their attendant bleeding risks. Modern guide catheters allow most cases to be completed through 6 F or

smaller vascular access sheaths, thereby reducing bleeding risk and enabling radial or femoral artery access (see below).

Modern guidewires combine atraumatic tip softness with precise torque control for steering, graduated support for device delivery, and improved radiographic visibility. Lubricated hydrophilic coatings are employed on specialty wires for tortuous or critically stenotic segments. Stiffer tip designs with different shaft and taper characteristics are now available for crossing chronic total occlusions (CTOs). The large selection of modern guidewires has improved procedural success in a wide range of challenging anatomic substrates.

The cross-sectional profiles of modern angioplasty balloon catheters and stent delivery systems have also decreased substantially while their flexibility has increased. Together with myriad other design improvements, modern balloon catheters and stent delivery systems can readily be made to pass through marked tortuousity and to access distal arterial segments. These improvements may also reduce trauma, endothelial injury and associated plaque progression in coronary segments proximal to the target lesion, though these benefits have not been clearly demonstrated.

Vascular access

A variety of vascular approaches are available for PCI. The right and left femoral arteries are the most commonly used access sites. Although Sones first introduced a cutdown approach for the brachial artery for diagnostic coronary angiography, this approach has been supplanted by percutaneous radial artery access. Access site selection currently depends on operator and patient preference, anticoagulation status, body habitus, and the presence of significant peripheral vascular disease (PVD).

Small trials suggest a transradial approach is preferred in patients with morbid obesity.[7,8] The recent Agostoni *et al* meta-analysis included 12 randomized trials (n = 3224)

(a)   (b)

Figure 26.1 (a) Photograph of a guiding catheter that provides stable access to the coronary ostium (1), a non-elastomeric balloon (with a mounted stent) (2) for dilating physiologically significant epicardial stenosis, and a steerable guidewire (3) that is advanced distal to the stenosis and acts as a rail for delivering a variety of therapeutic devices. (b) Expanded 5.0 × 32 mm bare metal stent.

comparing the transradial and transfemoral approach.[9] The risk of major adverse cardiac events (MACE) was similar for both the radial and femoral approach (odds ratio (OR) 0.92, 95% confidence interval (CI) 0.57–1.48; $P = 0.7$). Radial access was associated with a significantly lower rate of entry site complications and bleeding (OR 0.20, 95% CI 0.09–0.42; $P = 0.0001$) but a higher rate of procedural failure (OR 3.30, 95% CI 1.63–6.71; $P = 0.001$). The multicenter OASIS-7/CURRENT trial is enrolling patients and will help clarify the importance of access site selection in PCI.

Technology and pharmacology trials of percutaneous coronary intervention in stable coronary artery disease

Bare metal stents

Balloon-expandable metallic stents were the first advance to reduce restenosis, reduce acute complications and provide superior medium-term clinical outcomes when compared to balloon angioplasty alone.

BENESTENT-1 and STRESS were early pivotal trials comparing bare metal stents (BMS) with balloon angioplasty[10,11] in simple, short coronary stenoses. Elective Palmaz-Schatz stenting was compared to balloon angioplasty and the results provided the evidence base for FDA approval in 1994 for the prevention of restenosis in *de novo* lesions. Both studies showed improved initial angiographic results using quantitative coronary angiography (QCA), larger postprocedural minimal luminal diameters (MLD), fewer residual dissections, and decreased clinical and angiographic restenosis at six months. In BENESTENT-1 (n = 520), the mean (±SD) MLD immediately after the procedure were 2.48 ± 0.39 mm in the stent group and 2.05 ± 0.33 mm in the angioplasty group; at follow-up, the diameters were 1.82 ± 0.64 mm in the stent group and 1.73 ± 0.55 mm in the angioplasty group ($P = 0.09$), which correspond to rates of restenosis (diameter of stenosis (DS) >50%) of 22% and 32%, respectively ($P = 0.02$). In STRESS (n = 410), the mean (±SD) MLD immediately after the procedure were 2.49 ± 0.43 in the stent group and 1.99 ± 0.47 mm in the angioplasty group ($P < 0.001$). At six months, the patients with stented lesions continued to have a larger luminal diameter (1.74 ± 0.60 vs 1.56 ± 0.65 mm, $P = 0.007$) and a lower rate of restenosis (DS 31.6% vs 42.1%, $P = 0.046$). TOSCA-1 was the largest stent versus balloon trial in complex coronary stenoses (non-acute occlusions).[12] Stenting again resulted in larger mean six-month MLD (1.48 versus 1.23 mm, $P < 0.01$) and a reduced binary angiographic restenosis rate (55% versus 70%, $P < 0.01$).

Bare metal stents were initially limited by stiffness, modest radial strength and inconsistencies in paving which restricted their utility in complex anatomy. Numerous design iterations by stent manufacturers lead to second-, third- and fourth-generation stents that incorporated substantially improved stent flexibility (both before and after stent deployment), superior radial strength and paving, thinner struts, enhanced radiographic visibility, and innovative metallurgy. However, newer trials employed non-inferiority designs to compare different types of bare metal stents, making it difficult to confirm or quantify the effects of improved stent designs.

Two meta-analyses have been published comparing stenting with balloon angioplasty. Brophy *et al* identified a total of 29 trials involving 9918 patients (Figs 26.2, 26.3).[13] No overall difference between strategies of routine coronary stenting versus routine balloon angioplasty was observed for death or myocardial infarction outcomes (odds ratio 0.90, 95% CI 0.72–1.11) or the need for coronary artery bypass surgery (odds ratio 1.01, CI 0.79–1.31). However, nearly all trials allowed or encouraged early cross-over to stenting for patients experiencing balloon angioplasty failure due to marked recoil, dissection and threatened or actual abrupt closure, a design feature that almost certainly obscured from the primary intention-to-treat analyses an important safety advantage provided by stents. Coronary stenting did reduce the rate of restenosis by half (odds ratio 0.52, CI 0.37–0.69) and the need for repeated balloon angioplasty by 40% (odds ratio 0.59, CI 0.50–0.68]). Al Suwaidi *et al* performed a separate meta-analysis of 23 trials and reached similar conclusions.[14]

Clinical trials comparing routine stenting to routine balloon angioplasty enrolled anatomically and clinically selected patients. Outcomes in real-world practice including patients with complex stenoses, multivessel disease and a typical burden of co-morbidity were described in a population-based analysis from Canada.[15] After adjustment, this analysis showed the adoption of routine bare

metal stenting was associated with a 28% reduction in target vessel revascularization and 21% reduction in major adverse cardiac events. Clinical results and outcomes with bare metal stents have continued to improve with the development of more flexible and thin-strut stent designs[16] and widespread adoption of modern antithrombotic and antiplatelet therapies administered during and after stent insertion (see below).

Drug-eluting stents (DES)

Although BMS constituted an important advance over balloon angioplasty alone, restenosis due to neointimal overgrowth continues to pose a significant clinical challenge particularly when it is diffuse, proliferative or occlusive.[17] In a multicenter cross-sectional registry describing the burden of in-stent restenosis in the immediate pre-DES era, approximately 7% of all cardiac catheterization procedures performed involved patients with restenosis of one or more bare metal stents.[18] Local delivery of potent antiproliferative drugs via DES has proven an efficacious technology. At the time of writing, four DES device are approved for coronary use in Europe or North America. In order of regulatory approval, these are the Cypher™ (sirolimus eluting, Cordis, Miami Lakes, FL), Taxus™ (paclitaxel eluting, Boston Scientific, Boston, MA), Endeavor™ (zotarolimus eluting, Medtronic, Minneapolis, MN) and XienceV™ (everolimus eluting, Abbott Vascular, Santa Clara, CA). All are composed of a balloon-expandable metallic stent with an adherent polymer that serves as the reservoir for the antiproliferative drug. The drugs elute and diffuse into peri-stent vascular tissue in the weeks following stent deployment where, to a variable degree, they inhibit mitosis of smooth muscle cells that are the primary cellular constituent of restenotic neointimal tissue.

Multiple surrogates have been used to evaluate BMS and DES efficacy. In addition to the quantitative angiographic measures of lumen dimensions and binary restenosis, "ischemia driven" target lesion or target vessel revascularization (TLR or TVR) and clinical restenosis are commonly employed clinically relevant endpoints. Angiographic and

clinical restenosis rates after BMS implantation typically exceed 20% and 10% respectively, with rates more than doubling in certain patient subsets. Risk factors for restenosis include small reference vessel diameter, long lesion or stent length, and medically treated diabetes mellitus.[19] A small minimal stent cross-sectional area on intravascular ultrasound (IVUS) imaging also predicts restenosis (see below).[20] In contrast, clinical and angiographic restenosis rates are less than 10% in multiple DES series.[21–28]

SIRIUS[21] and TAXUS IV[22] were pivotal trials that demonstrated decreased clinical and angiographic restenosis with drug-eluting versus bare metal stents. Although TLR dramatically decreased, there was again no difference in death or myocardial infarction. In SIRIUS, the mean in-segment (stent plus 5 mm margins) MLD of the sirolimus-coated Bx Velocity stent at 240 days was 2.15 ± 0.61 mm vs 1.60 ± 0.72 mm ($P < 0.001$) for the bare metal stent with a restenosis rate (DS >50%) of 8.9 versus 36.3% (I < 0.01). In

TAXUS IV, the mean in-segment MLD of the paclitaxel-coated Express stent at nine months was 2.03 ± 0.55 mm versus 1.68 ± 0.61 mm ($P < 0.001$) for the bare metal stent with a restenosis rate of 7.9 versus 26.6% ($P < 0.001$).

Two non-inferiority trials have demonstrated similar MLD and restenosis rates with the remaining commercially marketed DES: ENDEAVOR-3 compared zotralimus-eluting and sirolimus-eluting stents and SPIRIT-3 compared everolimus-eluting and paclitaxel-eluting stents.

The widespread adoption of DES reduced restenosis and decreased the need for subsequent procedures compared to BMS.[23–28b] Stone *et al* performed a pooled analysis of four double-blind trials in which 1748 patients were randomly assigned to receive either sirolimus-eluting stents or BMS and five double-blind trials in which 3513 patients were randomly assigned to receive either paclitaxel-eluting stents or BMS (Figs 26.4, 26.5).[23] The four-year rates of stent thrombosis were 1.2% in the sirolimus stent group versus

0.6% in the BMS group (*P* = 0.20) and 1.3% in the paclitaxel stent group versus 0.9% in the BMS group (*P* = 0.30). However, after one year, there were five episodes of stent thrombosis in patients with sirolimus-eluting stents versus none in patients with BMS (*P* = 0.025) and nine episodes in patients with paclitaxel-eluting stents versus two in patients with BMS (*P* = 0.028). The four-year rates of target lesion revascularization were markedly reduced in both the sirolimus stent and the paclitaxel stent group, as compared with the BMS groups. The rates of death or MI did not differ significantly between the groups that received DES or BMS.

The decreased restenosis rates with DES may come at a price. Although the on-label randomized controlled trials failed to detect an increase in late stent thrombosis with DES, large off-label real-world registries have produced conflicting results. It appears that the increased late stent thrombosis observed with DES may be offset by decreased restenosis-driven myocardial infarctions over time. Large, multicenter trials powered to address these questions are ongoing. Currently, the data as a whole support the following conclusions.[29]

• DES significantly reduce restenosis compared with BMS.
• Overall stent thrombosis rates are low and occur with both BMS and DES.
• The timing of stent thrombosis appears to vary, with DES more likely to be associated with late and very late stent thrombosis. Cessation of clopidogrel appears to be an important but not universal precipitating factor.
• In the carefully selected and monitored patient populations enrolled in the randomized trials leading to FDA approval, there was no difference in death or MI during follow-up.
• The optimal duration of dual antiplatelet therapy with clopidogrel remains uncertain.

Atherectomy

Plaque volume is a predictor of restenosis.[30] The directional atherectomy catheter gained FDA approval in 1990 and allowed cutting and removal of coronary plaque in a controlled ("directional") manner. It was hypothesized that plaque removal, by avoiding barotrauma and reducing plaque volume, would incite a less vigorous neointimal response and restenosis. However, increased rates of myocardial infarction, death, and major complications without a significant reduction in restenosis were found in adequately powered randomized trials, leading to abandonment of this technology.[31–33]

Rotational atherectomy (Rotablator™, Boston Scientific, Boston, MA) is a debulking procedure employing a rapidly rotating diamond-tipped abrasive burr (160000–180000 rpm). The device pulverizes calcified atherosclerotic plaque into tiny particles intended to pass through the

microcirculation and be removed by the reticuloendothelial system. Unfortunately, sludging of particles can result in obstruction of the microcirculation with an increased risk of ischemia and non-Q wave myocardial infarction.[34–36] Its use is primarily limited, therefore, to removal of superficial calcium that may otherwise prevent lumen and vessel expansion.

Intravascular ultrasound (IVUS)

Since the introduction of IVUS to interventional cardiology in 1988, it has gained acceptance as both a research tool and

Class IIa indications
IVUS is reasonable for the following:
• Assessment of the adequacy of deployment of coronary stents, including the extent of stent apposition and determination of the minimum luminal diameter within the stent. (**Level B**)
• Determination of the mechanism of stent restenosis (inadequate expansion versus neointimal proliferation) and to enable selection of appropriate therapy (vascular brachytherapy versus repeat balloon expansion). (**Level B**)
• Evaluation of coronary obstruction at a location difficult to image by angiography in a patient with a suspected flow-limiting stenosis. (**Level C**)
• Assessment of a suboptimal angiographic result after PCI. (**Level C**)
• Establishment of the presence and distribution of coronary calcium in patients for whom adjunctive rotational atherectomy is contemplated. (**Level C**)
• Determination of plaque location and circumferential distribution for guidance of directional coronary atherectomy. (**Level B**)

Class IIb indications
IVUS may be considered for the following:
• Determination of the extent of atherosclerosis in patients with characteristic anginal symptoms and a positive functional study with no focal stenoses or mild CAD on angiography. (**Level C**)
• Preinterventional assessment of lesional characteristics and vessel dimensions as a means to select an optimal revascularization device. (**Level C**)
• Diagnosis of coronary disease after cardiac transplantation. (**Level C**)

Class III indications
• IVUS is not recommended when the angiographic diagnosis is clear and no interventional treatment is planned. (**Level C**)

a clinical modality useful for clarifying epicardial coronary anatomy when the angiographic interpretation is unclear or ambiguous. IVUS can provide not only high spatial resolution images of the vessel lumen and stent, but also detailed and potentially useful information about plaque and arterial wall characteristics.

Despite an extensive literature validating the precision and intraprocedural utility of IVUS, data supporting the ability of this technology to improve clinical outcomes are few. The CLOUT trial evaluated IVUS-guided balloon angioplasty.[37] IVUS use resulted in a larger mean MLD, from 1.95 to 2.21 mm ($P < 0.0001$), and a larger luminal area from 3.2 to 4.5 mm^2 ($P < 0.0001$). Periprocedural complication rates and six-month restenosis rates were nevertheless similar. The SIPS trial (n = 269) compared IVUS-guided versus angiographically guided balloon angioplasty with bailout stenting where appropriate.[38] There was a significant improvement in TLR in the IVUS optimized group at two-year follow-up (17% vs 29%; Pp < 0.05).

Subsequent IVUS-guided stent trials have demonstrated that minimum stent area (MSA), as measured by IVUS, is a predictor of late angiographic and clinical restenosis.[39] However, the conflicting findings of small IVUS-guided stent optimization trials have been rationalized by the differing angiographic procedural endpoints in the IVUS-guided arms, as well as the disparate adjunctive medical treatment strategies employed (see below).

Recent concerns with late stent thrombosis with DES have fuelled speculation that the mechanism may be related to incomplete stent apposition against the arterial wall.[40–42] Using IVUS to guide DES deployment and thereby ensure adequate stent expansion and complete stent–vessel wall apposition has therefore been advocated in anatomically complex target lesions, but large randomized long-term studies that evaluate clinical outcomes after procedures with and without IVUS are needed to confirm this hypothesis. Presently there are no randomized or compelling outcome data that support the contention that routine IVUS during PCI improves clinical results.

Pressure wire

The ratio of the mean coronary artery pressure distal to a stenosis to the mean aortic pressure during maximal vasodilation (maximal hyperemia) is called the fractional flow reserve (FFR).[43] Comparisons with differing stress testing modalities in patients with stable coronary artery disease revealed that in 45 consecutive patients, the sensitivity of FFR for the identification of reversible ischemia was 88%, the specificity 100%, the positive predictive value 100%, and the negative predictive value 88%. A 0.014 inch pressure sensor-tipped coronary angioplasty guidewire is advanced across a stenosis, and the absolute distal pressure is recorded at rest and at maximal hyperemia induced by

BOX 26.2 Coronary artery pressure and flow: use of fractional flow reserve and coronary vasodilatory reserve (modified from 2005 ACC/AHA/SCAI guideline update for percutaneous coronary intervention)

Class IIa indications
Reasonable to use intracoronary physiologic measurements (IVUS, pressure wire) in the assessment of the effects of intermediate coronary stenoses (30–70% luminal narrowing) in patients with anginal symptoms. Coronary pressure or Doppler velocimetry may also be useful as an alternative to performing noninvasive functional testing (e.g. when the functional study is absent or ambiguous) to determine whether an intervention is warranted. (**Level B**)

Class IIb indications
- Intracoronary physiologic measurements may be considered for the evaluation of the success of PCI in restoring flow reserve and to predict the risk of restenosis. (**Level C**)
- Preinterventional assessment of lesional characteristics and vessel dimensions as a means to select an optimal revascularization device. (**Level C**)
- Intracoronary physiologic measurements may be considered for the evaluation of patients with anginal symptoms without an apparent angiographic culprit lesion. (**Level C**)

Class III indications
- Routine assessment with intracoronary physiologic measurements such as Doppler ultrasound or fractional flow reserve to assess the severity of angiographic disease in patients with a positive, unequivocal noninvasive functional study is not recommended. (**Level C**)

intracoronary or intravenous infusion of adenosine. The ischemic threshold value of FFR is <0.75 and current indications are listed in Box 26.2.

The appropriateness of intervening on stable coronary artery lesions of intermediate severity and without functional obstruction using pressure wire criteria was assessed in the DEFER study.[44] In 325 patients scheduled for PCI of an intermediate stenosis, FFR was measured prior to the planned intervention. If the FFR was ≥0.75, patients were randomly assigned to deferral (Defer group, n = 91) or PCI (Perform group, n = 90). If FFR was <0.75, PCI was performed as planned and these patients were followed up as the reference group (Reference group, n = 144). At five years, event-free survival was not different between the Defer and Perform groups (80% and 73% respectively; $P = 0.52$), but was significantly worse in the reference group (63%; $P = 0.03$). The composite rate of cardiac death and acute myocardial infarction in the Defer, Perform, and Reference groups was 3.3%, 7.9%, and 15.7%, respectively ($P = 0.21$ for Defer vs Perform group; $P = 0.003$ for the Reference vs both other groups). The risk that a hemody-

namically non-significant stenosis (FFR ≥0.75) would cause death or myocardial infarction in patients with stable CAD was <1% per year and was not decreased by stenting.

The efficacy of the pressure wire in multivessel disease was recently assessed in the large multicenter FAME study.[45] Before randomization, lesions requiring PCI were identified on the basis of their angiographic appearance. In 1005 randomized patients, those assigned to angiography-guided PCI had drug-eluting stents placed in all indicated lesions. Those assigned to FFR-guided PCI underwent stenting of indicated lesions only if the FFR was 0.80 or less. The 1-year rate of death, nonfatal myocardial infarction, and repeat revascularization was 18.3% (91 patients) in the angiography group and 13.2% (67 patients) in the FFR group ($P = 0.02$). Seventy-eight percent of the patients in the angiography group were free from angina at 1 year versus 81% of the patients in the FFR group ($P = 0.20$). Like IVUS, routine or selected use of the pressure wire has not yet been demonstrated to improve long-term clinical outcomes.

Adjunctive pharmacology trials

PCI results in de-endothelialization and deep arterial injury that exposes luminal blood to tissue factor and other highly thrombotic molecules. Moreover, the artificial surfaces on catheters, guidewires and implanted metallic stents are themselves thrombogenic. Because thrombosis at the site of PCI can lead to catastrophic ischemic complications, periprocedural administration of antiplatelet and antico-agulant drugs is integral to PCI success and safety. Through intensive and rigorous study, antithrombotic agents and strategies have evolved rapidly over the past three decades.

Aspirin
Aspirin has been universally used in all forms of coronary heart disease for decades, based upon clinical trials performed in a wide variety of clinical settings and presentations.[46] Its specific role in PCI for preventing peri- and postprocedural ischemic events was demonstrated in a randomized controlled trial performed in the balloon angio-plasty era. The active treatment comprised an oral aspirin/dipyridamole combination (330/75 mg) given three times daily, beginning 24 hours prior to PCI. Among the 376 randomized patients, there were 16 periprocedural Q-wave myocardial infarctions – 13 in the placebo group and three in the active drug group (6.9% vs 1.6%, $P = 0.0113$).[47] Aspirin has since been standard therapy before and after coronary intervention of all types, and has provided background anti-platelet therapy for all interventional clinical trials testing new antithrombotic regimens, devices and strategies.

The optimal daily dosage of aspirin with a reliable effect in PCI is uncertain. In the USA, 325 mg is common, while in Europe 100 mg or 75 mg is accepted. Higher doses (over 100 mg) are associated with more, predominantly gastrointestinal, side effects but have not been convincingly demonstrated to provide greater long-term protection from thrombotic or ischemic events. *Post hoc* analysis of the PCI-CURE trial examining patients undergoing BMS placement reported an increased risk of bleeding on long-term higher-dose aspirin (162–325 mg) compared to lower dose (75–100 mg).[48] On the other hand, clinically relevant inhibition of platelet aggregation requires 95% blockade of TXA_2 synthesis,[49] a level often not reached for 48 hours after initiating daily oral dosages of 75 mg. The OASIS-7/CURRENT trial is presently enrolling patients in a randomized comparison of ASA 81 mg versus 325 mg administered in combination with clopidogrel.

Thienopyridines
Ticlopidine was the first agent in this class to be widely used as an oral adjunct to ASA and heparin during and after PCI. The STARS trial randomized 1653 patients undergoing native coronary artery stenting, including elective procedures for stable CAD, and demonstrated that a combination of aspirin and ticlopidine was superior to an anticoagulation regimen in preventing subacute stent thrombosis at 30 days.[50] The benefit was obtained at the expense of increased bleeding complications (mostly access site related), but this trial formed the basis for modern ASA/thienopyridine combination therapy after PCI. Later trials, such as CLASSICS[51] and TOPPS,[52] demonstrated non-inferiority of clopidogrel vs ticlopidine, in combination with aspirin, for patients undergoing elective stenting. A meta-analysis of randomized and registry comparisons of ticlopidine and clopidogrel post stenting showed clopidogrel to be associated with a lower adverse cardiac event rate (2.1% versus 4.0%, $P = 0.001$) and mortality (0.48% versus 1.09%, $P = 0.001$) at 30 days.[53] These data, together with poor GI tolerance and infrequent but serious blood dyscrasias (neutropenia in ~2% of patients and rare cases of agranulocytosis), have resulted in abandonment of ticlopidine except for those intolerant of clopidogrel.[54]

The omnipresence of clopidogrel in contemporary PCI trials and guidelines (Box 26.3) has led to its routine use for patients in North America and Europe.[55] The duration of clopidogrel therapy was evaluated in the CREDO trial and demonstrated that optimal benefit was achieved by continuing 75 mg daily for 12 months post PCI in stable patients.[56] Clopidogrel in combination with aspirin conferred a 3% absolute risk reduction in the combined risk of death, MI or stroke ($P = 0.02$) when compared to aspirin alone. The timing and dosage of clopidogrel loading prior to PCI for patients not chronically treated appear to influence PCI outcome. *Post-hoc* analysis of the CREDO trial suggested that loading with oral clopidogrel 300 mg at least 15 hours pre-procedure was associated with the lowest adjusted risk of thrombotic and ischemic events. The ISAR-REACT trial showed that for patients at low-to-intermediate risk for early ischemic complications after elective PCI, pretreat-

BOX 26.3 Oral antiplatelet therapy (modified from 2007 focused update of the ACC/AHA/SCAI 2005 guideline update for percutaneous coronary intervention)

Class I indications
- Patients already taking daily long-term aspirin therapy should take 75 mg to 325 mg of aspirin before PCI is performed. (**Level A**)
- Patients not already taking daily long-term aspirin therapy should be given 300 mg to 325 mg of aspirin at least 2 hours and preferably 24 hours before PCI is performed. (**Level C**)
- After PCI, in patients without allergy or increased risk of bleeding, aspirin 162 mg to 325 mg daily should be given for at least 1 month after BMS implantation, 3 months after sirolimus-eluting stent implantation, and 6 months after paclitaxel-eluting stent implantation, after which daily long-term aspirin use should be continued indefinitely at a dose of 75 mg to 162 mg. (**Level B**)
- A loading dose of clopidogrel, generally 600 mg, should be administered before or when PCI is performed. (**Level C**) In patients undergoing PCI within 12–24 hours of receiving fibrinolytic therapy, a clopidogrel oral loading dose of 300 mg may be considered. (**Level C**)
- For all post-PCI stented patients receiving a DES, clopidogrel 75 mg daily should be given for **at least 12 months** if patients are not at high risk of bleeding. For post-PCI patients receiving a BMS, clopidogrel should be given for a minimum of 1 month and **ideally up to 12 months** (unless the patient is at increased risk of bleeding; then it should be given for a minimum of 2 weeks). (**Level B**)

Class IIa indications
- If clopidogrel is given at the time of procedure, supplementation with GP IIb/IIIa receptor antagonists can be beneficial. (**Level B**)
- For patients with an absolute contraindication to aspirin, it is reasonable to give a 300–600 mg loading dose of clopidogrel, administered at least 6 hours before PCI, and/or GP IIb/IIIa antagonists, administered at the time of PCI. (**Level C**)
- In patients for whom the physician is concerned about risk of bleeding, a lower dose of 75 mg to 162 mg of aspirin is reasonable during the initial period after stent implantation. (**Level C**)

Class IIb indications
- Continuation of clopidogrel therapy beyond 1 year may be considered in patients undergoing DES placement. (**Level C**)

ment with a 600 mg loading dose of clopidogrel was not associated with a measurable clinical benefit, irrespective of increasing the pretreatment interval beyond 2–3 hours or adjunctive treatment with abciximab.[57] The ARMYDA-2 trial showed reduced periprocedural marker elevation and MI in patients who were given a 600 mg clopidogrel loading dose rather than 300 mg.[58] The large CURRENT/OASIS 7 trial is testing a low dose (300 mg loading dose, followed by 75 mg/day maintenance therapy) versus high dose (600 mg loading dose, followed by 150 mg/day for a week and then 75 mg/day thereafter) clopidogrel regimen and a low (81 mg) versus high-dose (325 mg) ASA regimen and is powered to examine clinical events at 30 days.

The optimal loading and maintenance dose of clopidogrel to achieve rapid, predictable and sustained platelet inhibition is further confounded by interindividual variability. Platelet aggregation and expression of activation-dependent receptor expression in patients undergoing elective PCI treated with clopidogrel 300 mg orally followed by 75 mg daily has been found to vary widely.[59] Using a cut-off of <10% absolute change in aggregation to define clopidogrel resistance, the prevalence was 50–60% at 2 h, ~30% at 1 and 5 days and ~15% at 30 days post PCI. However, point-of-care platelet function assays are neither readily available nor well correlated to clinical outcomes; thus most centers have adopted a standard regimen of 600 mg loading dose followed by 75 mg maintenance dose.

The optimum duration of clopidogrel therapy following PCI, especially after DES implantation, is uncertain. Pivotal trials leading to approval of contemporary DES devices required ASA plus clopidogrel for at least three months after PCI. Late stent thrombosis was infrequent, but most patients were anatomically simple and the majority were treated with clopidogrel for at least six months. Subsequent recognition of late and very late DES thrombosis as infrequent but life-threatening events linked to anatomic or procedural complexity and associated with clopidogrel withdrawal has led to guideline revisions calling for one year's therapy after DES insertion. Recently published recommendations aimed at reducing the incidence of late DES thrombosis emphasize patient education regarding the hazards of premature clopidogrel discontinuation.[60] However, there is no randomized trial to directly inform optimum duration of therapy.

Prasugrel is a new, potent platelet $P2Y_{12}$ receptor inhibitor, and in combination with aspirin performed favorably against clopidogrel in a large trial of ACS patients undergoing PCI.[61] Overall, major adverse cardiac events were reduced (9.9% versus 12.1%, $P < 0.001$) but at the expense of increased serious bleeding. At the time of writing, prasugrel is not commercially available.

Glycoprotein IIb/IIIa receptor blockers

Three glycoprotein IIb/IIIa receptor inhibitors (GPI) have been evaluated in PCI clinical trials that included patients with stable CAD. These are abciximab, derived from a chimeric murine monoclonal antibody, and the synthetic peptides eptifibatide and tirofiban. Only abciximab and eptifibatide remain in frequent use. Both were evaluated with background aspirin and heparin.
Figure 26.6 Improved 30-day mortality in GP IIb/IIIa inhibition arm of trials. (Adapted from Karvouni et al.[65])

The utility of abciximab in non-emergent PCI was evaluated in the EPIC, EPILOG, and EPISTENT trials.[62–64] EPIC enrolled 2099 patients deemed to be at high risk for ischemic complications of PCI and demonstrated that abciximab administered as a bolus plus infusion reduced the primary 30-day endpoint of death, MI or urgent intervention by 35%, compared to placebo or to abciximab bolus alone. EPILOG extended this experience into lower risk elective PCI procedures, and tested abciximab in combination with reduced-dose heparin. The trial was terminated early for efficacy after enrollment of 2792 patients (4800 planned). Greater than 50% relative reduction in death or MI, and in death, MI or urgent intervention was observed at 30 days in both abciximab arms (standard dose or reduced dose heparin) when compared to placebo. Major bleeding was numerically least frequent with the combination of abciximab and reduced dose heparin (2.0% versus 3.1% placebo versus 3.5% abciximab plus standard dose heparin, P = NS). EPISTENT compared three PCI strategies: balloon angioplasty plus abciximab, stenting plus placebo, or stenting plus abciximab, and employed the reduced dose heparin regimen from EPILOG. The primary endpoint of death, MI or urgent revascularization was observed in 10.8% of those assigned stent plus placebo, 6.9% of those assigned balloon angioplasty plus abciximab and in 5.5% of those assigned stent plus abciximab ($P < 0.001$). Many of the endpoints in these trials were small periprocedural myocardial infarctions. However, a subsequent meta-analysis of abciximab PCI trials demonstrated that abciximab significantly reduced death; this quelled much of the criticism that had focused on endpoint definition[65] (Fig. 26.6).

In summary, abciximab has been demonstrated to reduce early ischemia, abrupt vessel closure, subacute thrombosis, and MI, but late target vessel revascularization events (due to restenosis) are not affected.[66] As with any therapeutic intervention, the greatest benefit is likely observed in the highest risk patients.

IMPACT-II, the initial Phase III evaluation of eptifibatide, randomly assigned 4010 patients undergoing non-emergent balloon angioplasty to eptifibatide 135 μg/kg bolus followed by 24-hour infusions of 0.5 or 0.75 μg/kg/min, or placebo.[67] No statistically significant reduction in the primary endpoint of death, MI, emergency revascularization or bailout stenting was observed. Pharmacodynamic studies, however, suggested that eptifibatide dosing may have been inadequate in IMPACT II. This led to the development of the ESPRIT trial that compared a double bolus regimen followed by a larger 2.0 μg/kg/min infusion for 18–24 hours to placebo in 2064 patients undergoing elective stenting.[68] Thienopyridine-pretreated patients were excluded. The primary endpoint was the composite of death, MI, urgent target vessel revascularization and bailout GPI use within 48 hours. The trial was terminated early due to efficacy, with significant endpoint reduction in the eptifibatide arm (6.6% versus 10.5%, P = 0.0015) and durable benefit to six months. As with the abciximab trials, many events in ESPRIT were small periprocedural myocardial infarctions.

Proven regimens with abciximab and eptifibatide depended upon administration of a prolonged intravenous infusion that required nursing time, may have contributed to bleeding, and delayed hospital discharge. Because length of hospitalization substantially impacts cost, shorter

duration abciximab and eptifibatide regimens have recently been studied. Following uncomplicated PCI, the BRIEF trial demonstrated that eptifibatide infusion can be safely abbreviated to ≤2 h, without compromising efficacy compared to the standard 18-h regimen, with less major bleeding.[69]

Pivotal trials testing GPI use in non-emergent PCI were performed in the 1990s before clopidogrel pretreatment was routine practice. The incremental benefit of GPI use in patients pretreated with both aspirin and clopidogrel was addressed in the ISAR-REACT series of randomized, placebo-controlled trials. For patients undergoing elective PCI and at low to intermediate risk for thrombotic complications, abciximab did not provide incremental benefit after 600 mg clopidogrel pretreatment. This contrasted with results in a higher risk patient group defined by presentation with non-ST elevation myocardial infarction (STEMI) (ISAR-REACT 2) where abciximab, in addition to periprocedural unfractionated heparin (UFH), conferred a 25% relative risk reduction in 30-day major adverse cardiac event rate compared to placebo (8.9% versus 11.9%, P = 0.03), without compromise in safety, and with benefit maintained at one year.[70,71] The CLEAR PLATELETS 1b trial evaluated the effect of combining eptifibatide with clopidogrel loading (300 or 600 mg) versus clopidogrel loading alone on myonecrotic and inflammatory marker release in 120 patients after elective stenting.[72] The combination regimen reduced the release of CK-MB, myoglobin, troponin-I and CRP (P < 0.01 for each parameter). The clinical translation of the attenuated release of these markers suggests that more potent platelet inhibition is beneficial.

Periprocedural anticoagulant

Unfractionated and low molecular weight heparin Use of a potent anticoagulant during PCI has been standard therapy since coronary balloon angioplasty was first described. Until recently, unfractionated heparin (UFH) has been unchallenged as the most commonly employed agent for this indication. Large placebo-controlled trials demonstrating the need for UFH during PCI were never performed. Anecdotal experience from PCI performed without heparin or other anticoagulant, sometimes by medical error, suggest a high incidence of acute coronary thrombosis in its absence.

Attention has been paid to heparin dosing during PCI. In the balloon angioplasty era, heparin was commonly administered as a non-weight adjusted high dose bolus of 10 000–12 000 units. When combined with concurrent practices that included larger bore arterial sheaths (8 F) and delayed sheath removal, arterial access site bleeds were common.[62] Contemporary heparin dosing is dependent on whether there is concurrent GPI administration.[68,73] In those patients without GPI, sufficient UFH should be given during PCI to maintain an activated clotting time (ACT) of 300 seconds. A weight-adjusted heparin bolus (70–100 IU/kg) is usually used to achieve the target anticoagulation

and supplemented as necessary with boluses of 2000–5000 IU. The UFH bolus should be reduced to 50–70 IU/kg in the presence of GPI to achieve an ACT of 200 seconds. Postprocedural UFH infusions are not recommended.

Compared to UFH, low-molecular weight heparins (LMWH) display more consistent protein and cellular binding, resulting in greater bioavailability and less interpatient variability with respect to potency and clearance. Other potential advantages of LMWH relevant to PCI include a low incidence of heparin-induced thrombocytopenia, freedom from activated partial thromboplastin time (APTT) monitoring, and avoidance of need to switch antithrombotic agents in acute coronary syndrome (ACS) patients medically stabilized with subcutaneous LMWH.[74] The safety and efficacy of intravenous LMWH (enoxaparin; 1 mg/kg) in elective PCI were validated in the NICE-1 trial.[75] STEEPLE was the largest trial directly comparing a LMWH (enoxaparin) to UFH in elective PCI.[76] Patients were randomly assigned to one of two bolus doses of intravenous enoxaparin (0.5 mg/kg or 0.75 mg/kg) or to UFH (70–100 IU/kg or 50–70 IU/kg bolus) with or without a GPI. Concerns arose that the lower enoxaparin dose was associated with higher mortality due to thrombotic complications. The overall mortality rate of 1.0% in the 0.5 mg/kg enoxaparin group was twice that expected for patients undergoing elective PCI, especially patients at low risk for complications. This observation was argued to be directly treatment related rather than a chance effect. Another confounding factor with this trial is that interpretation of the primary endpoint, the incidence of major or minor bleeding not related to coronary artery bypass grafting, varied depending on the bleeding index used. The authors employed unique definitions of major and minor bleeds that had not been shown to have prognostic import. Reanalysis of the results using TIMI bleeding criteria showed no significant differences in bleeding rates between the enoxaparin and UFH groups, whereas the GUSTO index demonstrated superiority of the lower dose enoxaparin regimen. A meta-analysis incorporating 11 trials among patients undergoing elective PCI demonstrated similar efficacy between LMWH and UFH with respect to all-cause mortality and major adverse cardiac events (P = 0.93).[77] A significant reduction in major bleeding risk with LMWH compared with UFH (P = 0.002) and a trend towards a reduction in minor bleeds (P = 0.24) were also apparent.

There are currently two strategies guiding the use of LMWH (with or without concomitant GPI) for PCI:[78] UFH may substituted for LMWH prior to angiography and coronary intervention if the last LMWH dose was given more than 8–12 hours before the procedure, or alternatively, LMWH may be safely continued as the sole anticoagulant throughout the PCI without switching to UFH.

Hirudin/bivalirudin In REPLACE-2, the direct thrombin inhibitor bivalirudin[79] was compared to UFH plus planned

BOX 26.4 Anticoagulation therapy (modified from 2007 focused update of the ACC/AHA/SCAI 2005 guideline update for percutaneous coronary intervention)

Class I indications
- For patients undergoing PCI after having received an anticoagulant regimen, the following dosing recommendations should be followed:
  ○ For prior treatment with UFH, administer additional boluses of UFH as needed to support the procedure, taking into account whether GP IIb/IIIa receptor antagonists have been administered. (**Level C**) Bivalirudin may also be used in patients treated previously with UFH. (**Level C**)
  ○ For prior treatment with enoxaparin, if the last subcutaneous dose was administered at least 8 to 12 hours earlier, an IV dose of 0.3 mg/kg of enoxaparin should be given; if the last subcutaneous dose was administered within the prior 8 hours, no additional enoxaparin should be given. (**Level B**)
  ○ For prior treatment with fondaparinux, administer additional intravenous treatment with an anticoagulant possessing anti-IIa activity, taking into account whether GP IIb/IIIa receptor antagonists have been administered. (**Level C**)

Class III indications
- Because of the risk of catheter thrombosis, fondaparinux should not be used as the sole anticoagulant to support PCI. An additional anticoagulant with anti-IIa activity should be administered. (**Level C**)

GPI, using a non-inferiority design in a diverse population undergoing PCI.[80] Elective cases comprised 56% of enrollment. The primary endpoint was a composite of death, MI, urgent revascularization or in-hospital major bleeding at 30 days and occurred in 9.2% of the bivalirudin cohort compared with 10% patients in the UFH plus GPI group ($P = 0.32$). In hospital major bleeding was significantly reduced by bivalirudin (2.4% versus 4.1%, $P < 0.001$), with the results driven by access site-related complications and gastrointestinal bleeds.

High-risk patients undergoing PCI have also been evaluated in several important trials including HELVITCA,[81] HAS[82] and ACUITY.[83] Together, these trials suggest that direct antithrombin inhibitors reduce acute thrombotic complications and bleeding when compared to heparin. This evidence has led to the incorporation of bivalirudin into the latest AHA/ACC guidelines for routine interventional practice (Box 26.4).

Fonadaparinux
Fondaparinux is an indirect factor Xa inhibitor with proven superiority to standard therapies for the prevention of venous thrombosis, the safety and efficacy of which were piloted in the ASPIRE trial in patients who underwent elec-

tive or urgent PCI for ACS.[84] Concerns regarding inadequate protection against lesion-related or catheter-related thrombus first surfaced with fondaparinux-treated patients in ASPIRE. The subsequent and much larger OASIS-5 trial randomized ACS patients to either fondaparinux or enoxaparin treatment.[85] After additional reports of catheter thrombus with fondaparinux, the protocol was amended to encourage open-label administration of supplemental UFH for fondaparinux-treated patients undergoing PCI. With this hybrid strategy, subcutaneous fondaparinux (2.5 mg/day for ≤8 days) was non-inferior to subcutaneous enoxaparin (1 mg/kg twice daily, once daily in those with renal dysfunction) in reducing death or ischemic events at nine days, with efficacy being maintained for up to six months. Major bleeding occurred in fewer fondaparinux recipients, resulting in a benefit/risk balance favoring fondaparinux. Importantly, catheter thrombus was more common with fondaparinux than with enoxaparin (0.9% versus 0.4%), but this complication was largely prevented by the addition of UFH at the time of PCI, with no increase in the bleeding rate.

Strategic trials of percutaneous coronary intervention versus medical therapy in stable coronary artery disease

Insofar as ischemia due to coronary stenosis is a defining feature of coronary artery disease ("ischemic heart disease"), the prevention of ischemia through the relief of coronary stenoses with PCI would at first appear to offer self-evident potential for improving long-term outcomes. At least in the case of patients with chronic ischemia, demonstrating such a benefit has been conspicuously difficult. The degree to which this reflects the biology of chronic ischemic heart disease versus limitations in trial design and power, populations enrolled, advances in medical therapy, and the PCI technologies and techniques employed remains a matter of some debate.

Historic trials

A Comparison of Angioplasty with Medical Therapy in the Treatment of Single-Vessel Coronary Artery Disease (ACME)[86] randomly assigned 212 patients with stable, single-vessel CAD and exercise-induced myocardial ischemia to coronary balloon angioplasty or medical therapy alone. Angioplasty resulted in a greater proportion of patients free from angina at six months (64% versus 46%, $P < 0.01$) and greater objective improvement in treadmill exercise duration (2.1 versus 0.5 minutes; $P < 0.0001$) compared to medical therapy alone. These results were obtained despite a high rate of PCI failure (20%) and in an era that predated modern interventional or medical therapies. A subsequent trial from the ACME group enrolled 328 patients with double-vessel disease and was reported in

1997.[87] Patients with double-vessel disease, treated with balloon angioplasty versus medical therapy, experienced comparable improvement in exercise duration (+1.2 versus +1.3 min, respectively, $P = 0.89$), freedom from angina (53% and 36%, respectively, $P = 0.09$) and improvement of overall quality of life score (+1.3 versus +4.4, respectively, $P = 0.32$) at six months compared with baseline. This contrasts with greater advantages favoring PTCA by these criteria in patients with single-vessel disease ($P = 0.0001$ to 0.02). Trends present at six months persisted at late follow-up. Patients undergoing double-vessel dilation had less complete initial revascularization (45% versus 83%) and greater average stenosis of worst lesions at 6 months (74% versus 56%). Likewise, patients with double-vessel disease showed less improved myocardial perfusion imaging (59% versus 75%). Neither trial was powered to show differences in myocardial infarction or death.

The largest prospective trial of balloon angioplasty versus medical therapy was the multicenter Randomized Intervention Treatment of Angina (RITA) 2 trial.[88] Most of the patients had mild symptoms (80% Canadian Cardiovascular Society (CCS) class 0 to II), 60% had single-vessel CAD, and one-third had two-vessel disease. The primary endpoint of death or myocardial infarction occurred in 6.3% (32 patients) of the balloon angioplasty group and 3.3% (17 patients) of the medical therapy group (absolute difference 3.0%, 95% CI 0.4–5.7; $P = 0.02$). The combined rates of death, myocardial infarction, and non-protocol revascularization were similar at three years. Angina pectoris, treadmill exercise time and quality of life measures improved significantly in both groups. The subgroup of patients with baseline angina CCS class II or worse, however, appeared to derive incremental benefit from PCI that included a lower incidence of angina, longer treadmill exercise times, greater improvements in physical functioning, vitality, and general health at three months and one year. By three years, however, this advantage was lost, likely due in part to cross-over PCI rescue of the most symptomatic medically assigned patients (cross-over rate 27%).[89]

The Atorvastatin Versus Revascularization Treatment (AVERT) trial[90] enrolled 341 patients with low-risk CAD (99% of patients had stable CCS class 0 to II angina) in a randomized trial of controversial design comparing percutaneous revascularization plus usual medical care to medical care that included high-dose atorvastatin. Overall, 166 patients in the angioplasty group underwent the assigned procedure (with a total of 213 treated lesions). Concomitant stenting was used in 64 of the lesions. Though a greater proportion of the PCI group had improved angina (54% versus 41%, $P = 0.009$), fewer cardiac events (cardiac death or arrest, revascularization, stroke or worsening angina) developed in the atorvastatin group (21% PCI versus 13% atorvastatin, $P = 0.048$). The potentially complementary combination of PCI and high-dose statin therapy was not tested.

The ACIP (Asymptomatic Cardiac Ischemia Pilot) study examined 558 patients with silent ischemia who were judged angiographically suitable for revascularization.[91] Three treatment strategies were tested: angina-guided drug therapy (n = 183), ischemia-guided drug therapy (n = 183) or revascularization by angioplasty or bypass surgery (n = 192). Two-year total mortality was 6.6% in the angina-guided strategy, 4.4% in the ischemia-guided strategy, and 1.1% in the revascularization strategy ($P < 0.02$). Of the 92 undergoing PTCA, two-year event rates were mortality 1.1% (one patient); death or MI 5.5% (five patients); and death, MI or recurrent hospitalization 31.7% (29 patients). The corresponding rates for the 78 patients undergoing CABG were respectively 0%, 2.7% (two patients) and 12.9% (10 patients). Death or myocardial infarction was 12.1% in the angina-guided strategy, 8.8% in the ischemia-guided strategy, and 4.7% in the revascularization strategy ($P < 0.04$). Recurrent hospitalization was also reduced by the strategy of revascularization. ACIP was a pilot study which was not planned to have sufficient statistical power to detect differences in clinical outcomes. The difference in two-year mortality between the angina-guided and revascularization strategies is based on only 14 deaths (12 in the angina-guided strategy and 2 in the revascularization strategy). The results for death or non-fatal MI are based on only 31 events (22 in the angina-guided strategy and nine in the revascularization strategy). Although the dramatic differences seen produced a statistically significant result, there are too few events to allow for reliable assessment of effect size.

Bucher *et al* performed a systematic review of six randomized clinical trials that enrolled 1904 patients (from 1979 to 1998) with stable, predominantly single-vessel CAD and generally normal left ventricular function, assigned to balloon angioplasty plus medication versus medication alone.[92] The AVERT trial, with the limitations discussed above, contributed the second largest pool of patients. Routine PTCA resulted in significant improvement in angina (risk ratio (RR) 0.70, 95% CI 0.50–0.98); however, patients assigned to PTCA required CABG more frequently (RR 1.59, 95% CI 1.09–2.32). No differences in death (RR 1.32, 95% CI 0.65–2.70) or myocardial infarction (RR 1.42, 95% CI 0.90–2.25) were observed. The review did not include enough patients for informative estimates of the effect of angioplasty on myocardial infarction, death, or subsequent revascularization.

A more recent meta-analysis by Katritsis *et al* that considered 11 trials (1987–2001) including 2950 patients concluded that a strategy of routine PTCA performed in patients with stable symptoms, predominantly single-vessel CAD and normal left ventricular function does not prevent death, myocardial infarction or the need for subsequent revascularization when compared with routine medical treatment (Fig. 26.7).[93] By random effects, the risk

(a) Death
(b) Cardiac death or myocardial infarction
(c) Non-fatal myocardial infarction
(d) Coronary artery bypass grafting
(e) Percutaneous coronary intervention
Figure 26.7 Comparison of PCI vs conservative medical treatment for (a) death, (b) cardiac death or any MI, (c) non-fatal MI, (d) CABG, and (e) PCI during follow-up. Each study is shown by name along with point estimate of risk ratio and respective 95% CIs. In each panel, size of box denoting point estimate in each study is proportional to weight of study. Also shown are summary risk ratio and 95% CIs according to Der Simonian and Laird random effects (RE) model. Meta-analysis of studies on the effect of PCI versus medical therapy. (From Katritsis et al.[93])

ratios (95% CI) for the PCI versus conservative treatment arms were for mortality 0.94 (0.72–1.24), cardiac death or myocardial infarction 1.17 (0.88–1.57), non-fatal myocardial infarction 1.28 (0.94–1.75), CABG 1.03 (0.80–1.33), and PCI 1.23 (0.80–1.90). A possible survival benefit was seen for PCI only in trials of patients who had a relatively recent myocardial infarction (RR 0.40, 95% CI 0.17–0.95). Except for PCI during follow-up, there was no significant between-study heterogeneity for any outcome. A large proportion of patients again came from the RITA-2 and AVERT trials.

Current era trials

Two recent trials of PCI versus medical therapy have focused attention on the appropriate use of PCI in stable CAD: MASS (Medicine, Angioplasty, or Surgery Study)-2 trial[94] and the COURAGE (Clinical Outcomes Utilizing Revascularization and Aggressive DruG Evaluation) trial.[95]

The MASS-2 study assigned 611patients (enrolled between 1995 and 2000) with limited multivessel CAD, stable angina, and preserved ventricular function to CABG (n = 203), PCI (n = 205) or medical therapy (n = 203). The one-year survival rates were 96.0% for CABG, 95.6% for PCI, and 98.5% for medical therapy (P = NS). The rates for one-year survival free of Q-wave MI were 98% for CABG, 92% for PCI, and 97% for medical therapy. After one-year follow-up, 8.3% of medical therapy patients and 13.3% of PCI patients underwent additional revascularization procedures, compared with only 0.5% of CABG patients. At one-year follow-up, 88% of the patients in the CABG group, 79% in the PCI group, and 46% in the medical therapy group were free of angina (P < 0.0001).

The COURAGE study compared an initial management strategy of percutaneous coronary intervention and optimal medical management (PCI) to optimal medical therapy (OMT) alone in patients with stable CAD.[95] Between 1999 and 2004, 1149 patients were assigned to PCI and 1138 to OMT. Baseline characteristics included: 43% of patients had either no angina or only class 1 angina, 30% of patients had single-vessel disease, the ejection fraction was approximately 61% in both groups, and DES were not routinely available. Balloon angioplasty (no stent) was used in 6% of those assigned PCI, and DES were employed in fewer than 3%. Neither glycoprotein inhibitors nor thienopyridine pretreatment was provided routinely. PCI was judged angiographically unsuccessful in 7%.

There were 211 primary events (death from any cause and non-fatal MI) in the PCI group and 202 events in the medical therapy group. The 4.6-year cumulative primary-event rates were 19.0% in the PCI group and 18.5% in the medical therapy group (hazard ratio (HR) for the PCI group 1.05; 95% CI 0.87–1.27; P = 0.62). There were no significant differences between the PCI group and the medical therapy group in the composite of death, MI, and stroke (20.0%

versus 19.5%; HR 1.05; 95% CI 0.87–1.27; P = 0.62); hospitalization for ACS (12.4% versus 11.8%; HR 1.07; 95% CI 0.84–1.37; P = 0.56) or MI (13.2% versus 12.3%; HR 1.13; 95% CI 0.89–1.43; P = 0.33). These results were not unexpected given the low-risk baseline characteristics of the enrolled population, low overall mortality, and the results of prior CABG versus medicine trials demonstrating the futility of CABG for prolonging survival in similar cohorts.[96]

COURAGE documented symptomatic benefits attributable to routine PCI, but these were modest. A significantly larger proportion of PCI-assigned patients were angina free during most of the follow-up period, though the two arms converged in this regard. At five years, 74% of patients in the PCI group and 72% of those in the medical therapy group were free of angina (P = 0.35). Routine PCI also resulted in a lower rate of non-protocol revascularization during follow-up (21.1% versus 32.6%; HR 0.60; 95% CI 0.51–0.71; P < 0.001). Critics of the study note that larger differences in metrics of symptom burden may have been buffered by several factors, including the enrolment of many patients with mild or no angina at entry, enrollment bias toward medical responders, unusually intensive medical follow-up and treatment, relatively high PCI failure rates, infrequent use of DES, and cross-over to PCI in one-third of those assigned OMT. A recent meta-analysis of trials of BMS vs optimal medical therapy, including the COURAGE trial, found similar results.

A substudy of COURAGE enrolled 314 patients evaluated with centrally analyzed quantitative SPECT myocardial perfusion imaging before treatment and again 6–18 months after enrollment.[97] The observed reduction in ischemic myocardium was significantly greater with PCI (–2.7%; 95% CI –1.7% to –3.8%) than with OMT (–0.5%; 95% CI –1.6–0.6%; P < 0.0001). The difference favoring routine PCI was most marked amongst patients with moderate to severe pretreatment ischemia in whom 78% experienced significant ischemia reduction with PCI versus 52% with OMT (P = 0.007). Patients with ischemia reduction had lower unadjusted risk for death or myocardial infarction (P = 0.037 [risk-adjusted P = 0.26]), particularly if baseline ischemia was moderate to severe (P = 0.001 [risk-adjusted P = 0.08]).

Overall, the strategy of PCI as a routine or frequent component of therapy to reduce major cardiac events in patients with stable symptomatic or silent ischemia has not been adequately tested. Trials performed to date have significant limitations with respect to populations studied, procedural success, pharmacology and technology, and statistical power to detect differences in long-term mortality. The degree to which the results of these trials can be generalized to contemporary cardiology practice is therefore limited. Moreover, widespread application of PCI for symptom relief may, at this stage, make performing a definitive trial difficult or impossible. Trials comparing PCI to

medical therapy in high-risk patient groups may still be feasible and could provide important insights. For example, the recent BARI 2D trial performed in patients with type 2 diabetes and stable coronary artery disease, found no difference in major outcomes between PCI and optimal medical therapy.[97a] Existing and ongoing trials comparing PCI to CABG in cohorts already known to benefit from CABG are discussed in Chapter 30.

Conclusions: elective percutaneous coronary intervention versus medical therapy (Boxes 26.5 and 26.6)

• Among patients with medically refractory angina pectoris, PCI is indicated for symptom improvement (**Class I**).
• In the absence of symptoms or myocardial ischemia, PTCA is not indicated merely for the presence of an anatomic stenosis (**Class I**).
• Electively placed stents are superior to balloon angioplasty for reducing the need for repeat procedures (**Class I**).
• DES are superior to BMS for reducing the need for repeat procedures (**Class I**).
• PCI is reasonable for patients with recurrent stenosis after PTCA, a large area of viable myocardium at risk or high-risk criteria on non-invasive testing (**Class II**).

Future directions and challenges

A variety of anatomic circumstances present unique challenges during PCI. These include aorto-ostial lesions, chronic total occlusions (CTOs), bifurcation lesions, and saphenous vein grafts (SVGs). Numerous prospective, randomized trials published over the past 10 years have compared elective stenting to balloon angioplasty under various conditions. These studies have enrolled patients with various lesion types, including elective procedures for single discrete lesions in vessels of 3 mm or larger,[10,11,98–106] restenosis lesions after previous balloon angioplasty,[107] lesions of saphenous vein grafts.[108] small-caliber vessels[109–112] and chronic total occlusions.[12,113–118] BMS implantation decreases the need for target vessel revascularization in these challenging anatomic substrates.

Aorto-ostial lesions extend proximal to the coronary ostia into the aortic wall where abundant elastic fibers contribute to elastic recoil and poor outcome after balloon angioplasty.[119] By resisting recoil, stents maintain significantly larger lumens and lower the risk of restenosis in aorto-ostial lesions. Preliminary data suggest DES may further improve outcomes.[120] SVGs remain a challenging problem. Following bypass graft surgery, approximately 5–10% of patients per year develop recurrent angina and by 10 years almost 50% of SVGs are occluded.[16] Although

BOX 26.5 Patients with asymptomatic ischemia or CCS class I or II angina

Class IIa indications
• PCI is reasonable in patients with asymptomatic ischemia or CCS class I or II angina and with 1 or more significant lesions in 1 or 2 coronary arteries suitable for PCI with a high likelihood of success and a low risk of morbidity and mortality. The vessels to be dilated must subtend a moderate to large area of viable myocardium or be associated with a moderate to severe degree of ischemia on noninvasive testing. (**Level B**)
• PCI is reasonable for patients with asymptomatic ischemia or CCS class I or II angina, and recurrent stenosis after PCI with a large area of viable myocardium or high-risk criteria on non-invasive testing. (**Level C**)
• Use of PCI is reasonable in patients with asymptomatic ischemia or CCS class I or II angina with significant left main CAD (greater than 50% diameter stenosis) who are candidates for revascularization but are not eligible for CABG. (**Level B**)

Class IIb indications
• The effectiveness of PCI for patients with asymptomatic ischemia or CCS class I or II angina who have 2- or 3-vessel disease with significant proximal LAD CAD who are otherwise eligible for CABG with 1 arterial conduit and who have treated diabetes or abnormal LV function is not well established. (**Level B**)
• PCI might be considered for patients with asymptomatic ischemia or CCS class I or II angina with non-proximal LAD CAD that subtends a moderate area of viable myocardium and demonstrates ischemia on non-invasive testing. (**Level C**)

Class III indications
• PCI is not recommended in patients with asymptomatic ischemia or CCS class I or II angina who do not meet the criteria as listed under the class II recommendations or who have 1 or more of the following:
  ○ Only a small area of viable myocardium at risk (**Level C**)
  ○ No objective evidence of ischemia. (**Level C**)
  ○ Lesions that have a low likelihood of successful dilation. (**Level C**)
  ○ Mild symptoms that are unlikely to be due to myocardial ischemia. (**Level C**)
  ○ Factors associated with increased risk of morbidity or mortality. (**Level C**)
  ○ Left main disease and eligibility for CABG. (**Level C**)
  ○ Insignificant disease (less than 50% coronary stenosis). (**Level C**)

From ACC/AHA/SCAI 2005 Guideline Update for Percutaneous Coronary Intervention.[6]

DES may improve outcomes, the need for repeat revascularization is often driven by progressive disease in other segments within the same vein graft.

Clinical and angiographic rates of restenosis are high following recanalization and treatment of CTOs with either balloon angioplasty or BMS. Initial results suggest improved angiographic restenosis rates with DES; definitive results are expected with publication of TOSCA-4 (personal communication, D. Kandzari and C. Buller). A reliable technology for navigating and crossing total coronary occlusions in the first place, however, is urgently needed. CTOs resistant to crossing with current guidewires remain a frequent source of medically refractory angina and a common reason for CABG.

Atherosclerosis frequently develops at branch points and thus more than 20% of lesions treated with PCI involve bifurcations.[121] For lesions that have atherosclerotic involvement of both the main and side branch, a decision as to whether to undertake a provisional approach (in which the side branch is stented only if treatment of the main branch results in compromised flow) or dual stent strategy (in which both main and side branches are treated with DES devices *de novo*) is required. Although a complete discussion of bifurcation stenting is beyond the scope of this chapter, observational studies show the dual stent strategy is associated with higher risk of stent thrombosis[122] and a provisional strategy was shown to be safe and effective in the randomized NORDIC trial.[123] Dedicated-design bifurcation stents are currently under development and clinical investigation but have yet to be demonstrated superior. Technology that provides predictable and durable treatment of the left main coronary artery and its bifurcation or trifurcation point is required before PCI can be legitimately compared to CABG in this important subset.

27 Surgical coronary artery revascularization

Morgan L Brown and Thoralf M Sundt III
Mayo Clinic, Rochester, MN, USA

Introduction and historic perspective

Throughout its development, coronary artery bypass grafting (CABG) has been studied extensively through randomized trials, prospective registries, and retrospective studies. It is arguably one of the most studied procedures in medicine. Despite improvements in medical therapies and percutaneous interventions, CABG remains an important therapy for millions of patients every year. Pioneering methods to restore blood supply to ischemic myocardium included placement of a pectoralis muscle flap on abraded pericardium by Beck in 1935,[1] direct implantation of the internal thoracic artery (ITA) onto the myocardium in 1950 by Vineberg,[2,3] and "myocardial acupuncture" in 1965 by Sen.[4] Direct revascularization was possible after the development of the cardiopulmonary bypass (CPB) machine by Gibbon[5] which, along with cardioplegia, allowed the heart to be stopped and the coronary arteries opened safely. In 1958, Longmire reported an ITA to coronary anastomosis after an unsuccessful coronary atherectomy.[6] Goetz performed the first successfully planned CABG using a metal connector in 1960, with angiographic patency confirmed two weeks after operation.[7] The first saphenous vein was used as a graft in 1962 by Sabiston.[8] Kolessov, a Russian surgeon, was credited with the first successful planned sutured ITA to coronary artery anastomosis in 1964.[9]

After the development of coronary angiography at the Cleveland Clinic in 1957, the elective treatment of coronary atherosclerosis began to grow.[10] The first large-scale series of CABG procedures were published between 1968 and 1970 demonstrating the success of CABG and ensuring its place in the treatment of coronary artery disease (CAD).[11–15] Over the ensuing three and a half decades, the procedure has been refined with a decline in mortality rate below

2.5% currently.[16] Curiously, one of the most recent developments is a return to "off-pump" techniques obviating the need for CPB, the very technologic innovation arguably most responsible for the widespread adoption of CABG.

Incidence, natural history, and prognosis

Given the clinical importance of the condition, the incidence, natural history, and prognosis of CAD in general are covered in detail elsewhere in this volume. Still, it is worth emphasizing that in contrast to percutaneous techniques, surgical revascularization has been definitively shown to improve five-year survival among patients with multivessel disease.[17–19] This may be due to the ability of CABG to protect against future culprit lesions (Fig. 27.1).[20]

Management

Coronary artery bypass grafting versus medical management

The American Heart Association and American College of Cardiology have developed comprehensive guidelines (Box 27.1) describing the indications for CABG based on patient symptom status and angiographic features of CAD.[21] These guidelines are based on the best available evidence; however, many of the classic studies have limitations. Most patients in the CABG versus medical management trials were younger than 65 years of age, 80% had a left ventricular (LV) ejection fraction of ≥50%, and the majority of patients were men. Thus, patients enrolled in these trials were generally low risk from the standpoint of both the risk of performing the procedure and the risk of the natural history of the disease itself. Furthermore, the surgical patients did not routinely receive arterial bypass conduits nor did they receive routine aspirin postoperatively, both
Figure 27.1 PCI is targeted at a specific culprit lesion. CABG protects against future culprit lesions by bypassing much of a coronary artery including both culprit and "future culprit" lesions. The dark shading indicates the residual lumen. (Reproduced with permission from Elsevier Ltd. Opie LH, Commerford PJ, Gersh BJ. *Lancet* 2006;**367**:69–78.)

of which may be expected to positively impact graft patency. Of course, they also underwent surgical procedures without current myocardial protection strategies which may be expected to reduce perioperative risk. Equally, it must be said that among the patients who received medical therapy alone, there was no routine aspirin, beta-blockade or lipid-lowering therapy, nor were angiotensin-converting enzyme (ACE) inhibitors routinely prescribed. Despite these major limitations, these studies are remarkably consistent in their primary findings and their conclusions continue to be supported by recent studies, suggesting that they remain generalizable to current practice.

The Coronary Artery Surgery Study (CASS),[22] the Veterans Administration (VA) Co-operative Study Group,[23,24] the European Coronary Surgery Study (ECSS),[25,26] and several other smaller randomized trials[27–30] conducted between 1972 and 1984 provide outcome data comparing medical and surgical therapy. The relative benefits of CABG over medical therapy on survival are greatest in patients at highest risk of complications of their disease as defined by the severity of angina and/or ischemia, the number of diseased vessels, and the presence of LV dysfunction[31] (Fig. 27.2). The survival advantage of surgery over medicine has not been demonstrable among patients with single-vessel disease.[32–34] It should be emphasized, however, that these trials involved primarily patients with moderate chronic stable angina. These conclusions may, therefore, not necessarily apply to patients with unstable angina or to patients with more severe degrees of chronic

stable angina in whom the area of myocardium at risk may be higher.

A meta-analysis[31] of the seven randomized trials cited above demonstrated a survival benefit at five, seven and 10 years for surgically treated patients at highest risk of death due to their disease and among those at moderate risk, but no evidence of a survival benefit for those patients at lowest risk, as defined by a modified version of the Veterans Administration Risk Score[23] and a stepwise risk scoring system.[31] These scoring systems used a combination of both clinical and angiographic variables including angina class, history of hypertension, history of myocardial infarction, depressed ejection fraction (<50%), and a proximal left anterior descending (LAD) lesion >50%. Non-randomized studies have also demonstrated a beneficial effect of surgery on survival of patients with multivessel disease and severe ischemia regardless of LV function.[35–38]

The more recent randomized trials of CABG versus medical therapy also support a strategy of revascularization among patients with symptomatic angina. The Trial of Invasive versus Medical therapy in Elderly (TIME) enrolled elderly (>70 y) patients with chronic symptomatic CAD. The incidence of major adverse events (death, non-fatal myocardial infarction (MI) or hospitalization) was lower (19% vs 49%, $P < 0.0001$) and angina relief was greater (anginal class decreased by 2 vs 1.3, $P < 0.0001$), and all measures of quality of life ($P < 0.05$ for SF36 score, Duke activity score, and Rose score) were superior for those undergoing coronary angiography and surgical revascularization than in those randomized to an initial trial of medical therapy without angiography.[39] In the Asymptomatic Cardiac Ischemia Pilot (ACIP) trial, patients with anatomy amenable to CABG were randomized to anti-ischemic therapy directed at relief of angina, to drug therapy guided by non-invasive measures of ischemia, or to revascularization by CABG or percutaneous coronary interventions (PCI).[40] At two years, mortality was 6.6% in the angina-guided group, 4.4% in the ischemia-guided group, and 1.1% in the revascularization group ($P < 0.02$). At two years of follow-up, the rates of death or MI were 12.1%, 8.8%, and 4.7% respectively ($P < 0.04$). In the recent BARI 2D trial performed in patients with type 2 diabetes and stable coronary artery disease, by 5 years of follow-up there were fewer major cardiovascular events among CABG patients than among those receiving only optimal medical therapy.[40a]

Early concern over high operative mortality in patients with decreased LV systolic function has been replaced by the realization that the survival benefit to these patients is particularly great with surgical revascularization compared with medical therapy. Thus, LV dysfunction in patients with documented ischemia is now considered an important indication for CABG[21,22,35,41,42] with operative mortality rates as low as 4.6%.[43] Evidence that hibernating or stunned myocardium regains contractile function

BOX 27.1 American College of Cardiology/American Heart Association Guidelines published in 2004 outline the indications for coronary artery bypass grafting.[21] This box summarizes guidelines for asymptomatic or mild angina and stable angina.

Asymptomatic or mild angina

Class I
- Significant left main coronary artery stenosis. (**Level A**)
- Left main equivalent: ≥70% stenosis of the proximal LAD and proximal left circumflex artery. (**Level A**)
- Three-vessel disease. (Survival benefit is greater in patients with abnormal LV function, e.g. LVEF <50% and/or large areas of demonstrable myocardial ischemia.) (**Level C**)

Class IIa
- Proximal LAD stenosis with one- or two-vessel disease. (Becomes a Class I if extensive ischemia is documented by non-invasive study and/or LVEF <50%.) (**Level A**)

Class IIb
- One- or two-vessel disease not involving the proximal LAD. (If a large area of viable myocardium and high-risk criteria are met on non-invasive testing, this recommendation becomes Class I.) (**Level B**)

Stable angina

Class I
- Significant left main coronary artery stenosis. (**Level A**)
- Left main equivalent: ≥70% stenosis of the proximal LAD and proximal left circumflex artery. (**Level A**)
- Three-vessel disease. (Survival benefit is greater when LVEF <50%.) (**Level A**)
- Two-vessel disease with significant proximal LAD stenosis and either LVEF <50% or demonstrable ischemia on no-ninvasive testing. (**Level A**)

- One- or two-vessel CAD without significant proximal LAD stenosis but with a large area of viable myocardium and high-risk criteria on non-invasive testing. (**Level B**)
- Disabling angina despite maximal non-invasive therapy, when surgery can be performed with acceptable risk. If angina is not typical, objective evidence of ischemia should be obtained. (**Level B**)

Class IIa
- Proximal LAD stenosis with one-vessel disease. (This recommendation becomes Class I if extensive ischemia is documented by non-invasive study and/or LVEF <50%). (**Level A**)
- One- or two-vessel CAD without significant proximal LAD stenosis but with a moderate area of viable myocardium and demonstrable ischemia on non-invasive testing. (**Level B**)

Class III
- One- or two-vessel disease not involving significant proximal LAD stenosis, patients who have mild symptoms that are unlikely to be due to myocardial ischemia, or who have not received an adequate trial of medical therapy and have only a small area of viable myocardium or have no demonstrable ischemia on non-invasive testing. (**Level B**)
- Patients with angina who have borderline coronary stenoses (50–60% diameter in locations other than the left main coronary artery) and no demonstrable ischemia on non-invasive testing. (**Level B**)
- CABG is not recommended for patients with stable angina who have insignificant coronary stenosis (<50% diameter reduction). (**Level B**)

Figure 27.2 After 10 years of follow-up, CABG extends survival in most moderate- and high-risk subgroups when compared to medical management. Patients were classified into low, moderate, and high risk using the formula: (0.015 × age) + (0.56 × presence of class III/IV angina) + (0.35 × history of myocardial infarction) + (0.62 × abnormal ejection fraction) + (0.53 × proximal lesion of >50% in LAD). (Reproduced with permission from Elsevier Ltd. Yusuf S, Zucker D, Passamani E *et al. Lancet* 1994;**344**:563–70.)
following effective revascularization[44,45] has prompted expansion of the indications for surgical revascularization among patients with severe LV dysfunction to encompass most patients, including those who would otherwise be considered candidates for cardiac transplantation.

Apart from affording a survival benefit, CABG is indicated for the relief of angina pectoris and improvement in quality of life. Between 80% and 90% of patients who are symptomatic on medical therapy become symptom free following CABG. This benefit extends to low-risk patients for whom survival benefit from surgery is not likely.[31] Relief of symptoms appears to relate to both the completeness of revascularization and maintenance of graft patency, with the benefit of CABG diminishing with time. Recurrence of angina following CABG surgery occurs at rates of 3–20% per year.[46–49] Although enhanced survival is reported when an ITA graft is used to the LAD, there is no significant difference in postoperative freedom from angina when compared to venous grafts.[50] This may be due to occurrence of ischemia due to diseases in the vein grafts used to targets other than the LAD or ischemia due to progression of native disease.

Unfortunately, few patients experience an advantage in work rehabilitation with surgery as compared with medical management. Generally, employment declines in both groups and is determined nearly as much by socioeconomic factors such as age, preoperative unemployment, and type of job, as by type of therapy or clinical factors such as postoperative angina.[51–53] Notably, surgical revascularization has not been shown to reduce the incidence of non-fatal events such as MI, although this may be due to perioperative infarctions which offset the lower incidence of infarction in follow-up.[36,54]

Coronary artery bypass grafting versus percutaneous interventions

This topic is discussed in Chapter 28.

Techniques

On-pump and off-pump coronary artery bypass grafting

The current results of conventional on-pump CABG (ONCAB) are excellent. Perioperative mortality rates as reported to the Society of Thoracic Surgeons (STS) database have demonstrated a consistent decline despite an increasing patient risk profile (Fig. 27.3).[55] In 2005, the unadjusted mortality rate for isolated primary CABG in the STS database was 2.2% and the median hospital length of stay was only five days.[16] In return, the operation provides durable relief from angina pectoris and improves long-term survival.

ONCAB comes at a physiologic price, however, as CPB causes trauma to red cells and platelets while inducing a generalized inflammatory response and activation of the cytokine, coagulation, and fibrinolytic cascades.[56] Nonpulsatile flow may have adverse effects on end-organ function[57] and cannulation for arterial inflow may cause embolization of either air or calcium. Despite these risks, ONCAB became the predominant method of surgical revascularization through the 1980s.[58]

While the techniques and technologies to perform ONCAB were being refined, including the introduction of biocompatible surfaces and centrifugal pumps,[59] interest in off-pump (OPCAB) techniques persisted among a small number of surgeons. In the early 1990s, observational studies were published[60–63] demonstrating good outcomes using OPCAB techniques. These data, along with a drive to make procedures less invasive by avoiding the known adverse effects of CPB, stimulated the development of cardiac stabilizing and positioning devices which have simplified OPCAB procedures.

Unfortunately, despite initial enthusiasm, it has been difficult to prove unequivocal superiority of OPCAB to ONCAB. As a general statement, retrospective studies have tended rather consistently to demonstrate benefit of OPCAB, while prospective randomized studies have not. This may be in part due to the tendency of randomized trials to enroll low-risk patients and observational studies to include higher-risk patients. When mainly low-risk patients are enrolled, demonstration of differences between any two therapies – OPCAB vs ONCAB or PCI vs CABG – becomes very difficult, as adverse events are infrequent and large numbers of patients are required for differences between treatments to reach statistical significance. Statistically significant differences are more likely to be demonstrable in observational trials thanks to the inclusion of high-risk patients.

Differences in mortality have been demonstrated by some investigators but not others. Randomized trials such
Figure 27.3 The Society of Thoracic Surgeons database demonstrates a decreasing unadjusted operative mortality for patients undergoing isolated CABG procedures. This is despite increasing numbers of high-risk patients undergoing CABG. http://www.sts.org/sections/stsnationaldatabase/publications/executive/article.html.

as Octopus,[64,65] SMART,[66,67] PRAGUE-4,[68,69] and others[70–73] found no difference in survival. In an observational study of more than 68 000 patients, Racz and colleagues found no difference in risk-adjusted mortality between OPCAB and ONCAB.[74] In a large propensity-matched cohort, however, Mack *et al* demonstrated a difference in adjusted mortality (2.2% vs 3.7%, $P < 0.001$) favoring OPCAB.[75] Apparent differences in mortality have also been demonstrated among specific high-risk subgroups. In a retrospective study of patients with a low ejection fraction ($\leq 30\%$), OPCAB had a lower risk-adjusted mortality rate (1.47% vs 4.13%; $P < 0.001$).[76] Puskas *et al* demonstrated that OPCAB was associated with a significant reduction in death (odds ratio (OR) 0.39, $P = 0.001$) when compared to ONCAB in a cohort of 7740 women.[66,67] An important subgroup of patients with CAD are those with renal failure. In an analysis of patients with end-stage renal disease (ESRD), OPCAB was associated with an operative mortality of 1.7%, whereas the mortality rate of ONCAB was 10-fold higher (17.2%, $P = 0.003$).[77] At late follow up, however, the OPCAB group of patients with ESRD had an increased late mortality when compared to the ONCAB group (38.1% vs 19% annual mortality, $P = 0.03$). This somewhat surprising result may be due to the lower number of mean grafts per patient in the OPCAB group (2.4 ± 1.0 vs 3.3 ± 0.9, $P < 0.001$).[77]

Apart from mortality, a number of retrospective studies have shown a benefit to OPCAB with regard to morbidity, including lower need for blood products, less reoperation for bleeding, and less renal failure,[74,75] although the results of randomized trials have varied. Puskas reported results of the SMART study in 2003, in which patients randomized to OPCAB received fewer units of blood and cardiopulmonary bypass was an independent predictor of blood transfusion (OR 2.42, $P = 0.007$).[66] The reduction in blood transfusion rates was also reported in both the BHACAS trial and by Khan *et al*[72] but was not found to be different between OPCAB and ONCAB in other studies.[69,70] In the SMART trial, postoperative length of stay was shorter in the OPCAB group by one day ($P = 0.005$)[66] but in both the PRAGUE-4 study[68,69] and others,[70,72,73] no differences in hospital stay were observed between OPCAB and ONCAB.

There has been heightened awareness of neurocognitive changes occurring after CABG surgery. While this is a "soft" endpoint and defined by complex neurocognitive testing, the degree of public concern is justifiably great. It is arguable that a reduction in either neurologic decline or stroke would be the greatest benefit of OPCAB surgery. Unfortunately, this has been difficult to prove. A small randomized study demonstrated a dramatic superiority in cognitive outcomes at one week after OPCAB surgery.[78] Conversely, a randomized study of 60 patients demonstrated no difference in cognitive function after three months in OPCAB and ONCAB patients.[79] The largest pro-

spective randomized study performed to address this question was the Octopus Study which enrolled 281 low-risk patients randomized to OPCAB or ONCAB. There was no difference in cognitive outcomes at five years after surgery ($P > 0.99$).[64,65] Interpretation of these data is made more difficult by the variability in neurocognitive testing, the impact of other factors on testing outcomes such as depression, and the anticipated decline in neurocognitive function with aging, particularly among patients with advanced atherosclerotic disease. Indeed, similar changes in neurocognitive function have been identified after PCI.[80] Furthermore, the majority of individuals demonstrating neurocognitive changes early after cardiac surgery experience a return to baseline by three months.[81]

While subject to underrecognition on clinical grounds, the endpoint of stroke is at least in some regards more clearly objective than that of neurocognitive decline. Hopes that OPCAB would reduce the incidence of this endpoint have also been largely unmet. Multiple small studies have been reported with results on both sides of the argument. In two different meta-analyses, however, the incidence of stroke following OPCAB surgery was not statistically significantly reduced in comparison with ONCAB.[82,83] Similarly, there has been no difference in stroke in most randomized trials.[66–69,72,74] Arguments have been made that, as is the case for the issue of operative mortality, differences in stroke rate have not been demonstrable in these relatively small studies due to the low-risk nature of the populations studied. This notion is supported by the results of a recent analysis of 49 830 patients in the New York State Registry in which a lower incidence of stroke was demonstrable in OPCAB patients (adjusted OR 0.70, 95% confidence interval (CI) 0.57–0.86) (84). Unfortunately, most surgeons still place a clamp on the ascending aorta to perform proximal anastomoses for vein grafts when performing OPCAB. The operation is, therefore, not truly "no touch" with respect to the likely culprit source of cerebral embolic material, and it has been argued that the incidence of stroke after CABG may be determined more by the amount of aortic manipulation and less by the use of CPB.[85]

Technically, OPCAB is more difficult to perform than ONCAB. This was particularly true in the early experience, and is still true today despite the introduction of a variety of stabilizing and positioning devices that facilitate anastomoses on the beating heart. Accordingly, in almost every study, the number of grafts performed off-pump is less than the number performed in the ONCAB control group. The quality of the anastomoses performed on the beating heart is also questioned by some. A meta-analysis of seven trials of patients undergoing OPCAB demonstrated a lower rate of complete revascularization (relative risk (RR) 0.959) and lower graft patency than patients undergoing traditional on-pump grafting (standardized mean difference

−0.164).[86] Others argue that this is a manifestation of inadequate institutional and surgeon experience, as centers with extensive experience in OPCAB have reported similar numbers of grafts to those performed in ONCAB.[66]

Thus, while there is some controversy over the benefits of OPCAB over ONCAB, there is general agreement among surgeons that, in experienced hands, OPCAB can be performed with mortality rates at least similar to, if not lower than, those for ONCAB procedures. There is likely a lower rate of transfusion and may well be a lower risk of renal failure with OPCAB. A reduction in stroke likely depends upon complete avoidance of aortic manipulation. There may be particular benefit with regard to morbidity among high-risk patients such as women and the elderly (**Class IIa, Level B**). Utilization of the technique has stabilized in the United States at approximately 20%.[16]

Left anterior small thoracotomy procedure

There was some interest in the use of limited anterior small thoracotomy (LAST) procedures during the early years of OPCAB. This procedure was also called minimally invasive direct coronary artery bypass grafting (MIDCAB), and was applicable for revascularization of the LAD with the left ITA (LITA). It was argued that the small thoracotomy allowed for preservation of chest wall integrity while improving cosmesis due to the smaller incision. The procedure proved technically demanding, however, with an increased risk of injury to the LITA during harvesting and lower anastomotic patencies when compared to a full sternotomy approach[87] (**Class IIb, Level C**). The chest wall incisions proved painful for the patients as well, indeed more so than a full sternotomy, and lung herniation was also a problem, dampening enthusiasm for the procedure. Furthermore, with advances in stent technology, the enthusiasm of cardiologists to refer patients for single-vessel bypass grafting waned. Currently, the principal application of the LAST procedure is in hybrid procedures involving surgical revascularization of the LAD artery and coronary stenting of the circumflex and right coronary arteries.[88,89]

Robotics

Efforts to apply robotic and endoscopic techniques to perform CABG are ongoing. Robotics have been applied to every aspect of the procedure, ranging from mechanical stabilization of the endoscopic cameras to actual closed-chest, port-assisted ITA harvesting. Perhaps the most challenging aspect has been the robotic coronary artery anastomosis, a necessary step to accomplish the ultimate goal of totally endoscopic coronary artery bypass or TEACAB.[90–93] The main limiting factors include the difficulty with coronary artery anastomoses without using mechanical connectors and difficulty accessing the posterior aspects of the heart. Thus far clinical experience is

small and there are no data concerning long-term graft patency rates. As technology improves, this may find a role in the future (**Class IIb, Level C**).

Conduits

The choice of conduit is dictated by three features: the anatomy of the CAD, the projected patency of various conduits, and conduit availability. Conduits are not all created equal, and their choice can have an important impact on long-term results. This must be kept in mind when evaluations of the ultimate role of surgical CABG are made.

Arterial conduits

Although the first conduits used were venous, due to their ready availability and favorable handling characteristics, a number of visionary individuals explored the use of arterial conduits almost from the inception of CABG. Theoretically, arterial conduits should have a number of advantages over venous conduits, including inherent structural characteristics adapted to higher, pulsatile pressures and an ability to autoregulate to meet increasing oxygen demand. Fortuitously, the most convenient of these, the internal thoracic artery (ITA), is particularly resistant to atherosclerosis. However, both arterial and venous grafts are limited by the target native coronary artery anatomy, as competitive flow and poor run-off may limit patency.

Internal thoracic arteries The left ITA (LITA) should be used preferentially to graft the LAD artery (**Class I, Level C**). The durability of the LITA to the LAD has been demonstrated repeatedly to be superb, with angiographic patency rates as high as 96–98% at one year, 88–95% at 10 years, and 88% at 15 years.[44,94–96] This compares with saphenous veins anastomosed to the LAD which demonstrate patencies of 79% at two years.[97] The use of the LITA has been shown to increase late survival when compared to saphenous vein grafts.[44,98,99] Use of the LITA has also been shown to be associated with lower operative mortality, even in the elderly, perhaps as a reflection of superior patency even in the immediate postoperative period.[100–102] Some reports have also shown a decrease in subsequent MI and reoperation.[44,103]

The right internal thoracic artery (RITA) has similarly good patency rates when compared to the LITA when grafted to the LAD. The patency of both arteries, however, is dependent on the territory to which it is anastomosed. Tatoulis *et al* have reported on over 2000 arterial conduits, with overall RITA patency of 96% patency at five years, 81% at 10 years, and 65% at 15 years.[96] Patency was best when the RITA was anastomosed to the LAD and worst when anastomosed to the right coronary artery territory. An adverse effect of competitive flow was also apparent, with optimal patencies obtained when the native coronary artery had obstructive disease greater than 70–90%.[96,104]

Accordingly, the RITA should be utilized as an alternative conduit to the LAD in patients who have appropriate anatomy (**Class IIa, Level C**).

These findings have lead to the use of both right and left (bilateral) internal thoracic arteries (BITA). Large observational studies have shown slightly lower reoperative and reintervention rates in patients who receive two internal thoracic arteries (ITA).[105–107] It has been more difficult to demonstrate a clear survival benefit for BITA grafting. A large retrospective study from the Cleveland Clinic, however, has demonstrated seven-, 10-, 15-, and 20-year survival to be 87%, 78%, 58%, and 37% in patients who received one internal mammary compared to 89%, 81%, 67%, and 50% in patients who received BITA ($P < 0.001$).[108,109] However, retrospective comparisons such as this are subject to selection bias (despite propensity matching), as it was likely younger healthier patients were more likely to receive BITA grafting. A slightly increased risk of mediastinitis has been noted in diabetics[110] but this has been refuted in other studies,[111,112] particularly when the arteries are taken in a skeletonized fashion (the artery is isolated from its surrounding veins and other tissues).[113,114] BITA are used mainly in younger patients in whom long-term patency is especially important (**Class IIa, Level C**).

Radial artery The radial artery was first employed by Carpentier early in the experience with CABG; however, early experience suggested high graft occlusion and graft spasm in this artery.[115] Subsequently, a number of grafts thought to be occluded at early study were found to be patent at late angiography,[116] stimulating renewed interest. The randomized Radial Artery Patency Study (RAPS) demonstrated increased patency of radial arteries at one year when compared to venous grafts (91.8% vs 86.4 %, $P = 0.009$).[117] Occlusion or stenosis of the radial artery was more likely in native vessels with <90% stenoses. However, in patients with peripheral vascular disease, radial arteries had a poorer patency when compared to venous grafts.[118] Radial arteries may also be used as part of a composite graft with the LITA to achieve a total arterial grafting strategy (Fig. 27.4). In composite grafts, radial arteries can achieve statistically similar patencies to the LITA when anastomosed to critically stenosed targets in the left coronary artery system.[119,120] The radial artery is generally harvested from the forearm of the non-dominant hand in patients with an intact palmar arch and various vasodilators are used to decrease spasm intraoperatively and postoperatively. Radial arteries can be used as an alternative to venous grafting (**Class IIa, Level B**).

Other arterial conduits Other arterial conduits have been proposed including the inferior gastroepiploic artery (IEA) and right gastroepiploic artery (GEA). The GEA is most frequently anastomosed to the posterior descending artery and GEA grafts have a reported one-, five- and 10-year patency rate of 91–93%, 80%, and 62%.[121–124] Patency of the GEA improves as the severity of coronary artery lesions increases in native coronary arteries, much like the radial artery. Previous gastric resection, GEA instrumentation or documented mesenteric vascular insufficiency are contraindications to its use. GEA use has generally been superseded by the radial artery, as the GEA has limited long-term

data, frequent spasm, potential for intra-abdominal complications, and size mismatch with the native coronary arteries (**Class IIb, Level C**).

Other arterial conduits have been proposed in patients who have limited conduit availability. Use of the ulnar, left gastric, splenic, thoracodorsal, and lateral femoral circumflex arteries has been reported.[125–127] As these conduits do not have proven long-term patencies, they should not be considered preferable to venous grafts and should be generally used only when other conduits are unavailable (**Class IIb, Level C**).

Venous conduits

Greater saphenous veins The saphenous vein continues to be commonly used due to its accessibility, versatility, and availability of both early and late results (**Class IIa, Level B**). The greater saphenous vein has two recognized modes of failure. Early failure is generally a technical problem, due to anastomotic problems, kinking of the graft, poor run-off or progression of native CAD. At one year, approximately 75–80% of veins will remain angiographically patent.[128] Late failure of vein grafts is usually due to progression of atherosclerotic disease of the graft itself. Freedom from graft failure at five and 10 years is approximately 60% and 40%, respectively.[129]

These vein graft patency estimates were produced before many routine medical therapies such as early aspirin administration and lipid-lowering therapy,[130–133] which may increase late vein patency (**Class IIa, Level B**). A trial is under way to determine if aspirin and clopidogrel may further decrease intimal hyperplasia of vein grafts when compared to aspirin alone.[134] Newer therapies are also in development, and the recent PREVENT IV trial tested the impact of edifoligide, an inhibitor of E2F transcription factors, on short-term vein patency. Unfortunately, no benefit was found as the graft failure rate was 45.2% in the edifoligide group and 46.3% in the placebo group at one year ($P = 0.66$), although longer follow-up may be required to demonstrate benefit of this novel therapy.[135]

With increasing frequency, saphenous veins are harvested using a minimally invasive endoscopic technique (**Class IIa, Level B**). Despite concerns regarding the potential of increased trauma during harvesting, there appears to be little evidence of damage.[136–139] The advantages of endoscopic harvest include decreased wound complications and improved cosmetic results. The three- and six-month patency rates were similar to open harvest in two small randomized studies.[140,141] However, there are no data on long-term patency, which may be when intimal damage is most apparent with accelerated atherosclerosis of the vein grafts.

Alternative venous conduits The lesser saphenous and cephalic veins, as well as cryopreserved homologous vein grafts and glutaraldehyde-treated homologous vein grafts, have poor patencies in comparison to the greater saphenous vein.[142,143] These alternative conduits should only be used in the absence of any other conduit material (**Class III, Level C**).

Endarterectomy

Coronary endarterectomy may be performed in combination with bypass grafting in patients with diffuse CAD for whom no acceptable site for distal anastomosis can be found. The operative mortality rate is in most series approximately twofold greater than that of patients who undergo CABG, but this may be a reflection of greater co-morbidities in these patients.[144] It is generally accepted that the graft patency rate is less when the target has been endarterectomized when compared to direct grafting; however, it is not prohibitive.[145] Therefore, endarterectomy remains a valuable tool in selected patients who have some of the most severe CAD (**Class IIb, Level C**).

Conclusion

Surgical coronary artery bypass grafting continues to evolve. There have been novel developments in both CABG and medical management which have enabled good survival and quality of life for patients with CAD. With greater understanding of which patients derive the greatest benefit from surgical revascularization, CABG will continue to be an important modality in the treatment of CAD. In stable angina, surgical revascularization remains indicated according to AHA/ACC guidelines for left main CAD, left main equivalent CAD, and triple-vessel disease (**Class I**). Also, proximal LAD disease with either a depressed ejection fraction (<35%) or documented ischemia, proximal LAD disease with two-vessel disease and a large territory of myocardium at risk, and disabling angina despite maximal non-invasive therapy are also Class I indications. Furthermore, Class II indications in stable angina include proximal LAD stenosis with one-vessel disease and one- or two-vessel disease with a documented moderate amount of myocardium at risk and demonstrable ischemia.

Comparisons of percutaneous coronary intervention and coronary artery bypass grafting

Arashk Motiei, Thoralf M Sundt III and Charanjit S Rihal
Mayo Clinic, Rochester, MN, USA

Introduction

Coronary artery bypass grafting (CABG) and percutaneous coronary intervention (PCI) are the most commonly performed major procedures in the world today. Since their introduction, these procedures have been increasingly used for the treatment of coronary artery disease (CAD). In the United States, according to National Center for Health Statistics estimates, nearly 427 000 CABG and 1.2 million PCI procedures were performed in 2004.[1] It is estimated that these interventions account for a significant proportion of healthcare expenditures, with the estimated direct and indirect costs of CAD for 2007 being $151.6 billion.[1] The immediate risks inherent in these procedures need to be balanced against the expected benefits. Sound clinical judgment and decision making with respect to revascularization options in patients who have CAD require detailed knowledge of both the evidence in support of these procedures and the specific patient subsets that are likely to derive the most benefit.

In general, the broad indications for myocardial revascularization are to:
• improve prognosis (probability of survival)
• improve symptoms
• potentially prevent non-fatal events, such as myocardial infarction (MI), arrhythmias or heart failure.

Over the past four decades, a considerable volume of literature from prospective randomized clinical trials and large national databases has been published on the application and comparisons of various revascularization strategies. These data have helped in formulating well-defined indications for and the selection of appropriate revascularization methods. However, because of rapid growth and refinements in revascularization techniques and technologies, the optimal method of revascularization for numerous patients continues to be a subject of intense debate. In this chapter, we summarize the data from clinical trials and databases, with a view to developing a conceptual framework that allows the application of this information to clinical practice.

The effectiveness of coronary artery bypass graft surgery versus medical therapy (see also Chapter 27)

The early randomized trials of the 1970s first established CABG as an effective treatment for angina pectoris. These small, prospective, randomized controlled trials included the European Coronary Surgery Study (ECSS),[2,3] the Veterans Administration Coronary Artery Bypass Surgery Cooperative Study (VA)[4] and the Coronary Artery Surgery Study (CASS).[5,6] The trials compared CABG with medical therapy in patients who had stable angina. In a collaborative meta-analysis,[3] the primary patient information on 2649 patients enrolled in the evaluated trials was combined to assess outcomes at five and 10 years. Overall, CABG improved survival across all patients by 4.3 months at 10-year follow-up ($P = 0.003$). Because of the perioperative mortality rate associated with CABG, the mortality rate at one year was not significantly different between the groups, and a net benefit in favor of CABG was not observed for 2–3 years. At 5–7 years, the advantage with CABG increased before it narrowed again at 10–12 years (Fig. 28.1). A significant heterogeneity of treatment effect was observed among various angiographic and clinical subsets. The patients who seemed to derive the most benefit were those with left main CAD (n = 174) (relative risk (RR) 0.32; $P = 0.004$), multivessel disease (RR 0.58; $P < 0.001$), and one- or two-vessel disease with proximal left anterior descending coronary artery (LAD) involvement (RR 0.58; $P = 0.05$). Although the relative benefits were similar
Figure 28.1 Comparison of mortality rates of all studies in meta-analysis of trials of coronary artery bypass grafting (CABG) versus medical treatment. (Reproduced with permission from Yusuf et al[3])

regardless of left ventricular (LV) function, the absolute benefit was greater in patients with abnormal LV ejection fraction (EF) because of the higher risk of death in this group. Absolute mortality benefits were also greater among patients with evidence of myocardial ischemia as manifested by severe anginal symptoms or an abnormal exercise test (Table 28.1).

It has been established that, in regard to symptomatic improvement, surgically treated patients have a higher likelihood of staying symptom free than medically treated patients, and use less antianginal medication than medically treated patients at five years.[7] However, at 10 years, these differences are not statistically significant. It should be noted, however, that a high degree of cross-over from medical treatment to surgical treatment by 10 years may account for these findings.

In the application of these results to patient care in the current era, several limitations of the trials must be recognized. These early trials tended to include low-risk patients of whom only 20% had an EF of less than 50%. Furthermore, almost all patients were male and between 40 and 60 years of age. Only one trial (CASS) included women and, in this trial, medical therapy was limited to nitrates and beta-blockers. At the time of these trials, aspirin and lipid-lowering agents were not routinely prescribed for patients with CAD. In CASS, only 14% of patients received an internal mammary artery (IMA) graft.[8] The profound impact of these grafts on survival is now well documented.[9,10] The limited use of IMA grafts is a critical limitation of earlier trials of CABG. Also, patients with severe LV dysfunction were excluded from most of the randomized controlled trials. Data on this patient group are largely based on observational studies. In their meta-analysis of randomized trials, Yusuf et al[3] found that 40% of the patients assigned to medical therapy in the trials had had surgery by 10 years. These cross-overs in treatment tended to occur in the subgroups at highest risk. Therefore, the true benefits

of surgery, particularly in the high-risk groups, are likely underestimated. In the recent BARI 2D trial performed in patients with type 2 diabetes and stable coronary artery disease, by 5 years of follow-up there were fewer major cardiovascular events among CABG patients than among those receiving only optimal medical therapy.[40a]

Patients older than 75 years are increasingly undergoing CABG, and population-based rates estimates are higher than for patients younger than 75 years.[2,11] Despite this profile of increasing risk, operative mortality rates have continued to decline.[12] Since the early trials, advances have been substantial in the medical, percutaneous, and surgical management of CAD. Beta-blocker use is now more widespread, and the introduction of newer antiplatelet agents, statins, and angiotensin-converting enzyme inhibitors has revolutionized the medical management of these patients. Percutaneous revascularization techniques are common and continue to evolve with improved technology, experience, and the use of drug-eluting stents (DES) and adjuvant antiplatelet therapies. The operative and perioperative management of patients who undergo bypass surgery has also improved with increased use of arterial grafting, less invasive procedures, and improved attention to secondary prevention. Although the main messages obtained from the early trials are still relevant today, estimates of the degree of risks and benefits are likely to be different today from those suggested by these studies.

The effectiveness of percutaneous coronary intervention

Since the introduction of percutaneous transluminal coronary angioplasty (PTCA) in the 1970s as a treatment for single-vessel CAD, it has become one of the most commonly performed procedures. During the past three decades, PTCA procedures have been applied to multivessel CAD and even to left main CAD. Initial trials of PTCA compared balloon angioplasty with medical therapy. However, with the advent of coronary artery stents, subsequent studies saw an increasing use of these devices.

Balloon angioplasty versus medical therapy
(see also Chapter 26)

A meta-analysis of six prospective, randomized clinical trials comparing balloon angioplasty with medical therapy included 1904 patients with nonacute CAD.[13,14] Among the low-risk patients with symptomatic CAD (Canadian Cardiovascular Society (CCS) angina class II or greater; average mortality rate <1% per year), balloon angioplasty clearly provided superior control of angina pectoris, although it was associated with an increased need for subsequent CABG. There was no significant impact on subsequent

Table 28.1 Results of subgroups with medical therapy and with coronary artery bypass grafting (CABG) at five years

Subgroup	Overall numbers		Medical treatment mortality rate, %	Odds ratio (95% CI)	P for CABG surgery vs medical treatment	P for interaction

death, MI or subsequent balloon angioplasty. These data suggested that balloon angioplasty was indicated when the desired level of anginal relief and physical activity could not be achieved with medical therapy alone and that prophylactic balloon angioplasty could not be recommended for the treatment of CAD in the absence of angina or ischemia.[14] However, most of these studies were undertaken before 1997. Balloon angioplasty was plagued by restenosis, with a need for repeat procedures in up to 34% of patients at one year.[15]

Bare metal stents

The high incidence of restenosis after balloon angioplasty was initially addressed with the introduction of bare metal stents (BMS). Introduced for the treatment of coronary dissections after balloon angioplasty, BMS were rapidly adopted by clinicians for routine use during balloon angioplasty, thus leading to immediate improvements in procedural safety and success. In particular, the rate of emergency CABG decreased from about 5% to less than 1%, and angiographic success became routine and independent of lesion morphologic factors[16] (Fig. 28.2). The short-term therapeutic effects of these stents have been evaluated in several trials,[17,18] and although restenosis was significantly decreased, it continued to be a substantial clinical problem.[17] In a meta-analysis based on 29 trials involving 9918 patients, there was no evidence of a difference between routine coronary stenting and standard PTCA in terms of deaths or MI (odds ratio (OR) 0.90, 95% confidence interval (CI) 0.72–1.11) or the need for CABG (OR 1.01, CI 0.79–1.31). Coronary stenting decreased both the rate of restenosis (OR 0.52, CI 0.37–0.69) and the need for repeated PTCA (OR 0.59, CI 0.50–0.68).[19] It is important to note that these trials did not include higher-risk lesions treatable with stenting but not with PTCA alone.

Several studies have compared PCI performed with or without stents with medical therapy in patients who have stable CAD. A meta-analysis of 11 randomized controlled trials of PCI versus medical therapy included a total of 2950 patients with non-acute CAD.[20] The use of stents in the trials of this meta-analysis was variable (range, 30–100%). There was no substantial difference between initial PCI and initial medical strategies with regard to mortality rate, cardiac death, fatal MI or non-fatal MI[20] (Fig. 28.3).

The most recent comparison of PCI and medical therapy was the Clinical Outcomes Utilizing Revascularization and Aggressive Drug Evaluation (COURAGE) trial.[21] The investigators randomly assigned 2287 patients with stable CAD to receive either optimal medical therapy alone or PCI with optimal medical therapy on the basis of carefully selected clinical and angiographic criteria. At a median follow-up of 4.6 years, the cumulative frequency of the primary endpoint of death or non-fatal MI was 19.0% in the PCI group and 18.5% in the medical therapy group ($P = 0.62$).

In conclusion, PCI and medical therapy appear to lead to similar outcomes in rates of death and MI in patients with stable CAD. PCI with BMS is consistently associated with lower rates of angina and subsequent revascularization compared with medical therapy. In patients who have characteristics similar to those of patients enrolled in the randomized controlled trials, either strategy, medical therapy or PCI, is appropriate.

Drug-eluting stents

Despite the introduction of BMS, the chief limiting factor of percutaneous revascularization continued to be restenosis. Consequently, numerous agents have been used as stent coatings in the hope of preventing thrombosis, neointimal proliferation, and subsequent restenosis. Currently, all FDA-approved DES are a device-polymer-drug combination. Several randomized clinical trials have found that these stents are efficacious in decreasing the rates of restenosis and revascularization.[22–37]

In a meta-analysis of 19 randomized controlled trials that included 8987 patients and compared DES with BMS, the overall mortality rate was not significantly different between the treatment groups (0.9% with DES vs 1.2% with BMS; $P = 0.92$).[38] The overall adjusted rate for angiographic restenosis was 10.6% in the DES group versus 31.8% in the BMS (control) group ($P < 0.001$) (Fig. 28.4). The overall adjusted rate for angiographic target-lesion revascularization was 6.2% in the DES group versus 16.6% in the control group ($P < 0.001$). The Q-wave MI-adjusted percentage was 1.1% with DES versus 0.8% with BMS ($P = 0.33$).

There has been a tendency to regard restenosis as a benign process. However, emerging data seem to challenge
Figure 28.3 Results of meta-analysis comparing percutaneous coronary intervention (PCI) with conservative management. (a) Death. (b) Cardiac death or myocardial infarction. this notion, largely because a substantial fraction of patients who have restenosis present with acute coronary syndromes. In a study of 4503 consecutive patients treated with at least one BMS, 667 patients had 836 occurrences of clinical restenosis.[39] The cumulative incidence of at least one restenosis was 9.6% at one year, 13.9% at five years, and 18.1% at 10 years. Among all patients, the 10-year incidence of restenosis according to mode of presentation was stable angina in 9.0%, unstable angina in 7.4%, MI in 2.1%, and other unstable presentations, such as decompensated heart failure or ventricular arrhythmia, in 0.4%. Among 87 patients with an MI presentation of restenosis, non-ST segment elevation MI (NSTEMI) was seen in 87% and ST segment elevation MI (STEMI) was seen in 13%. Presentation of MI with restenosis was associated with a significantly greater mortality risk than either a presentation of MI with no restenosis (hazard ratio (HR) 2.37, 95% CI 1.72–3.27; $P < 0.001$) or a non-MI presentation of restenosis (HR 2.42, 95% CI 1.68–3.47; $P < 0.001$). Interestingly, there was no significant difference in long-term survival among patients with no restenosis compared to patients with a non-MI presentation of restenosis (HR 0.99, 95% CI 0.85–1.14; $P = 0.85$).

Safety

There have been recent concerns about the long-term safety of DES. However, recent pooled analyses of the trials of

sirolimus-eluting stents and paclitaxel-eluting stents show no difference in the long-term rates of death, MI or stent thrombosis.[40–42] In one analysis, the risk of stent thrombosis increased after one year with the use of a DES.[43] This did not translate into an increased frequency of death or of MI. Data from the Swedish Coronary Angiography and Angioplasty Registry (SCARR)[44] seemed to suggest an increased incidence of both death and MI on long-term follow-up of patients with DES. More recent data from SCARR showed no differences in death or MI.[45] In the clinical trials, the enrolled subjects were patients with PCI who were at relatively low risk.

A 2006 review of patient data in the American College of Cardiology (ACC) National Cardiovascular Data Registry found that 24% of procedures involving DES were for off-label indications (i.e. STEMI, in-stent restenosis, saphenous vein graft stenosis, and chronic total occlusion).[46] Of the 3323 patients in the Evaluation of Drug-eluting Stents and Ischemic Events (EVENT) registry, 1817 (54.7%) patients had at least one off-label characteristic on the basis of FDA-approved indications for sirolimus- and paclitaxel-eluting stents. During the index hospitalization, the composite clinical outcome occurred in 198 (10.9%) patients in the off-label group and 76 (5.0%) patients in the on-label group (adjusted OR 2.32, 95% CI 1.75–3.07; $P < 0.001$). At one year, the composite clinical outcome occurred more often in the off-label group (309 (17.5%) patients) than in the on-label group

(131 (8.9%) patients) (adjusted HR 2.16, 95% CI 1.74–2.67; P < 0.001). In-stent thrombosis also occurred more frequently among patients in the off-label group than among patients in the on-label group during the initial hospitalization (8 (0.4%) patients vs 0 patients) and at one year (29 (1.6%) patients vs 13 (0.9%) patients) (adjusted HR 2.29, 95% CI 1.02–5.16; P = 0.05).[47]

A higher prevalence of complex interventions that use DES in subsets of patients at relatively higher risk will in all likelihood translate into increased event rates in DES subgroups in registry studies. For all these high-risk groups, compared to low-risk groups, event rates are increased after any treatment. The available data on the use of DES in specific complex subsets of patients and lesions seem to suggest that these stents may be superior to BMS in these circumstances.[48,49] Randomized clinical trials are needed to fully define the role of DES in such patient groups.[50]

Comparisons of percutaneous coronary intervention versus coronary artery bypass graft

Considerable controversy has existed, and continues to exist, about the relative benefits of PTCA compared with CABG as initial treatment strategies. Up to 15 randomized trials comparing PCI, with or without stents, with CABG have been published and were reviewed extensively by both Eagle et al[51] and Hoffman et al.[52] Recently, the 10-year results of the Bypass Angioplasty Revascularization Investigation (BARI), the largest of the randomized trials of PTCA versus CABG, were published.[52] In this trial, 1829 symptomatic patients with multivessel CAD were randomly assigned to initial treatment with PTCA or CABG and were observed for an average of 10.4 years. The 10-year survival was 71.0% for the PTCA group and 73.5% for the CABG group ($P = 0.18$). At 10 years, the PTCA group had substantially higher subsequent revascularization rates than the CABG group (76.8% vs 20.3%; $P < 0.001$), but angina rates for the two groups were similar. In the subgroup of patients with no treated diabetes mellitus, survival rates were nearly identical for the PTCA group compared with the CABG group (77.0% vs 77.3%; $P = 0.59$). In the subgroup with treated diabetes, the group assigned CABG had higher survival rates than the group assigned PTCA (57.8% vs 45.5%; $P < 0.03$).

Another recent publication comparing CABG, PCI, and medical therapy was based on the five-year outcomes of the Medicine, Angioplasty or Surgery Study-II (MASS-II)[53,54] which randomly assigned 611 patients with stable angina to medical therapy, PCI or CABG. Medical therapy included aspirin, angiotensin-converting enzyme inhibitors, beta-blockers, and statins. At five-year follow-up, the primary endpoints had occurred in 21.2% of patients who underwent CABG compared with 32.7% of patients treated with PCI and 36% of patients who received medical therapy alone ($P < 0.003$).

The paired treatment comparisons of the primary endpoints showed no difference between PCI and medical therapy (RR 0.93, 95% CI 0.67–1.30) and a significant protective effect of CABG compared with medical therapy (RR 0.53, 95% CI 0.36–0.77). The cumulative survival rate was 88.4% for PCI, 92.1% for CABG and 87.7% for medical therapy; the survival rates were not significantly different. Additional interventions were performed for 32.2% of the PCI patients, 24.2% of the medically treated patients, and 3.5% of the surgically treated patients ($P < 0.03$). Non-fatal MI occurred in 11.2% of the PCI group, 15.3% of the medically treated group, and 8.3% of the CABG group ($P < 0.79$). It is important to note, however, that the degree of revascularization achieved in the PCI group and the CABG group differed. Although 74% of all intended vessels were grafted in the surgical cases, only 41% of cases in the PCI group were completely revascularized. Adjunctive pharmacotherapy with clopidogrel and glycoprotein IIb/IIIa inhibitors was not utilized. Although stenting was performed in at least one vessel in 72% of cases, BMS were used. Because of these considerations, and even though this trial suggests a relative inferiority of PCI as a treatment strategy, the argument could be made that the results are not applicable to the current setting.

Since the advent of coronary stenting, several trials have compared stents with CABG in patients with multivessel disease. The Arterial Revascularization Therapy Study (ARTS)[56] randomly assigned 1205 patients with multivessel disease to PCI with stents or to CABG. At five years, the mortality rate was 8.0% in the stent group and 7.6% in the CABG group ($P = 0.83$). Among 208 diabetic patients, the mortality rate was 13.4% in the stent group and 8.3% in the CABG group ($P = 0.27$) (see section on diabetic patients, below). Overall, freedom from death, stroke or MI was not significantly different between the stent group (18.2%) and the surgical group (14.9%) ($P = 0.14$). The incidence of repeat revascularization was significantly higher in the stent group than in the CABG group (30.3% vs 8.8%; $P < 0.001$). The rate of composite event-free survival (freedom from cardiovascular and cerebrovascular events) was 58.3% in the stent group and 78.2% in the CABG group ($P < 0.0001$).

Two additional trials showed the superiority of CABG in terms of fewer repeat revascularization procedures. In the multicenter Stent or Surgery (SoS) trial,[57] based on 988 patients, the primary endpoint of repeat revascularization occurred in 21% of the patients in the stent group versus 6% of those in the surgical group ($P < 0.001$). In the Argentine Randomized Trial: Coronary Angioplasty Versus Coronary Bypass Surgery in Multivessel Disease-II (ERACI-II),[58] 450 patients with multivessel disease were randomly assigned to undergo either PCI or CABG. At five years, there were no significant differences in the rate of death from all causes between the CABG and PCI arms (11.5% vs 7.1%; $P < 0.19$). There also were no significant differences in the incidence rates of new non-fatal MI between the PCI and CABG groups (2.8% vs 6.2%; $P < 0.13$). However, the incidence of repeat revascularization was 28.4% in the PCI group and 7.2% in the CABG group ($P < 0.001$). Of note, none of these trials included patients treated with DES, which have been shown to decrease the rate of repeat revascularization.

In a recent meta-analysis based on 23 randomized controlled trials, in which 5019 patients were randomly assigned to PCI and 4944 to CABG, the difference in subsequent survival rates with PCI versus CABG was less than 1% over 10 years of follow-up.[59] Survival did not differ between the PCI group and the CABG group for patients with diabetes mellitus in the six trials that reported on this

subgroup. Procedure-related strokes were more common after CABG than after PCI (1.2% vs 0.6%; $P = 0.002$). Angina relief was greater after CABG than after PCI, with absolute risk differences ranging from 5% to 8% at 1–5 years ($P < 0.001$). Angina was relieved at five years in 79% of PCI patients and 84% of CABG patients. Repeat revascularization was more common after PCI than after CABG (absolute risk difference 24% at one year and 33% at five years; $P < 0.001$); the absolute rates at five years were 46.1% after balloon angioplasty, 40.1% after PCI with stents, and 9.8% after CABG. In the observational studies, the HR for death favored PCI among patients with the least severe disease and CABG among those with the most severe disease.

It should be noted that these trials did not include patients who were considered to be at high risk for an adverse outcome with surgical treatment. Data comparing surgical intervention with PCI in this subgroup of patients are limited. The Angina With Extremely Serious Operative Mortality Evaluation (AWESOME) study enrolled 454 patients of high surgical risk at 16 Veterans Affairs hospitals.[60] This five-year, multicenter, randomized clinical trial was designed to compare long-term survival among patients with medically refractory myocardial ischemia and a high risk of adverse outcomes who were assigned to either a CABG or a PCI strategy, which could include stents. At 36 months, the survival rates in both groups were similar (79% with CABG vs 80% with PCI).

For treatment of patients with single-vessel CAD, the trial most relevant to clinical practice was the Stenting Versus Internal Mammary Artery (SIMA) trial,[61] in which 121 patients with isolated LAD disease were randomly assigned to BMS or CABG with the left IMA. At 2.4 years, patients assigned to stenting had experienced more revascularization procedures than patients who were surgically treated (31% vs 7%). Mortality rates did not differ between the two groups.

In summary, these trials have shown that CABG tends to give better relief of angina with less need for repeat procedures than does PCI. However, with PCI, initial costs are lower, complications occur less frequently, and patients are able to return to work earlier. Because of the greater need for reinterventions, patients who have PCI generate direct costs over the long term that are similar to those of patients who have CABG. Long-term survival rates also tend to be similar with the two forms of treatment. This similarity appears to hold true for diabetic patients, as well as the patients described earlier in this chapter.

It must be recognized that the patients enrolled in such trials are not always representative of the global population of patients with CAD; therefore, the results of such trials are not necessarily applicable to the general population of patients. Indeed, only 5% of screened patients with multivessel disease were enrolled in these trials, and patients with left main disease were excluded. Registry studies have provided valuable information about the relative benefits of medical therapy, PCI, and CABG, particularly for the global population of patients with CAD. In general, these studies have yielded results that are congruent with the findings of the randomized trials.

Jones *et al*[62] reviewed the Duke University Medical Center database of 9263 patients with CAD who underwent PCI (n = 2924), CABG (n = 3890) or medical therapy (n = 2449) only. Patients were observed for a mean of 5.3 years. The anatomic severity of the coronary artery stenoses best defined the survival benefit from CABG and PCI versus medical treatment. All patients with single-vessel disease, except those with proximal LAD stenosis of 95% or greater, benefited from PCI compared with CABG. All patients with three-vessel disease and those with two-vessel disease and proximal LAD stenosis of 95% or greater were best treated by CABG.

A recently published study based on the New York State PCI and CABG registries examined the outcomes of 37 212 patients who had undergone CABG and 22 102 patients who had undergone PCI with stenting.[63] The adjusted HR for the long-term risk of death after CABG relative to stent implantation was 0.64 (95% CI 0.56–0.74) for patients with three-vessel disease with involvement of the proximal LAD and 0.76 (95% CI 0.60–0.96) for patients with two-vessel disease with involvement of the non-proximal LAD. Additionally, the three-year rates of revascularization were considerably higher in the stenting group compared to the CABG group (7.8% vs 0.3% for subsequent CABG; 27.3% vs 4.6% for subsequent PCI). However, 85% of patients with multivessel disease underwent CABG. Therefore, only those patients who had specific reasons not to undergo bypass surgery underwent PCI. Such reasons may have included high surgical risk, poor target vessels, and patient refusal. This clearly leads to a substantial selection bias. The superior results observed with CABG in such studies seem to derive from more frequent complete revascularization. In a subsequent publication assessing patients with PCI who received stents, the authors compared long-term mortality rates and subsequent revascularization among patients with complete versus incomplete revascularization. After adjustment for these baseline differences, the data show that patients who received incomplete revascularization were significantly more likely to die at any time (adjusted HR 1.15, 95% CI 1.01–1.30) than patients who received complete revascularization. Patients with total occlusions and a total of two vessels with incomplete revascularization were at higher risk compared with patients who received complete revascularization (HR 1.36, 95% CI 1.12–1.66).

Given that the advantage of CABG seems to be driven largely by a decreased frequency of revascularization procedures, there is great interest in comparisons of CABG with PCI using DES. The ARTS-II registry is a non-

randomized comparison of contemporary PCI with historic controls from the ARTS-I in patients with multivessel CAD (n = 607 patients).[64] The primary endpoint of the study was major adverse cardiovascular and cerebrovascular events (MACCEs), including death, cerebrovascular event, MI, and revascularization at one year. The event-free survival was 89.5% in ARTS-II compared with 88.5% in the ARTS-I CABG registry. Survival free from reintervention was 91.5% in ARTS-II compared with 95.9% in the ARTS-I CABG registry. There were no differences in terms of death, cerebrovascular event, MI, and repeat CABG between the ARTS-I patients who received BMS, the ARTS-II patients who received DES, and the ARTS-I patients who had CABG. However, a significantly higher revascularization rate was seen in the ARTS-I stent group. These observations suggest that DES may significantly improve outcomes in patients with multivessel disease.

The current relevance of the trials mentioned above is limited because of the use of non-contemporary PCI techniques. In recent years, progress has been made in surgical revascularization. The impact on mortality rate of an IMA graft to the LAD is clear.[65] On the basis of studies demonstrating superior outcomes with bilateral IMA grafts[10] and complete arterial revascularization, surgeons are increasingly using additional arterial conduits. Even among those surgeons using venous conduits, long-term outcomes are improving with the routine use of pharmacologic agents for secondary prevention.[66] Furthermore, off-pump techniques likely reduce operative risks in some subsets of patients.[67]

Currently, at least four randomized clinical trials are comparing DES with CABG in multivessel or left main disease.[68] The Synergy Between PCI With Taxus Drug-eluting Stent and Cardiac Surgery (SYNTAX) trial[68a] was based in multiple centers in Europe and the United States and enrolled 1800 patients. The primary outcome of 12-month MACCEs was significantly higher in the PCI group (17.8%, vs. 12.4% for CABG; $P = 0.002$), mainly because of an increased rate of repeat revascularization (13.5% vs. 5.9%, $P < 0.001$). The rates of death and myocardial infarction were similar between the two groups, whereas stroke was more frequent with CABG (2.2% vs. 0.6% with PCI; $P = 0.003$). At least three trials of PCI with DES versus CABG are being conducted in diabetic patients and are discussed below.

In the decision about revascularization for a patient, many factors must be taken into consideration, including the patient's age, coronary anatomy, extent of stenoses, co-morbidities, LV function and, to some degree, preference. In addition, the technical suitability for either PCI or CABG and the urgency of the procedure must be considered. The importance of such an approach was highlighted by data from the BARI registry, where physician-selected procedures resulted in excellent outcomes. The mortality rates at seven years were similar for PTCA (13.9%) and CABG (14.2%) ($P = 0.66$) before and after adjustment for baseline differences between patients selected for PTCA versus those selected for CABG (adjusted RR 1.02; $P = 0.86$).[69] Both PCI and CABG provide good relief of symptoms in most patients who are appropriately selected. These procedures need to be considered as complementary, and many patients will undergo both of these techniques of revascularization during their lifetime.

Coronary artery bypass graft versus percutaneous coronary intervention in diabetic patients

The prevalence of diabetes mellitus in the United States is increasing rapidly, mirroring the rapid rise in obesity. In 1999, 4.9% of the US population were estimated to have diabetes; by 2002, this percentage had increased to 6.3%.[70–72] Of individuals older than 60 years, 18.3% are estimated to be diabetic. These demographic changes are almost certainly related to the aging of the US population, a sedentary lifestyle, poor diet, and obesity. This alarming increase in prevalence of diabetes has important consequences related to CAD and its management, and for society as a whole.

For persons with type 1 diabetes, the mortality rate from cardiovascular disease is four times that of the general population[73] and, by age 55 years, one-third of these patients will have died of CAD.[74] For persons with type 2 diabetes, the incidence of atherosclerosis is estimated to be 2–3 times that of the general population.[75] The risk of an acute MI for persons with diabetes is 20% over seven years, with a hospital mortality rate that is 1.5–2.0 times higher than that for people without diabetes.[76] Moreover, persons with diabetes who have an MI are more likely to experience congestive heart failure, cardiogenic shock, recurrent ischemia, and reinfarction and eventually have a poorer survival rate.[77]

The observed poorer clinical outcomes among diabetic patients with CAD are likely due to multiple factors, including co-existent renal disease, hypertension, peripheral vascular disease and the aggressive nature of the CAD itself. Compared with persons who do not have diabetes, diabetic people are more likely to have left main disease,[78–82] multivessel disease, diffuse disease with smaller luminal diameters, and a larger number of lipid-rich plaques, which are more prone to rupture.[83] Persons with diabetes who have CAD represent a special high-risk subset of patients in whom very aggressive treatment strategies are warranted.

Indications for coronary revascularization in patients with diabetes are generally the same as for non-diabetic patients and include symptom improvement, left main disease, three-vessel disease (particularly with decreased LV function), and severe angina. However, diabetic patients are more likely to be asymptomatic than non-diabetic patients, with significant myocardial ischemia. In the

absence of angina, progression of ischemia with decreased LV function may occur, and this ischemia may explain, in part, the ultimate poorer prognosis in diabetic patients. The Asymptomatic Cardiac Ischemia Pilot (ACIP) study, including patients with and without diabetes, showed that, in the absence of angina, coronary revascularization was beneficial in selected patients.[84] Overall, when therapy was directed by the onset of subsequent angina, the mortality rate at two years was 6.6% in patients with known CAD. Patients who received revascularization in the absence of angina but as guided by the presence of ischemia had a mortality rate at two years of 1.1%. Because of the asymptomatic nature of CAD in many persons with diabetes, an aggressive approach should be adopted in these patients to detect myocardial ischemia and to advise subsequent revascularization.

According to the 10-year outcomes of the BARI trial and in the subgroup with treated diabetes, the group assigned CABG had a higher survival rate than the group assigned PTCA (57.8% vs 45.5%; $P < 0.03$).[53] Similar findings showing a trend toward improved results with CABG compared with PCI for diabetic patients were also observed in the Emory Angioplasty Versus Surgery Trial (EAST)[85] (the eight-year mortality rate with CABG was 24.5%; with PCI, 39.9%). As mentioned previously, the patients in ARTS who had diabetes and underwent stenting had a mortality rate of 13.4% at five years compared with 8.3% in those who underwent CABG.[69] Within the stent group, diabetic patients had a significantly higher mortality rate than non-diabetic patients. In the meta-analysis reported by Hoffman *et al*, patients with multivessel disease and diabetes had a survival advantage at four years with CABG compared with PCI.[52]

These observations were further put into perspective in the BARI registry, where the mode of revascularization was determined by physician preference. In this registry, patients who were sicker and at higher risk were preferentially referred for CABG, whereas those with lesser degrees of CAD often underwent PCI. During follow-up, diabetic patients in the BARI registry had equal survival rates (74%) whether treated with PCI or with CABG.[69] Interestingly, in a recent meta-analysis comparing PCI with CABG, survival did not differ between PCI and CABG for patients with diabetes in the six trials that reported on this subgroup.[59]

The better survival results observed with CABG than with PCI seem to result from both the use of arterial grafting and the extent of revascularization. The improved survival rate seen in diabetic patients who underwent CABG was contingent on the presence of an IMA graft to the LAD (seven-year survival rate, 83.2%; for IMA graft, n = 140), whereas long-term survival of patients treated with saphenous vein grafts was similar to that of patients treated with balloon angioplasty.[86] Patients with an IMA graft had a

dramatic reduction in the mortality rate after subsequent MI compared with patients who did not receive an IMA graft. Further data from the BARI trial indicated that diabetic patients appeared to have more complete revascularization and less jeopardized myocardium at risk after CABG compared with diabetic patients who received revascularization with PCI. Diabetic patients also had increased rates of restenosis after PCI compared with non-diabetic patients, whereas graft patency in those who underwent CABG (venous and arterial) was not influenced by diabetes status.[87] These data suggest that the survival advantage of CABG in diabetic patients may result from a more complete and more durable revascularization than that achieved by PCI.

A meta-analysis of eight randomized controlled trials of DES versus BMS in diabetic patients showed that target lesion revascularization occurred in 22.9% of patients treated with BMS and 7.5% of patients treated with DES. These data indicate a 66% decrease in the need for target lesion revascularization with DES compared with BMS ($P < 0.001$).[88] Therefore, interest has grown in comparisons of DES with CABG in diabetic patients.

The Future Revascularization Evaluation in Patients With Diabetes Mellitus: Optimal Management of Multivessel Disease (FREEDOM) study is enrolling diabetic patients with multivessel disease, in a randomized controlled trial of PCI with DES versus CABG. The target enrollment is 2400 patients; the primary endpoint is the composite of non-fatal infarction, stroke, and death due to all causes. The minimum planned follow-up is three years.

The Department of Veterans Affairs has approved funding for a similar trial that will randomly assign CABG or PCI to patients with diabetes mellitus who have both a hemoglobin A1c level of greater than 7 and angiographically significant disease with involvement of the anterior wall and one or more other territories. The minimum planned follow-up for this trial is two years. Another trial in diabetic patients is the Coronary Artery Revitalization in Diabetes (CARDia) trial, based in the United Kingdom and Ireland. This trial is making a comparison between PCI with both DES and abciximab and CABG in patients with multivessel disease or complex single-vessel disease. The primary endpoint is the composite of death, non-fatal MI, and a cerebrovascular accident at one year.

The BARI 2D trial[10a] focused on earlier revascularization and the use of insulin sensitizing therapies. In the PCI stratum, there was no difference in major vascular events between those randomized to PCI vs those to optimal medical therapy. However, in the CABG stratum, there were significantly fewer major vascular events among those randomized to CABG vs. those to optimal medial therapy.

On the basis of the data presented herein, CABG is the best revascularization procedure for most diabetic patients

with multivessel disease. In the near future, ongoing trials comparing DES with CABG will help define the role of PCI in the management of these patients.

Conclusions and recommendations

The following recommendations summarize the points of care for revascularization of patients with chronic stable angina.

• Revascularization by means of CABG or PCI is indicated in patients with chronic stable angina refractory to medical therapy (**Class I, Level A**).

• Patients at moderate to high risk for adverse outcomes with medical therapy should be treated with CABG. Such patients include those with left main or multivessel disease; two-vessel disease with involvement of the proximal LAD; LV dysfunction; and diabetes mellitus (**Class I, Level A**).

• For single-vessel disease, both PCI and CABG are effective, but repeat revascularization is required more frequently after PCI than after CABG. However, given the increased initial morbidity and hospitalization with CABG, most patients with single-vessel disease should be treated with PCI (**Class I, Level B**).

• For patients with left main CAD, CABG is indicated (**Class I, Level A**).

• In patients with two-vessel disease and significant proximal LAD involvement and either LV dysfunction or demonstrable ischemia on stress testing, CABG is indicated (**Class I, Level A**).

• For multivessel CAD that is potentially amenable to therapy with either PCI or CABG, a distinction should be made between diabetic patients and non-diabetic patients, and an assessment of LV function should be completed. For diabetic patients and patients with LV dysfunction, CABG is the superior therapy and is the preferred mode of revascularization (**Class I, Level A**). For non-diabetic patients with preserved LV function, the choice of a revascularization strategy has to weigh the initial morbidity associated with CABG against the higher risk of subsequent repeat revascularization and attendant repeat hospitalizations associated with PCI. In this circumstance, a decision is best made by taking the patient's preferences into account after an extensive discussion of the risks, benefits, advantages, and disadvantages of both procedures (**Class I, Level C**).
