Acute coronary syndromes

John A Cairns and Bernard J Gersh, Editors

29 Non-ST segment elevation acute coronary syndromes: unstable angina and non-ST segment elevation myocardial infarction

Pierre Theroux[1] and John A Cairns[2]

[1]Montreal Heart Institute, Montreal, Quebec, Canada
[2]University of British Columbia, Vancouver, British Columbia, Canada

Introduction and historic perspective

The rapid evolution of the understanding, definition and management of acute myocardial ischemic syndromes constitutes a major milestone of modern cardiology. The widely used terminology of "acute coronary syndromes" (ACS) highlights the specific pathophysiologic mechanisms that distinguish unstable angina (UA), non-ST segment elevation myocardial infarction (NSTEMI), and ST segment elevation myocardial infarction (STEMI) from stable coronary artery disease.[1] Pathologic studies have documented the presence of intracoronary thrombus on a ruptured or fissured complex atherosclerotic plaque in 95% of patients with unstable angina who have developed sudden cardiac death.[2–4] These plaques are rich in lipids and inflammatory cells and possess a thin cap that makes them prone to rupture.[5] At autopsy, the thrombi may be of various ages and at multiple sites; they typically overlie stenotic lesions of only moderate severity; platelet aggregates in the distal small intramyocardial arteries and microscopic foci of necrosis are often found as well.

DeWood documented by angiography that the very early stage of STEMI was consistently associated with a completely occlusive thrombus.[6] Subsequent studies focused on the characteristics of culprit lesions associated with ACS, visualized using a variety of methods including angiography, intravascular angioscopy, ultrasound, and thermography. It became recognized that the active plaque was often not unique, suggesting a more diffuse inflammatory state. These concepts led to a new era of research in cell biology and clinical investigation supported by emerging technologies and methodologically sophisticated clini-

cal research, providing a foundation for our current evidence-based approaches to therapy.

New dimensions and definitions

The definitions of ACS encompass various aspects of the disease including epidemiology, prognosis, clinical manifestations, pathophysiology, and therapeutic options. Their delineation has led to improved understanding of the mechanisms and manifestation of plaque activation, and has opened new therapeutic perspectives. Professional practice guidelines for the management of UA and NSTEMI were first published in 1979, jointly by the American College of Cardiology and the American Heart Association and independently by the European Society of Cardiology. They were subsequently updated in 2002 and 2007 to incorporate algorithms for rapid diagnosis, risk stratification, patient triage, and therapy.[1,7] Large registries[8–10] monitor national and international adherence to guidelines and their performance in various hospital settings as well as their impact on quality of care and prognosis. CRUSADE has been succeeded by the American College of Cardiology's NCDR-ACTION Registry™ (Acute Coronary Treatment and Intervention Outcomes Network), which collects data from hundreds of hospitals across the US into one unified platform with standardized clinical data elements to facilitate benchmarking outcomes, and to analyze treatment regimens.[11] Such initiatives are leading the way in the monitoring and evaluation of quality of care and are facilitating the systematic application of guidelines.

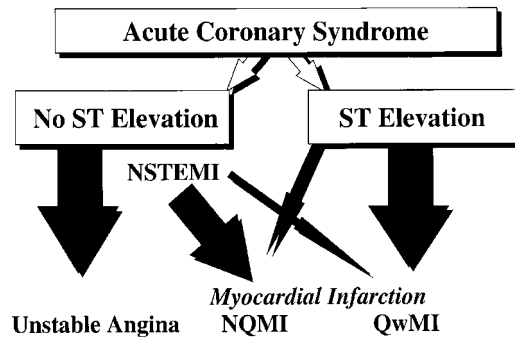
From a clinical perspective, a fundamental aspect of an acute coronary syndrome is the recognition of a change in the pattern of ischemic symptoms to one of increased severity. In the absence of evidence of causative extracoronary factors, such symptoms may signal a rapid progression in the severity of the coronary artery disease. As this


Figure 29.1 Nomenclature of acute coronary syndromes (ACS). The spectrum of clinical conditions that range from unstable angina to non-Q wave MI and Q-wave MI is referred to as acute coronary syndrome. Patients with ischemic discomfort may present with or without ST segment elevation on the ECG. Most patients who present with non-ST segment elevation ACS will eventually be classified as having unstable angina or non-Q wave MI. The distinction between these two diagnoses is ultimately made based on the presence or absence of a cardiac marker detected in the blood. Only a minority of patients with non-ST elevation ACS will develop a Q-wave MI. Most patients with ST segment elevation ACS will evolve to develop a Q-wave MI, although some may evolve to a non-Q wave MI or may occasionally resolve without myocardial necrosis. (Adapted with permission from Anderson JL, Adams CD, Antman EM et al.[1])

Table 29.1 Clinical presentation of non-ST segment elevation acute coronary syndrome

New-onset angina	New-onset angina of at least CCS class III in severity[12] **I.** Angina at strenuous, rapid or prolonged exertion. **II.** Slight limitation of ordinary activity, e.g. angina occurs on walking or climbing stairs rapidly. **III.** Marked limitation of of ordinary activity; angina occurs on walking 1–2 blocks on level or climbing 1 flight of stairs in normal conditions at normal pace. **IV.** Inability to perform any physical activity without discomfort; anginal syndrome may be present at rest.
Increasing (crescendo) angina	Angina that has become distinctly more severe, more frequent, longer in duration, or lower in threshold (that is, increased by greater than or equal to 1 CCS class to at least CCS class III severity)
Rest angina	Angina occurring at rest and prolonged, usually >20 minutes
Early post-MI ischemia	Ischemic chest pain recurrent within 30 days after MI

situation may demand immediate attention, any healthcare professional should be able to make a diagnosis of possible ACS on first seeing the patient. The term "acute coronary syndrome" has thus become a working diagnosis which facilitates rapid access to diagnostic and therapeutic procedures. It provides a logical framework within which to categorize and risk stratify patients who present with a constellation of clinical symptoms compatible with acute myocardial ischemia. It also encourages consistent diagnostic terminology and patient selection for clinical trials and epidemiologic studies. The working diagnosis of ACS is based upon clinical and ECG characteristics which guide immediate management. The subsequent clinical course and appropriate laboratory tests will lead to a final diagnosis which could be ST segment elevation myocardial infarction (STEMI), non-ST segment elevation myocardial infarction (NSTEMI), unstable angina, stable angina or another cardiac or non-cardiac condition (Fig. 29.1).

Clinical diagnosis

Table 29.1 summarizes the clinical manifestations and Figure 29.1 provides current nomendature for ACS. An immediate 12-lead ECG must be obtained, and repeated when the pattern of pain changes, to detect ST elevation or new left bundle branch block (LBBB) indicative of evolving STEMI and the need for immediate reperfusion

therapy.[13] In the absence of ST segment elevation, the working diagnosis becomes a non-ST segment elevation acute coronary syndrome, the likelihood of which is increased by the presence of ST segment depression and/or T-wave inversion on the ECG.[1] An elevated cardiac troponin T or I level then indicates an evolving NSTEMI, while normal values point to unstable angina. If troponin assays are not available, the best alternative is CK-MB measured by mass assay.

The availability of troponins T and I has increased the sensitivity of the diagnosis of myocardial infarction and has sharpened the distinction between unstable angina and myocardial infarction.[1] Troponin measurements allow the detection of cell necrosis and myocardial infarction in up to 30% of patients who would otherwise be diagnosed as having unstable angina based on normal CK-MB blood values, ultimately improving patient care and outcomes.[13] On the other hand, although highly sensitive and specific for myocardial cell necrosis, cardiac troponins are not specific for cell death related to ischemia resulting from coronary artery disease. The latest expert consensus document for a universal definition of myocardial infarction[14] lists the potential causes of troponin elevation outside the context of ischemia; some of them are commonly found in the age range of patients with an ACS, e.g. congestive heart failure, aortic valve disease, tachy or brady arrhythmias, renal

failure, and pulmonary embolism. Myocardial infarction is defined as myocardial cell death due to prolonged myocardial ischemia. Myocardial infarction may be diagnosed when a rise and/or fall of cardiac biomarkers (preferably troponin) is detected, with at least one value above the 99th percentile of the upper reference limit, together with evidence of myocardial ischaemia with at least one of: i) symptoms of ischaemia; ii) ECG changes indicative of new ischemia (new ST-T changes or new LBBB); iii) development of pathologic Q-waves in the ECG; or iv) imaging evidence of new loss of viable myocardium or new regional wall motion abnormality. Detection of a rising and/or falling pattern of troponin is needed to distinguish MI from elevated background levels; but this pattern is not absolutely required for the diagnosis of MI in a patient presenting >24 hours after the onset of symptoms because troponin values may remain elevated for 7–14 days following the onset of symptoms. Thus, troponin elevation is an indicator of MI, usually STEMI when there is ST segment elevation or a left bundle branch block and NSTEMI when there is not. True posterior or high lateral MIs can be electrocardiographically silent. Furthermore, the absence of ST segment shifts on the admission ECG does not rule out an acute coronary syndrome. Serial ECGs are required and cardiac markers must be measured 6–9 hours after the onset of pain when the first determination is negative. A negative work-up may not totally exclude ACS or even coronary artery disease and the need for treatment, but generally does confer a favorable prognosis.

A quick appraisal of the patient's demographics, risk factors, cardiac and non-cardiac antecedents, and medications is mandatory for decision making. The characteristics of chest pain and associated symptoms complement the evaluation of disease severity. Thus new-onset angina, crescendo or progressive angina, pain at rest, nocturnal pain, prolonged pain, and recurrent ischemia after myocardial infarction carry increasingly worse prognoses. Although the Canadian Cardiovascular Classification[12] was designed to describe the severity of stable exertional angina, in practice it is often applied to describe angina of sufficient progression and severity to warrant the designation of ACS.

Incidence, natural history and prognosis

There were 4 497 000 visits to US emergency departments (EDs) with a primary diagnosis of cardiovascular disease (CVD) in 2003.[15] The National Center for Health Statistics reported 1 565 000 hospitalizations for primary or secondary diagnosis of an ACS in 2004, 669 000 with UA and 896 000 with MI.[15] Statistics on NSTE-ACS are less reliable than those of STEMI because the diagnostic criteria have been evolving over time, with the introduction of more sensitive and specific criteria allowing the identification of more patients with the diagnosis but limiting the hospitalization to higher-risk patients. On the other hand, the absolute incidence of STEMI has been decreasing for various reasons that are likely related to better control of risk factors and use of drugs effective in primary prevention.[16] Reperfusion therapy and antithrombotic therapy have also dramatically reduced the short- and long-term mortality and morbidity associated with STEMI. Such is not the case in NSTEMI, which is often associated with more risk factors, including older age, and with a more advanced and diffuse atherosclerotic process. Accordingly, NSTEMI is now associated with a worse prognosis than STEMI past the acute phase. The average age of a person having a first heart attack is now 65.8 years for men and 70.4 years for women; 43% of ACS patients of all ages are women.[15]

Epidemiologic data using the WHO MONICA criteria for the diagnosis of Q-wave MI showed a more than 30% decrease in the mortality rates from Q-wave MI between 1975 and 1995, two-thirds of this decline being attributable to reduced incidence and one-third to decreased hospital mortality.[17–20] The ENACT registry, which included 3092 patients from 29 European countries in the mid-1990s, showed that the distribution of admission diagnosis was unstable angina/NSTEMI in 46%, myocardial infarction in 39%, and suspected ACS in 14%, with no regional differences across Europe.[21] In the more recent Global Registry of Acute Coronary Events (GRACE) that collected data from 10 693 patients across North and South America, Australia, New Zealand, and Europe between 1999 and 2001, two-thirds of admitted patients had unstable angina/non-ST segment elevation ACS and one-third STEMI.[22] This ratio is reversed in India, with its low socio-economic status.[23]

In an epidemiologic study of 5832 residents from metropolitan Worcester, Massachusetts, the annual incidence of Q-wave MI between 1975 and 1997 decreased from 171 per 100 000 population to 101 per 100 000 compared with an increase from 62 to 131 per 100 000 for non-Q wave MI.[24] The hospital mortality for Q-wave MI in the registry declined from 24% to 14%, but that of non-Q wave MI remained constant at 12%. Similarly in the GRACE registry, the risk-adjusted hospital deaths declined between 1999 and 2006 by 18% in STEMI and 0.7% in NSTEMI.[25] It appears that despite impressive declines in the incidence and in-hospital and long-term mortality rates of Q-wave MI, the incidence of non-Q wave MI has been stable or increasing with mortality rates that have changed little over the last decade. Part of these data in NSTEMI might be explained by the wide use of troponin resulting in higher sensitivity and specificity for the diagnosis, and selective hospitalization of higher risk patients.

The natural history of UA/NSTEMI is difficult to assess given the increasingly effective therapeutic interventions introduced over the last 2–3 decades in parallel with better

diagnostic and risk stratification tools. Treatment now targets multiple facets of the disease, combining drugs and interventions. Early studies have shown a 10-fold increase in the short-term risk of an event in patients with unstable angina compared with patients with stable angina, and several-fold more compared with individuals with risk factors but no known coronary disease. Recent randomized trials have shown an impressive decrease in MI and death. Prior to the routine prescription of bed rest, nitrates and beta-blockers for unstable angina, the one-month rate of MI was in the range of 40%, and of death, 25%.[26] By the 1970s these rates had fallen to about 10% and 2%. In 1979–80, a study of all patients hospitalized with unstable angina in Hamilton, Canada, over a period of one year noted showed in-hospital and one-year mortalities rates of 1.5% and 9.2% respectively.[27] By the time of the studies with heparin in the late 1980s, study inclusion criteria had shifted toward patients at somewhat higher risk with some trials limiting enrollment to patients with NSTEMI. The rates of the composite outcome of death or non-fatal myocardial infarction by five days were then about 10%.[28,29] They fell to about 4% with the addition of heparin to aspirin, and further with enoxaparin and the glycoprotein IIb/IIIa antagonists. The event rates at 30 days in recent trials with new antithrombotic therapies and an invasive management strategy are shown in Figure 29.2.[30–41] The risk of the disease is highest in the first few days, decreases over the following weeks and months, and eventually becomes similar to the prognosis of patients with stable angina. The long-term prognosis is influenced by the severity of the underlying disease. In the OASIS registry, the incidence of events was 10% at

one month and increased steadily in the following two years to reach more than 20% after 24 months (Fig. 29.3), and was still higher in diabetic patients and in patients with previously known coronary artery disease.[42] In the GUSTO-II study, the in-hospital mortality rate was highest, as expected, in patients with STEMI; however, increasing mortality during follow-up in patients with ST segment depression exceeded that of patients with ST elevation after six months, reaching 8.7% vs 6.8% (Fig. 29.4).[43]
Figure 29.3 Kaplan–Meier event curves for diabetic and non-diabetic patients for total cardiovascular death, MI, stroke, and new onset of congestive heart failure during a 24-month follow-up period after an episode of non-ST segment elevation ACS. (Data from the OASIS Registry study reproduced with permission from Malmberg et al.[42])
Figure 29.2 Rates of death and of death or myocardial infarction in contemporary trials that evaluated new antithrombotic drugs and routine invasive treatment strategy in patients with non-ST segment elevation ACS. Data are the average of events in the intervention and control groups. The interventions resulted in a reduction in rates of death ranging from –5% to 36% and in rates of death or myocardial infarction ranging from –8% to 27%.[29–40]
Figure 29.4 Kaplan–Meier estimates of probability of death at six months by ECG changes at admission. The event rate was highest in-hospital in patients with ST segment elevation MI. However, by six months, mortality in patients with ST depression exceeded that of patients with ST elevation. (Data from the GUSTO-II study, reproduced with permission from Savonitto et al.[43])

The empiric concept that NSTEMI represents an unresolved ACS at risk of completion, likely due to an underlying disease process that remains active, appears to be correct for a significant number of patients. This is supported by data showing that markers of inflammation and of activation of coagulation may remain elevated months past the acute phase of an episode of ACS.[44,45]

Risk stratification

A gradient in risk exists in ACS from relatively benign to severe; accordingly, patient management should be guided by clinical risk stratification. The high-risk features for death and ischemic events present at admission, or developing rapidly, have been identified in many registries and clinical trials. Registry studies look at a broad spectrum of patients with acute chest pain and are likely to provide more "real-world" data[22,24,42] while clinical trials enroll more selected and homogeneous populations predefined by entry criteria, collect data prospectively, and often include innovative substudies to test new hypotheses. The two approaches are complementary.

Cardiac risk factors are strong predictors of the presence and prognostic of coronary artery disease, but are generally not useful for the diagnosis of an ACS and its associated risk.[46] Angiographic predictors of a future episode of ACS are a known high extent score of the disease defined by the number of coronary artery segments showing a stenosis whatever its severity.[47] On the other hand, the occurrence of an ACS is a strong indicator that the severity of an obstructive lesion has progressed significantly.[48] Many parameters influence prognosis, some related to the acute thrombotic events, others to the extent and severity of the underlying disease, and still others to co-morbidities.

The clinical evaluation, the 12-lead ECG, and the troponin T or I blood levels are powerful and now standard first-line instruments for risk evaluation. These are included in risk scores, are part of recommended treatment algorithms, and are used as entry criteria in clinical trials to identify the high-risk patients. There are, however, other strong demographic and clinical predictors of prognosis that impact on the prognosis of UA and that should now also be considered in risk stratification. These are mainly older age, left ventricular function, and co-morbid conditions, particularly renal failure and diabetes. Bleeding has recently emerged as a strong prognostic factor; it is largely iatrogenic as a result of aggressive treatment.

Clinical features

In the evaluation of prognosis, the physician is first oriented by symptoms, recognizing an increasingly severe prognosis from new angina, to progressive angina, rest angina, and prolonged chest pain, further worsened if ischemic episodes are accompanied by hemodynamic or electrical instability and if they are recurrent despite optimal medical therapy.[1] It is important to recognize that women, the elderly, and the diabetic patient are more likely to have atypical presentations, because the prognosis with atypical symptoms at the time of an infarction can be worse than that of patients with more typical symptoms.[49] Women enrolled in clinical trials are in general older than men and have more risk factors such as diabetes and hypertension. The proportion of women with ST segment elevation is less than in men but their prognosis is then worse. Women who present with NSTE-ACS less often have an elevation of the cardiac markers and have a better prognosis. The odds ratio (OR) for infarction and death in the GUSTO-IIb study in women compared to men was 0.65 (95% confidence interval (CI) 0.49–0.87; $P = 0.003$),[50] and in the non-invasive strategy arm of the FRISC-II study was 0.64 (95% CI 0.43–0.97; $P = 0.03$).[51] Coronary angiography in general revealed less severe coronary artery disease among women than men.[51]

Diabetes

Diabetes has become a major determinant of risk as its prevalence has reached epidemic proportions. It is present in 20–25% of patients enrolled in trials in ACS. Diabetes increases morbidity and mortality in the setting of ACS and after percutaneous interventions and coronary artery bypass grafting. In the OASIS registry, diabetes was an important and independent predictor of two-year mortality (relative risk (RR) 1.57; 95% CI 1.38–1.81; $P < 0.001$), as well as of cardiovascular death, new myocardial infarction, stroke, and new congestive heart failure.[42] The relative risk of death in diabetic women was significantly higher than in diabetic men (RR 1.98 and 1.28 respectively). Diabetic patients without known prior cardiovascular disease had the same event rates for all outcomes as non-diabetic patients with previous vascular disease (see Fig. 29.3). In a subgroup analysis of patients enrolled in 11 independent TIMI Group clinical trials from 1997 to 2006 that included 62 036 patients (46 577 with STEMI and 15 459 UA/NSTEMI), 17.1% had diabetes.[52] The unadjusted 30-day mortality rates were significantly higher among patients with diabetes than those without for both UA/NSTEMI (2.1% vs 1.1%, $P < 0.001$) and STEMI (8.5% vs 5.4%, $P < 0.001$), as were the odds ratios adjusted for baseline characteristics and management (1.78; 95% CI 1.24–2.56 and 1.40, 95% CI 1.24–1.57 respectively). The hazard ratio (HR) for one-year mortality after UA/NSTEMI was 1.65; 95% CI 1.30–2.10) and after STEMI (HR 1.22; 95% CI 1.08–1.38). By one year following ACS, patients with diabetes presenting with UA/NSTEMI had a risk of death that
Figure 29.5 Hospital outcomes according to degree of renal impairment for the subgroup of patients with non-ST-elevation myocardial infarction/unstable angina from the GRACE Registry. *P < 0.05 across all categories of renal function; **P < 0.0001 across all categories of renal function. (Reproduced with permission from Santopinto et al.[59].)

approached that of patients without diabetes presenting with STEMI (7.2% vs 8.1%).

Depression may also have a negative impact on prognosis. In a study of 430 patients with NSTE-ACS, depression predicted the endpoint of cardiac death or non-fatal MI, with an adjusted odds ratio of 6.73 (95% CI 2.43–18.64; P < 0.001) after controlling for other significant prognostic factors that included baseline ECG, left ventricular ejection fraction, and number of diseased coronary vessels.[53]

Chronic kidney disease

Chronic kidney disease (CKD) is associated with a higher risk of cardiovascular and all-cause mortality.[54–56] It is also a marker of impaired prognosis in patients with coronary artery disease or with a myocardial infarction, and in patients with an ACS (Fig. 29.5) or undergoing coronary angiography. These cross-interactions are likely linked to a high incidence of traditional risk factors in CKD, mainly diabetes and high blood pressure, and also of non-traditional risk factors such a proinflammatory state, a prothrombotic state, and hyperhomocysteinemia. Complicating these issues, CKD is associated with a higher bleeding risk (see Fig. 29.5); the more severe the dysfunction, the higher is the bleeding risk.[57] Routine calculation of the estimated creatinine clearance rate by the Cockcroft–Gault method or of the estimated glomerular filtration rate (GRF) by the Modification of Diet in Renal Disease (MDRD) formula is strongly recommended over the simple measure of plasma creatinine levels.[58] Cystatin C is also emerging as a valid marker of GFR.[59]

The 12-lead ECG

Current information on the prevalence of ECG abnormalities is difficult to obtain, in part because the ECG and other diagnostic criteria used to select patients for clinical registries are often less homogeneous and rigorous than those used for clinical studies. In the TIMI-III Registry of 1416 patients enrolled because of unstable angina or non-Q wave MI,[60] ST segment deviation ≥1mm was present in 14.3% of patients, isolated T-wave inversion in 21.9%, and LBBB in 9.0%. By one-year follow-up, death or MI had occurred in 11% of patients with ST segment depression, 6.8% of patients with isolated T-wave inversion, and in 8.2% of those with no ECG changes. ST segment depression 0.5mm or more and LBBB were significant predictors of death and MI, with rates of 16.3% and 22.9%, respectively. The ECG is not infrequently confounded by LBBB, left ventricular hypertrophy, paced rhythm or other derangements. In the PARAGON-A study, these confounders were associated with near doubling in the one-year mortality rates (12.6% versus 6.5%). Among the 12 142 patients enrolled in the GUSTO-II trial with symptoms at rest within 12 hours of admission and ischemic ECG changes, 22% had T-wave inversion, 28% ST segment elevation, 35% ST segment depression, and 15% ST segment elevation and depression.[43] The 30-day rates of death or myocardial reinfarction were 5.5%, 9.4%, 10.5%, and 12.4% respectively (P < 0.001). The cumulative rates of death in this study are shown in Figure 29.4.

There is a gradient of increasing risk of death or myocardial infarction in hospital and up to one year, from nonspecific ECGs to T-wave inversion to ST segment depression including confounding ST-T changes. Such a gradient exists from ST segment depression >0.05mm, to >1mm, to >2mm, to ≥2mm, and to depression in more than two contiguous leads.[61] The prognostic value of ST segment depression extends to four years following hospital discharge.[62] Special attention is required for patients showing deep T-wave inversions in leads V1 through V6 and in leads I and AVL on the admission or on subsequent ECGs even in the absence of symptoms; the changes are quite specific for the presence of significant disease in the proximal left anterior coronary artery and are predictive of a high risk of progression to an infarction that can be massive; when the T-wave inversions spare leads I and AVL, the mid-LAD is more often the site of the culprit lesion.[63] Similarly, ST segment elevation in lead AVR associated with ST-T changes in other leads can be a marker of left main disease and severe three-vessel disease. The two last criteria deserve special attention.

The importance of recording the 12-lead ECG during chest pain must be emphasized. The detection of ST segment depression during pain has diagnostic and prognostic value.[64] Occasionally, transient ST segment elevation will be detected in association with a critical dynamic coronary artery stenosis due to spasm or thrombus formation, or with small vessel disease. ST segment shifts during pain occurring on medical management indicate refractory

ischemia, an endpoint commonly used in clinical trials. Such refractory ischemia predicts near tripling of adjusted one-year mortality.[65]

Biomarkers

Markers of necrosis

Elevation of serum troponin follows the ischemic insult by six hours, as does CK-MB; with newer assays, troponin elevation may be detected earlier. Myoglobin can be useful as an early and sensitive marker of necrosis as it rises within two hours after the onset of pain to peak within 4–6 hours; however, it is non-specific and mandates confirmation of the cardiac origin by elevation of CK-MB or troponin. CK-MB is a valid second choice to troponin when determined by a mass assay. The measurement of ancillary markers such as total CK, AST, ALT is unnecessary and can be misleading.

In contrast to CK-MB and myoglobin, cardiac troponins T and I are not normally detectable in the peripheral blood and therefore provide an exquisitely sensitive and specific marker of cardiomyocyte necrosis. The necrosis is usually of ischemic origin, but there are multiple causes of myocardial necrosis other than MI. Only one elevated value is required for the diagnosis of myocardial infarction as long as the patient presents within 24 h after the onset of compatible symptoms. Otherwise, such as in patients with renal failure, the diagnosis of acute MI requires the demonstration of a rising and/or falling pattern against the background value.

Multiple studies have validated the prognostic value of an elevation in the serum troponin levels.[66] Figure 29.6 depicts the results of a clinical trial of a study of patients
Figure 29.6 Risk of death or non-fatal myocardial infarction during 30 days of follow-up by troponin T (TnT) and I (TnI) levels, elevation (positive) or no elevation (negative), and ST segment depression on the ECG. The risk for myocardial infarction and death increases with increasing serum troponin concentrations and may be 20% in 30 days and 25% within six months in patients with the highest troponin levels. (Reproduced with permission from Hamm and Braunwald.[70])

consulting in the emergency department for acute chest pain;[18] the 30-day rate of death or myocardial infarction was highest in patients with elevated troponin T or troponin I levels, intermediate in patients with ST segment depression, and lowest in patients with normal troponin levels. The higher the elevation in troponin levels,[67] the worse the prognosis, but even small elevations are associated with a significantly impaired prognosis.[68] In the FRISC study, among patients with a non-ST segment elevation ACS, the risk of myocardial infarction or cardiac death at six months was respectively 4.3%, 10.5%, and 16.1% in patients within the first, second, and third tertile of maximal elevation of troponin during the first 24 hours.[69,70]

A meta-analysis among patients with unstable angina, including 12 reports with troponin T and nine with troponin I, demonstrated a risk ratio for the occurrence of myocardial infarction at 30 days of 4.2 (95% CI 2.7–6.4; $P < 0.001$) for troponin I and of 2.7 (95% CI 2.1–3.4; $P < 0.001$) for troponin T.[71] A second meta-analysis included 18 982 patients with unstable angina from 21 studies and showed odds of death or myocardial infarction at 30 days of 3.44 (95% CI 2.94–4.03; $P < 0.00001$) for the total population of troponin-positive patients, 2.86 (95% CI 2.35–3.47; $P < 0.0001$) for patients with ST segment elevation, 4.93 (95% CI 3.77–6.45; $P < 0.0001$) for patients with non-ST segment elevation, and 9.39 (95% CI 6.46–13.67; $P < 0.0001$) for patients with unstable angina.[72] A third meta-analysis included seven clinical trials and 19 cohort studies. The odds of mortality among 11 963 patients with positive troponin T or I was 3.1 (5.2% versus 1.6%). The discriminative value of elevated troponin levels was greater in cohort studies than in clinical trials: 8.4% versus 0.7% (OR 8.5) for troponin I, and 11.6% versus 1.7% (OR 5.1) for troponin T.[73]

Determination of troponin levels has many utilities. Elevated levels in the setting of NSTE-ACS strongly suggest the presence of an active intracoronary thrombotic process that is associated with small foci of myocardial necrosis, likely because of distal embolization of thrombotic material originating from the culprit lesion. Beyond providing a highly sensitive and specific test for the diagnosis of myocardial infarction, any elevation provides important prognostic information in acute coronary syndromes. Patients with troponin elevation are also more likely to profit from therapy with a Gp IIb/IIIa antagonist,[74] from a low molecular weight heparin,[75] and from interventional procedures.[76] Some have recently questioned the prognostic significance of the very small elevation of troponin that can be detected with the new generations of ultrasensitive tests.

Markers of inflammation

Consistent with excessive plaque inflammation as the main trigger to plaque rupture and thrombus formation, a wide range of markers of inflammation are found to be elevated in ACS. These include acute phase proteins (C-reactive

protein, serum amyloid A protein, fibrinogen), soluble adhesion molecules (sVCAM-1, sICAM-1, E-selectin, P-selectin), proinflammatory cytokines (interleukin-6, TNF-alpha, interleukin-18), degradation enzymes (myeloperoxidase, matrix metalloproteinases, placenta-associated plasma protein-A), and markers of thrombosis (D-dimers, F1.2), oxidative stress (myeloperoxidase), inflammation (CD40 ligand), and of immune system activation (neopterin).

C-reactive protein (CRP) is a non-specific but highly sensitive marker of an inflammatory state. It is produced by the liver upon stimulation by interleukin-6, which is induced by TNF-alpha, IL-1, IL-18, platelet-derived growth factor, antigens, and endotoxins. As CRP half-life is 19 hours, blood levels are determined mainly by rates of production, These can be very high in inflammatory and infectious disease, and in the acute phase of a large infarction where they rise within six hours and peak at 48 hours. In NSTEMI, the elevation precedes that of markers of myocardial necrosis in patients who had previous progressive angina, but not in patients without.[77] The early levels may thus be less useful for risk evaluation; on the other hand, levels obtained after 24–48 hours can represent a transient non-specific acute phase reaction caused by the ongoing cell necrosis. and inconsistently predict future events. Elevated levels at a later time and before hospital discharge are found in up to 40–50% of patients and are associated with high rates of late cardiac events, including death/MI/recurrent ischemia at 12 months,[78] death/MI at six months[79,80] and up to two years,[81] and death at 36 months.[82] In the CAPTURE trial of 447 patients, CRP levels >10 mg/L did not predict mortality or myocardial infarction at 72 hours in contrast to elevated troponin T levels, but did predict death or MI at six months (18.9% compared to 9.5%), independently of the troponin status.[80] Of interest, high levels of neopterin levels have been linked with the presence of multiple active inflammatory plaques.[83]

The assessment of CRP levels is not currently part of the recommendations of various guidelines. The cut-off points that best predict early and late prognosis as well as the ideal timing for blood sampling remain to be better defined and no study has yet documented that a treatment specific for CRP has improved prognosis. In one study, PCI or CABG had little effect on the one-year excess of recurrent ischemic events in patients with NSTE-ACS and high CRP levels. Elevated CRP levels are associated with increased risk of restenosis and acute complications after PCI,[84,85] and with an increased risk of new ischemic events up to eight years after CABG.[86] The JUPITER trial was designed to determine whether long-term treatment with rosuvastatin (20 mg orally od) would reduce the rate of first major cardiovascular events, defined as the combined endpoint of cardiovascular death, stroke, myocardial infarction, hospitalization for unstable angina, or arterial revascularization

among individuals with LDL-C levels <130 mg/dL (3.36 mmol/L) at high vascular risk because of an enhanced inflammatory response as indicated by hsCRP levels ≥2 mg/L.[87] The trial was terminated prematurely upon the recommendation of the DSMB because early efficacy.

Beta-type natriuretic peptides

Beta-type natriuretic peptides are cardiac neurohormones released in response to ventricular myocyte stretch; proBNP is enzymatically cleaved to the N-terminal proBNP (NTproBNP) and subsequently to BNP. The value of assessing BNP was first shown for the diagnosis and evaluation of heart failure. Since then, large data sets have documented a high predictive value independent of conventional risk factors and other biomarkers in patients with STEMI and with UA/NSTEMI.[88,89] This predictive value extends to early and late blood sampling. Increasing levels are associated with proportionally higher short- and long-term mortality rates. In the GUSTO-IV trial of 6809 patients, the one-year mortality rates by increasing quartiles were 1.8%, 3.9%, 7.7%, and 19.2%, respectively ($P < 0.001$). (Fig. 29.7) This prognostic value was independent of a previous history of HF and of clinical or laboratory signs of LV dysfunction on admission or during hospital stay. A previous study had shown that this prognostic value was applicable to patients with unstable angina, STEMI, and particularly NSTEMI. The exact reasons for this selective predictive value in ACS are not clear but likely relate to larger zones of ischemic myocardium associated with necrosis and stunning and is in line with the impaired prognosis shown with modest depression of LVEF.[90] Current guidelines do not recommend routine determination of natriuretic factors
Figure 29.7 Patients with acute coronary syndromes without ST segment elevation in GUSTO-IV. Kaplan–Meier survival curves regarding probability of death during 1 year for patient strata, according to quartiles of NT-proBNP. (Reproduced with permission from James et al[89].)

because elevations would be unlikely to prompt the use of specific evidence-based therapies, and the prognostic value lies more in long-term than in short-term outcomes. It is stated as a class II recommendation, however, that natriuretic factors may be measured to supplement the assessment of global risk in patients with suspected ACS.[1] They should also be used if another indication exists.

Multiple markers and panels of markers

The mechanisms of ACS are highly complex and involve many pathophysiologic cascades with numerous interactions between them. Many studies have shown that a multimarker approach will improve the prognostic value. In the TIMI-11A study of 630 patients with a non-ST segment elevation ACS, the risk of death at 14 days was highest with elevated troponin T and CRP, intermediate when either marker was elevated, and lowest when both were normal (CRP < 1.55 mg/L).[91] In the GUSTO study, levels of NT-proBNP, troponin (Tn) T, CRP, heart rate, and creatinine clearance, in addition to ST segment depression, correlated independently with one-year mortality, but NT-proBNP was the marker with the strongest relation.[89] In contrast, only troponin T, creatinine clearance, and ST segment depression were independently related to future MI. The combination of NT-proBNP and creatinine clearance provided the best prediction, with a one-year mortality of 25.7% with both markers in the top quartile vs 0.3% with both markers in the bottom quartile. The cumulative benefit of using TnI, CRP and BNP was demonstrated in substudies of two large clinical trials[92] (Fig. 29.8). Multimarker measurement is not recommended at the present time since the cost/benefit ratio would be low in the absence of a prospectively validated scenario. Troponin assessment is a must – another marker and the only one recommended for routine use. BNP or NT-proBNP could be useful in some patients for a more global evaluation and CRP as well.

The near future will see the introduction of growing numbers of markers to help delineate the complex and dynamic pathophysiology of cardiovascular diseases and tailor treatment selection to specific patient needs. These will include clusters of blood markers tracking various pathophysiologic pathways, cell membrane markers, the genome and proteome, and molecular probes for tissue imaging.

Risk scores

Prognosis can be predicted by various clinical, ECG, and laboratory parameters. Accordingly, predictive models have been derived from various databases by applying multiple regression analyses to identify independent predictors of prognosis. However, the results of such analyses are influenced by the characteristics of the test populations

(a)

(b)

and by the baseline data collected. The GUSTO, TIMI and PURSUIT scores[93] were developed from the databases of large clinical trials of NSTE-ACS, whereas the GRACE score was built on registry data acquired across the entire spectrum of ACS. The TIMI score excluded patients with planned revascularization within 24 h and those at high bleeding risk from enoxaparin treatment (including significant renal dysfunction); it looked at the rates of death/MI and recurrent ischemia requiring an intervention by 14 days. Renal failure was an exclusion criterion in the PURSUIT trial, and the outcome of death or MI was assessed at 30 days. The GRACE score was shown to be useful to predict death or MI at one year and death at six months and four years.[94,95] It can be measured at admission, to assess the risk of death or death or MI from admission to discharge or to six months, or at hospital discharge to evaluate the risk to six months or to one year. These scores all add to the prognostic value of biomarkers and the ECG and are useful to identify patients who will most benefit from more aggressive medical and invasive treatment.[96]

Age is a strong predictor in all scores. The TIMI score can be readily and simply assessed at admission or shortly thereafter by calculating the sum of seven independent

	TIMI (7 points)		GRACE (Odds Ratio, score)		Others

Figure 29.9 Risk scores used in UA/NSTEMI. The components of the TIMI and GRACE scores are shown in detail. Each component in the TIMI score counts for 1. Odds ratios are given for the components of the GRACE score. Algorithms to calculate these scores can be easily downloaded from the Web for use in bedside devices.

predictors, allowing discrimination of a 10-fold difference in risk through 14 days (Fig. 29.9). The PURSUIT and GRACE scores added an important dimension of LV function and the GRACE score a component of chronic renal disease.

Pathophysiology

This section will focus on the mechanisms of acute coronary syndromes that are the most relevant with respect to management. Interested readers are referred to more exhaustive reviews.[5,97] The culprit lesion becomes clinically manifest only with the development of an obstruction severe enough to impede coronary blood flow at rest, or when it is the site of a thrombotic occlusion shedding thromboembolic material into the distal coronary circulation. Therefore, the active plaque is clinically detected only at an advanced stage of the underlying disease. Further, the concept of a single active plaque has been challenged. Pathologic studies have shown multiple rupture sites and thrombi at multiple sites often associated with platelet aggregates in small intramyocardial arteries and microscopic foci of necrosis.[4,98,99] An angiographic study in 253 patients with an acute myocardial infarction documented that complex and ruptured plaques could be found in 40% of patients and that these were associated with a 10-fold increase in the risk of a recurrent ACS.[100]

Atherosclerosis is the substrate for ACS. The severity of atherosclerosis underlying an episode of an acute coronary syndrome is highly variable, ranging from absence of significant stenoses to the presence of left main disease in 5–10% of patients, and single-, double- or three-vessel disease in respectively 20%, 30%, and 40%.[101] A severely obstructive lesion containing a variable amount of dynamic thrombus over a plaque is most often identified, providing

a rationale for coronary revascularization. On inspection and histologic analyses, the culprit lesion is clearly distinct from the stable plaque which is most often of only moderate severity, with an inner core rich in cholesterol and cholesterol esters and a thin fibrous cap, poor in connective tissue and smooth muscle cells.[5] At microscopy, the culprit lesion is rich in monocyte-macrophages, mast cells, lymphocytes, and neutrophils. Biologically, it is extremely active, with an intense inflammatory reaction marked by heterotypic cell-to-cell interactions and activity of proinflammatory cytokines, matrix-degrading metalloproteinases, and growth factors.[97] This culprit lesion is the site of a rupture or fissure, occurring most often at the shoulder region of the plaque. The endothelial disruption is overlain by a thrombus extending variably within the lumen of the artery and the vessel wall.[5] A number of intravascular imaging technologies have allowed description of the culprit lesion in the living man, including intravascular angioscopy, ultrasound (IVUS), thermography (recording plaque temperature), optical coherence tomography (OCT) (generating images from backscattered reflections of infrared light), intravascular spectroscopy, and magnetic resonance imaging-based approaches.[102]

Thrombus formation is triggered by tissue factor (TF), which is expressed by lipid-laden macrophages in the core of the atherosclerotic plaque and diseased endothelium. When exposed to the circulating blood, TF binds circulating factor VIIa (FVIIa). The complex triggers the proximal coagulation cascade by activating factor IX and X within the tenase complex. Factor X forms a quaternary complex with TF-FVIIa and tissue factor pathway inhibitor (TFPI) to limit the generation of TF-FVIIa and the thrombogenic stimulus. The thrombus will progress, however, when large enough amounts of FXa are produced. FXa is pivotal in the coagulation cascade. It converts prothrombin to thrombin within the prothrombinase complex. Thrombin has multiple pathophysiologic effects, converting fibrinogen to fibrin, activating factor XIII, which cross-links fibrin, and amplifying its own generation by activation of factors V, VIII, and XI on the platelet surface. It is the most potent platelet agonist *in vivo*, acting mainly through the thrombin protease-activated receptor type 1 (PAR-1). Additional thrombin receptors in human platelets are PAR-4 and GP Ib-IX-V. Platelet activation is promptly associated with an outside translocation of the inner anionic phospholipid layer of platelets, providing a membrane surface well suited to the assembly of coagulation factors and thrombus formation and growth. Circulating platelets also promptly adhere to the damaged endothelium through receptor–ligand interactions. Gp Ib/IX recognizes von Willebrand factor present in large quantities in the subendothelium, and Gp Ia/IIa recognizes collagen. Platelet adhesion and other local agonists produce intracellular signaling that increases cytosolic Ca^{2+} content and induces shape change,

release of potent vasoactive, proaggregant and procoagulant substances, and activation of Gp IIb/IIIa receptors.[5] Activated Gp IIb/IIIa receptors recognize and bind the RGD sequence of various moieties, particularly fibrinogen, resulting in platelet cross-bridging and aggregation. P-selectin, CD40L, and other compounds secreted by activated platelets attract leukocytes, linking mechanisms of thrombosis and inflammation.

The mainstay of immediate therapy in ACS is the control of the thrombotic activity to prevent its rapid progression to occlusion or distal microembolization of thrombotic material. The best results have been achieved with combinations of antiplatelet and anticoagulant therapy consistent because of the contributions to arterial thrombosis of both platelet activation/aggregation and intravascular coagulation.

Management

The goals of treatment in ACS are to control ischemia, decrease the substantial early risk of myocardial infarction and death, and prevent recurrences of the syndrome. These objectives can be collectively regrouped under the terms stabilization or passivation of culprit lesions during the acute phase, and secondary prevention of the underlying atherosclerosis thereafter. They are best achieved acutely by judicious use of anti-ischemic therapy, antithrombotic agents, and reperfusion procedures, then by a program of risk factor control. There are no clear boundaries between these two phases. Treatment is generally guided by risk evaluation based on patient demographics, clinical presentation, the 12-lead ECG, troponin levels, and other patient characteristics associated with an enhanced risk (Table 29.2). Risk stratification is an ongoing process that must be repeatedly updated during the hospital stay and follow-up after discharge.

Initial measures (generally Class I, Level C)

Patient's response to symptoms
The patient may first consult with family or colleagues, may visit a medical clinic, doctor's office or emergency department, or may call a healthcare provider, optimally 911. Rapid access to the emergency cardiac care system increases the likelihood of prehospital care and prompt prehospital recording of a 12-lead ECG, and rapid transport to an appropriate center for prompt optimal therapy.

Medical triage
Patients are further evaluated in an emergency department where blood levels of biomarkers of infarction are obtained. Patients with milder symptoms such as new onset of

Table 29.2 Determinants of prognosis of non-ST segment elevation ACS

Confirming high-risk ACS	Clinical pattern of pain
	ST-T ischemic changes
	Troponin T or I elevation
	Hemodynamic or electrical instability
	Recurrent ischemia
	Previous aspirin use
Other cardiovascular	Left ventricular dysfunction
	Congestive heart failure
	Previous myocardial infarction
	Previous CABG
	Extensive coronary or vascular disease
	Provocative testing
Other non-cardiac	Older age
	Bleeding
	Diabetes
	Chronic renal failure
	Depression
Biomarkers	BNP, NTpro-BNP
	CRP
	Other markers (e.g. MCP-1, IL-6, MPO)

angina and/or mild exacerbation of previously stable angina, stable hemodynamics, no angina at rest, no ECG changes and normal serial troponin levels can be further triaged by provocative testing before discharge or as an outpatient soon after discharge. If coronary artery disease (CAD) is suspected, educational material is provided and initial treatment is instituted and re-evaluated at subsequent follow-up. Patients at intermediate risk might go to a coronary care unit (CCU), an intermediate care unit or to a regular ward depending on the availability of facilities and the specific level of risk. High-risk patients should go to the CCU for prompt treatment and are considered for urgent coronary angiography.

General measures

Ischemia at rest or low threshold activity mandates measures to minimize myocardial oxgen demand, including rest in bed or a recliner chair and stool softeners. Emotional distress is minimized by judicious control of the environment, supportive medical and nursing care, limitation and education of visitors, provision for restful sleep, and the control of ischemic pain whenever present with nitrates, intravenous narcotics and other specific anti-ischemic agents as appropriate. Morphine (1–5 mg IV to be repeated if needed) is a useful adjunct, although a note of caution has been raised, by a finding in a large observational registry, of a higher adjusted likelihood of death in patients

administered morphine (OR 1.41, 95% CI 1.26–1.57).[103] A randomized trial may be warranted. Oxygen is administered to patients with cyanosis or respiratory distress or if finger pulse oximetry reveals an SaO_2 under 90%. Attention is indicated to detect depressive symptoms which may adversely affect prognosis independently of other predictors.[53]

Anti-ischemic therapy

Nitroglycerin

Nitroglycerin remains a mainstay of angina therapy. It is converted to nitric oxide to cause endothelium-independent vasodilation of capacitance veins (resulting in decreased venous return and preload) and of arterioles (resulting in a reduction in blood pressure and afterload). Together these effects strikingly reduce wall stress and myocardial oxygen demand. Myocardial oxygen delivery may be enhanced if small coronary arteries are concomitantly dilated and no coronary steal occurs. The decrease in myocardial oxygen demand is partly offset by reflex increases in heart rate and contractility, which can be counteracted by adequate beta-blockade.

Nitroglycerin (NTG) is given as a sublingual tablet, by oral or sublingual spray or as an intravenous bolus for the immediate relief of chest pain; long-acting oral or transdermal nitrates or nitroglycerin intravenous infusion are useful to prevent recurrent angina, and to rapidly control blood pressure during the acute phase. Intravenous NTG may be initiated at a rate of 10 μg per min through continuous infusion via non-absorbing tubing and increased by 10 μg increments every 3–5 min until there is some relief of symptoms or blood pressure response, or headache occurs which is not promptly controlled by acetominophen. In general, systolic blood pressure should not be titrated to less than 110 mmHg in previously normotensive patients or to more than 25% below the starting mean arterial blood pressure if hypertension was present.

To minimize the rapid tolerance which occurs with nitroglycerin, a drug-free interval of 6–12 hours a day is generally recommended. This may be undesirable in unstable patients in whom tolerance can be attenuated by reducing the infusion rate once chest pain and blood pressure are under control and increasing the rate subsequently if needed. A ceiling dose of 200 μg per min is empirically advised although prolonged (2–4 weeks) infusion at rates of 300–400 μg per min has not resulted in increased methemoglobin levels.[104]

Nitroglycerin should be avoided in patients with initial systolic blood pressure less than 90 mmHg and in patients with marked bradycardia or tachycardia. Pre-existing hypovolemia is common in the elderly and may predispose to nitroglcerin-induced hypotension. Side effects include headache and hypotension. Hypotension associated with inappropriate bradycardia, reflecting vagal stimulation, may be corrected by Trendelenburg positioning and volume administration or the administration of atropine or glycopyrrolate. Even though the half-life of NTG is short, exacerbation of ischemic changes following abrupt cessation of intravenous NTG has been described[105] and a graded reduction in the intravenous dose is advisable.

The phosphodiesterase-5 inhibitors used for the treatment of erectile dysfunction decrease the biodegradation of cyclic guanosine monophosphate (cGMP) whereas organic nitrates also increase levels of cGMP by activating guanylate cyclase. Synergistic decreases of both systolic and diastolic pressure can result in an excessive fall in blood pressure which has been associated with profound hypotension, MI, and even death. The duration of the interaction is variable depending on the half-life of the various drugs. It is advised not to administer nitrates for 4–6 half-lives after the use of a phophodiesterase-5 inhibitor (24 hours for sildenafil and vardenafil and 48 hours for tadalafil). A recent study of healthy individuals suggested that the sildenafil–nitroglycerin interaction could be gone after four hours.[106] The presence of even trace amounts of nitrates could have deleterious effects in combination with a PDE-5 inhibitor, and the administration of sildenafil or another PDE-5 inhibitor to a patient who has taken a nitrate in the preceding 24 hours is contraindicated, as is the administration of any nitrate within 24–48 hours of the administration of a PDE-5 inhibitor. In general, PDE-5 inhibitors should be avoided altogether in patients who require nitroglycerin for treatment of their angina.[107] Most studies of nitrates in unstable angina were small, employed case series or case–control designs, and dose regimens varied considerably.[108] Many issues such as nitrate tolerance were not addressed. Partial relief of anginal episodes was usually achieved, occasionally relief was complete, and absence of benefit was infrequent. Thus, the widespread use of oral, topical, and IV nitrates in unstable angina is based upon reasonable extrapolation from pathophysiologic observations, case series, evidence of modest reduction of mortality in acute MI,[109–111] and extensive clinical experience using regimens developed in careful clinical studies[111] (**Class I, Level C**).

Beta-blockers and calcium antagonists

Based on their effectiveness in the treatment of stable angina, beta-blockers were widely used for the management of unstable angina in the absence of objective evidence for their efficacy. As the calcium channel blockers became available and their effectiveness for the control of stable angina was demonstrated, they also began to be used for the management of unstable angina, and therapeutic trials generally focused on comparisons of beta-blockers and various calcium antagonists. A small randomized and placebo-controlled trial of 126 patients

hospitalized with unstable angina showed similar protective effects with nifedipine and the combination of propranolol/isosorbide dinitrate to prevent recurrent chest pain during an evaluation period of 14 days.[112] It was noted that the propranolol/isosorbide combination was more effective than nifedipine in patients not taking beta-blockers prior to admission, whereas nifedipine was more effective among patients already on beta-blockade. In the subsequent HINT study,[113] 338 patients not receiving beta-blocker on admission were randomly allocated, double blind, to nifedipine, metoprolol, both or neither. Metoprolol was significantly more effective than nifedipine ($P < 0.05$) in preventing acute MI or recurrent angina with ST change. The 177 patients already on a beta-blocker at admission were randomly allocated, double blind, to nifedipine or placebo, and nifedipine was superior ($P > 0.05$). In a trial of patients receiving "optimal" doses of nitrates and nifedipine who were then randomized to the addition of either propranolol or placebo,[114] propranolol was effective. In another study in patients who had failed maximum treatment with propranolol and long-acting nitrates and were then randomized to the addition of nifedipine or placebo, nifedipine was effective ($P > 0.03$).[115]

Diltiazem was compared to propranolol in a randomized single-blind study of patients hospitalized for angina accompanied by ECG abnormalities and occurring in a crescendo pttern, at rest or following MI.[116] Chest pain frequency was significantly reduced by both regimens, and there was no difference in efficacy. In another study, patients with rest angina were randomized to diltiazem or propranolol in maximum tolerated doses.[117] The agents were equally effective in reducing the frequency of daily anginal episodes, but in the subgroup with angina only at rest, diltiazem was efficacious whereas propranolol was not. The Multicenter Diltiazem Postinfarction Trial Research Group randomly assigned 2466 patients with a non-W wave MI to diltiazem (240 mg daily) or placebo for 12–52 months (mean 25). Mortality rates were nearly identical among the two treatment groups. First recurrent cardiac events (death from cardiac causes or non-fatal reinfarction) were 11% fewer in the diltiazem group (202 vs 226; HR 0.90; 95% CI 0.74–1.08). A significant ($P = 0.0042$) bidirectional interaction between diltiazem and pulmonary congestion was observed on X-ray examination. In patients without pulmonary congestion, diltiazem was associated with a reduced number of cardiac events (HR 0.77; 95% CI 0.61–0.98); in patients with pulmonary congestion, diltiazem was associated with an increased number of cardiac events (HR 1.41; 95% CI 1.01–1.96). A similar pattern was observed with respect to the ejection fraction, dichotomized at 0.40.[118] A retrospective analysis of the DAVIT trial with verapamil suggested the same detrimental effect on mortality rates in patients with LV dysfunction.[119] Small placebo-controlled trials of verapamil demonstrated statistically significant reductions in the frequency of ischemic pain, but longer-term follow-up showed a relatively high incidence of AMI and death.[120] Yusuf *et al*[121] examined five trials involving about 4700 patients with threatened MI who were placed on intravenous beta-blocker followed by oral therapy for about a week. There was a modest 13% reduction in the risk of development of MI in this group. Although a meta-analysis of verapamil[122] therapy indicated a favorable effect on outcomes, the Yusuf meta-analysis found no overall reduction of death and non-fatal MI with calcium antagonists among patients with unstable angina.[121]

Altogether these trials suggest that patients not receiving a beta-blocker or a calcium antagonist prehospitalization may benefit from a beta-blocker, diltiazem or verapamil. However, the the meta-analytic data for benefit of beta-blockers but not calcium antagonists and the evidence for improved long-term outcomes with beta-blocker therapy among survivors of myocardial infarction[121] and those with chronic ischemia, support beta-blockers over rate-limiting calcium antagonists as the first-choice therapy in patients with unstable angina (**Class I, Level A**). Patients at high risk may benefit from initial intravenous beta-blocker, followed by an oral regimen (**Class I, Level C**). Diltiazem or verapamil are suitable alternatives for patients with a contraindication to beta-blocker therapy (**Class I, Level C**). A short-acting dihydropyridine without a beta-blocker is contraindicated as it can increase the incidence of MI[123] (**Class III, Level A**). A long-acting dose preparation or an agent with an intrinsically long half-life such as amlodipine appears to be preferable, but there has been no rigorous assessment (**Class I, Level C**). Patients already receiving a beta-blocker can benefit from the addition of a calcium antagonist to prevent recurrent angina (**Class I, Level A**). Beta-blockers, diltiazem and verapamil should be avoided in patients with severe LV dysfunction (**Class III**).

Among patients with variant angina, characterized by recurrent ischemic episodes occurring mainly at rest and in the early morning hours and accompanied by transient ST segment elevation, randomized, placebo-controlled, double-blind trials of verapamil,[124–126] diltiazem,[127–129] and nifedipine[130–132] have demonstrated the efficacy of each of these agents in reduction of angina frequency. Several comparisons of calcium antagonists to beta-blockers have demonstrated greater efficacy with the calcium antagonists.[125,126,130] These agents, along with nitrates, are regarded as the therapy of choice for variant angina (Class I, Level A), although there are few direct comparative data with long-acting nitrates.

Ranolazine

This is a piperazine derivative approved for the control of angina in patients with chronic stable angina who have failed to respond to prior angina therapy with beta-blockers, calcium channel blockers or nitrates.[133] It is

contraindicated in patients with pre-existing QT interval prolongation. Patients with moderate to severe hepatic impairment and those taking CYP3A4 inhibitors should be closely monitored for adverse effects, including QT prolongation. Ranolazine has no effects on heart rate and blood pressure. Although the exact mechanism of action is unknown, it acts as a partial fatty acid oxidase inhibitor to shift adenosine triphosphate (ATP) production away from fatty acid oxidation to more oxygen-efficient glucose oxidation during periods of myocardial ischemia. It also inhibits the inward late sodium current during cardiac repolarization, leading to a reduction in intracellular sodium and calcium overload, and a decrease in the inotropic state and myocardial oxygen demand.

In the recent MERLIN TIMI 36 trial,[134] 6560 patients with unstable angina/NSTEMI were randomized within 48 hours of ischemic symptoms and subsequently followed up for a median of 348 days. The drug was first administered intravenously, then orally. The primary efficacy endpoint of cardiovascular death, MI, or recurrent ischemia did not differ between ranolazine and placebo. However, recurrent ischemia was less frequent with ranolazine (13.9% versus 16.1% with placebo, $P = 0.03$). Side effects were unfrequent, including QTc prolongation which required a reduction in the dose of intravenous drug in 0.9% receiving ranolazine and 0.3% receiving placebo. There was no difference in the rates of documented symptomatic arrhythmias or of mortality in the two groups. The risk of clinically significant arrhythmias on Holter monitoring was reduced by 11% ($P < 0.001$) in the patients assigned to ranolazine.

Antithrombotic therapy

Antithrombotic therapy is a cornerstone in the management of ACS. It reduces the incidence of death and myocardial infarction whether patients are managed by medical therapy only or by the addition of invasive therapy. Antithrombotic effects are enhanced with combined inhibition of platelets and of the coagulation process, but the risk of hemorrhage is increased. Thrombolytic therapy is beneficial in ST segment elevation ACS but contraindicated in non-ST segment elevation ACS.[135]

Antiplatelet therapy

Whereas aspirin remains the gold standard of antiplatelet therapy, an armamentarium of new agents acting on different aspects of platelet function has been developed.[136] Antiplatelet agents evaluated in ACS include aspirin, dipyridamole, prostacyclin, sulfinpyrazone, inhibitors of thromboxane synthase and/or its receptor, ticlopidine, clopidogrel, prasugrel and the intravenous and oral Gp IIb/IIIa antagonists. The various drugs can be classified first by their site of action on the main steps of platelet function from adhesion to activation and aggregation, and secondarily by their specific effects at each step. Adhesion can be inhibited by agents under development which act mainly on von Willebrand factor and its ligand, Gp 1b/IX. Activation can be inhibited by agents acting on intracellular calcium mobilization such as dypiridamole, and by agents inhibiting more specific activation pathways. Aspirin blocks the thromboxane pathway and the thienopyridines block the $P2Y_{12}$ ADP-receptor pathways. Gp IIb/IIIa antagonists occupy the receptor to prevent fibrinogen binding and platelet aggregation.

Aspirin Four clinical trials with differing designs and aspirin dosages have shown statistically significant improvements in major clinical outcomes among patients with non-ST segment elevation ACS. The Veterans Administration Study included 1338 men with unstable angina randomly allocated within 72 hours of admission to ASA 324 mg or placebo.[137] The rate of death or myocardial infarction was reduced from 10.1% to 5.0% (RR 49%, $P = 0.0005$) over a 12-week treatment period. In the Canadian Multicenter Trial, 555 patients (73% men) with unstable angina were randomized before hospital discharge to aspirin (325 mg four times daily), sulfinpyrazone (200 mg four times daily), placebo, or both drugs.[138] Aspirin reduced the outcome of death or myocardial infarction at two years from 17% to 8.6% (RR 49.2%; $P = 0.008$) by efficacy analysis and by 30% ($P = 0.072$) by intention-to-treat analysis, and the outcome of death was reduced by 71% ($P = 0.004$) and 43.4% ($P = 0.035$) respectively. Sulfinpyrazone had no significant effect or interaction with aspirin. In the Montreal study, 479 patients were randomized during the acute phase of disease to aspirin (325 mg bid), heparin, both or neither in a 2 × 2 factorial design.[29] Aspirin reduced the risk of death or myocardial infarction at six days from 6.3% to 2.6%, a 63% risk reduction ($P = 0.04$). The RISC study randomized 945 patients to aspirin (80 mg daily), intravenous heparin, both or placebos.[28] Endpoints were assessed in 796 patients meeting the entry criteria. Aspirin, compared to no aspirin, reduced the rate of death or MI at five days from 5.8% to 2.6% ($P = 0.033$), at seven days from 13.4% to 4.3% ($P = 0.0001$), and at 30 days from 17.1% to 6.5% ($P = 0.0001$). Overviews of these trials[1,7] have shown a reduction of death or MI from 12.5% to 6.4% ($P = 0.0005$) and a NNT of 17.

The most recent meta-analysis by the Antiplatelet Trialists' Collaboration reviewed 287 studies involving 135 000 patients in comparisons of antiplatelet therapy versus control and 77 000 patients in comparisons of different antiplatelet regimens.[139] Antiplatelet therapy reduced the outcome of any serious vascular event by 22%, non-fatal MI by 34%, non-fatal stroke by 25%, and vascular mortality by 15%. Aspirin was the most widely studied antiplatelet drug. The absolute benefit of aspirin increases with the

inherent risk of the condition for which it is prescribed, and is substantial in patients with a non-ST segment elevation ACS.[139]

The mechanism accounting for the benefit of aspirin in ACS is its acetylation of platelet cyclo-oxygenase-1 (COX-1), which is irreversible and saturable at low doses and blocks the formation of thromboxane A2. The APT meta-analysis found the risk reductions did not vary significantly among aspirin doses ranging from 75 to 1500 mg per day, although the benefits appeared to be less for doses under 75 mg per day.[139] The risk of bleeding appears to rise when daily dose exceeds 200 mg.[140] A loading dose of 150–365 mg (non-enteric coated and chewed) is recommended followed by doses of 75–162 mg daily (**Class I, Level A**). Atherosclerotic vascular events have a variety of pathophysiologic origins, only some of which are responsive to aspirin, and yet the term "aspirin resistance" is often used to describe failure of aspirin to prevent vascular events in some patients. A more appropriate descriptive term might be "aspirin treatment failure" with aspirin resistance being considered as a subcategory in which there is a failure of aspirin to inhibit TXA2 production.[141] Aspirin resistance might result from non-compliance, inadequate dose, poor absorption or rapid metabolism (particularly at low doses), steric interference with aspirin's access to the active site of COX-1 by ibuprofen or naproxyn and possibly genetic polymorphisms of the COX-1 gene. Other possibilities include aspirin-insensitive TXA_2 production catalyzed by COX-2 in inflammatory cells and immature platelets or by COX-1 in immature platelets. To define aspirin resistance as a failure to inhibit TXA_2 production, specific and reliable assays such as serum TXB_2 or possibly urinary 11-dehydro-TxB_2 must be employed. Currently the recommendations from expert panels and societies are to avoid testing platelet function in an attempt to assess the clinical antiplatelet effect of aspirin in individual patients[1,7,142] (**Class I, Level C**).

Other agents acting on the cyclo-oxygenase pathway The inhibition of prostacyclin (PGI_2) generation by low-dose aspirin does not appear to limit its protective effects significantly, and a study of the infusion of prostacyclin in unstable angina patients resulted in no benefit.[143] The thromboxane synthase inhibitors and/or receptor antagonists investigated so far were not shown to be superior or inferior to aspirin.

ADP receptor antagonists There are three subtypes of purinergic receptors on platelets: P2Y1 receptors are involved in platelet aggregation, P2Y12 receptors in stabilization of platelet aggregates, and the precise roles of ion-gated P2X1 receptors are still being evaluated. Currently available ADP receptor blockers, classified as thienopyridines and non-thienopyridines, target P2Y12. The thienopyridines

(ticlopidine, clopidogrel, and prasugrel) are all prodrugs whose metabolites inhibit P2Y12 irreversibly. Because of its greater safety and ease of administration, clopidogrel has largely replaced ticlopidine, although the latter is still used in some countries and may be useful in some patients allergic to clopidogrel, although cross-reactions are possible. The prasugrel metabolite is produced more rapidly than that of clopidogrel, resulting in a more rapid and complete receptor inhibition and fewer non-responders.[144]

Newer non-thienopyridines which are direct and reversible inhibitors of the P2Y12 receptor have improved dose–response profiles. Cangrelor is administered intravenously and can fully inhibit P2Y12; its effect is immediate with a half-life of 3–5 minutes, allowing full receptor recovery within 30 minutes after discontinuation of the infusion. The drug is currently being investigated in the CHAMPION PLATFORM and CHAMPION-PCI trials.[145] Ticangrelor (AZD6140) is administered orally. Its onset of action is within two hours with peak effect at approximately two hours; its offset is approximately after 12 hours but significant inhibition is still present after 24 hours. Using a twice-daily dosing regimen, the DISPERSE and DISPERSE-2 clinical studies demonstrated more potent and consistent platelet aggregation inhibition as compared with clopidogrel, with an increase in minor but not in major bleeding.[146,147] The PLATO trial compared the drug to clopidogrel in patients with ACS with continuing admisistration for up to one year; results are expected for early 2009. PRT060128, a non-thienopyridine inhibitor of P2Y12 that can be administered both intravenously and orally, allowing seamless transition from IV to oral administration, is at an early stage of investigation.

Many placebo-controlled trials of ticlopidine in unstable angina and in the secondary prevention of stroke found risk reductions in the same range of those observed in aspirin trials,[148] while a direct comparison among patients with prior stroke found that ticlopidine was superior to aspirin.[149] Clopidogrel 75 mg/day was compared to aspirin 325 mg/day in the CAPRIE trial,[150] which randomized 19 185 patients with atherosclerotic vascular disease manifested as recent ischemic stroke, recent myocardial infarction, or symptomatic peripheral vascular disease. The annual risk of ischemic stroke, myocardial infarction, or vascular death during a follow-up of 1–3 years was reduced by 8.7% from 5.83% to 5.32% by clopidogrel ($P = 0.043$). The risk reductions (RR) were 23.8% ($P = 0.00028$) in patients enrolled because of peripheral vascular disease and 7.3% in patients enrolled because of stroke, but there was a risk increase of 5.03% ($P = 0.66$) in patients enrolled because of a myocardial infarction. In two randomized trials of ticlopidine versus clopidogrel added to aspirin among patients receiving stents, there were no significant differences in major vascular outcomes.[151,152] However, clopidogrel has supplanted ticlopidine, because of its lower incidence of GI

Placebo   6303   5780   4664   3600   2388
Clopidogrel   6259   5866   4779   3644   2418
Figure 29.10 Cumulative hazard rates for the outcome of cardiovascular death, non-fatal myocardial infarction, or stroke during the 12 months of the CURE study with the use of clopidogrel versus placebo on a background of aspirin in all patients. The results demonstrate sustained benefit of clopidogrel from the time of randomization through to the end of the study. (Reproduced with permission from the CURE Investigators.[152])

side effects and freedom of serious hematologic and hepatic toxicity, and once-daily dose regimen.[150]

In the CURE trial,[153] 12562 patients were randomized within 24 hours after the onset of NSTE-ACS to receive clopidogrel (300 mg bolus, 75 mg daily) or placebo in addition to aspirin 160–360 mg daily for 3–12 months. The primary composite outcome of cardiovascular death, non-fatal MI, or stroke occurred in 9.3% of patients in the clopidogrel group and 11.4% in the placebo group (RR 0.80; 95% CI 0.72–0.90; $P < 0.001$) (Fig. 29.10). Clopidogrel also reduced the rates of in-hospital severe ischemia and of revascularization, the need for fibrinolytic therapy or intravenous Gp IIb/IIIa-receptor antagonists, and the occurrence of heart failure. The benefits became apparent within a few hours of beginning treatment and increased throughout the follow-up period to one year. These benefits were homogeneous among all secondary endpoints, subgroup analyses, and patients at low, medium, and high risk, enhancing the clinical relevance of the trial. There were benefits even among patients without ST segment depression and those without elevation of cardiac markers, in contrast to trials of enoxaparin and the GP IIb/IIIa antagonists in which benefits were apparent only among high-risk patients. There were significantly more patients with major bleeding in the clopidogrel group than in the placebo group (3.7% versus 2.7%; RR 1.38; $P = 0.001$), but there was no excess in life-threatening bleeding (2.2% versus 1.8%; $P = 0.13$) or hemorrhagic stroke (0.1% versus 0.1%). The risk of major bleeding was increased in patients undergoing CABG surgery within the

first five days of stopping clopidogrel (9.6% versus 6.3%, RR 1.53; $P = 0.06$) but not when CABG was performed after five days (4.4% versus 5.3%).

The CURE trial focused mainly on medical management, but revascularization was performed during the initial admission in 23% of the patients, among whom 4.5% of clopidogrel patients had cardiovascular death, myocardial infarction, or urgent target vessel revascularization within 30 days of PCI, compared with 6.4% in placebo patients (RR 0.70, 95% CI 0.50–0.97, $P = 0.03$). Long-term administration of clopidogrel after PCI was associated with a lower rate of cardiovascular death, myocardial infarction, or any revascularization ($P = 0.03$), and of cardiovascular death or myocardial infarction ($P = 0.047$).[154] Clopidogrel is generally recommended at a daily dose of 75 mg, preceded by a loading dose of 300 mg in ACS, as in the CURE regimen, but if the angiogram is required urgently, the loading dose is generally increased to 600 mg to achieve faster platelet inhibition; these doses are generally well tolerated.[155]

The CURRENT trial has tested higher doses of clopidogrel and of aspirin in a 2×2 factorial design in NSTE-ACS undergoing PCI; the high dose of clopidogrel is a 600 mg loading dose and 150 mg daily dose for one month; the high dose of aspirin is a 300 mg loading dose and 300–325 mg daily for one month. There are currently no provisions in the various treatment guidelines for the so-called clopidogrel poor or non-responders.

Prasugrel was recently directly compared with clopidogrel in the TRITON TIMI-38 trial.[156] The trial enrolled 13608 patients, 10074 with unstable angina or NSTEMI with ischemic symptoms within the previous 72 hours, a thrombolysis in myocardial infarction (TIMI) risk score ≥3 and ST segment deviation ≥1 mm or elevated cardiac biomarker, and 3534 with STEMI within 12 hours after onset of symptoms if primary PCI was planned or within 14 days after receiving medical treatment. Coronary anatomy had to be known and suitable for PCI before randomization with the exception of planned primary PCI in STEMI or coronary anatomy already known to be suitable for PCI (very rarely encountered) in which case pretreatment with the study drug was permitted for up to 24 hours before PCI. On a background of aspirin, a loading dose of prasugrel 60 mg or clopidogrel 300 mg was administered after randomization and until one hour after leaving the catheterization laboratory followed by maintenance doses of 10 mg and 75 mg daily for 6–15 months (median 14.5 months). Prasugrel significantly reduced the primary endpoint of cardiovascular death, non-fatal myocardial infarction, or non-fatal stroke at three days from 5.6% in the clopidogrel group to 4.7% (HR 0.82; 95% CI 0.71–0.96; $P = 0.01$). From three days to the end of the study, the endpoint was reduced from 6.9% to 5.6% (HR 0.80; 95% CI 0.70–0.93; $P = 0.003$) largely in relation with a reduction in myocardial infarction. The benefits of prasugrel extended to other prespecified endpoints,

without significant interactions with patient characteristics or subgroups, including the entry diagnosis of UA/NSTEMI or NSTEMI and the use of a GPIIb/IIIa antagonists.

Excess bleeding occurred with prasugrel: major non-CABG related bleeding in 2.4% vs 1.32% with clopidogrel (95% CI 1.03–1.68; $P = 0.03$), and life-threatening bleeding from randomization to day 3 (0.4% vs 0.3%; HR 1.38; 95% CI 0.79–2.41; $P = 0.26$) and from day 3 to the end of the study (1.0% vs 0.6%; HR 1.60; 95% CI 1.05–2.44; $P = 0.03$) for a total of 1.4%, vs 0.9% at the end of the study (HR 1.52; 95% CI 1.08–2.13; $P = 0.01$). More patients treated with prasugrel (2.5%, vs 1.4% of patients treated with clopidogrel; $P < 0.001$) discontinued the study drug owing to adverse events related to hemorrhage. The combination of non-CABG related TIMI major or minor hemorrhage occurred also more frequently (HR 1.31; 95% CI 1.11–1.56; $P = 0.002$). Fatal TIMI major bleeding occurred in 0.4% and 0.1% of patients respectively ($P = 0.002$) and intracranial hemorrhage in 19 patients (0.3%) receiving prasugrel and 17 patients (0.3%) receiving clopidogrel ($P = 0.74$). Among the few patients who underwent CABG, the rate of TIMI major bleeding was also in excess with prasugrel (13.4% vs 6 3.2%, HR 4.73; 95% CI 1.90–11.82; $P < 0.001$).

A series of *post hoc* exploratory analyses were conducted to identify the subgroups of patients with no favorable net clinical benefit or with net harm, taking into account death from any cause, non-fatal myocardial infarction, non-fatal stroke and non-CABG related non-fatal TIMI major bleeding. Three such subgroups emerged: 1. patients with previous stroke or transient ischemic attack (n = 518) had net harm from prasugrel (HR 1.54; 95% CI 1.02–2.32; $P = 0.04$); 2. patients ≥75 years of age had no net benefit (HR 0.99; 95% CI 0.81–1.21; $P = 0.92$); and 3. patients weighing <60 kg had no net benefit (HR 1.03; 95% CI 0.69–1.53; $P = 0.89$). Patients with a history of stroke showed a strong trend toward a greater rate of TIMI major bleeding ($P = 0.06$), including intracranial hemorrhage in six patients (2.3%) in the prasugrel group, as compared with none in the clopidogrel group ($P = 0.02$).

Analogous to aspirin's specificity for the TXA_2 pathway, clopidogrel's specificity for the PGY_{12} receptor limits its effectiveness to the the prevention of vascular events which arise from activation of this receptor. Accordingly, the term "clopidogrel resistance" should be reserved for those phenomena which may impede clopidogrel's capacity to reduce the action of the $P2Y_{12}$ pathway.[157] These include inadequate dosing, poor absorption, drug competition for the P450 enzymes, and polymorphisms of these enzymes, the $P2Y_{12}$ receptor or of other platelet receptors. The standard test for clopidogrel resistance has been the assessment of platelet aggregation in platelet-rich plasma or whole blood following activation with ADP, but this test is not specific for clopidogrel. The platelet vasodilator-stimulated phosphoprotein-phosphorylation assay using flow cytometry is the most promising available assay[158] but as for aspirin, it is recommended that no test of platelet function should be performed in the attempt to assess the clinical antiplatelet effect of clopidogrel in individual patients.[1,7,139] Prasugrel might be a preferable alternative therapy for those patients who are truly clopidogrel resistant.

Gp IIb/IIIA-receptor blockers Three Gp IIb/IIIa antagonists are approved for IV use: abciximab, eptifibatide, and tirofiban. Abciximab is a Fab fragment of a chimeric monoclonal antibody that binds the RGD and dodecapeptide recognition sequences of the receptor. The plasma half-life of the drug is approximately 10 minutes but the biologic half life extends to 6–12 hours. Abciximab has strong affinity for the receptor and receptor occupancy persists weeks after drug exposure, although platelet aggregation progressively returns to normal within 12–24 hours. Abciximab is not specific for the Gp IIb/IIIa integrin, also inhibiting the vitronectin receptor ($\alpha v\beta 3$) on the endothelium and smooth muscle cell and the MAC-1 ($\alpha m\beta 2$) integrin on neutrophils and monocytes. The clinical relevance of occupancy of these receptors involved in cell proliferation and leukocyte activation respectively remains ill defined. Eptifibatide is a cyclic heptapeptide derived from the structure of barbourin in the venom of the pigmy rattlesnake, possessing a KGD sequence recognized by the receptor. Tirofiban is a non-peptide mimetic of the RGD sequence. The half-life of the two small molecules is approximately two hours. After drug discontinuation, there is 50% recovery of receptor occupancy and platelet aggregation within four hours and nearly 100% within eight hours. These drugs have no special affinity for the receptor and receptor occupancy parallels blood levels.

Many trials have documented the efficacy of abciximab in reducing periprocedural MI and the need for urgent revascularization when it is administered in the cardiac catheterization laboratory before a revascularization procedure and continued for 12 hours thereafter.[159,160] In the c7E3 Fab Antiplatelet Therapy in Unstable Refractory angina (CAPTURE)[161] trial involving 1265 patients with refractory unstable angina, abciximab was administered after identification at previous angiography of a culprit lesion suitable for coronary angioplasty. The procedures were performed 20–24 hours later and abciximab was continued for one hour after the procedure. Abciximab, compared with placebo, reduced the rate of death and myocardial infarction by 30 days from 15.9% to 11.3% ($P = 0.012$). In a comparison trial, abciximab was shown to be significantly superior to tirofiban in preventing complications associated with urgent or elective stent placement.[162] The doses of tirofiban that were used just before the procedure in this study are now known to have been suboptimal to achieve adequate receptor inhibition.[163] Contrasting with the benefits observed in percutaneous intervention and in stent

implantation trials, the GUSTO-IV trial failed to show a benefit of abciximab in the medical management of patients with a non-ST segment elevation ACS. In this trial, 7800 patients with chest pain and either ST segment depression or raised troponin T or I concentrations were randomly assigned placebo, an abciximab bolus and 24 h infusion, or an abciximab bolus and 48 h infusion.[39] The primary outcome of death or myocardial infarction 30 days after randomization occurred in 8.0% of patients on placebo, 8.2% of patients on 24 h abciximab, and 9.1% of patients on 48 h abciximab (OR 1.0 between placebo and 24 h abciximab, and 1.1 (95% CI 0.94–1.39) for difference between placebo and 48 h abciximab). The lack of benefit with abciximab was consistent in most subgroups investigated including, remarkably, patients with elevated troponin T or I, although they were at a high risk of subsequent events.

Tirofiban was investigated in two ACS trials. In one, tirofiban alone with placebo heparin versus heparin with placebo tirofiban resulted in an early benefit at 72 hours that was not sustained, however, after 30 days.[32] The second trial compared the combination of tirofiban with heparin to heparin alone. The combination reduced the occurrence of the primary endpoint of death, myocardial infarction or refractory ischemia at seven days by 32% (P = 0.004) and of death or myocardial infarction by 43% (P = 0.006).[37] The gain appeared early and was sustained after six months.

Many trials were performed with eptifibatide. In the PURSUIT trial, 9461 patients with a non-ST segment elevation ACS were randomized to eptifibatide or placebo; the rate of death or myocardial infarction after 30 days was reduced by 10% with eptifibatide (14.2% versus 15.7%, P = 0.042).[36] In the placebo-controlled ESPRIT trial, eptifibatide used at higher doses with a double bolus injection significantly reduced the event rate associated with coronary stenting to an extent similar to that observed with abciximab.[164] Altogether, these trials show efficacy of abciximab and eptifibatide in reducing event rates in percutaneous coronary interventions and of tirofiban and eptifibatide in non-ST segment elevation ACS. The benefits were additive to those of aspirin and of heparin.

Several meta-analyses found a benefit of intravenous Gp IIb/IIIa antagonist therapy in patients with an ACS. One meta-analysis published in 1999, before the confounding results of GUSTO-IV appeared, included the data from the CAPTURE, PURSUIT, and PRISM-PLUS trials, and showed event rates of 2.5% with treatment and 3.8% with placebo during the period of medical management and of 4.9% and 8.0% respectively in the 48 hours that followed PCI in the subgroups of patients who underwent a procedure (RR reduction 34%, P < 0.001). An early benefit of Gp IIb/IIIa inhibitors during medical treatment was then documented, and a larger benefit when PCI was performed on drug therapy.[165] A second meta-analysis with individual data on

31 402 patients from six trials not mandating coronary angiography except for the PRISM-PLUS, and that included GUSTO-IV,[33,166] showed reduced odds of death or MI at 30 days of 9% (10.8% versus 11.8%; OR 0.91; 95% CI 0.84–0.98; P = 0.015) with the Gp IIb/IIIa antagonists. The relative treatment benefit matched patients' risk. Benefit was present in both males and females when the baseline troponin levels were elevated but only in males when normal. A third meta-analysis examined more specifically the subset of 6458 diabetic patients enrolled in the six trials. In these patients, the Gp IIb/IIIa inhibitors reduced the mortality at 30 days from 6.2% to 4.6% (OR 0.74; 95% CI 0.59–0.92; P < 0.007) with a statistically significant interaction between treatment and diabetic status (P = 0.036). Mortality at 30 days among the 1279 who underwent PCI was reduced from 4.0% to 1.2% (OR 0.30; 95% CI 0.14–0.69; P < 0.002).[167] A significant risk reduction in 30-day mortality was observed in another meta-analysis that included 20186 patients (0.9 vs 1.3%, OR 0.73, 95% CI 0.55–0.96, P = 0.024).[168]

The overall management of ACS, including the use of antithrombotic therapy, has changed markedly since these early trials and meta-analyses were performed. First, the early invasive approach is undertaken earlier, shortening to a few hours the time between admission and cardiac catheterization and reducing the risk of an early event; second, bare metal or drug-eluting stents are routinely deployed, improving blood flow and reducing shear-induced platelet aggregation and stent thrombosis; third, clopidogrel and new anticoagulants (e.g. enoxaparin, bivaluridin, and fondaparinux) are widely used. As clopidogrel yielded 20% risk reductions over the use of aspirin alone, the need for an agent that blocks the GPIIb/IIa receptors become less critical. Thus a recent randomized placebo-controlled trial in stable patients undergoing PCI and prescribed a loading dose of 600 mg of clopidogrel in addition to aspirin was associated with such a low frequency of early complications that the use of abciximab offered no clinically measurable benefit at 30 days.[169] A second trial that used the same study design and included stable diabetic patients also failed to show a benefit of abciximab.[170] A third trial conducted by the same group of investigators enrolled 2022 ACS patients managed invasively, and all administered aspirin and the same loading dose of clopidogrel at least two hours prior to the procedure.[171] The primary endpoint of death, MI, or urgent target vessel revascularization within 30 days was reached in 90 patients (8.9%) assigned to abciximab vs 120 patients (11.9%) assigned to placebo (RR 0.75; 95% CI 0.58–0.97; P = 0.03). All the benefit occurred among patients with elevated troponin levels (RR 0.71; 95% CI 0.54–0.95; P = 0.02 vs RR 0.99; 95% CI 0.56–1.76 with normal troponin levels). The benefits were maintained at one year as the primary outcome was reached in 23.3% of abciximab patients and 28.0% of placebo patients (RR 0.80; 95% CI 0.67–0.95,

$P = 0.012$), and the incidence of death or MI in 11.6% and 15.3% (RR 0.74, 95% CI 0.59–0.94, $P = 0.015$) respectively.[172] The risk of major and minor bleeding as well as need for transfusion was the same in the abciximab and placebo groups.

Many studies and registry data have, however, showed a significant increase in the risk of bleeding with Gp IIb/IIIa antagonists that not only neutralized the benefits of the drug but could result in harm, particularly among elderly and female patients. In the GRACE registry,[173] mortality rates with LMWH were lower than with UFH, among patients not treated with Gp IIb/IIIa inhibitors, whether they had PCI (OR 0.45; 95% CI 0.21–0.98) or not (OR 0.77; 95% CI 0.63–0.94); there was excess bleeding in LMWH-treated patients who had PCI. Elderly patients (>75 years) who were manged medically with Gp IIb/IIIa antagonists had a very high bleeding risk with both LMWH and UFH. The issue of excess bleeding in women was explored among 32 601 patients in the CRUSADE registry, 18 436 of whom were treated with a Gp IIb/IIIa antagonist. Major bleeding was defined as a hematocrit drop ≥0.12, need for transfusion or intracranial bleeding; it was adjusted for clinical factors and antithrombotic dose. Gp IIb/IIIa inhibitor dose was defined as excessive if not reduced when creatinine clearance was <50 mL/min for eptifibatide or <30 mL/min for tirofiban. Women in general had higher rates of major bleeding than men with a Gp IIb/IIa antagonist (15.7% vs 7.3%; $P < 0.0001$) or without (8.5% vs 5.4%;$P<0.0001$). Women who received Gp IIb/IIIa inhibitors were more likely to receive excessive doses than men (46.4% versus 17.2%, adjusted OR 3.81, $P < 0.0001$). Excess dosing was associated with increased risk of bleeding in women (OR 1.72, 95% CI 1.30–2.28) and in men (OR 1.27, 95% CI 0.97–1.66), but risk attributable to dosing was much higher in women (25.0% versus 4.4%).[174]

Another current issue with Gp IIb/IIIa antagonists is the optimal timing of administration, whether routine upfront at admission or deferred until after coronary angiography and before angioplasty. This issue was examined in the 9207 patients enrolled in the ACUITY-Timing trial[175] and is now being tested in the very large EARLY-ACS trial.[176] In the former, upfront was a mean of 1.3 hours and deferred was a mean of 13.1 hours, showing that PCI was performed very early. Deferred use resulted in less 30-day major bleeding by the ACUITY definition (4.9% vs 6.1%, $P = 0.009$); by the TIMI criteria, rates of major bleeding were not reduced but those of minor bleeding were, and rates of transfusion were less (2.3% vs. 3%, $P = 0.05$). Ischemic events, however, did not meet the criterion for non-inferiority (7.9% vs 7.1%, $P = 0.04$) mainly due to an excess unplanned revascularization (2.8 vs 2.1%, $P = 0.03$). The net clinical outcome at 30 days assessed by the composite of death/MI/unplanned revascularization/major bleeding) was the same (11.7%) in each group.

Oral Gp IIb/IIIa antagonists In an attempt to extend the benefit of intravenous Gp IIb/IIIa antagonists to the sub-acute and chronic phases of the disease, orally active inhibitors were developed. Four different agents – xemilofiban, orbofiban, sibrafiban and latrofiban – were investigated in five large trials. No single trial showed a benefit in reducing ischemic events and two were prematurely interrupted because of excess mortality. A meta-analysis of four of these trials totaling 33 326 patients showed a statistically significant increase in mortality with therapy (OR 1.37; $P = 0.001$) and trends to more MI. There was a twofold increase in the rate of major bleeding and a high rate of less severe bleeding leading to study drug discontinuation.[177] The trials have provided a lesson on the validity of evidence-based medicine, as they ended by trying to find why they were toxic. Contrasting with the IV agents used as infusion, the oral agents have rapid on and off binding to the receptor with the potential of reactivation of the disease at trough levels; they further bind the inactivated receptors, resulting in outside-to-inside signaling and paradoxic platelet activation.

PAR antagonists A new class of antiplatelet agents is emerging targeting the platelet protease-activated receptor (PAR-1). Thrombin is the most potent platelet agonist *in vivo*. Its effects on platelets (as well as on endothelial cells and leukocytes) are uniquely blocked by these agents, without affecting its conversion of fibrinogen to fibrin and fibrin clot formation, creating the potential for greater efficacy and less bleeding. PAR antagonists are now in clinical investigation, some in advanced Phase III trials.

Anticoagulants

Anticoagulants evaluated during the acute phase of non-ST segment elevation ACS include unfractionated heparin (UFH), low-molecular weight heparins (LMWH), direct thrombin inhibitors and the pentasaccharide fondaparinux. New and promising agents such as r-tissue factor pathway inhibitor, r-protein C, and other specific inhibitors of factor Xa are under investigation (Fig. 29.11). Documentation of reactivation of the disease following the discontinuation of heparin[178,179] and persisting prothrombotic activity past the acute phase have led to the evaluation of long-term therapy with coumadin and the LMWHs.

Unfractionated and low molecular weight heparins Unfractionated heparin, low molecular weight heparins, and the pentasaccharides inhibit coagulation factors by greatly enhancing the physiologic properties of circulating antithrombin, with differential effects on factor Xa and thrombin related to the molecular weight of the various heparins (Fig. 29.12).[180] In the study by Theroux *et al* of 479 patients, the incidence of fatal and non-fatal myocardial infarction was reduced from 7.5% to 1.2% (RR 85%; $P = 0.007$) with

Figure 29.11 The coagulation cascade and sites of action of new anticoagulants. Initiation of coagulation is triggered by the tissue factor/factor VIIa complex (TF/VIIa), which activates factor IX (IX) and factor X (X). Activated factor IX (IXa) propagates coagulation by activating factor X in a reaction that utilizes activated factor VIII (VIIIa) as a co-factor. Activated factor X (Xa), with activated factor V (Va) as a co-factor, converts prothrombin (II) to thrombin (IIa). Thrombin then converts fibrinogen to fibrin. Active site-blocked VIIa (VIIai) competes with VIIa for TF, whereas tissue factor pathway inhibitor (TFPI) and nematode anticoagulant peptide (NAPc2) target VIIa bound to TF. Synthetic pentasaccharide and DX-9065a inactivate Xa, activated protein C (APC) inactivates Va and VIIIa, and hirudin, bivalirudin, argatroban, and ximelagatran target thrombin. (Reproduced with permission from Weitz and Buller.[179])

unfractionated heparin compared with placebo, and of recurrent refractory ischemia from 19.7% to 9.6% (RR 51%; $P = 0.02$).[30] In the RISC study, which enrolled 945 men, the combination of aspirin and heparin resulted in a significant risk reduction in death and myocardial infarction at five days.[29] In the FRISC study, 1506 patients were randomized to subcutaneous dalteparin twice daily for six days followed by once a day for 35–45 days or placebo.[181] During the first six days the rate of death or MI was reduced with dalteparin (1.8% versus 4.8%; RR 0.37; 95% CI 0.20–0.68). Survival analysis showed a risk of reactivation and reinfarction when the dose was decreased; the benefit persisted at 40 days but not at 4–5 months.[151] A meta-analysis of 12 trials that compared unfractionated heparin or a low molecular weight heparin to placebo in a total of 17157 patients showed an odds ratio for myocardial infarction or death during the short term (up to seven days) of 0.53 (95% CI 0.38–0.73; $P = 0.0001$) in favor of the anticoagulant.[182] These results validate the use of unfractionated heparin or of a LMWH in combination with aspirin in patients with a non-ST segment elevation ACS.

Low molecular weight heparins present distinct advantages over unfractionated heparin. They can be administered subcutaneously once or twice a day. They bind
Figure 29.12 Antithrombin (AT)-mediated inhibition of coagulation factors. The complex heparin/AT inhibits especially factor Xa and thrombin (IIa) and also factor XIIa, factor XIa, and factor IXa. The shorter saccharide chains contained in the low molecular weight heparins (LMWH) allow more selective inhibition of factor Xa than factor IIa. The unique pentasaccharide chain of fondaparinux allows highly specific inhibition of factor Xa. (Adapted with permission from Hirsh *et al.*[180])

plasma proteins and endothelial cells less avidly than unfractionated heparin, resulting in more predictable anticoagulation, with no need for monitoring. The ratio of inhibition factor Xa/thrombin is greater. Low molecular weight heparins also stimulate platelets less and are less often associated with heparin-induced thrombocytopenia.

Four trials have directly compared a LMWH with unfractionated heparin. No advantages were observed with dalteparin in a trial involving 1482 patients[183] and with nadroparin in a trial of 3468 patients.[184] Enoxaparin was shown to be superior to unfractionated heparin in the two trials that evaluated the drug. In the ESSENCE trial, enoxaparin, 1 mg/kg administered twice daily for 48 hours to eight days (median 2.6 days) in 3171 patients, reduced the composite outcome of death, MI or recurrent angina by 16.2% at 14 days (16.6% versus 19.8%; $P = 0.019$), and by 19% at 30 days (19.8% versus 23.3%; $P = 0.017$) compared to unfractionated heparin. The rate of death was unaffected, but the rate of myocardial infarction was reduced by 29% (3.2% versus 4.5%; $P = 0.06$) at 14 days, and by 26% (3.9% versus 5.2%) at 30 days ($P = 0.08$).[31] The TIMI-11B trial showed in 3910 patients a reduction in the composite outcome of death, myocardial infarction or refractory ischemia requiring an urgent revascularization from 16.6% to 14.2% at 14 days ($P = 0.04$) and from 19.6% to 17.3% at 43 days ($P = 0.06$).[38] A meta-analysis of trials that directly compared any LMWH to unfractionated heparin showed no statistically significant difference in the odds of death or MI (OR 0.88; 95% CI 0.69–1.12; $P = 0.34$). On the other hand, a combined analysis of the data from ESSENCE and TIMI-11B showed a statistically significant reduction in the rate of death or myocardial infarction in favor of enoxaparin.[185]

Fondaparinux A synthetic pentasaccharide which selectively binds antithrombin III, causing rapid and predictable inhibition of factor Xa. OASIS-5[186] randomized 20 078 patients with NSTE-ACS to fondaparinux (2.5 mg SC, once

daily) or enoxaparin (1 mg/kg SC, twice daily) within 24 h of onset of symptoms. Fondaparinux was not inferior to enoxaparin in terms of the primary outcome (death, MI, or refractory ischemia at nine days) (5.8% vs 5.7%; HR 1.01; 95% CI 0.90–1.13) with a markedly lower rate of major bleeding at nine days (2.2% versus 4.1%; HR 0.52; $P < 0.001$). Fondaparinux was associated with significantly fewer deaths at 30 days (2.9% versus 3.5%; HR 0.83; 95% CI 0.71–0.97; $P = 0.02$) and at 180 days (5.8% versus 6.5%; HR 0.89; 95% CI 0.80–1.00; $P = 0.05$). A concern in the management of patients undergoing PCI is that of catheter thrombosis with fondaparinux, necessitating supplementary UFH administration during the procedure. The drug is now approved for the prevention of deep vein thrombosis in a variety of clinical settings, pulmonary embolus, and in Europe for patients with ACS not expected to undergo early PCI.

Direct thrombin inhibitors These drugs are potent anticoagulants that directly inhibit thrombin, require no co-factor for their effects (see Fig. 29.11) and have a highly predictable response. Hirudin, now produced by recombinant technology, and bivalirudin, a synthetic agent, are bivalent, binding to both the active site and the fibrinogen-binding exosite of thrombin, whereas the low-molecular weight thrombin inhibitors argatroban, efegatran and inogatran bind only to the active site.[179]

Hirudin in a dose of 0.2 mg/kg bolus with infusion of 0.1 mg/kg/h was used in the GUSTO-IIb, which enrolled 12 142 patients, two-thirds of them with a non-ST segment elevation ACS and one-third with ST segment elevation MI,[30] and in the TIMI-9B trial, which enrolled 3002 patients with ST segment elevation MI.[187] Among patients with no ST segment elevation in GUSTO-IIb, the composite endpoint of death or MI at 30 days occurred in 8.3% of the patients on hirudin and in 9.1% of patients on heparin (OR 0.90; 95% CI 0.78–1.06; $P = 0.22$); at 24 h, the risk of death or MI was significantly lower in the patients who received hirudin (2.1% versus 1.3%; $P = 0.001$). The OASIS pilot study suggested a greater benefit with an intermediate dose of 0.4 mg/kg bolus and 0.15 mg/kg/h infusion.[188] This dose was used in the large OASIS-2 trial, which randomized 10 141 patients with NSTE-ACS to UFH (5000 IU bolus plus 15 U/kg/h) or recombinant hirudin for 72 h.[37] The primary endpoint of cardiovascular death or new MI at seven days was reduced with hirudin from 4.2% to 3.6% ($P = 0.064$); there was an excess of major bleeds requiring transfusions (1.2% versus 0.7%; $P = 0.014$). A meta-analysis of the GUSTO-IIb, TIMI-9B, OASIS pilot and OASIS-2 showed that the risk of death or MI at 35 days was significantly reduced with hirudin compared with heparin (RR 0.90; $P = 0.015$).[41]

A meta-analysis of 35 970 patients in 11 trials of hirudin, bivalirudin, and low-molecular weight antithrombins in

ACS and PCI showed an overall reduction in the risk of death or MI at the end of the treatment period with the direct antithrombins (4.3% versus 5.1%; OR 0.85; 95% CI 0.77–0.94; $P = 0.001$) and after 30 days (7.4% versus 8.2%; OR 0.91; 95% CI 0.84–0.99; $P = 0.02$).[189] The benefit was restricted to hirudin and bivalirudin; hirudin increased the risk of major bleeding compared with heparin but bivalirudin reduced it.[189] No further studies were performed with hirudin because of this excess bleeding. Bivalirudin, a less potent and reversible antithrombin, was further evaluated in the context of PCI, in the ACUITY trial. There were 13 819 patients with moderate- or high-risk NSTE-ACS randomized to UFH or enoxaparin plus a Gp IIb/IIIa inhibitor, bivalirudin plus a Gp IIb/IIIa inhibitor, or bivalirudin alone.[190] The composite efficacy endpoint (death, MI or unplanned revascularization for ischemia) occurred in 7.8% of bivalirudin patients and 7.3% of heparin plus abciximab patients (RR 1.08; 95% CI 0.93–1.24; $P = 0.32$) with rates of bleeding of 3.0% and 5.7% respectively (RR 0.53; 95% CI 0.43–0.65; $P < 0.001$). This reduced rate of bleeding resulted in a significant net clinical benefit of bivalirudin. Previous trials with bivalirudin had used a similar non-inferiority design comparing the drug alone to the combination in stable patients undergoing PCI[191] and in ST segment elevation MI patients undergoing primary PCI.[192] These also generally showed non-significant trends to more ischemic events and a significant reduction in bleeding with bivaluridin alone, resulting in a significant net clinical benefit when combining the efficacy and safety endpoints. Hirudin, bivalirudin, and argatroban are approved for use in patients with heparin-induced thrombocytopenia. Hirudin is also approved for the prevention of deep vein thrombosis in patients undergoing orthopedic surgery, and bivalirudin for use in the cath lab during PCI in stable patients. The FDA expressed concerns, however, with the results of the ACUITY trial in patients with NSTE-ACS and those of the HORIZON trial in STEMI, and did not approve bivalirudin for these indications.

Long-term anticoagulation Prolonged administration of LMWH and of warfarin has been evaluated to prolong the benefit of anticoagulants past the acute phase and prevent reactivation of the disease. In the ATACS trial, 214 patients were randomized to ASA alone or the combination of ASA plus UFH followed by warfarin. At 14 days, there was a reduction in the composite outcome of death, MI, and recurrent ischemia with the combination therapy (27.0% versus 10.5%; $P = 0.004$). In a small randomized pilot study of 57 patients allocated to warfarin or placebo in addition to ASA, there was less progression and more regression in the severity of the culprit lesion after a few weeks of treatment with warfarin. The OASIS pilot study[188] compared a fixed dosage of 3 mg of warfarin with a moderate dose titrated to an international normalized ratio (INR) of 2 to 2.5 administered for seven months. Low-intensity warfarin had no benefit, whereas the moderate-intensity regimen reduced the risk of death, MI or refractory angina by 58% and the need for rehospitalization for unstable angina by 58%. These results were not reproduced in the larger OASIS-2 trial[37] which randomized 3712 patients to the moderate-intensity regimen. The rate of cardiovascular death, MI or stroke after five months was 7.65% with the anticoagulant and 8.4% without ($P = 0.37$). The authors suggested that poor compliance with treatment in some countries could have explained the negative results. A meta-analysis of 30 randomized studies published between 1960 and July 1999 among patients with CAD showed that high-intensity and moderate-intensity anticoagulation were effective in reducing MI and stroke but increased the risk of bleeding. In the presence of aspirin, low-intensity anticoagulation was not superior to aspirin alone, while moderate- to high-intensity anticoagulation and aspirin versus aspirin alone appeared promising with a modest increase in bleeding risk.[193]

In FRISC-II, dalteparin was administrated double-blind for three months following five days of open-label administration. A significant reduction in rates of death, MI, and revascularization was observed after 30 days (3.1% versus 5.9%; RR 0.53; $P = 0.02$) and three months (29.1% versus 33.4%; $P = 0.03$), which was not sustained at six months.[183] A meta-analysis of prolonged use of LMWH for up to tjree months after hospital discharge showed no consistent benefit (OR 0.98; 95% CI 0.81–1.17; $P = 0.80$) but an excess risk of major bleeding (OR 2.26; 95% CI 1.63–3.14; $P < 0.0001$).[182]

Most modern trials that have compared a novel anticoagulant to UFH have used the former for the duration of hospitalization but the latter for only about 48 hours. In these trials, the novel anticoagulant benefit generally appeared after 24–72 h, suggesting that the longer duration of therapy could account for the benefit. A Phase II pilot study of ximelagatran, an orally active direct thrombin inhibitor, suggested a benefit of prolonged therapy with the drug initiated after an acute myocardial infarction[194] but the subsequent development was discontinued because of liver toxicity. A similar study is now being conducted with dagibatran, an orally active direct thrombin inhibitor with a better safety profile.

Summary of treatment recommendations for antiplatelet and anticoagulant drugs

The ACC/AHA recommends that all patients should receive aspirin (150–325 mg load, 75–162 mg maintenance) (**Class I, Level A**) and an anticoagulant (**Class I, Level A**), as soon as the diagnosis of NSTE-ACS appears likely or definite.

With invasive management, acceptable anticoagulant options include UFH or enoxaparin (**Class I, Level A**) or

fondaparinux or bivalrudin (**Class I, Level B**). In addition, either clopidogrel (600 mg load, 75 mg maintenance) or a IIb/IIIa inhibitor should be started as soon as possible and before angiography (**Class I, Level A**), and both may be indicated if there is a delay to angiography, there are high risk features present or chest discomfort recurs (**Class IIa, Level B**). Generally eptifibatide or tirofiban is the preferred IIb/IIIa inhibitor, although abciximab is a reasonable choice if there is no appreciable delay to angiography and PCI is likely (**Class IIa, Level B**). If significant coronary artery disease is found on angiography, aspirin should be continued indefinitely in all patients (**Class I, Level A**). Clopidogrel should be continued for at least one month (**Class I, Level A**), and ideally for up to one year (**Class I, Level B**); prolonged use is more important if a DES is implanted. UFH may be discontinued within 48 h of cessation of chest discomfort (**Class I, Level A**), enoxaparin and fondaparinux should be maintained for the duration of the hospital stay (up to eight days) (**Class I, Level A**). UFH and LMWH may be discontinued shortly following uncomplicated PCI, bivalirudin may be either stopped or continued at reduced doses for 72 h and tirofiban and eptifibatide may be continued for 12–24 h (**Class I, Level B**). If the patient is to have CABG, antithrombotic agents should ideally be discontinued at the following times prior to surgery: clopidogrel 5–7 days, a IIb/IIIa inhibitor 4 h, enoxaparin 12–24 h, fondaparinux 24 h and bivalrudin 3 h (**Class I, Level B for all**).

With conservative, management, acceptable anticoagulant options include UFH, enoxaparin or fondaparinux (**Class I, Level A**), although enoxaparin or fondaparinux are preferred (**Class I, Level B**) and clopidogrel (load and maintenance) should be started (**Class I, Level A**). Eptifibatide or tirofiban may be added if there are high-risk features or chest discomfort recurs (**Class IIa, Level B**). Aspirin should be continued indefinitely in all patients (**Class I, Level A**). Clopidogrel should be continued for at least one month (**Class I, Level A**), and ideally for up to one year (**Class I, Level B**). Enoxaparin and fondaparinux should be maintained for the duration of the hospital stay (up to eight days) (**Class I, Level A**), while if UFH was used, it should be discontinued within 48 h of cessation of chest discomfort (**Class I, Level A**). If a IIb/IIIa inhibitor was used it should be discontinued within 12 h of the cessation of chest discomfort (**Class I, Level B**).

The ESC recommends, in all patients without contraindications, immediate aspirin (160–325 mg load, 75–100 mg maintenance), clopidogrel (300 mg load, 75 mg maintenance) and anticoagulation.

With invasive management, UFH (**Class I, Level C**), enoxaparin (**Class IIa, Level B**) or bivalrudin (**Class I, Level B**) should be started immediately. The loading dose of clopidogrel should be 600 mg (**Class I, level A**). Whichever anticoagulant is chosen, it should be maintained during the PCI. If fondaparinux has been chosen, additional standard doses of UFH (50–100 IU/kg bolus) are required during PCI (**Class IIa, Level C**). In high-risk patients not pretreated with a GP IIb/IIIa inhibitor, abciximab is recommended immediately following angiography (**Class I, Level A**), whereas if tirofiban or eptifibatide was begun prior to angiography, it should be maintained during and after PCI (**Class IIa, Level B**). Anticoagulation can be stopped within 24 h after an invasive procedure (**Class IIa, Level C**). Aspirin should be continued indefinitely (**Class I, Level A**), and clopidogrel for 12 months unless there is an excessive risk of bleeding (**Class I, Level A**).

With conservative management, or prior to a decision about invasive manangement, fondaparinux is recommended (**Class I, Level A**). In patients at intermediate to high risk, particularly those with elevated troponins, ST depression or diabetes, either eptifibatide or tirofiban is recommended in addition to oral antiplatelet agents and anticoagulant (**Class IIa, Level A**). Fondaparinux, enoxaparin or other LMWH may be maintained up to hospital discharge. Aspirin should be continued indefinitely (**Class I, Level A**), and clopidogrel for 12 months unless there is an excessive risk of bleeding (**Class I, Level A**).

Coronary reperfusion procedures

There is a strong rationale for early reperfusion in patients with NSTE-ACS, given the thrombotic pathophysiology, although fibrinolytic therapy is harmful.[135,195] A number of randomized trials have been conducted in the context of 15 years of increasing procedural experience, technologic improvements in revascularization procedures and the development of new antiplatelet and anticoagulant regimens. Two general approaches have emerged from reviews of these studies.

• Routine early *invasive management* whereby patients receive optimal medical therapy with the addition of either (a) urgent angiography/revascularization (as quickly as possible after hospital presentation) for clinically unstable presentations or (b) early angiography/revascularizataion (within a few hours) as part of a standard approach to managment of NSTE-ACS.

• Routine early *conservative management* ("selective invasive therapy"), whereby patients receive optimal medical therapy, with angiography/revascularization reserved for those who cannot be medically stabilized or in whom objective evidence of significant ischemia is provoked in the subacute phase.

TIMI-3B randomized 1473 patients with NSTE-ACS to early invasive versus early conservative therapy. The primary outcome of death, MI or an unsatisfactory symptom-limited exercise stress test performed at six weeks occurred in 16.2% of patients assigned to the early invasive strategy versus 18.1% of patients assigned to the early

conservative strategy (NS). The average length of initial hospitalization, the incidence of rehospitalization within six weeks, and days of rehospitalization were all decreased in the early invasive group.[195] VANQWISH randomized 920 patients with NSTEMI on the basis of CK-MB elevation within 72 hours of admission. More patients in the early invasive group experienced inhospital death (21 versus 6; $P = 0.007$) or a composite of death or MI (36 versus 15; $P = 0.004$); statistically significant differences persisted at one year and a trend towards higher mortality was still observed at two years.[196] The clinical applicability of the results was questioned on the basis of the high mortality associated with CABG; no mortality was seen with PCI.

More recently, the FRISC-II study enrolled 2457 patients with chest pain within the previous 48 hours plus either (a) ST or T-wave changes or (b) elevated troponin T or CK-MB.[40] All patients received dalteparin in addition to aspirin in the first five days and were thereafter randomized to placebo or continued dalteparin administration for three months. Coronary angiography was done within the first seven days in 96% of patients in the invasive arm and in 10% in the non-invasive arm, and revascularization was performed within the first 10 days in 71% and 9% of patients respectively. After six months there was a decrease in the composite endpoint of death or MI in the invasive group (9.4% versus 12.1%; RR 0.78; 95% CI 0.62–0.98; $P < 0.031$). At one year the mortality rate in the invasive strategy group was 2.2% compared with 3.9% in the non-invasive strategy group ($P = 0.016$).[197] The frequencies of symptomatic angina and readmission were halved by the invasive strategy. It was concluded that patients who first received an average of six days of treatment with LMWH, ASA, nitrates, and beta-blockers have a better outcome at six months.

TACTICS-TIMI 18 enrolled 2220 patients with NSTE-ACS characterized by ST-T changes suggestive of ischemia, elevated levels of cardiac markers, or a history of coronary artery disease.[198] All patients received aspirin, heparin, and tirofiban. Patients were randomized to invasive therapy (routine coronary angiography at a median of 22 h and revascularization as appropriate) or ongoing medical therapy. The primary outcome of death, non-fatal MI or rehospitalization for an acute coronary syndrome at six months was 15.9% with use of the early invasive strategy and 19.4% with use of the conservative strategy (OR 0.78; 95% CI 0.62–0.97; $P = 0.025$). The rate of death or non-fatal MI at six months was similarly reduced (7.3% versus 9.5%; OR 0.74; 95% CI 0.54–1.00; < 0.05).

RITA 3[199] enrolled 1810 patients with NSTE-ACS who were all managed with optimal medical therapy and randomized to angiography (median two days), followed by PCI or CABG as appropriate, or to ongoing medical therapy. Of the PCI patients, 88% received a stent and 25% a GP IIb/IIIa inhibitor. The relative risk of death or non-

fatal MI at one year in the invasive group was 0.91 ($P = 0.58$), while that of death, non-fatal MI or refractory angina was 0.66 ($P = 0.001$). A meta-analysis of these five large trials and two smaller trials found that the incidence of death or non-fatal MI in the invasive group was 12.2% versus 14.4% in the conservative group (OR 0.82, 95% CI 0.72–0.93, $P < 0.001$).[200]

ISAR-COOL[201] was designed to determine whether prolonged antithrombotic pretreatment might improve the outcomes of patients undergoing routine invasive management. There were 410 patients enrolled with symptoms of unstable angina plus either ST segment depression or elevation of cardiac troponin T. All patients received UFH, aspirin, clopidogrel and tirofiban and were randomized to early (<6 h) or delayed (3–5 days) angiography/revascularization. The principal outcome of death or non-fatal MI by 30 days occurred in 5.9% of the early invasive group versus 11.6% of the delayed invasive group (RR 0.51, $P = 0.04$). The most recent such large study, ICTUS,[202] enrolled 1200 patients with accelerated angina or angina at rest accompanied by an elevated troponin plus either ischemic ECG changes or a history of coronary artery disease. They all received aspirin, enoxaparin, clopidogrel and a statin and were randomized to invasive therapy (addition of abciximab, routine angiography at a median of 23 h, with 88% of PCI patients receiving a stent) or to a selective invasive strategy with angiography/revascularization reserved for those with refractory angina, instability or significant ischemia on predischarge exercise testing. The composite outcome of death, non-fatal MI or rehospitalization within one year occurred in 22.7% of the early invasive group versus 21.2% of the selective invasive group (RR 1.07, $P = 0.33$). Mortality was no different, whereas in the early invasive group MI was more frequent and rehospitalization less frequent.

A meta-analysis of trials performed in the current era of the use of stents and GP IIb/IIIa agents found that two-year mortality was 4.9% in the early invasive group versus 6.5% in the conservative therapy group (RR 0.75, 95% CI 0.63–0.90, $P = 0.001$).[203] A Cochrane systematic overview[204] confirmed earlier findings of trends toward increased hospital mortality and non-fatal MI in the early invasive group, but statistically significant reductions at all subsequent follow-up intervals out to 2–5 years. This overview also confirmed earlier evidence for the independent contributions to risk and the likelihood of observing a benefit of early invasive therapy among patients with ST segment depression or troponin elevation, or both. However, the authors stressed the importance of making an assessment of global risk (PURSUIT, TIMI, GRACE risk scores).

A more recent collaborative meta-analysis[205] of eight trials involving 7075 men and 3075 women found one-year composite outcome of death, MI or rehospitalization with ACS was 21.1% in the invasive group versus 25.9% in the conser-

vative group (OR 0.78; 95% CI 0.61–0.98) (Fig. 29.13). The OR was significant in men (OR 0.73, 95% CI 0.55–0.98) but not in women (OR 0.81, 95% CI 0.65–1.01). Among biomarker-positive women, the OR was 0.67 (95% CI 0.50–0.88) but among biomarker-negative women the OR was 0.94 (95% CI 0.61–1.44). Among biomarker-positive men, the OR was 0.56 (95% CI 0.46–0.67) while among biomarker-negative men the OR was 0.72 (95% CI 0.51–1.01). As in previous meta-analyses, the rates of death or non-fatal MI were higher in the invasive group during the index hospitalization, but by one year they were significantly less in this group.

An early invasive strategy is recommended for patients with refractory angina or hemodynamic or electrical instability (**Class I, Level B**) and for those who have a relatively high risk of clinical events as predicted by a positive biomarker assay, ST segment changes or a high risk score according to the TIMI scale or equivalents (**Class I, Level A**). This recommendation is equally applicable to men and women. A conservative strategy is recommended for women who are stabilized and remain biomarker negative (**Class IIa, Level A**). Either early invasive or conservative therapy is a reasonable option for men who are stabilized and remain biomarker negative (**Class IIa, Level A**).

Cell protection

Cell necrosis remains a significant problem in patients with UA/NSTEMI as close to 50% of patients have some degree of necrosis at admission and 5–15% develop a new MI within a few weeks. Reperfusion procedures are also frequently associated with MI which impacts on prognosis; there is a correlation between subsequent mortality and elevation of blood markers of necrosis, particularly CK-MB, even within the range of only one and three times normal.[206] Measures that could prevent or limit the progression of myocardial cell ischemia to necrosis might optimize the benefit to be derived from other treatment strategies. These protective measures have been investigated mainly in evolving STEMI. Although often effective in animal models, none of these interventions was sufficiently convincing in human studies to be incorporated in routine management, including Na^+/H^+ exchanger inhibition to prevent accumulation of calcium within the ischemic cell,[207] antibodies against leukocyte integrins and against the cytokine tissue necrosis factor alpha (TNF-alpha)[208] and pexelizumab, a monoclonal antibody against C5 blocking formation of the terminal complement and excessive inflammatory reactions.[209] So far, adenosine has been the only agent that could reduce infarct size in subgroups of patients with an anterior myocardial infarction successfully reperfused and lead to a non-statistically significant reduction in the endpoint of death or new heart failure.[210]

Although beta-blockers were shown in a meta-analysis to be of moderate benefit to prevent myocardial infarction in patients with threatened myocardial infarction,[121] many large randomized clinical trials have documented their efficacy in reducing death following MI and guidelines have advised their use, a recent randomized trial of IV followed by oral metoprolol among patients with acute MI showed no reduction of in-hospital mortality and recommended that beta-blockers be reserved for those patients not at risk of heart failure or cardiogenic shock.[211]

Plaque passivation

Control of inflammatory processes associated with plaque degradation and resulting in plaque rupture and thrombus formation could be an effective management strategy for ACS, but since there are no means to easily and reliably identify vulnerable plaques, administration of such a therapy prior to the clinical manifestations of ACS is not practicable. On the other hand, secondary preventive measures initiated during the acute phase and continued at hospital discharge are effective and practical. PCI, including stenting, is very effective acutely, possibly by interrupting some of the processes implicated in the disease. A 48-hour course of methylprednisone in a small pilot study in patients with unstable angina was ineffective to prevent ischemic events and even accelerated their manifestations.[212]

Statins and ACE inhibitors can promote plaque stabilization by so-called pleiotropic effects that include anti-inflammatory, antioxidant, anti-cell proliferative and anticoagulant properties.[213] Many trials and registries have shown that statins started early after an ACS, even at admission, are well tolerated, effective in reducing LDL cholesterol, and possibly protective against ischemic events associated with interventions. In pooled observational data of 20 809 ACS patients enrolled in clinical trials, the presence of lipid-lowering therapy at hospital discharge was associated with a 56% reduction in risk of mortality at one month ($P = 0.001$).[214] A Swedish registry of 5528 AMI survivors reported a one-year mortality of 9.3% in the 14 071 patients who had no statin at hospital discharge and 4.0% in the 5528 patients with a statin.[215] The MIRACL study[216] randomized 3086 patients with no interventions anticipated within 24–96 hours of hospitalization to high-dose atorvastatin or placebo. At 16 weeks, the primary outcome of death, non-fatal MI, resuscitated cardiac arrest or worsening angina requiring urgent revascularization was 14.8% in treated patients and 17.4% in placebo patients (RR 0.84; $P = 0.048$). More recently, the PROVE-It trial[217] randomized 4162 patients within 10 days of an ACS to pravastatin 40 mg daily or atorvastatin 80 mg daily to determine if the then standard therapy to lower LDL-C to the recommended goal of 100 mg/dL was as effective in preventing further coronary events as more aggressive therapy that lowered LDL-C to 70 mg/dL. The rate of the primary endpoint

Figure 29.13 Death, MI or rehospitalization with ACS in trials of invasive vs conservative strategy in NSTE-ACS. ACS, acute coronary syndromes; CI, confidence interval; MI, myocardial infarction; NSTE, non-ST segment elevatlion. Size of data markers is wieghted based on the inverse variance. (Reproduced with permission from O'Donaghue et al[205].)

(death from any cause, MI, documented UA requiring hospitalization, PTCA or coronary bypass surgery, or stroke) was reduced by 16% after a mean follow-up of 24 months from 26.3% in the pravastatin group to 22.4% in the atorvastatin group ($P = 0.005$). Early initiation of statin therapy also increases the likelihood that patients will continue to comply with statin therapy and results in a greater percentage of patients using a statin after one year.[218]

Subacute therapy

The subacute and longer term management of patients who undergo urgent, early or selective angiography/revascularization is generally similar to, although more aggressive than, that of patients undergoing PCI or CABG for stable angina (see Chapters 26–28). Nitroglycerin can be discontinued rapidly in patients successfully managed with an invasive strategy and in those whose acute ischemia resolves quickly and who remain stable with no recurrence of ischemic pain for about 24–48 hours. Beta-blockers should be continued indefinitely. If a rate-limiting calcium antagonist was chosen because of contraindications to a beta-blocker, although there is no rigorous evidence for long-term benefit in terms of major cardiovascular outcomes, it is reasonable to continue it. If large doses of beta-blocker or calcium antagonists, or combined therapy, were required for control of the ischemic episodes, judicious decrements of intensity are likely to be appropriate once the patient is fully mobilized. Those patients found to be at relatively low risk, based upon a variety of prognostic factors and non-invasive testing, may be promptly discharged on medical therapy with careful long-term follow-up (**Class I, Level A**).

Whether or not the patient undergoes revascularization, aspirin should be continued indefinitely, based upon the evidence from the initial trials of aspirin for unstable angina[137,138] demonstrating ongoing benefit for up to two years, consistent with evidence in survivors of MI and patients with stable angina[139] (**Class I, Level A**). Clopidogrel should be started on admission, and continued for at least 9–12 months, in conjunction with aspirin whether the patient has been treated medically or invasively (**Class I, Level A**). The one-year duration of administration is particularly important in patients who have received a DES and likely in diabetics as well[219] (**Class I, Level B**). For those patients intolerant of aspirin, clopidogrel alone is indicated (**Class I, Level A**). Among patients receiving medical therapy only, fondaparinux, LMWH or UFH is indicated (**Class I, Level A**) and should be sustained for at least 48 hours following the resolution of acute ischemic episodes and preferably until hospital discaharge[149] (**Class I, Level B**). In patients being managed non-invasively, fondaparinux and LMWHs appear to be at least as efficacious as UFH, and may be preferable in terms of ease of use, less bleeding and cost–benefit considerations (**Class IIa, Level B**). Fondaparinux causes less bleeding than LMWH (**Level A**). Intravenous Gp IIb/IIIa receptor antagonists should be added only in the early hospital phase in particularly unstable patients, with eptifibatide or tirofiban being the preferred agents (**Class IIb, Level B**) and should be discontinued within 48 hours of resolution of acute ischemic episodes.

The long-term use of an ACE inhibitor is likely to be beneficial in all patients who have experienced NSTE-ACS[220] (**Class I, Level A**). An angiotensin receptor blocker should be substituted for patients with ACE-I intolerance (**Class I, Level A**). A statin should be commenced early in hospital, regardless of the LDL-C, and should be continued indefinitely with a target LDL-C <2.0 (**Class I, Level A**). Early attention to optimal management of coronary risk factors (**Class I**) blood pressure (**Level A**), smoking (**Level B**), diabetes (Level B), weight (Level B), and exercise (**Level B**) is mandatory for all patients with NSTE-ACS, including those who have undergone revascularization, with the expectation of limiting progression of disease in non-revascularized vessels and in areas of percutaneous intervention and bypass conduits. The HPS study showed benefit independently of initial cholesterol levels.[221] Recent evidence indicates that tight control of glucose in patients with type 2 diabetes may reduce the risk of death following MI and among patients with newly detected type 2 diabetes.[222–224]

The recurrence of an unstable phase of coronary artery disease or poor symptomatic control in patients being managed on medical therapy generally mandates reconsideration of the option of angiography/revascularization (**Class I, Level B**) or, if not feasible, augmented or alternative medical therapy (**Class I, Level C**).

Conclusion

The underlying pathophysiology of NSTE-ACS is most often the rupture of a vulnerable atherosclerotic plaque followed by the development of an overlying subtotally occlusive, platelet-rich thrombus. The symptoms are usually those of angina at rest, of new onset or with a pattern of increasing severity. Management should be focused initially on preventing death and MI (patient recognition of symptoms, activation of the 911 system, and expeditious management in the ambulance and emergency room), relieving ischemic symptoms (bed rest, nitrates, beta-blockers/calcium antagonists) and resolving coronary thrombosis (aspirin, clopidogrel, an anticoagulant (a choice of UFH, LMWH, bivalirudin or fondaparinux) and Gp IIb/IIIa antagonists). Immediate and ongoing risk stratification must govern the pace, intensity and extent of therapy. Angiography and revascularization (PCI or CABG) as appropriate should be undertaken urgently for patients in

whom ischemic symptoms are severe, progressive and/or accompanied by hemodynamic instability. Patients who are stabilized quickly should be managed by a strategy of early invasive therapy if they are at higher risk. For men at intermediate or low risk the management strategy may be either early invasive or selective invasive, whereas for women in the lower risk categories the management strategy should be selective invasive. Aspirin should be started immediately and continued indefinitely; clopidogrel should be started early unless there is a high likelihood of CABG, and continued for at least a year. A beta-blocker (or calcium antagonist), initially used to control ischemic symptoms, should generally be continued indefinitely unless the patient undergoes revascularization. Most patients should begin an ACE inhibitor (or ARB if there is ACE intolerance), and all should begin a statin in hospital and continue indefinitely. Optimal management of coronary risk factors and ongoing follow-up are indicated for all patients whether or not they undergo revascularization.

30 Early prehospital management of ST elevation myocardial infarction

Robert C Welsh and Paul W Armstrong

University of Alberta, Edmonton, Alberta, Canada

Introduction

Over the last three decades, major advances have occurred in the treatment of patients with ST elevation myocardial infarction (STEMI) that have significantly enhanced our knowledge and understanding. A commensurate improvement in outcomes has ensued. Despite this burgeoning knowledge and a multi-pronged investment in both the content and process of STEMI care, important care gaps exist. These include a significant proportion of patients not treated with reperfusion therapy, inadequate patient triage, delayed time to reperfusion, suboptimal utilization of appropriate adjunctive medical therapy, subsequent underutilization of cardiac rehabilitation programs, and failure to undertake lifestyle modifications.

Time to initiation of reperfusion remains a critical factor pivotal to modulating STEMI patient outcomes. Clinical evidence and guidelines have defined key parameters necessary to achieve optimal time to reperfusion once patients establish first medical contact.[1–3] In Figure 30.1 the specific temporal segments are outlined and include time from medical presentation to acquisition of the first 12-lead ECG, first ECG until completion of patient assessment and confirmation of diagnosis, and time from diagnosis to reperfusion therapy. Contemporary STEMI guidelines indicate that time from first medical contact to initiation of fibrinolysis should be 30 minutes or less and within 90 minutes to first balloon inflation in the case of mechanical reperfusion,[1,2,4]

Rich and often unrealized opportunities exist, prior to arrival at hospital, to limit STEMI patient morbidity and mortality by enhancing early management via the prehospital emergency medical system (EMS). The initial early activation of EMS depends upon appropriate recognition of symptoms or circumstances, which must be coupled with timely and appropriate responses from affected individuals, often assisted by family members, friends, co-workers or bystanders. Unfortunately, utilization of EMS remains suboptimal with many STEMI patients presenting to the hospital using personal transportation. Despite dedicated public education strategies, little impact on this behavior has ensued. Advanced prehospital STEMI management which expedites patient assessment, diagnosis, triage, and treatment has been successful in various health systems worldwide, including over two decades of experience in France and Ireland. These prehospital STEMI treatment protocols are most effective when operating within an integrated system-wide regional reperfusion program which includes continuous quality improvement.

Patient symptom recognition, public education strategies and activation of the prehospital emergency medical system

The American College of Cardiology (ACC) and American Heart Association (AHA) guidelines, with a current focused update, have encouraged the reduction of total ischemic time to less than two hours.[1,2,4] Unfortunately it has been consistently demonstrated that patient delay in seeking medical attention is the major limitation to realizing this goal and time to reperfusion remains suboptimal. Within clinical trials greater than 50% of reperfusion delay occurs prior to first medical contact; an even longer delay is evident within "real-world" registry data.[5–8] Addressing patient delay requires understanding the patient's perception, interpretation, and action as well as the influence of other factors modulating behaviors (Fig. 30.2).

Specific patient demographic factors have been identified which affect the duration of symptoms prior to seeking medical advice (Table 30.1). Older patients and women have consistently been shown to delay seeking medical

Fibrinolysis   **Goal** = 1st medical contact to fibrinolysis **30 min**

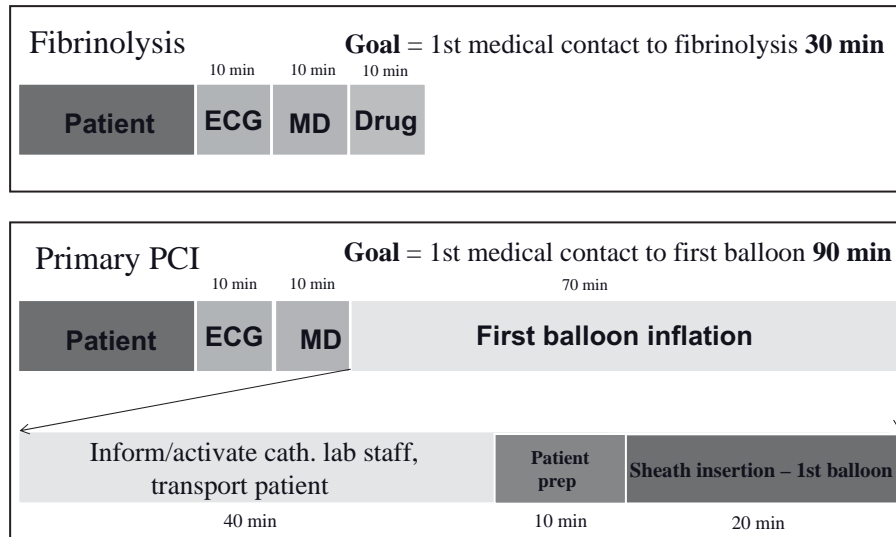

Figure 30.1 Understanding time to treatment: pharmacologic and mechanical reperfusion. Understanding process of care and associated temporal delay required to deliver reperfusion therapy facilitates healthcare providers' ability to achieve goal times and develop appropriate systematic interventions. Upon arrival in the catheterization laboratory the patient is prepared for the procedure and the interventional cardiologist achieves arterial access and undertakes diagnostic coronary angiography. If the anatomy is consistent with PCI, appropriate equipment is prepared and anticoagulant therapy administered prior to crossing the specific lesion and achieving first balloon inflation; the total process typically requires 30 minutes. Therefore, it is essential that systematic interventions are implemented to expedite activation of the interventional cardiologist and catheterization laboratory personnel as well as patient transportation from the emergency department such that the time from confirmed diagnosis to arrival in the laboratory is abbreviated to 40 minutes or less.
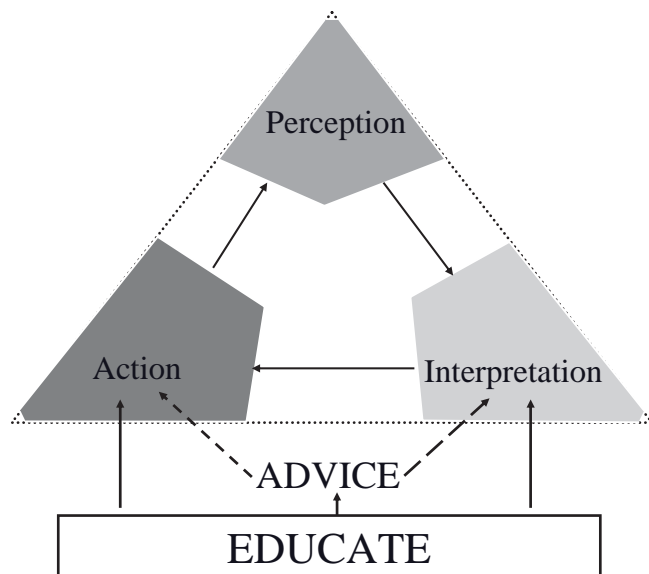

Figure 30.2 Understanding time to reperfusion – patient delay. When a person perceives a novel or recurrent sensation (such as chest pressure) their interpretation is influenced by the severity of the symptom as well as a host of factors influenced by past experience and education. Seeking advice from friends, family, co-workers or bystanders regarding the interpretation of the symptom as well as appropriate action required may occur. Education influences the personal interpretation of symptoms and appropriate action as well as the advice that may be offered from others.

RCTs, randomized controlled trial; CT, controlled trial; Before and after, analysis prior to and following the intervention.[66]

attention until later in the course of their symptoms.[8–11] Ironically, patients with known past medical diagnoses with increased risk of cardiovascular events have also prolonged delay, including those with prior angina, hypertension, diabetes mellitus, and congestive heart failure.[8–11] Patients with prior percutaneous coronary revascularization and prior acute myocardial infarction appear to present after less symptomatic delay.[8,9,11]

A host of situation-specific factors have also been shown to modulate time from symptom onset to medical presentation (Table 30.2). The most consistent of these are linked to severity of symptoms at presentation, especially those of cardiogenic shock or resuscitated arrhythmia presenting earlier.[8,9] Longer delays in presentation also occur outside regular working hours or on weekends and holidays.[8,10,11]

Psychosocial factors also influence patient delay. These include misinterpretation of symptoms and denial of their importance. Female STEMI patients are known to deny or misinterpret their symptoms since they are conditioned to interpret acute myocardial infarction as a "male" disease.[8,9,11–13] There are also significant socioeconomic factors related to the cost of healthcare, particularly activation of the prehospital EMS which has additional associated cost implications in many countries.[14]

Remarkably, in industrialized nations, only 50% of patients with symptoms suggestive of acute myocardial infarction activate the prehospital EMS. This figure is staggering and tragic considering the evidence indicating that ambulance assistance leads to shortened time to definitive care and diminishes the potential individual patient and population hazards with self-transportation of patients at risk of hemodynamic compromise and dysrhythmia.

Although they are logical, dedicated educational programs that have attempted to increase appropriate utilization of EMS and decrease reperfusion delay through enhanced patient response have typically met with limited

success (Table 30.3). Within the United States, the Rapid Early Action for Coronary Treatment (REACT) trial randomized 20 cities, matched for community size and patient demographics, to receive an 18-month educational intervention.[15] The premises of this program were that: (1) time to treatment was currently excessive; (2) patient response accounted for the majority of delay; and (3) dedicated community educational intervention would improve knowledge and decrease patient-related delay. Central educational themes were promulgated, aimed at early symptom recognition and rapid response by calling 911 if symptoms suggestive of myocardial ischemia persisted for more than 15 minutes. This interventional strategy focused on: (1) community organizations including health professionals and other leaders; (2) public education to develop general awareness of acute myocardial infarction symptoms, the presence of heart disease in females, and appropriate action through MI survival plans, bystander response, and the importance of calling 911; (3) professional education including focused discussions with physicians, nurses, cardiac rehabilitation, emergency department and ambulance staff through academic detailing, continuing health education events and special seminars; and (4) education of patients with a past history of coronary artery disease or significant cardiovascu-

lar disease risk factors. Each community involved in these programs had a local office with two staff to organize events and promote the program. Despite enhancing awareness and increasing utilization of EMS, this intensive educational program, which was associated with an annual cost between $156 000 and $294 000 per 100 000 person community, did not demonstrate a reduction from symptom onset to first medical presentation in STEMI patients.[15,16] Paradoxically greater utilization of EMS occurred in patients with symptoms determined to be non-cardiac.

Although these results are discouraging and highlight the limitation of current educational strategies to reduce patient treatment delay, enhancing awareness of those with established disease or other risks remains a legitimate goal. Future campaigns to shorten patient delay are likely to be more effective if they address psychosocial and behavioral impediments to action, are sustained rather than short term, and focus on those patients and families at highest risk, including those with known coronary heart disease.

Prehospital diagnosis of ST elevation myocardial infarction

During the acute phase of STEMI, patients may experience a diverse range of symptoms varying from classic crushing retrosternal chest discomfort with typical associated symptoms, to isolated dyspnea, syncope, malaise, and neurologic impairment. In elderly patients, females, diabetics, and those taking non-steroidal anti-inflammatory drugs (NSAIDs), symptoms may be subtle or absent and such patients are known to be at increased risk of suffering "silent myocardial infarctions".[17–22] This reality makes recognition of patients with STEMI challenging for frontline medical personnel in emergency departments as well as in the prehospital environment.

EMS programs typically have a system of triage to be implemented at the time of a 911 call, which are based upon key symptoms communicated from patients or their families, including chest discomfort, shortness of breath, syncope, and other indicators of potential myocardial ischemia. In some centers, this involves physician participation to prioritize prehospital response to appropriate patients with mobilization of advance care mobile intensive care units. In other regions where prehospital care is delivered by non-physician paramedical staff, preliminary triage may also be undertaken to facilitate the activation of advanced cardiac life support (ACLS) units capable of delivering advanced prehospital cardiac care.

On arrival at a scene where symptoms compatible with myocardial infarction are recognized or confirmed, rapid completion of a prehospital 12-lead ECG is a key factor in determining diagnosis and guides subsequent therapy. It has been shown that prehospital 12-lead ECGs can be expeditiously completed with reliable lead placement and provide high-quality diagnostic tracings.[23,24] Furthermore, provision of a prehospital 12-lead ECG adds little incremental prehospital delay, i.e. a 1–10 minute increase in prehospital on-scene time.[24–27]

Various approaches to 12-lead ECG interpretation have been employed within the prehospital environment. When an experienced physician is present, onsite interpretation is feasible; if not, opportunities exist for either ECG remote transmission for physician interpretation or computer-assisted interpretation by paramedical staff. Evidence demonstrates that well-trained paramedics can efficiently use the 12-lead ECG to guide early treatment. Although this has been proven effective in a research environment, more widespread implementation carries the potential for over-, under- and inappropriate diagnosis of STEMI, and robust evaluations of the success of such programs are warranted.

Remote prehospital 12-lead ECG interpretation requires appropriate technology at both ends of the transmission, the immediate availability of an experienced physician, and a system of communication between the physician and prehospital paramedics with the attendant liability of system failure at multiple levels. Transmission of all prehospital 12-lead ECGs for remote interpretation is impractical given that only about 5% of such patients, i.e. those identified with symptoms possibly related to myocardial infarction, have confirmed evidence of STEMI.[28] Preliminary paramedic ECG interpretation has been effectively employed in several regions for selective transmission of the prehospital 12-lead ECG. In a single-center analysis, greater than 70% of all STEMI patients were correctly identified by prehospital paramedic teams following modest training in STEMI patient identification and 12-lead ECG interpretation.[22] Even within the setting of a prehospital fibrinolysis trial, where stringent inclusion and exclusion criteria are employed, paramedic EMS staff correctly identified and enrolled 46% of all STEMI patients.

In conjunction with completion of the prehospital 12-lead ECG, prehospital paramedical staff can effectively and thoroughly complete prehospital reperfusion checklists to determine eligibility for reperfusion. Thereafter, prehospital reperfusion can be administered or patients can be triaged to centers capable of achieving expedited mechanical or pharmacologic reperfusion.

Prehospital management of ST elevation myocardial infarction

In patients with a likely or confirmed diagnosis of STEMI, implementation of contemporary guidelines should be considered prior to hospital arrival to minimize patient distress, morbidity, and mortality, especially those with demonstrated time dependency (Table 30.4)[1,2,4] Prehospital

Table 30.4 ACC/AHA guidelines for management of STEMI relevant to the prehospital environment

Procedure or therapy	Class	Level of evidence
911 – dispatch recommend ASA (in absence of contraindications)[1]	IIa	C
Paramedics perform prehospital 12-lead ECG[1]	IIa	B
Complete prehospital reperfusion check list[1]	IIa	C
Defibrillation (hemodynamically significant dysrhythmia)[1]	I	A
ASA 162–325 mg (chew and swallow – in absence of CI)[1]	I	C
Oxygen – hypoxia[1]	I	B
Oxygen – 1st six hours to all confirmed STEMI[1]	IIa	C
NTG SL with ongoing ischemic discomfort[1] 0.4 mg × 3 does every 5 min	I	C
NTG IV for relief of ongoing ischemic discomfort or to manage significant hypertension or pulmonary edema[1]	I	C
NTG contraindicated:[1]	III	C
BP < 90		
HR < 50		
HR > 100		
RV MI		
Recent administration of a phosphodiesterase inhibitor[1]	III	B
Morphine sulfate is the analgesic of choice (2–4 mg IV with increments of 2–8 mg IV repeated at 5–15 min. intervals)[4]	I	C
Beta-blocker therapy[4]		
Oral initiated in first 24 hours without contraindications	I	B
Intravenous is reasonable to administer for the management of hypertension without contraindications	IIa	B
Contraindications for early beta-blocker therapy: 1) signs of heart failure, 2) evidence of low output state, 3) increase risk of cardiogenic shock, and 4) other relative contraindications	III	A
Prehospital fibrinolysis[1]	IIa	B
Prehospital destination protocols for primary PCI[1,4]		
Expected time from first medical contact to balloon inflation is less than 90 min (with experienced interventional cardiologists present)	I	A
Cardiogenic shock <75 years	I	A
Contraindication to fibrinolysis	I	B
Cardiogenic shock ≥75 years	IIa	B

EMS teams managing patients with STEMI should be capable of advanced cardiac life support techniques to address hemodynamic and electrical instability as well as respiratory compromise. Synchronized cardioversion, defibrillation or percutaneous pacing can be employed to treat malignant arrhythmias. In the setting of symptomatic hypotension, intravenous fluid resuscitation is standard and intravenous inotropes can be administered when appropriate medical supervision exists.

Oxygen and respiratory support

Supplemental oxygen is administered to patients with oxygen saturation less than 90%. There is experimental evidence that oxygen administration may limit ischemic myocardial injury; therefore even in uncomplicated myocardial infarction this may be an effective strategy.[29] It has become ubiquitous to administer oxygen to virtually all patients with symptoms suggestive of myocardial ischemia.

In patients with cardiopulmonary compromise, such as pulmonary edema, severe congestive heart failure, cardio-genic shock or presumed mechanical complications of STEMI, advanced respiratory support may be required. This may include bag, valve and mask with oral airway or endotracheal intubation to provide adequate oxygenation and ventilation.

Analgesia

It is the expectation that patients with STEMI will receive reperfusion therapy although not all will be candidates; continuing pain relief is required in either case. Although retrospective data have raised concerns about potential adverse events from morphine in patients with non-STEMI, this has not been the case with STEMI patients.[30] Therefore, administration of morphine sulfate (2–4 mg IV with increments of 2–8 mg IV repeated at 5–15 minute intervals) is the analgesic of choice for management of pain associated with STEMI. This should be undertaken judiciously in patients with hemodynamic or respiratory instability.

In the STEMI patient population treated within the EXTRACT TIMI 25 trial, an increased risk of death, rein-

farction, heart failure or shock was demonstrated in those taking NSAIDs within seven days of enrollment.[31] Although not as pertinent to the prehospital environment, there is a known increased risk of cardiovascular events among patients taking COX-2 inhibitors and other NSAIDs; therefore, patients who are taking these agents at the time of STEMI should discontinue them immediately.

Nitroglycerin

In the setting of ongoing ischemic discomfort, sublingual nitroglycerin should be administered (0.3–0.4 mg) every five minutes up to a maximum of three doses or until symptoms are relieved. If prehospital infusion pumps are available, intravenous nitroglycerin is indicated for relief of refractory ischemic symptoms, to control hypertension or manage pulmonary congestion. Nitroglycerin should not be administered with: hypotension (systolic blood pressure <90 mmHg), significant bradycardia, suspected right ventricular infarction, or in patients who have received a phosphodiesterase inhibitor to treat erectile dysfunction within 24 hours.

Beta-blockers

Administration of intravenous and oral beta-blockers has been encouraged in the early period following diagnosis of STEMI, based upon evidence acquired largely in the pre-reperfusion era. The COMMIT-Metoprolol Trial allocated 45 852 patients within 24 hours of diagnosis of STEMI to receive metoprolol administered as three doses of 5 mg IV in the first 15 minutes followed by 200 mg/day orally or matching placebo.[32] This strategy did not improve the primary endpoint and was associated with an excess risk of cardiogenic shock of 11 per 1000 treated with the incidence increased in patients with age >70 years, systolic blood pressure <120 mmHg, presenting heart rate >110/min or congestive heart failure as measured by Killip class >I. These results underscore the potential risk of administering intravenous or aggressive oral beta-blockers in the prehospital setting.

Antithrombotic agents

Because of the potential benefits of early ASA (aspirin) use, its limited risk and low cost, it is reasonable for prehospital care providers to administer it to all patients with symptoms suggestive of STEMI in the absence of contraindications. In fact, ASA 162–325 mg to chew should be initiated remotely by 911 dispatchers to non-ASA allergic patients with symptoms suspicious for STEMI while awaiting arrival of EMS.

Although not extensively investigated, additional antiplatelet agents could be considered for administration in the prehospital environment. Clinical and pharmacody-

namic evidence indicates some delay in the onset of action of clopidogrel following oral administration.[33] Although not yet supported by evidence in clinical guidelines, administration of this agent in the prehospital environment seems logical in STEMI patients in whom early percutaneous coronary intervention is intended. Since a proportion of patients may require urgent coronary artery bypass grafting, this strategy requires definitive investigation prior to widespread implementation. The early utilization of intravenous glycoprotein IIb/IIIa receptor blockers and the host of novel oral antiplatelet agents in current development require assessments in the prehospital environment to clarify their risk and benefit.

Clear evidence supports the importance of appropriate and adequate anticoagulation in conjunction with pharmacologic reperfusion to sustain coronary patency. In the setting of mechanical reperfusion, the optimal antithrombin (e.g. unfractionated heparin, low molecular weight heparin, bivalirudin, fondaparinux) and dose remain unclear. Very early administration of an antithrombin in the setting of mechanical reperfusion currently lacks supportive evidence. Despite this, prehospital administration with seamless transition to the cardiac catheterization laboratory and in-hospital care seems reasonable.

Pharmacologic or mechanical reperfusion

The optimal choice of reperfusion therapy is best determined by assessing the time from symptom onset to first medical contact, the estimated baseline patient risk, location and extent of myocardial ischemia, and predicted percutaneous coronary intervention (PCI)-related delay (measured as the interval between initiation of fibrinolysis and the first balloon inflation). The decision is further influenced by regional staff, resources, hospital protocols, and physician and patient bias (Table 30.5). Although primary PCI is considered the reperfusion strategy of choice, it is clear that this advantage is time dependent and limited to specific patient populations. The DANAMI II trial has shown that the benefit of primary PCI is limited to a minority of patients, i.e. the 25% at highest risk as measured by TIMI risk score ≥5 (n = 393, three-year mortality primary PCI 25.3% vs fibrinolysis 36.2%, $P = 0.02$).[34] Of the 1134 patients with a TIM I risk score <5, three-year mortality for primary PCI was 8.0% vs 5.6% for fibrinolysis (P = ns).[34] Regardless of the form of reperfusion, rapid diagnosis and intervention are crucial for effective early management. Unfortunately, the polarizing debate over the advantage of primary PCI versus fibrinolysis has had a potentially negative impact on optimizing time to reperfusion for all STEMI patients.

The use of EMS in itself has been associated with expedited evaluation in the emergency department, wider use of acute reperfusion therapy, and earlier pharmacologic or mechanical reperfusion.[35–40] Opportunities to improve

Table 30.5 ACC/AHA guidelines for choice of reperfusion strategy[1]

Fibrinolysis generally preferred	Invasive strategy generally preferred
Early presentation (≤3 h from sx onset and delay to invasive strategy)	Skilled PCI lab available with surgical back-up (med contact to balloon <90 min)
Invasive strategy not an option (cath lab not available, no vasc access, lack of skilled PCI lab)	High risk from STEMI (cardiogenic shock, Killip class ≥3)
Delay to invasive strategy (door-to-balloon, door-to-needle) >1 h; first medical contact to balloon >90 min)	Contraindication to lysis (including increased bleeding/ICH risk) Late presentation (>3 h) Diagnosis in doubt

reperfusion delay utilizing prehospital EMS can be considered in four tiers of response and action. Tier one utilizes the prehospital 12-lead ECG to expedite in-hospital care upon arrival in the emergency department. Tier two employs the prehospital 12-lead ECG in conjunction with reperfusion screening checklists to facilitate activation of in-hospital response prior to arrival in the emergency department. Tier three utilizes these resources with communication to a remote physician or through implementation of predefined standardized protocols to deliver patients to the most appropriate center to provide expedited reperfusion, including bypass of community hospitals for mechanical reperfusion when appropriate. Tier four utilizes these resources in conjunction with an integrated treatment program whereby prehospital fibrinolysis can be administered or direct transportation to a cardiac catheterization laboratory occurs to reduce treatment delay and optimize patient outcomes.

The ACC/AHA guidelines for the treatment of STEMI suggest that "it is reasonable that all ACLS providers perform and evaluate 12-lead ECGs routinely in chest pain patients suspected of STEMI" (**Class IIa, Level C**).[1] Having a 12-lead ECG available to the in-hospital team upon the patient's arrival in the emergency department is associated with reduction in treatment delay to fibrinolysis by approximately 10 minutes and to primary PCI by approximately 20 minutes.[41,42] In combination with a prehospital reperfusion checklist addressing patient eligibility for reperfusion, communication of this information to the receiving emergency department may further facilitate care. After confirmation of the diagnosis by in-hospital emergency department staff, these patients may receive expedited in-hospital reperfusion.

Creation of regional cardiac destination hospitals capable of rapid cardiac catheterization and primary PCI delivered by experienced interventional cardiologists has been proposed as a means of improving outcomes in STEMI patients.[43,44] This strategy reduces time to treatment by 30–50 minutes.[45–47] In centers without prehospital confirmation of the diagnosis, i.e. tier two prehospital system, sig-

nificant financial and personnel strain may result from misdiagnosis based upon the paramedic-interpreted ECG and deployment of the cardiac catheterization team. Hence in one study of this issue, inappropriate activation of the catheterization laboratory occurred in 35% of patients with suspected STEMI (n = 1335) diagnosed in the emergency department as assessed by the following three criteria: no culprit coronary artery (14%), no significant coronary artery disease (9.5%), and negative cardiac biomarker results (11.2%).[48] Although the frequency of this phenomenon has not been determined in the prehospital environment, it is improbable that paramedical EMS staff would achieve better results than emergency physicians.

Fibrinolytic therapy of STEMI significantly improves mortality rates; treatment within six hours of the onset of symptoms leads to a reduction in mortality between 26–65 per 1000 patients treated which has been extensively documented.[49] Randomized trials of prehospital versus in-hospital fibrinolysis demonstrate a one-hour reduction in treatment delay with improved patient mortality (1.7% absolute reduction, odds ratio (OR) 0.83, 95% confidence interval (CI) 0.70–0.98).[50] Furthermore, prehospital STEMI patients tend to present sooner: in the two largest contemporary trials utilizing prehospital fibrinolysis, the median time to treatment was approximately two hours, comparing favorably with contemporary trials of in-hospital fibrinolysis (which includes ambulance or self-transportation patients).[51,52] These data provide a powerful impetus for healthcare systems to implement such programs.

Prehospital fibrinolysis has been validated in over two decades of clinical experience and research has demonstrated that this can be achieved in diverse health regions with variable population density, past experience with prehospital fibrinolysis, and the presence or absence of a physician in the prehospital environment.[53,54] Paramedics have been shown to be competent to complete on-scene assessment, record and transmit the 12-lead ECG for remote physician oversight, obtain informed consent and administer fibrinolytic therapy.[54] Prehospital fibrinolysis can be achieved rapidly with no evidence of adverse events in

those managed by the paramedical prehospital personnel. Although the clinical experience and enhanced training of physicians in the prehospital setting may represent the ideal situation, trials and the wealth of clinical experience worldwide have demonstrated the efficacy, safety, and feasibility of paramedic-based prehospital fibrinolysis. The ACC/AHA STEMI guidelines recommend prehospital fibrinolysis as a reasonable alternative when "1) physicians are present in the ambulance; or 2) in well-organized EMS systems with full-time paramedics capable of acquiring prehospital 12-lead ECG and preliminary interpretation with initiation and ongoing training, direct medical oversight, and a medical director with training and experience in STEMI management; and an ongoing continuous quality improvement program".[1]

Although successful in various regions, fully integrated advanced prehospital management of STEMI, i.e. tier four, has not been consistently employed across the globe. Such programs are based upon individualized patient triage utilizing available evidence as outlined by current guidelines (see Table 30.5) which recommend pharmacologic reperfusion in situations where mechanical reperfusion is not feasible within the appropriate time frame of 60 minutes of PCI-related delay. This opportunity is critical: (1) when the catheterization laboratory is occupied; (2) in periods of high traffic in urban regions or during adverse weather conditions which are common throughout many populous regions; and (3) during periods where hospital overcrowding has led to emergency room diversions of patients. With the majority of prehospital STEMI patients presenting early after symptom onset, expedited prehospital fibrinolysis can achieve excellent patient outcomes. In patients with contraindications to fibrinolysis or in the minority with high-risk clinical characteristics such as hypotension, cardiogenic shock or pulmonary edema, direct triage to a prehospital activated cardiac catheterization laboratory expedites mechanical reperfusion. Additionally a fully integrated system minimizes the need for "lights and sirens" transportation, which has been linked to vehicular accidents and excess risk to patients, ambulance personnel, and innocent bystanders.[55,56]

Mechanical co-intervention subsequent to prehospital fibrinolysis

Following prehospital fibrinolysis, direct triage of selected patients to the catheterization laboratory should be undertaken to expedite care and enhance outcomes. This should be considered in high-risk clinical scenarios including:
- cardiogenic shock (<75 years old; **Class I, Level B**, and ≥75 years old; **Class IIa, Level B**)
- severe congestive heart failure (**Class I, Level B**)
- hemodynamically compromising ventricular arrhythmias (**Class I, Level C**).[4]

Following full-dose fibrinolysis, coronary angiography with intent to perform PCI should be considered in patients failing to achieve reperfusion clinically (**Class IIa, Level C**) and in those with persistent ST elevation (<50% resolved after 90 minutes following initiation of fibrinolysis) and at least a moderate area of myocardium at risk (**Class IIa, Level B**). These recommendations are based upon a 50% reduction in the combined clinical endpoint of death, repeat myocardial infarction, cerebral vascular accident or severe heart failure within six months comparing rescue PCI (15.3%), conservative management (29.8%) or repeat administration of fibrinolysis (31%) in patients failing to achieve ECG evidence of reperfusion (<50% reduction in ST elevation) within 90 minutes of initial fibrinolysis.[57] In certain circumstances, optimal patient care may include observation for successful reperfusion in a community hospital emergency department with the EMS team on standby, thereby expediting transfer to a catheterization laboratory for rescue PCI (required in approximately 30% of patients).[51,58,59]

Facilitated PCI, where patients are routinely taken directly to the catheterization laboratory following administration of reduced-dose fibrinolysis, has been implemented in certain regions when patients are unable to achieve primary PCI within acceptable time intervals.[60–62] Although this strategy may appear attractive, large-scale clinical trials have failed to demonstrate enhanced patient outcomes with either full-dose or reduced-dose fibrinolysis followed by PCI.[63,64] A planned reperfusion strategy using full-dose fibrinolysis followed by immediate PCI has been discouraged in the recent ACC/AHA focused STEMI update (**Class III, Level B**).[4]

Integration of prehospital strategies in a system-wide reperfusion program

Expansion and enhancement of prehospital diagnosis, triage, treatment, and initiation of definitive reperfusion strategies in the prehospital environment provides a key opportunity to improve STEMI patient outcomes. For such programs to be successful over the long term, it is essential that they be integrated and supported by a system-wide reperfusion protocol. If prehospital teams are linked to such regional reperfusion programs, seamless integration of patient care may occur. If such programs are not fully supported, the sustainability of prehospital reperfusion strategies would be significantly hampered. Communication and continuous quality improvement programs with engagement of all partners within the healthcare team, including hospital and regional administration, physicians, nurses, and paramedical staff, are essential (Fig. 30.3).

Within a system-wide reperfusion program, establishing clear guidelines and empowering experienced decision

makers to implement best care for individual patients are required. This should include identifying high-risk patient populations suitable for early reperfusion, linked to appropriate triage to tertiary care centers for risk stratification and interventional management as required. Dedicated assessment of the success of reperfusion following pharmacologic therapies with aggressive rescue PCI may also improve patient outcomes. In the future, computer-based dynamic modeling may facilitate aligning patient risk with choice of therapy as well as subsequent destination hospital. Such dynamic modeling must be an ongoing process, with reassessment of risk in the early hours after initiation of therapies guiding subsequent investigation and management.

Conclusion

This chapter has discussed key opportunities that exist to limit STEMI patient morbidity and mortality by enhancing early management via the prehospital emergency medical system (EMS). Advanced prehospital STEMI management which expedites patient assessment, diagnosis, triage, and treatment has been successfully implemented. Empowering adequately trained paramedic teams to administer life-saving therapy such as fibrinolysis in the prehospital environment deserves a high international priority.

Although this chapter has focused on STEMI patients and the enhancement of their care through advanced prehospital management, the importance of early diagnosis, triage and treatment is not unique to these patients. The development of prehospital STEMI protocols can be seen as the initial template from which to advance care in other acute cardiovascular diseases (Fig. 30.4).[65] This could include high-risk NSTEMI with implementation of early pharmacologic therapy and prehospital triage to appropriate tertiary care centers for early angiography. Early implementation of therapy in stroke and survivors of cardiac arrest may also be linked to improved outcomes following these potentially devastating events. Opportunities will continue to expand as technology continues to advance, with enhanced diagnostic and therapeutic capability across the spectrum of cardiovascular disease.

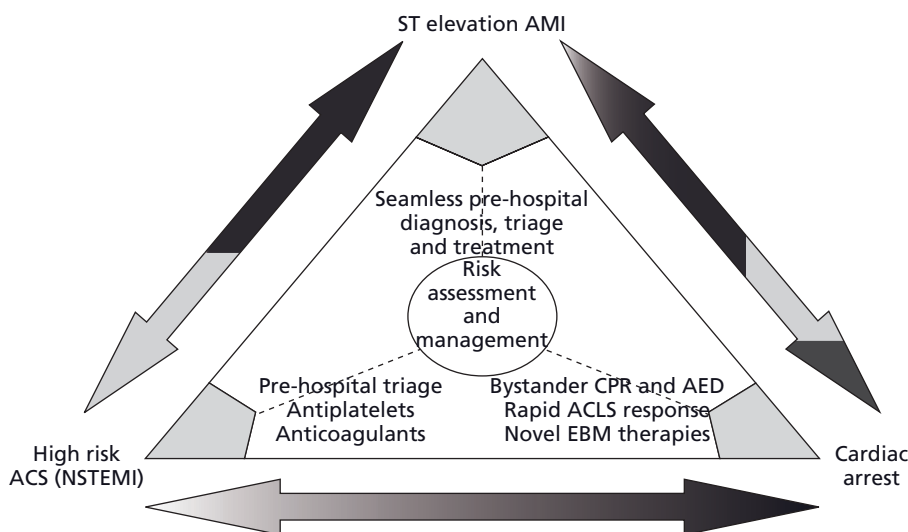
Figure 30.3 Reflections on STEMI care; success through co-operation. Within the healthcare system all stakeholders from paramedics to administrative staff must adopt a patient-centered focus to deliver base care to each patient.


Figure 30.4 Opportunities in prehospital cardiovascular care. Opportunities provided by enhanced prehospital cardiovascular care move beyond the scope of this chapter focused on ST elevation myocardial infarction (STEMI) and include non-ST elevation acute coronary syndromes (ACS), cardiac arrest (sudden death), and a host of other cardiovascular disease.[65] The capacity of prehospital teams to assess and manage patient risk with rapid initiation of evidence-based treatments and triage to appropriate medical institution portends optimal medical treatment. ACLS, advance cardiac life support; AED, automated external defibrillator; CPR, cardiopulmonary resuscitation; EBM, evidence-based medicine.

31 Reperfusion therapies for ST segment elevation myocardial infarction

Joseph B Muhlestein and Jeffrey L Anderson
Cardiovascular Department, Intermountain Medical Center, Murray, UT, USA

Introduction

The primary pathophysiology of acute ST segment elevation myocardial infarction (STEMI) is the total occlusion of a coronary artery, usually through thrombosis of a ruptured or eroded atherosclerotic plaque, with a subsequent lack of blood flow to the myocardium. This then results in a time-dependent "wave-front" of myocardial necrosis beginning at the subendocardium and moving towards the epicardial surface.[1] Although in a dog model that has very minimal collateral coronary circulation, the progression to complete transmural necrosis usually takes less than 3 hours, in humans the time may vary anywhere from 2 hours to 12 hours depending on the degree of available collateral coronary circulation, the degree of ischemic preconditioning and whether the thrombotic coronary occlusion is permanent or intermittent. The minimization of the total amount of myocardial necrosis during STEMI has been associated with improved long-term clinical outcomes. Although some evidence exists that myocardial salvage may be accomplished by a variety of pharmacologic maneuvers designed to reduce the oxygen demands of the heart, by far the most effective approach has been to produce reperfusion of the occluded artery as fast as possible, by either fibrinolytic therapy or mechanical means. Multiple studies have validated the "need for speed" approach to this effort and justified the mantra that "time is myocardium."

The benefits of therapy depend on the rate and extent to which myocardial reperfusion is effectively achieved.[2–4] Reperfusion is scored by the Thrombolysis In Myocardial Infarction (TIMI) visual[2] or frame-counts[5] methods supplemented, recently, by a TIMI myocardial perfusion (TMP) score.[6] Restoration of TIMI grade 3 (normal) epicardial flow is associated with lower mortality rates than TIMI grades 0–2 (3.7% vs 7.0%). Among those with TIMI 3 flow, lower mortality is associated with TMP grade 3 (0.7%) than with TMP grades 2 (2.9%) or 0–1 (5.4%). The factors differentiating epicardial and myocardial reperfusion are incompletely understood. Platelet and platelet–leukocyte aggregates, distal thrombus embolization and secreted vasoactive and thrombogenic factors have received recent attention, and a variety of targeted therapies, adjunctive to either fibrinolytic or mechanical reperfusion therapy and designed to further improve myocardial perfusion, are being actively studied.[7,8] However, despite the promise shown by multiple agents in the experimental situation, the results of clinical trials have been extremely disappointing and no trial to date has achieved its primary endpoint.[9]

Historic perspective

Although both fibrinolytic and mechanical approaches to coronary reperfusion therapy are presently used, depending on the clinical circumstances, from a historic perspective, fibrinolytic therapy was first developed and validated. In 1933, Tillet and Garner published their discovery of a streptococcal fibrinolysin.[10,11] Clinical application of streptokinase (SK) to AMI was first reported in 1958.[12] From then until 1979, at least 17 studies were published, but AMI pathophysiology was not well understood and results were inconclusive and poorly accepted.[13,14] With the establishment of the thrombotic nature of coronary occlusion[15] several groups demonstrated the feasibility of clinical fibrinolysis to achieve early reperfusion under angiographic monitoring (~75% success with intracoronary (IC) SK) in the period 1976–83.[16–19]

Randomized studies in AMI followed. Anderson *et al* reported in 1983[20] a benefit of early (<4h) IC SK on clinical, enzymatic, and imaging endpoints. Later therapy (at >6 hours) relieved ischemic pain but did not benefit regional myocardial function in another study.[21] The potential for

mortality benefit of IC SK was suggested by subsequent Western Washington and Dutch studies in a few hundred patients.[22–24] The logistic difficulties with intracoronary administration stimulated the re-evaluation of IV SK (Schröder *et al*[25]). By the mid-1980s, favorable comparisons with IC SK[26–28] and a larger outcomes study of IV SK (ISAM)[29] established the intravenous route for subsequent clinical trials.

Although intravenous fibrinolytic therapy is certainly superior to placebo in patients who present early with STEMI, there remain a number of problems associated with this approach. First, many patients have significant contra-indications to the use of fibrinolytic agents.[30] Second, even with the newer fibrinolytic agents, a small but significant risk of intracranial hemorrhage remains and results in death or disability, especially in the very old patients.[31] Third, fibrinolytics establish normal TIMI grade 3 flow in only 50–60% of the patients.[32,33] Only a third of treated patients have complete resolution of ST segment elevation, and only about 50% have >70% resolution of ST segment elevation 24–36 hours after fibrinolytic administration – a marker of lower mortality.[34] Since there are no absolutely reliable clinical signs or symptoms that indicate success of fibrinolytic therapy, it is difficult to evaluate whether the infarct artery is open with the treatment in an individual patient. Even in those patients with successful fibrinolysis, many go on to have reocclusion and reinfarction due to the ongoing vulnerability of the underlying atherosclerotic plaque.[35,36]

Mechanical reperfusion has the potential to overcome many of these limitations.[37] Direct (or primary) PCI, inter-vention on the infarct artery without prior fibrinolysis, can be done in many patients with contraindications to fibrino-lytic therapy. The overall risk of intracranial bleeding is sig-nificantly lower with direct PCI.[38] With the strategy of direct PCI, there is an opportunity to evaluate the overall coronary anatomy, ventricular function, and intracardiac pressures essentially at the time of admission and possibly detect ana-tomic features or mechanical complications that would require earlier treatment with surgery. Another benefit of direct PCI is the availability of highly trained cardiac cathe-terization laboratory staff if circulatory resuscitation is needed. Additionally, there is a potential to significantly improve the proportion of patients who receive reperfusion with TIMI 3 flow. Early observational studies evaluating the potential of primary PCI were very promising.[39] This led to the performance of a number of randomized trials of fibrino-lysis versus mechanical reperfusion therapy in STEMI, most of which demonstrated a significant superiority of primary PCI, especially among patients in which it was logistically feasible to accomplish reperfusion within 90 minutes of pre-sentation (**Class I, Level A**).[40] As will be discussed in more detail later in this chapter, when all things are equal primary PCI is better than fibrinolytics.

Over the past decade, the results of multiple studies have led us to the present state in which, depending on a variety of circumstances, either fibrinolysis or mechanical reperfusion may be the treatment strategy of choice. This chapter will address in detail the evidence behind both approaches and provide guidelines to assist in choosing which form of reperfusion therapy to use when dealing with an individual patient. Potential adjunctive therapies to be used with each approach will be addressed in other chapters.

Fibrinolytic agents

General mechanisms of action and pharmacologic properties

Fibrinolysis is mediated by plasmin, a non-specific serine protease that degrades clot-associated fibrin and fibrino-gen, disrupting a forming thrombus and facilitating reper-fusion. The fibrinolytic (or "thrombolytic") agents are all plasminogen activators, directly or indirectly converting the proenzyme plasminogen to plasmin by cleaving the arginine 560- valine 561 bond (Fig. 31.1). Plasmin degrades several proteins, including fibrin, fibrinogen, prothrombin, and factors V and VII. The fibrinolytic agents differ in several properties, as summarized in the text and Table 31.1.
Figure 31.1 Schematic representation of the action of fibrinolytic enzymes. Streptokinase (SK) and urokinase (UK) work predominantly on circulating plasminogen, whereas tissue type plasminogen activator (tPA) and single chain urokinase-type plasminogen activator (scuPA) are relatively clot selective. (Modified with permission from Topol EJ. Clinical use of streptokinase and urokinase to treat acute myocardial infarction. *Heart Lung* 1987;**16**:760.)

Table 31.1 Comparison of fibrinolytic agents approved by the US FDA for intravenous use

	SK (streptokinase)	tPA (alteplase)	rPA (reteplase)	TNK (tenecteplase)
Dose	1.5 million units (MU) in 30–60 min	100 mg in 90 min[a]	10 U + 10 U, 30 min apart	30–50 mg over 5 seconds[b]
Circulating half-life (min)	≅20	≅6	≅18	≅20
Antigenic	Yes	No	No	No
Allergic reactions	Yes	No	No	No
Systemic fibrinogen depletion	Severe	Mild–moderate	Moderate	Minimal
Intracerebral hemorrhage	≅0.4%	≅0.7%	≅0.8%	≅0.7%
Patency (TIMI-2/3) rate, 90 min[c]	≅51%	≅73–84%	≅83%	≅77–88%
Lives saved per 100 treated	≅3[c]	≅4[d]	≅4	≅4
Cost per dose (approx US dollars)	290	2750	2750	2750

[a] Accelerated tPA given as follows: 15 mg bolus, then 0.75 mg/kg over 30 min (maximum 50 mg), then 0.50 mg/kg over 60 min (maximum 35 mg).

[b] TNK is dosed by weight (supplied in 5 mg/mL vials): 60 kg = 6 mL; 61–70 kg = 7 mL; 71–80 kg = 8 mL; 81–90 kg = 9 mL; 90 kg = 10 mL.

[c] Based on Granger et al[49] and Bode et al.[89]

[d] Based on the finding from the GUSTO trial[42] that tPA saves 1 more additional life per 100 treated than does SK.

Approved fibrinolytic agents

Streptokinase

Streptokinase (SK) is a 415-amino acid bacterial protein sharing homology with serine proteases.[41,42] Upon injection, SK forms a 1:1 stoichiometric complex with plasminogen or plasmin, activating a catalytic site that cleaves plasminogen to plasmin. The half-life of the SK complex is about 23 minutes. SK is antigenic, has little fibrin specificity, and causes substantial systemic lytic effects in clinical doses. Least expensive of fibrinolytics and still widely used globally, SK is administered by short-term (1 h) infusions.

Urokinase

Urokinase (UK) is a native, 2-polypeptide protein derived from human urine or renal cell cultures.[43] UK directly converts plasminogen to plasmin. It is non-antigenic and is cleared from the circulation predominantly by the liver with a half-life of 16 minutes. Clinically used doses produce moderately extensive systemic fibrinolysis. Its principal use in North America has been for intra-arterial (including intracoronary) fibrinolysis. It has not been approved for and currently is not available for IV use in acute myocardial infarction (AMI).

Tissue-type plasminogen activator (tPA)

Tissue-type plasminogen activator (tPA), a 526-amino acid single polypeptide chain, is the major intrinsic (physiologic) plasminogen activator.[44] The marketed form (alteplase) is manufactured by recombinant DNA technology (rtPA). tPA is converted by plasmin to a double-chain form with equivalent fibrinolytic activity.[45] tPA has greater activity in the locale of the thrombus and causes less systemic plasminemia, fibrinogenolysis, and proteolysis than SK. tPA is non-antigenic, is inhibited by a circulating plasminogen activator inhibitor (PAI-I), and is rapidly cleared (half-life about 5 minutes). This short half-life has necessitated bolus/infusion regimens (over 1–3 hours); bolus-only tPA regimens have been tested but abandoned in favor of longer-acting mutant forms of tPA.

Reteplase

Reteplase (rPA) was the first variant (mutant) of tPA to be developed and marketed.[46] It is a non-glycosylated, single chain deletion variant consisting only of the kringle 2 and proteinase (plasmin cleavage site) domains of human tPA. Fibrin specificity is lower and half-life longer (14–18 minutes) than tPA, allowing more convenient, double-bolus administration.

Tenecteplase

Tenecteplase (TNK-tPA) is a triple-site substitution variant of tPA: at amino acid 103, threonine (T) is replaced by asparagine, adding a glycosylation site; at site 117, asparagine (N) is replaced by glutamine, removing a glycosylation site; at a third site, four amino acids (lysine (K), histidine, arginine and arginine) are replaced by four alanines.[47] The first two changes decrease clearance rate (half-life 20 minutes), allowing for single bolus dosing. The third change confers greater fibrin specificity and resistance to PAI-1.

Efficacy of intravenous fibrinolytic therapy

Effects on coronary arterial patency

Because myocardial reperfusion is the postulated mechanism of benefit of fibrinolysis for MI, many angiographic

studies have been undertaken to assess patency profiles of the infarct-related coronary artery after fibrinolylic therapy.[48] Granger *et al* summarized 14124 angiographic observations from 58 studies.[49] Because the extent of myocardial salvage is time dependent, early (0–90 min) patency has generally formed the primary endpoint in these studies. Without fibrinolytic therapy, spontaneous perfusion early after STEMI occurs in only 15% and 21% at 60 and 90 minutes after study entry, respectively, remains unchanged at 1 day, then gradually increases to about 60% by 3 weeks. All fibrinolytic regimens improve early patency rates. At 60 and 90 minutes, streptokinase had the lowest rates (48%, 51%), standard (3-hour) tPA infusions interme-diate rates (about 60%, 70%), and accelerated (90-minute) tPA infusions the highest rates (74%, 84%). However, patency rates at >3 hours were similar for all regimens, and reocclusion rates were higher after tPA than non-fibrin spe-cific (systemically active) agents (13% vs 8%) (I$P = 0.002$). The GUSTO angiographic study[50] embedded within a larger comparative mortality study,[42] directly demon-strated that early but not late patency rates accurately predict mortality differences among AMI therapies, pro-viding direct support for the open artery hypothesis of fibrinolytic benefit.

Effect on mortality

By the late 1980s, accumulating clinical trials data provided support for a survival benefit of IV fibrinolysis.[51–53] The most important survival trials, comparing fibrinolysis to placebo or standard non-fibrinolytic care, are summarized below.

Gruppo Italiano per lo Studio della Streptochinasi nell' Infarto Miocardico (GISSI) This study[54] was the first "definitive" mortality trial. Eleven thousand eight hundred and six AMI patients with ST elevation were randomized to receive 1.5 million units (MU) of IV SK over 1 hour or standard therapy. Aspirin was not routinely given. In-hospital mor-tality was 10.7% in the SK group and 13.0% in the control group, a 17.6% risk reduction ($P = 0.0002$; relative risk (RR); 0.81). Survival differences remained at 1–2 years.[55] Benefit was time dependent and particularly large for treatment within 1 hour of symptom onset (47% mortality reduction, RR 0.49) but was not significant after 6 hours.

Second International Study of Infarct Survival (ISIS-2) This study[56] randomized 17187 patients with suspected AMI within 24 hours to IV SK (1.5MU), aspirin (1 62.5mg), both or neither (placebos) in a 2 × 2 factorial design. The 35-day vascular mortality rate (13.2% for the double placebo group) was reduced 23% by aspirin alone, 25% by SK alone, and 42% by combined aspirin and SK (all $P < 0.00001$). When both were given early (within 4 hours of symptom onset), a 53% odds reduction was achieved.

Anglo-Scandinavian Study of Early Thrombolysis (ASSET) This study[57] evaluated tPA (alteplase) with heparin versus heparin alone within a randomized, double blind, placebo-controlled design. ASSET enrolled 5013 patients within 5 hours of suspected AMI. Therapies were IV tPA (100mg over 3 hours) plus heparin (5000U N bolus, then 1000U/h), or placebo plus heparin. The 30-day mortality was lower in the tPA than the placebo group (7.2% vs 9.8%, $P = 0.0011$). Hemorrhagic risk was acceptable.

Fibrinolytic Therapy Trialists' (FTT) Collaborative Group This group[58] pooled data from nine controlled trials that randomized 1000 or more patients with suspected AMI. The database consisted of 58600 patients of whom 6177 (10.7%) died, 564 (1.0%) had strokes, and 436 had major non-cerebral bleeds. The 45000 patients who presented with ST elevation or bundle branch block (BBB) had an absolute mortality reduction of 30 per 1000 for treatment within the first 6 hours, 20 per 1000 for hours 7–12, and a statistically uncertain reduction of 13 per 1000 beyond 12 hours. These data led to the national guidelines (**Class I, Level A**) that all STEMI patients should undergo rapid evaluation for reperfusion therapy and have a reperfusion strategy implemented promptly after contact with the medical system.[59]

Subgroup analyses by presenting electrocardiogram (ECG) (Fig. 31.2) showed mortality reductions for those with ST elevation (21%, $P < 0.00001$) and bundle branch block (BBB) (25%) $P < 0.01$. Benefit was greater for those with anterior (37 lives saved per 1000 treated) compared with inferior (8 per 1000) or other (27 per 1000) AMI sites. The absolute benefit was greater in those with greater risk – for example, BBB (49 lives saved per 1000 treated) and anterior ST elevation (37 per 1000). Those with normal ECGs or with ST depression alone showed no benefit and adverse trends (7 and 14 more deaths per 1000, respectively).
Figure 31.2 The effect of fibrinolytic therapy on mortality (lives saved per 1000 treated) in various patient subsets classified according to admission ECG. Patients presenting with bundle branch block and anterior ST segment elevations derived most benefit from fibrinolytic therapy. Patients with inferior ST segment elevation derived much less benefit, while those with ST depression or normal ECG did not benefit. (Based on data from FTT Collaborative Group.[57])

The FTT suggested that proportional mortality reduction was little influenced by systolic blood pressure or heart rate. Benefits also were confirmed for other high-risk groups, including those with prior MI and diabetes.

Benefits of very early (<1 hour) therapy

The magnitude of mortality reductions in FTT was dependent on time to therapy from symptom onset. For those with ST elevation or BBB, the absolute benefit was 39 (at 0–1h), 30 (>1–3h), 27(>3–6h), 21 (>6–12h), and 7 (>12–24h) lives saved per 1000 treated (Fig. 31.3).

Others also studied the benefits of therapy within 1 hour.[60] Boersma et al[61] reappraised very early therapy based on a larger database (50 246 patients, derived from all randomized trials of >100 patients). The absolute mortality reduction for treatment within 1 hour of symptom onset was 65 per 1000. The delay/benefit relation (Fig. 31.4) was non-linear. Other studies have demonstrated that if fibrinolytic therapy is given within 70 minutes of symptom onset, the mortality rate of STEMI can be as low as 1.4%[62] and in certain circumstances, very early therapy can even

result in aborted myocardial infarction.[63] This information has led to a push to provide fibrinolytic therapy in the prehospital setting. The ACC/AHA guidelines have given an indication (**Class IIa, Level A**) for the establishment of a prehospital fibrinolysis protocol in (1) settings in which physicians are present in the ambulance or (2) well-organized EMS systems with full-time paramedics who have 12-lead ECGs in the field with transmission capability, paramedic initial and ongoing training in ECG interpretation and STEMI treatment, on-line medical command, a medical director with training/experience in STEMI management, and an ongoing continuous quality improvement program.

Benefit of delayed (>6 hour) therapy

In contrast to earlier therapy, the benefit of fibrinolysis after 6 hours is less certain. The Late Assessment of Thrombolytic Efficacy (LATE) study[64] enrolled 5711 patients with evidence of AMI between 6 and 24 hours from symptom onset and randomized them to tPA (100 mg over 3 h) or placebo. A 26% relative mortality reduction (8.9% vs 11.9%, P = 0.02) was observed for those treated within 12 hours. The 12–24 hour subgroup showed a non-significant trend to benefit (8.7% vs 9.2% mortality rate). The South American EMERAS collaborative group[65] treated 4534 patients with IV SK or placebo within 24 hours after onset of suspected AMI and found a non-significant trend towards a mortality benefit between hours 7 and 12 (SK 1 l.7%, placebo 13.2%). Along with other late treatment trials,[58] these have provided the rationale for recommending fibrinolysis for hours 7–12 after the onset of AMI in patients with persistent symptoms and ECG changes.[66]
Figure 31.3 The effect of fibrinolytic therapy on mortality in various patient subsets classified according to duration of symptoms before treatment: (above) mortality in each subgroup of fibrinolytic treated (black bars) versus placebo-treated (white bars) patients; (below) absolute benefit (lives saved per 1000 treated, standard deviation in parentheses) with confidence intervals. (Based on data from FTT Collaborative Group.[57])
Figure 31.4 Absolute 35-day mortality reduction versus treatment delay: small closed dots, information from trials included in FTT analysis; open dots, information from additional trials; small squares, data beyond scale of X/Y cross. The linear (34.7–1.6X) and non-linear (19.4–0.6X + 29.3X⁻¹) closed regression lines are fitted within these data, weighted by the inverse of the variance of the absolute benefit at each data point. The black squares denote the average effects in six time-to-treatment groups (areas of squares inversely proportional to the variance of absolute benefits described). Risks of fibrinolytic therapy

Bleeding

Bleeding is the primary risk of fibrinolytic therapy. Intracranial (or intracerebral) hemorrhage (ICH) is the most important bleeding risk, occurring in about 0.5–1.0%, with substantial risk of fatality (44–75%) or disability.[67–71] Non-cerebral but not cerebral bleeding risk has benefited by increased fibrin selectivity. The absolute and relative contraindications to fibrinolytic therapy are summarized in Table 31.2.[59]

The risk of ICH varies with patient characteristics, the fibrinolytic agent, and adjunctive antithrombotic therapy. Simoons *et al*[70] identified four independent predictors of increased ICH risk: age >65 years (odds ratio (OR) 2.2; 95% confidence interval (CI) 1.4–3.51), weight <70 kg (OR 2.1; 95% CI 1.3–3.2), hypertension on admission (OR 2.0; 95% CI 1.2–3.2), and use of tPA (alteplase) (OR 1.6; 95% CI 1.0–2.5) versus SK. The GUSTO-1 group[71] identified seven

---

Table 31.2 Contraindications and cautions for fibrinolysis in STEMI*

Absolute contraindications
  Any prior ICH
  Known structural cerebral vascular lesion (e.g. arteriovenous malformation)
  Known malignant intracranial neoplasm (primary or metastatic)
  Ischemic stroke within 3 months EXCEPT acute ischemic stroke within 3 hours
  Suspected aortic dissection
  Active bleeding or bleeding diathesis (excluding menses)
  Significant closed-head or facial trauma within 3 months

Relative contraindications
  History of chronic, severe, poorly controlled hypertension
  Severe uncontrolled hypertension on presentation (SBP greater than 180 mmHg or DBP greater than 110 mmHg)
  History of prior ischemic stroke greater than 3 months, dementia, or known intracranial pathology not covered in contraindications
  Traumatic or prolonged (greater than 10 minutes) CPR or major surgery (less than 3 weeks)
  Recent (within 2–4 weeks) internal bleeding
  Non-compressible vascular punctures
  For streptokinase: prior exposure (more than 5 days ago) or prior allergic reaction
  Pregnancy
  Active peptic ulcer
  Current use of anticoagulants: the higher the INR, the higher the risk of bleeding

ICH, intracranial hemorrhage; SBP, systolic blood pressure; DBP, diastolic blood pressure; CPR, cardiopulmonary resuscitation; INR, international normalized ratio; MI, myocardial infarction.
*Viewed as advisory for clinical decision making and may not be all-inclusive or definitive.

---

predictors of ICH: advanced age, lower weight, history of cerebrovascular disease, history of hypertension, higher systolic or diastolic pressure on presentation, and randomization to tPA (vs SK). In contrast, the incidence of non-cerebral bleeding is higher with SK.[72]

The safety of bolus compared with infusion administration of fibrinolysis for ICH was questioned by a meta-analysis of several different agents.[73] However, problems with the meta-analysis have been raised[74,75] and large, well-controlled trials of the two bolus agents in general use, RPA[76] and TNK-PA,[77] have not shown excess ICH rates compared with front-loaded rt-PA.

The critical importance of dose and adjunctive therapies to ICH risk is now realized. Excessive ICH was observed with tPA doses >100 mg.[48] Excessive adjunctive therapy (for example, heparin, hirudin, glycoprotein IIb/IIIa receptor inhibition) with fibrinolytics also has resulted in unacceptable rates of bleeding including ICH.[78–80] In the GUSTO-I trial, the risk of ICH increased with aPTT levels beyond 70 seconds.[81] Three concurrent trials[77,78,79] were stopped prematurely and reconfigured because of excessive hemorrhage. With lower doses of antithrombins, hemorrhage rates subsequently decreased. Recommendations for adjuvant heparin therapy have been adjusted downward to 60 U/kg bolus (maximum 4000 units) and 12 units/kg/h (maximum 1000 units), adjusted after 3 hours to maintain aPTT at 50–70 seconds for 48 hours.[66]

Previously, prolonged cardiopulmonary resuscitation (CPR) has been considered a contraindication to fibrinolytic therapy. However, Bottiger *et al* observed 90 patients with AMI who had out-of-hospital cardiac arrest.[82] Patients treated with heparin and tPA more frequently had return of spontaneous circulation (68% vs 44%, *P* < 0.03), admission to the ICU (*P* < 0.01), and survival to discharge (15% ~ 8%). Bleeding complications were not problematic.

Allergy, hypotension, and fever

Streptokinase is antigenic and may be allergenic although serious anaphylaxis or bronchoconstriction is rare (<0.2–0.5%).[56] In ISIS-3[69] any allergic-type reaction was reported after SK in 3.6% and tPA in 0.8%; only 0.3% and 0.1%, respectively, required treatment. Angioneurotic and periorbital edema, hypersensitivity vasculitis, serum sickness or renal failure due to interstitial nephritis, and purpuric rashes have been rarely reported, especially after repeat administration.[41,56,69] SK may acutely release bradykinin, a vasodilator. The incidence of clinical hypotension after SK (11.8%) was greater than after tPA (7.1 %);[69] only half of episodes required treatment.

Fever occurs in 5–30% of SK-treated patients. Delayed-type hypersensitivity may provoke fever and may respond to acetaminophen. The role of fibrinolytics in reports of splenic rupture, aortic dissection, and cholesterol embolization is uncertain.

Reinfarction

Although reperfusion may be effected by fibrinolytic therapy, repeat thrombosis and its associated reinfarction is a known, potentially devastating risk after fibrinolytic therapy. In a combined analysis of several fibrinolytic trials including more than 20000 subjects, Gibson et al[83] reported that the frequency of symptomatic recurrent MI during the index hospitalization was 4.2%, and was associated with an increased 30-day mortality (16.4% vs 6.2%, $P = 0.001$).

Comparative fibrinolytic trials

After establishing the general utility of fibrinolysis in STE-AMI, clinical trials focused on comparisons with new drug regimens. The GISSI-2/International Study Group trial[84,85] randomized 20891 patients with STEM1 <6h to tPA (alteplase, 100 mg/3 h) or SK (1.5 MU/L h) and to subcutaneous (SC) heparin (12500U twice daily) beginning 12 hours later, or no heparin. Aspirin and atenolol were given as standard therapies. In-hospital mortality was SK 8.5% and tPA 8.9% (P = NS). ICH rates were 0.5% and 0.8% respectively; other major bleeds were most frequent with SK plus heparin. At 35 days, death or severe left ventricular dysfunction did not differ by fibrinolytic. Delayed, SC heparin added little benefit (RR 0.95; 95% CI 0.86–1.04).

The third ISIS study (ISIS-3)[69] randomized 41299 patients with suspected AMI <24h old to receive SK (1.5 MU/L h), tPA (duteplase 0.6 MU/kg/4h) or the streptokinase analog anisoylated plasminogen streptokinase activator complex (APSAC) (30U/3 min) and to SC heparin (12500U, 4 hours after beginning thrombolytics and bid) or no heparin. Aspirin (162 mg/day) was given to all patients. The median time to treatment was 4 hours; 88% presented within 6 hours and had ST elevation. Mortality rates at 35 days were: SK 10.6%, APSAC 10.5%, and tPA 10.3% overall, and 10.0%, 9.9%, and 9.6%, respectively, in those with clear indications (P = NS). Similar outcomes also were observed

after 6 months. SC heparin tended to improve 1-week mortality (7.4% vs 7.9%, $P = 0.06$) at the expense of increased bleeding, but mortality rates at 35 days were similar (10.3% vs 10.6%, P = NS).

In comparing fibrinolytic regimens, GISSI-2 and ISIS-3 were limited by the suboptimal use of heparin for short-acting fibrin-selective tPA (SC dosing after a delay of 4–12 hours); treatment was relatively late (mean times >4 hours) and did not require ST elevation (ISIS-3), and tPA was not front-loaded.[86–88]

These concerns led to the proposal that tPA might be most effective if given in an accelerated dosing regimen and in combination with IV heparin. Table 31.3 summarizes the results of studies comparing various treatment strategies with accelerated dose tPA. The Global Use of Streptokinase and tPA for Occluded Coronary Arteries (GUSTO) study[42] randomized 41021 patients with STEMI <6h to:

- SK 1.5 MU/L h with SC heparin 12500U every 12h starting 4h after SK
- SK 1.5 MU/L h with IV heparin, 5000U bolus then l000U/h, titrating aPTT to 60–85 seconds
- front-loaded tPA (15 mg bolus, 0.75 mg/kg (maximum 50 mg) over 30 minutes, then 0.50 mg/kg (maximum 35 mg) over 60 minutes, for a maximum of 100 mg over 90 minutes) and IV heparin as per the SK regimen
- a combination of tPA 1.0 mg/kg and SK 1.0 MU, administered concurrently over 60 minutes, plus IV heparin.

The primary endpoint, 30-day mortality, was lowest with accelerated tPA with IV heparin (6.3%), representing a 14% risk reduction (P = 0.001) compared to the two SK strategies (7.3%), which did not differ. Combined tPA and SK gave an intermediate outcome. The risk of hemorrhagic stroke was higher with tPA (0.7%) than SK (0.5%), but the combined endpoint of death or disabling stroke favored tPA (6.9% vs 7.8%, P = 0.006). Implications of GUSTO for selection of fibrinolytic regimens have been debated.

Table 31.3 Clinical endpoints in comparative trials of various agents with accelerated tPA

Endpoints	GUSTO-I		ASSENT-II		GUSTO-III		In-TIME-II		
	SK	tPA	SK + tPA	tPA	TNK	tPA	rPA	tPA	nPA
30-day death (%)	7.3	6.3*	7.0	6.2	6.2	7.2	7.5	6.6	6.8
Reinfarction (%)	3.7	4.0	4.0	3.8	4.1	4.2	4.2	5.5	5.0
Any stroke (%)	1.3	1.6	1.7	1.7	1.8	1.8	1.6	1.5	1.9
Hemorrhagic (%)	0.5	0.7*	0.9	0.9	0.9	0.9	0.9	0.6*	1.1*
Major bleed (%)	6.0	5.4*	6.1	5.9*	4.7*	1.2	1.0	0.6	0.5

*$P < 0.001$ for comparisons.

Comparative trials with bolus fibrinolytics

Reteplase

INJECT (International Joint Efficacy Comparison of Thrombolytics)[46] compared reteplase (rPA) and SK in a 6010-patient double-blind, randomized trial. Mortality rates at 35 days were rPA 9.0% and SK 9.5% (0.5% absolute reduction; 95% CI 1.9–0.96). On this basis "equivalence" (non-inferiority) of rPA to standard, SK therapy, was established and rPA approved. Reteplase was next favorably compared to tPA in an angiographic study, leading to a large mortality study. In RAPID 2 (Reteplase vs Alteplase Patency Investigation During acute myocardial infarction),[89] 90-minute TIM1 grade 2 or 3 patency rates among 324 patients were 83% vs 73% (rPA vs tPA, P = 0.03), with TIMI-3 flow rates of 60% vs 45%, P = 0.01. On this basis, a comparative mortality trial, GUSTO-3,[75] was undertaken and randomized 15 059 patients 2:1 to rPA (two 10 mg IV injections 30 minutes apart) or accelerated tPA (alteplase). A postulated advantage for rPA was not demonstrated (30-day mortality: rPA 7.5%, tPA 7.2%).

Tenecteplase

Tenecteplase (TNK-tPA), a fibrin-selective, single-bolus fibrinolytic, was evaluated in the TIMI-10 dose-finding trials.[90–91] In Phase II studies, a clear dose–response was observed both for coronary patency and hemorrhage (including ICH for the 50 mg dose). With limitation and weight adjustment of TNK-tPA dose and reduction and earlier down-titration of heparin dosing, satisfactory bleeding rates and comparable TIMI-3 patency rates were demonstrated at 90 minutes compared to accelerated rt-PA.[92] The double-blind Phase III Assessment of the Safety and Efficacy of a New Thrombolytic-2 (ASSENT-2) mortality equivalence trial[77] compared weight-adjusted TNK (as a 30–50 mg bolus over 5–10 seconds) and accelerated rt-PA. All patients received aspirin and heparin. Thirty-day mortality rates were virtually identical for TNK-tPA (6.18%) and rt-PA (6.15%) and met statistical criteria for equivalence. ICH rates also were identical (at 0.93% and 0.94%, respectively). However, major non-cerebral bleeding was lower with the more fibrin-selective TNK (4.66% vs 5.94%, P < 0.0002) as was need for blood transfusion (4.25% vs 5.49%, P < 0.0002). A lower mortality rate with TNK-tPA was observed among patients presenting 4 hours after symptom onset (7.0% vs 9.2%), which may be due to either greater activity of the more fibrin-specific TNK-tPA against older, fibrin-rich clots or chance.

Thus, none of the newer fibrinolytic regimens has surpassed accelerated tPA. However, the ease of administration of TNK-tPA, together with its reduced transfusion requirements, has led to its general acceptance and favored status in national guidelines.[59] Lower rates of dosing errors with bolus fibrinolytics such as TNK-tPA also may contribute to superior clinical outcomes.[93]

Fibrinolysis in the elderly

The appropriate use of fibrinolytics in the elderly continues to be debated. In an analysis of over 37 000 Medicare patients with AMI age 65 or older who were eligible for fibrinolytic therapy,[94] 38% received fibrinolytic therapy and 4.2% received primary angioplasty. After multivariate adjustments, fibrinolytic therapy was not associated with improved 30-day survival (OR 1.01; 95% CI 0.94–1.09), whereas primary angioplasty was (OR 0.79; 95% CI 0.66–0.94). However, at 1 year, both fibrinolytic therapy (OR 0.84; 95% CI 0.79–0.89) and primary angioplasty (OR 0.71; 95% CI 0.61–0.83) were associated with lower mortality rates. Another Medicare analysis[95] suggested that fibrinolytic therapy might even be harmful in those over 75 years. In contrast, a large Swedish registry found a 12% risk reduction in the composite endpoint of cerebral bleeding and 1-year mortality.[96] Similarly, the Fibrinolytic Therapy Trialists' overview of randomized trials data in patients over 75 years reported 35-day mortality to be reduced (trend) from 29.4% to 26.0% with fibrinolytic therapy.[97] Analyses restricted to elderly patients with clear indications for fibrinolytic therapy suggested similar or greater absolute benefit from fibrinolytic therapy than in younger patients. Fibrinolytic regimens should be chosen to minimize the risk of ICH, which increases in the elderly. Weight-adjusting treatment regimens and avoidance of excessive heparin and other adjunctive antithrombotics (for example, Gp IIb/IIIa inhibitors) are important. When safety concerns predominate, SK, which carries a lower risk of ICH, or primary angioplasty should be considered as preferred reperfusion strategies in the elderly.

Fibrinolysis after early presentation

Time from onset of symptoms to fibrinolytic therapy is an important predictor of MI size and patient outcome.[98] The efficacy of fibrinolytic agents in lysing thrombus diminishes with the passage of time.[99] Fibrinolytic therapy administered within the first 2 hours (especially the first hour) can occasionally abort MI and dramatically reduces mortality.[100,101] This has lead the recent ACC/AHA guidelines to recommend that if there might be any delay in getting a patient to the catheterization laboratory who has presented with STEMI within 2 hours of symptom onset, then fibrinolysis might be the preferred therapy.[66] Additionally, the National Heart Attack Alert Working Group[102] recommends that emergency departments strive to achieve a 30-minute door-to-needle time to minimize treatment delays. Finally, prehospital fibrinolysis reduces treatment delays by up to 1 hour and reduces mortality by 17%.[103]

Primary angioplasty

Primary percutaneous coronary intervention (PCI) has been very successful in accomplishing mechanical reperfusion of the coronary artery in patients presenting with STEMI.[104] In the 1980s, the results of primary coronary angioplasty were reported from several single-center experiences.[105–108] These observational studies showed a patency rate of 87% to 95%, an in-hospital mortality rate of between 1.5% and 9%, and an increase in left ventricular ejection fraction from admission to discharge. Although these were not randomized, controlled studies, the results were better than those of fibrinolytic therapy. O'Keefe and co-workers reported 1000 consecutive patients undergoing primary coronary angioplasty at the Mid America Heart Institute.[109] The recanalization rate in infarct-related arteries was 94% and the mortality rate 7.8%. The independent risk factors for in-hospital mortality were cardiogenic shock, failure of reperfusion, age over 70 years, a left ventricular ejection fraction of 40% or less, and anterior myocardial infarction. The results encouraged further studies to test the superiority of primary coronary angioplasty.

Studies comparing primary PCI to fibrinolytic therapy

After the preliminary feasibility trials, a number of small randomized controlled trials compared various regimens of fibrinolytic therapy with balloon angioplasty. These studies were small in size compared to the studies of fibrinolytics versus placebo, and the results may not be generalizable. Also, the studies were limited in that third-generation fibrinolytics such as tenecteplase and reteplase along with modern regimens of heparin were not used; nor did they include the use of stents and glycoprotein IIb/IIIa receptor inhibitors in those patients treated by direct PCI. However, overall, the early randomized trials tended to favor direct balloon angioplasty over fibrinolysis in certain settings.

The PAMI (Primary Angioplasty in Myocardial Infarction) trial,[110,111] one of the first randomized studies, enrolled 395 patients with AMI seen within 12 hours of onset of chest pain. Patients were assigned randomly to undergo primary PTCA or receive intravenous t-PA infusion (100 mg over 3 hours). The trial demonstrated that primary PTCA reduced the composite outcome of in-hospital death, non-fatal reinfarction, recurrent ischemia or intracranial hemorrhage (OR 0.40; 95% CI 0.16–0.89) and also that of hospital days. At 2 years after reperfusion, patients treated with primary PTCA had a lower incidence of the composite of death, repeat myocardial infarction, repeat PTCA, recurrent ischemia, and hospital readmissions than patients who had t-PA.[112] Zijlstra et al[113] also reported significant

mortality benefit for direct angioplasty (OR 0.25; 95% CI 0.04–0.99).

Since these preliminary studies, a large number of other randomized clinical trials comparing primary PCI with fibrinolytic therapy have been performed. In a meta-analysis of 23 randomized STEMI trials comparing primary PCI with fibrinolytic therapy[114] (Fig. 31.5), there were significant reductions in short-term (4–6 weeks) and long-term (6–8 months) mortality, non-fatal MI, and stroke. Furthermore, when stratified according to the type of fibrinolytic agent, benefits of primary PCI were similar regardless of whether or not medical reperfusion was fibrin specific. Additionally, the analysis of the five trials involving patient transfer for primary PCI found similar treatment benefits, despite a mean treatment delay of 39 minutes with PCI.

The greatest absolute benefit of primary PCI occurs among patients at highest risk, as reported in several randomized trials. The Should We Emergently Revascularize Occluded Coronaries for Cardiogenic Shock (SHOCK) Trial[115] randomized 302 patients with cardiogenic shock to emergency revascularization versus medical stabilization, and demonstrated a significant improvement in mortality at at 6 months (50% versus 63% respectively, $P = 0.03$).

The importance of door-to-balloon time

Shorter door-to-balloon times have been shown in multiple analyses to be associated with lower mortality,[116] but this principle must be tied to the other critical time variable of symptom onset to presentation for medical care. Indeed "symptom onset-to-balloon" time may be a more critical time factor. For example, the Zwolle study group[117] analyzed data on 1791 patients who underwent primary PCI from 1994 to 2001. In their analysis, no relationship was found between door-to-balloon time and mortality. Instead, symptom onset-to-balloon time was significantly associated with angiographically favorable outcomes and 1-year mortality. Using multivariate analysis, a symptom onset-to-balloon time of more than 4 hours was identified as an independent predictor of 1-year mortality. But regardless of the time of symptom onset to patient presentation, the longer the door-to-balloon time, the longer the symptom onset-to-balloon time will also be. Because door-to-balloon time is something physicians have direct control over, it still remains a very important factor. To emphasize that point, a large cohort study of 29 222 STEMI patients treated with PCI within 6 hours of presentation at 395 hospitals that participated in the National Registry of Myocardial Infarction (NRMI)-3 and -4 from 1999 to 2002[118] showed that longer door-to-balloon time was associated with increased in-hospital mortality (mortality rate of 3.0%, 4.2%, 5.7%, and 7.4% for door-to-balloon times of 90

minutes or less, 91–120 minutes, 121–150 minutes, and more than 150 minutes, respectively; P for trend <0.01).

As the time delay for performing PCI increases, the mortality benefit for primary PCI over fibrinolysis decreases. When a STEMI patient presents to a center without interventional cardiology facilities, fibrinolytic therapy can generally be provided sooner than primary PCI.[119] Compared with a fibrin-specific lytic agent, a PCI strategy may not reduce mortality when a delay greater than 60 minutes is anticipated versus immediate administration of a lytic (Fig. 31.6).[120] This information has led to the National Guideline (**Class I, Level A**) stating that STEMI patients presenting to a facility without the capability for expert, prompt intervention with primary PCI within 90 minutes of first medical contact should undergo fibrinolysis unless contraindicated.[66] The balance of risk/benefit between the transfer of patients for PCI and more immediate treatment with fibrinolytic therapy remains uncertain. The DANAMI-2 trial

STEP 1: Assess Time and Risk
- Time since onset of symptoms
- Risk of STEMI
- Risk of fibrinolysis
- Time required for transport to a skilled PCI lab

STEP 2: Determine if Fibrinolysis or an Invasive Strategy is Preferred
If presentation is less than 3 hours and there is no delay to an invasive strategy, there is no preference for either strategy

Fibrinolysis is generally preferred if	**An Invasive Strategy is generally preferred if**

Early Presentation (less than or equal to 3 hours from symptom onset and delay to invasive strategy) (see below)

Figure 31.7 ACC/AHA 2004 guidelines for the assessment of reperfusion options for patients presenting with STEMI. STEMI = ST-elevation myocardial infarction; PCI = percutaneous coronary intervention; ICH = intracranial hemorrhage. *Applies to fibrin-specific agents. †Operator experience greater than a total of 75 Primary PCI cases/year.

‡Team experience greater than a total of 36 Primary PCI cases/year. §This calculation implies that the estimated delay to the implementation of the invasive strategy is greater than one hour versus initiation of fibrinolytic therapy immediately with a fibrin-specific agent.

(DANish trial in Acute Myocardial Infarction), found that patients treated at facilities without interventional cardiology capabilities had better composite outcomes with transfer for PCI within 2 hours of presentation than with pharmacologic reperfusion treatment at the local hospital.[121] Whether these results could be replicated elsewhere is not known. ACC/AHA practice guidelines for management of STEMI have made specific recommendations regarding the choice of primary PCI versus fibrinolytic therapy (Fig. 31.7) (**Class I, Level A**).[59]

Important technical aspects related specifically to mechanical reperfusion in the setting of STEMI

Balloon angioplasty versus coronary stents

Balloon angioplasty was the primary mode of mechanical reperfusion in most of the early primary PCI studies. However, soon after coronary stents became available for routine PCI, potential advantages of coronary stent deployment over "plain old balloon angioplasty (POBA)" during primary PCI were postulated. Through the placement of a coronary stent, a larger lumen diameter could be obtained and maintained, spontaneous or procedure-related coro-

nary arterial dissections could be sealed and the long-term risk of restenosis could be reduced.[122] However, the concern remained whether the acute plaque rupture and resulting thrombosis associated with STEMI would increase the risk of stent thrombosis.

To test this question, stent implantation in the setting of STEMI has been studied in comparison to fibrinolytic therapy and balloon angioplasty alone with and without concomitant Gp IIb/IIIa inhibitor therapy. Schomig *et al*[123] randomized 140 AMI patients to receive either accelerated intravenous tPA or direct coronary stenting plus abciximab. The median size of the infarct as measured by Tc^{99m} sestamibi scan was smaller in the stent plus abciximab group compared to the tPA group (14.3% vs 19.4%, $P = 0.002$). The combined endpoint of death, reinfarction or stroke was also lower in the stent plus abciximab group (8.5% vs 23.3%, $P = 0.02$). Le May *et al*,[124] in a smaller study of 123 AMI patients, reported that compared to accelerated tPA, stenting reduced the combined endpoint of death, reinfarction, stroke or repeat target vessel revascularization in a 6-month follow-up (24.2% vs 55.7%, $P < 0.001$). The median length of hospital stay was significantly reduced in the stented patients (4 days vs 7 days, $P = 0.001$). Kastrati *et al*[125] compared the administration of alteplase plus abcix-

imab with stenting plus abciximab in 162 AMI patients. Stenting was associated with greater myocardial salvage than alteplase (median 13.6% vs 8.0%, *P* = 0.007). Stenting therefore results in superior outcomes to fibrinolytic therapy if done in appropriate settings.

Primary stenting has been compared with primary angioplasty in several studies.[126,127] In meta-analysis there were no differences in mortality (3.0% vs 2.8%) or reinfarction (1.8% vs 2.1%) rates. However, major adverse cardiac events were reduced (OR 0.52, P < 0.001), driven by the reduction in subsequent target vessel revascularization with stenting (OR 0.43, P < 0.001).

Preliminary reports suggest that compared with conventional bare metal stents (BMS), drug-eluting stents (DES) are not associated with increased risk when used for primary PCI in patients with STEMI. In a study by Lemos *et al*,[128] postprocedure vessel patency, biomarker release, and the incidence of short-term adverse events were similar in patients receiving sirolimus (n = 186) or bare metal (n = 183) stents. Thirty-day event rates of death, reinfarction or revascularization were 7.5% versus 10.4%, respectively (*P* = 0.4). There are also a handful of noteworthy randomized clinical trials directly evaluating the efficacy of DES in AMI. These studies include the Paclitaxel Eluting Stent versus Conventional Stent in Myocardial Infarction with ST-segment Elevation (PASSION),[129] the Trial to Assess the Use of the Cypher Stent in Acute Myocardial Infarction Treated with Balloon Angioplasty (TYPHOON),[130] the Sirolimus Eluting Stent Versus Bare Metal Stent in Acute Myocardial Infarction (SESAMI),[131] and the Comparison of Angioplasty with Infusion of Tirofiban or Abciximab and with Implantation of Sirolimus Eluting or Uncoated Stents for Acute Myocardial Infarction (MULTISTRATEGY trial).[132] These trials are summarized in Table 31.4. Despite the many differences in trial design and primary study endpoints, these trial data generally support the safety of using DES in patients with AMI. It has been consistently observed that DES

significantly reduce restenosis without increasing the short-term risk of thrombosis, as compared with BMS implantation.[133,134] No national guidelines regarding the use of coronary stents during primary PCI have been given. However, based on results of the above studies, we offer the following guidelines: when performing primary PCI for patients presenting with STEMI, coronary stents, either BMS (**Class I, Level A**) or DES (Class I, Level B), should be used whenever technically feasible.

Intracoronary aspiration/thrombectomy devices

Significant clot burden may complicate acute STEMI management. Prospective clinical studies have shown that intracoronary thrombectomy and thrombus aspiration may improve TIMI-3 flow, hasten ST segment elevation resolution, and enhance myocardial tissue perfusion and reduce MI. The Thrombus Aspiration during Percutaneous Coronary Intervention in Acute Myocardial Infarction (TAPAS) trial[135,136] showed that patients with STEMI benefit from aspiration thrombectomy. In TAPAS, patients presenting with STEMI were randomized to initial aspiration thrombectomy versus standard PCI regardless of the presence or absence of angiographically visible thrombus. At 1-year follow-up, cardiac death was 3.6% (19 of 535 patients) in the thrombus aspiration group and 6.7% (36 of 536) in the conventional PCI group (hazard ratio (HR) 1.93; 95% CI 1.11–3.37; P = 0.020). One-year cardiac death or non-fatal reinfarction occurred in 5.6% (30 of 535) of patients in the thrombus aspiration group and 9.9% (53 of 536) of patients in the conventional PCI group (HR 1.81; 95% CI 1.16–2.84; P = 0.009). Rheolytic thrombectomy, which employs a more sophisticated mechanism, has a greater potential to successfully remove a larger thrombus burden compared to manual aspiration. However, in a clinical trial of 480 STEMI patients (including those without visible clot) randomly assigned to PCI alone or PCI with AngioJet™ (Possis, Minneapolis, MN) catheter thrombectomy, there was a greater

infarct size measured by sestamibi imaging at 14–28 days with thrombectomy compared to PCI alone (12.5% vs 9.8%).[137] We therefore propose the following guideline: when performing primary PCI for STEMI, aspiration thrombectomy prior to balloon inflation should be performed whenever possible (**Class I, Level B**).

Embolization protection devices

Embolization protection devices, including the Guard-Wire™ (Medtronic Inc, Minneapolis, MN) balloon occluding device and FilterWire™ (Boston Scientific, Natick, MA) filter basket device, were designed to enhance myocardial tissue perfusion by reducing distal embolization of athero-thrombotic debris. Although both devices have demonstrated the ability to improve outcomes in elective PCI of degenerated saphenous vein grafts,[138,139] no benefit has been found when applied to native vessels in the setting of STEMI. In the Drug Elution and Distal Protection in ST-Elevation Myocardial Infarction (DEDICATION) Trial,[140] 626 patients with STEMI and undergoing primary PCI were randomized to distal protection using the Filter-Wire™ or standard therapy. There was no significant difference in the occurrence of the primary endpoint of complete (≥70%) ST segment resolution (76% vs 72%, $P = 0.29$), no difference in maximum troponin-T (4.8μg/L and 5.0μg/L, $P = 0.87$) or maximum creatine kinase-MB (185μg/L and 184μg/L, $P = 0.99$), and no difference in median left ventricular wall motion index (1.70 vs 1.70, $P = 0.35$). The rate of major adverse cardiac and cerebral events 1 month after PCI was 5.4% with distal protection and 3.2% with conventional treatment ($P = 0.17$).

Likewise, in the Enhanced Myocardial Efficacy and Recovery by Aspiration of Liberated Debris (EMERALD) trial,[141] 501 patients presenting with STEMI and undergoing primary PCI or rescue intervention after failed thrombolysis were randomized to receive PCI with a balloon occlusion and aspiration distal microcirculatory protection system versus angioplasty without distal protection. The co-primary endpoints were ST segment resolution (STR) measured 30 minutes after PCI and infarct size measured by technetium Tc 99m sestamibi imaging between days 5 and 14 and secondary endpoints included major adverse cardiac events. Complete STR was achieved in a similar proportion reperfused with or without distal protection (63.3% (152/240) vs 61.9% (148/239), $P = 0.78$), and left ventricular infarct size was similar in both groups (median 12.0% (n = 229) vs 9.5% (n = 208), respectively; $P = 0.15$). Major adverse cardiac events at 6 months also occurred with similar frequency in the distal protection and control groups (10.0% vs 11.0%, respectively; $P = 0.66$). Based on these randomized trials we offer the following guideline: when performing primary PCI for STEMI, use of distal protection devices during balloon inflation is not generally recommended (**Class III, Level A**).

Although the explanation for the failure of these studies is unclear, smaller thrombus burden in native coronary arteries, premature embolization due to crossing the infarct-related stenotic lesion with the device, delayed reperfusion due to the occlusive nature of the device, and difficulty in protecting vulnerable side branches are thought to be several possibilities.

The use of bypass surgery in the setting of STEMI

With the advent of stents for acute vessel closures, the percentage of patients requiring emergency bypass surgery for acute myocardial infarction has fallen below 1% in contemporary randomized studies of direct PCI.[37,128] However, earlier studies of direct PC1 and observational registries reported this rate as 4–6%.[115,116,142] Bypass surgery may be required owing to anatomic considerations, such as left main disease or coronary disease not suitable for immediate PCI, or mechanical complications from the MI such as acute severe mitral regurgitation, ventricular septal defect or a failed PCI. Observational studies report that stable patients with acute MI can undergo bypass surgery with good results, but the complexity of performing cardiac surgery in patients with acute MI and potentially other manifestations like failed PCI or cardiogenic shock is definitely greater. Randomized studies comparing surgery to medical therapy or PC1 in this situation are lacking.

When bypass surgery was the only available therapy for acute coronary reperfusion in the 1970s, there were some studies that reported surprisingly good results. DeWood *et al*[143] reported on their experience with 187 patients treated with early coronary bypass surgery. In this observational study, all patients under 65 years of age who presented with ST segment elevation underwent cardiac catheterization. After exclusion of 28 patients (co-morbidity, diffuse or no coronary disease), 187 patients were treated with bypass surgery and 200 were treated medically. Although treatment was not randomly assigned, the groups were well balanced in terms of age, prior history, and presenting signs and symptoms. Hospital and long-term mortality was lower in the bypass patients (5.8% vs 11.5%, $P = 0.08$ in hospital; 11.7% vs 20.5%, $P < 0.03$ at 56 months). In surgical patients placed on cardiopulmonary bypass within 6 hours of symptoms, hospital mortality was 2%. Similar results have been reported in 261 patients treated with acute bypass surgery at the Iowa Heart Center (hospital mortality 5.7%).[144]

These findings, however, are limited by the fact that the comparisons between surgical and medical therapy were not randomized. Patients were excluded from the surgical cohort due to coronary anatomy, co-morbidity or shock. Thus, these excellent results are probably not generalizable to the larger population of acute infarct patients.

In the PAMI-2 study of AMI patients treated with direct angioplasty, 10.9% underwent cardiac surgery before hospital discharge, 57% of whom underwent the surgery urgently.[145] The in-hospital mortality was 6.4% in those who underwent surgery urgently versus 2.0% in the elective surgery group. The mortality associated with bypass surgery after AMI increases with the instability of the patient. Lee et al[146] reported on 316 patients undergoing bypass surgery after AMI, among whom the mortality was 1.2% in stable patients and 26% in patients with cardiogenic shock. Hochman et al[147] reported the results of a randomized study comparing medical therapy versus revascularization therapy in 304 patients with acute MI and cardiogenic shock. In the revascularization group 64% were treated with angioplasty and 36% with surgery. At 30 days the mortality was 46.7% in the revascularization group versus 56% in the medical therapy group (*P* = 0.11) but at 6 months the mortality was significantly lower in the revascularization group (50.3% vs 63.1%, *P* = 0.027). There was no difference in mortality between the angioplasty group (45.3%) and the surgery group (42%). Although patients have a high mortality when they present with AMI and cardiogenic shock, a revascularization strategy may improve the outcome in selected patients.

As a subgroup, patients ≥75 years of age had higher mortality with the revascularization strategy (RR 1.41; 95% CI 0.97–2.03) than medical therapy. Therefore, it is unclear at this time whether elderly patients in cardiogenic shock should undergo revascularization therapy in the setting of an acute MI.

The 2004 American College of Cardiology/American Heart Association practice guidelines for the treatment of AMI[59] recommend that acute bypass surgery should be undertaken in the following circumstances:

• failed PCI with persistent pain or hemodynamic instability in patients with coronary anatomy suitable for surgery
• persistent or recurrent ischemia refractory to medical therapy in patients who have coronary anatomy suitable for surgery, have a significant area of myocardium at risk, and are not candidates for PCI or fibrinolytic therapy
• at the time of surgical repair of postinfarction ventricular septal defect or mitral valve insufficiency
• cardiogenic shock in patients less than 75 years old with ST elevation or LBBB or posterior MI who develop shock within 36 hours of STEMI, have severe multi-vessel or left main disease, and are suitable for revascularization that can be performed within 18 hours of shock, unless further support is futile because of the patient's wishes or contraindications/unsuitability for further invasive care
• life-threatening ventricular arrhythmias in the presence of greater than or equal to 50% left main stenosis and/or triple-vessel disease (**Class IIa, Level B**).

They also report that emergency CABG can be useful as the primary reperfusion strategy in patients who have suitable anatomy and who are not candidates for fibrinolysis or PCI and who are in the early stages (6–12 hours) of an evolving STEMI, especially if severe multivessel or left main disease is present. Also emergency CABG can be effective in selected patients 75 years or older with ST elevation, LBBB or posterior MI who develop shock within 36 hours of STEMI, have severe triple-vessel or left main disease, and are suitable for revascularization that can be performed within 18 hours of shock (**Class IIa, Level B**).

Conclusion

Acute ST segment elevation myocardial infarction remains one of the most dramatic cardiovascular complications of the modern world. STEMI is generally initiated by the rupture of a coronary arterial atherosclerotic plaque, the end result of which is a total thrombotic occlusion of the vessel. The most important initial management of STEMI is the timely and effective reperfusion of the acutely occluded coronary artery. This may be accomplished either by pharmacologic means, using fibrinolytic agents, or by mechanical means, using PCI or CABG. The most appropriate method of reperfusion depends on the baseline characteristics of the patient, the specific details of the STEMI presentation and the availability of timely PCI. In general, when timely PCI is available within a door-to-balloon time of 90 minutes, it is the preferred method of reperfusion. In most other circumstances, fibrinolysis still remains a viable option for therapy.

32 Antithrombotic therapies for patients with ST segment elevation myocardial infarction

Andrew J Lucking and Keith A A Fox

University of Edinburgh, Edinburgh, Scotland, UK

Introduction

Acute coronary syndromes (ACS) are caused by rupture or erosion of an atherosclerotic plaque leading to exposure of plaque contents and constituents of the vessel wall to flowing blood.[1] Driven primarily by the aggregation and adhesion of platelets to collagen and von Willebrand factor (vWF), subsequent thrombin generation promotes thrombus formation that may ultimately result in total or partial vessel occlusion. The principal aim of initial management in patients presenting with ST segment elevation myocardial infarction (STEMI) is to restore normal flow in the infarct-related artery as soon as possible.[2,3] This has been shown to preserve left ventricular function[4] and improve survival rate.[5] Reperfusion may be achieved mechanically using percutaneous coronary intervention (PCI) or pharmacologically with a fibrinolytic agent. Given that thrombus formation and dissolution is a dynamic process, adjunctive antithrombotic therapy is important in both establishing and maintaining patency of the infarct-related vessel. In addition, antithrombotic agents help prevent complications of STEMI including deep vein thrombosis, pulmonary embolism and left ventricular thrombus. For the increasing number of patients treated with primary PCI, iatrogenic vessel injury and stent insertion can promote further local thrombosis and may result in acute vessel closure.[6,7] The beneficial role of antithrombotic therapies, particularly antiplatelet agents, in reducing these events is well established.[8–11] For those treated with a fibrinolytic agent, antithrombotic therapies are also important. Whilst fibrin-specific agents promote local clot lysis in the infarct-related vessel, they may result in a systemic prothrombotic state through enhanced thrombin generation[12] and platelet activation.[13]

Although the development of antithrombotic agents has focused primarily on reducing thrombotic and ischemic complications, the importance of safety as well as efficacy of novel agents and regimens is increasingly recognized. Antithrombotic therapy is associated with an increased risk of bleeding and accompanying adverse outcomes, including death. The relationship between antithrombotic therapy, bleeding and ischemic events is complex. Whilst the adverse effects of fatal and intracranial hemorrhage may be clear, bleeding may also result in the premature cessation of antithrombotic therapy or necessitate blood transfusion which are themselves associated with an increased incidence of ischemic complications.

This chapter will examine evidence for antithrombotic use in patients with acute STEMI. Where possible, in order to enhance clinical relevance, discussion will be presented according to reperfusion strategy: those who have undergone primary PCI; those who have received fibrinolytic therapy; and those who have received no specific reperfusion therapy.

Antiplatelet agents

The role of platelets in STEMI

Platelets are central to the pathophysiology of arterial thrombosis (Fig. 32.1). Following rupture or erosion of an atherosclerotic plaque, platelet adhesion, activation and aggregation occur sequentially, culminating in formation of a platelet-rich thrombus. Platelet adhesion is mediated by the interaction of platelet surface receptors with exposed subendothelial proteins including vWF and collagen. Subsequent activation involves a conformational change in platelet shape from smooth discoid to spiculated, vastly increasing the surface area available for thrombin generation. Following conformational change, degranulation and secretion of prothrombotic and inflammatory mediators propagate and amplify the thrombotic process. The final
Figure 32.1 Schematic diagram showing the mechanisms responsible for thrombus formation at the site of a ruptured atherosclerotic plaque and the site of action of antithrombotic agents. ADP, adenosine diphosphate; ASA, acetylsalicyclic acid; AT III, antithrombin III; GP, glycoprotein receptor; LMWH, low molecular weight heparins; TF, tissue factor; TxA₂, thromboxane A₂; UFH, unfractionated heparin; VWF, von Willebrand factor.

step, platelet aggregation, involves glycoprotein IIb/IIIa receptor-mediated cross-linking of platelets via fibrinogen bridges.

Aspirin

Aspirin (acetylsalicylic acid, ASA) was the first antiplatelet therapy to be described and remains the principal agent used in the secondary prevention of all forms of cardiovascular disease. It exerts its antiplatelet effect by irreversibly inhibiting platelet cyclo-oxygenase 1. This results in decreased production of the platelet agonist and potent local vasoconstrictor, thromboxane A2.

The benefit of ASA in the context of acute myocardial infarction (MI) was established in the Second International Study of Infarct Survival (ISIS-2).[14] This 2 × 2 double-blind trial randomized patients (n = 17 187) to ASA (162.5 mg daily for one month), streptokinase (SK, 1.5 million IU over

one hour), both or neither. Aspirin reduced cardiovascular mortality at one month by 23% compared with placebo (9.4% versus 11.8%, relative risk reduction (RR) 23%, $P < 0.00001$). The benefit was maintained over at least 10 years of follow-up.[15] Aspirin also reduced rates of reinfarction (odds ratio (OR) 0.51) and stroke (OR 0.49) compared with placebo without a significant increase in major bleeding or stroke.

A 1992 meta-analysis suggested that ASA (loading dose 162–325 mg, maintenance dose 75–162 mg/day) reduces the incidence of vascular events (cardiovascular death, MI and stroke) following STEMI by almost a third (relative RR 30%).[16] Recent studies support earlier observations that compared to larger doses given long term, those in the range of 75–162 mg/day deliver efficacious antiplatelet activity[17] but with improved side-effect and safety profiles.[18]

Aspirin should be administered immediately to all patients with STEMI at a dose of 162–325 mg and continued

indefinitely at a maintenance dose of 75–162 mg/day. The only exception is true aspirin allergy (**Class I, Level A**).

Thienopyridines

Thienopyridines exert their antiplatelet effect by irreversibly inhibiting the binding of adenosine diphosphate (ADP) to the platelet P2Y12 receptor. As their mechanism of action is distinct from that of ASA, the effect of dual therapy is additive. Clopidogrel is currently the most widely used thienopyridine, being as efficacious as ticlopidine but possessing a more benign safety profile.[19] Trials in patients with unstable angina (UA), non-STEMI[18] and more latterly STEMI have established it as a key component of contemporary integrated management protocols for all patients presenting with ACS. Despite clear benefits, it has a number of important limitations including a delayed onset of action,[20] a prolonged effect following cessation of therapy and inter-individual variation in antiplatelet effect[21,22] that has been associated with an increased risk of ischemic events in poor responders.[21,23] These limitations have prompted the development of novel agents, including prasugrel, capable of more rapid, consistent and efficacious inhibition of ADP-induced platelet aggregation than clopidogrel.

Thienopyridines in patients receiving fibrinolytic therapy

The use of clopidogrel in combination with a fibrinolytic agent was investigated in the CLARITY-TIMI-28 (Clopidogrel as Adjunctive Reperfusion Therapy (Thrombolysis In Myocardial Infarction)) trial.[24] This study randomized patients (n = 3491) with STEMI to either clopidogrel (300 mg loading dose, followed by 75 mg/day) or placebo in addition to ASA and a standard thrombolytic regime. The initial clopidogrel dose was administered concurrently or within 10 minutes of fibrinolysis. All patients had coronary angiography performed prior to discharge. The primary endpoint (a composite of an occluded infarct-related artery at angiography or death/MI prior to angiography) occurred in 15.0% of those in the clopidogrel group compared with 21.7% of those receiving placebo (relative RR 31%, *P* < 0.001). At 30 days, clopidogrel reduced the odds of cardiovascular death, reinfarction or need for urgent revascularization by 20% compared with placebo (14.1% versus 11.6%, *P* = 0.03). The overall reduction in clinical events was similar to that in patients with UA and NSTEMI treated with clopidogrel.[25] Encouragingly, there was no increase in TIMI major or minor bleeding. A subsequent analysis of patients who underwent coronary artery bypass grafting during the index admission found no increase in bleeding from randomization to the end of follow-up or from the time of surgery to the end of follow-up, including patients in whom clopidogrel was continued until within five days of surgery.[26]

The COMMIT/CCS-2 (Clopidogrel and Metoprolol in Myocardial Infarction Trial/Second Chinese Cardiac) Study also investigated the role of clopidogrel in a substantial cohort of patients with STEMI managed in non-interventional settings (n = 45852).[27] Patients were randomized to clopidogrel 75 mg/day or placebo for up to four weeks (mean 15 days) in addition to ASA. In contrast to the CLARITY-TIMI-28 trial, no loading dose of clopidogrel was administered, patients >75 years old were not excluded and the delay between symptom onset and fibrinolysis was longer (just under three hours in CLARITY-TIMI-28 compared with over 10 hours in COMMIT/CCS-2). In addition, only 55% received fibrinolysis (all with urokinase, a non-fibrin specific agent), whereas in CLARITY-TIMI-28 all patients received fibrinolysis (approximately two-thirds with a fibrin-specific agent and the remainder with SK). Despite the absence of a loading dose in COMMIT/CCS-2, there was a lower incidence of death, reinfarction or stroke during the index admission (9.3% versus 10.1% in the placebo group, relative RR 9%, *P* < 0.002). Rates of major bleeding were low and similar in those treated with clopidogrel and placebo (0.58% versus 0.55%, *P* = 0.59).

Despite differences in the design of the two studies, the results of CLARITY-TIMI-28 and COMMIT-CCS-2 demonstrate that addition of clopidogrel to standard therapy including ASA and fibrinolysis is safe and reduces the incidence of major vascular events and mortality.

Clopidogrel 75 mg/day should be administered to all patients with STEMI undergoing fibrinolytic therapy (**Class I, Level A**) and continued for at least 14 days (**Class I, Level B**).

For patients less than 75 years of age, it is reasonable to administer a loading dose of clopidogrel 300 mg (**Class IIa, Level B**).

Thienopyridines in patients undergoing primary PCI

Three trials, CREDO (Clopidogrel for the Reduction of Events During Observation),[20] the PCI arm of the CURE (Clopidogrel in Unstable Angina to Prevent Recurrent Events) trial (PCI-CURE)[25] and PCI-CLARITY, a substudy of the CLARITY-TIMI-28 trial, have considerably strengthened the evidence for early administration of clopidogrel alongside ASA in patients undergoing PCI in a wide range of clinical settings.

The PCI-CLARITY (Clopidogrel as Adjunctive Reperfusion Therapy) trial was a prospective subgroup analysis of patients (n = 1863) from the CLARITY-TIMI-28 study who underwent PCI following mandated angiography[28] (PCI was performed between two and eight days following admission and *not* as the primary reperfusion strategy). As discussed above, a 300 mg loading dose of clopidogrel or placebo was administered at the time of fibrinolysis, in addition to standard therapy (ASA, fibrinolytic and

unfractionated heparin (UFH) as appropriate). In contrast to other clopidogrel trials, patients in the control group also received clopidogrel (loading dose of 300–600 mg) after the diagnostic catheterization. All patients were given clopidogrel 75 mg/day for 30 days after the procedure. Thus, the trial compared pretreatment with clopidogrel with delayed administration at the time of PCI. In the pretreatment group, there was a 46% reduction in the odds of death, MI or stroke at 30 days compared with the delayed treatment group (3.6% versus 6.2%, $P = 0.008$). In addition, a 38% reduction in MI or stoke was observed prior to PCI ($P = 0.028$). The authors also performed a meta-analysis including data from CREDO (patients undergoing elective PCI) and PCI-CURE (patients with non-ST elevation acute coronary syndrome undergoing PCI) demonstrating a significant and consistent benefit of dual antiplatelet therapy initiated as early as possible prior to PCI.

Despite the size and consistency of data supporting the use of clopidogrel in the context of PCI, there have been no published studies specifically investigating its use in patients with STEMI undergoing primary PCI.

Limited data pertaining to the use of prasugrel in patients with STEMI undergoing PCI are available from the Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel–Thrombolysis in Myocardial Infarction (TRITON–TIMI) 38.[29] Moderate- to high-risk patients (n = 13 608) with ACS (with and without ST segment elevation) who were scheduled for PCI were randomized to either clopidogrel (300 mg loading dose followed by 75 mg daily) or prasugrel (60 mg loading dose followed by 10 mg daily) in addition to ASA and followed for a mean of 14.5 months. A quarter of the study population had STEMI (n = 3534) although the proportion of this subgroup that underwent primary compared to delayed PCI was not specified. In the overall study population, prasugrel reduced cardiovascular death, MI and stroke (9.9% with prasugrel versus 12.1% with clopidogrel, $P < 0.001$) and resulted in a marked reduction in stent thrombosis (2.4% versus 1.1% with clopidogrel, $P < 0.001$). Whilst all-cause mortality, MI, stroke and TIMI major bleeding (taken as a marker of overall clinical benefit) were reduced in the prasugrel group (12.2% versus 13.9% with clopidogrel, $P < 0.004$) there was an excess of TIMI major bleeding (2.4% versus 1.8%, $P = 0.03$) and fatal bleeding (0.4% versus 0.1%, $P = 0.002$). The balance of risk appeared to be in favor of prasugrel during the first few hours and days when it reduced ischemic events with little adverse effect on bleeding. Following this initial period, however, its ability to reduce ischemic events was limited and associated in the longer term with an excess of major bleeding compared to clopidogrel. It should be noted that study drugs were administered following angiography, and therefore prasugrel was effectively being compared with placebo for the first few hours following randomization as conversion of clopidogrel to its active metabolite takes a number of hours.

Whilst the results from TRITON-TIMI-38 suggest that greater inhibition of platelet function can reduce ischemic events, there is an associated increase in major bleeding. Although a limited subgroup analysis has been performed to assess bleeding risk, further analysis of the existing data as well as forthcoming trials will be necessary to define more precisely the patient subgroups in whom most benefit is obtained as well as the optimal timing, duration and dose in patients with ACS including patients with STEMI.

Glycoprotein IIb/IIIa receptor antagonists

The glycoprotein (Gp) IIb/IIIa receptor antagonists inhibit the Gp IIb/IIIa integrin, found exclusively on platelets and megakaryocytes. The interaction of the receptor with its primary ligand, fibrinogen, is considered the final common pathway of platelet aggregation and blockade results in inhibition of aggregation irrespective of the initial agonist. There are close to 100 agonists known to stimulate platelet aggregation. Given the central role of platelets in arterial thrombosis and the fact that ASA and clopidogrel inhibit only the thromboxane A2 and ADP pathways respectively, the Gp IIb/IIIa receptor antagonists represent an attractive potential therapy in patients with STEMI.

There are three Gp IIb/IIIa receptor antagonists currently licensed for use. Abciximab is a chimeric (murine-human) monoclonal antibody directed against the IIb/IIIa receptor whereas tirofiban and eptifibatide are both small-molecule non-competitive IIb/IIIa inhibitors.

Gp IIb/IIIa receptor antagonists in patients receiving fibrinolytic therapy

The combination of a Gp IIb/IIIa receptor antagonist with a fibrinolytic agent (in full and reduced dose) has been evaluated extensively in efforts to improve the outcome from pharmacologic reperfusion.

Gp IIb/IIIa receptor antagonists and full-dose fibrinolytics The relatively small Combined Accelerated t-PA and Platelet Glycoprotein Integrin Receptor Blockade with Integrillin in Acute Myocardial Infarction (IMPACT-AMI) study randomized patients (n = 180) to alteplase and either placebo or one of six doses of eptifibatide (in addition to ASA and UFH).[30] The highest dose of eptifibatide (180 μg/kg bolus followed by an infusion at a rate of 0.75 μg/kg/min) achieved higher rates of TIMI 3 flow at 90 minutes compared with placebo (66% versus 39%, $P = 0.007$). The accompanying major bleeding rates were 3.9% and 5.4% respectively. A further pilot study (n = 181) investigated the efficacy of three doses of eptifibatide (180 μg/kg bolus followed by an infusion at a rate of 0.75, 1.33 or 2 μg/kg/min) compared with placebo in combination with full-dose

SK.[31] There appeared to be an increase in the rate of TIMI 3 flow at 90 minutes with eptifibatide (44% for the combined eptifibatide groups versus 31% in the placebo group, $P = 0.07$). However, rates of bleeding were higher in those treated with the highest dose of eptifibatide compared with the two lower doses and placebo (17% versus 11% versus 0% respectively, $P = 0.007$).

In summary, these small angiographic pilot studies suggested that whilst the addition of Gp IIb/IIIa receptor antagonists to full-dose fibrinolytics was effective at increasing target vessel patency, there appeared to be an excess in bleeding.

Gp IIb/IIIa receptor antagonists and reduced-dose fibrinolytics

Angiographic studies The TIMI-14 trial investigated abciximab use in combination with SK or alteplase.[32] Patients (n = 888) were randomized to one of four treatment groups: alteplase only (100 mg); abciximab only (0.25 mg/kg bolus followed by a 12 h infusion of 0.125 µg/kg/min); abciximab with 20–65 mg of alteplase; or abciximab with 0.5–1.5 million IU of SK. The highest rate of TIMI-3 flow was seen with abciximab in combination with 50 mg of alteplase (77% at 90 minutes versus 62% in the alteplase-only group, $P = 0.02$). Overall, there was no significant difference in major bleeding between these two groups (7% versus 6% respectively, $P = $ ns). However, high bleeding rates led to discontinuation of treatment arms where abciximab was used in combination with SK.

The SPEED (Strategies for Patency Enhancement in the Emergency Department) trial randomized patients (n = 323) to either abciximab only (0.25 mg/kg bolus followed by a 12 h infusion of 0.125 µg/kg/min), reteplase only (two 10 mg boluses) or both (reteplase being given as a double bolus of 2.5–15 mg).[33] The rate of TIMI-3 flow with abciximab in combination with two 5 mg boluses of reteplase was 54% at 90 minutes. This compared with a rate of 47% in those given full-dose reteplase only. The rate of major bleeding was numerically higher with combination therapy compared with reteplase alone (9.8% versus 3.7%, $P = 0.11$).

In the INTRO-AMI (Integrellin and Low-Dose Thrombolytics in Acute Myocardial Infarction) study, eptifibatide was administered as a single (180 µg/kg) or double bolus (180 then 90 µg/kg or 180 then 180 µg/kg separated by 90 minutes), followed by an infusion of 1.33 or 2.00 µg/kg/min for 72 h in combination with 25 or 50 mg of alteplase.[34] The rate of TIMI-3 flow at 60 minutes was higher in those who received 50 mg of alteplase with eptifibatide 180 followed by 90 µg/kg bolus and a 1.33 µg/kg/min infusion compared to those receiving full-dose alteplase alone (56% versus 40%, $P = 0.04$). Rates of major bleeding and intracranial hemorrhage were again numerically higher in the group who received combination therapy (11% versus 6% and 3% versus 2% respectively; $P = $ ns for both).
Figure 32.2 Clinical outcomes in the ASSENT-3,[46] GUSTO-V,[47] and HERO-2[48] trials: (a) mortality; (b) reinfarction.

Studies with clinical endpoints Following the potentially encouraging results seen in the angiographic pilot studies, randomized trials with clinical endpoints have investigated the potential of combining a Gp IIb/IIIa receptor antagonist with a fibrinolytic agent (Fig. 32.2).

The ASSENT-3 (Assessment of the Safety and Efficacy of a New Thrombolytic Regimen) trial randomized patients (n = 6095) within six hours of onset of STEMI to one of three treatment arms: full-dose tenecteplase and enoxaparin, half-dose tenecteplase and UFH plus abciximab or full-dose tenecteplase and UFH (control group). Compared with the control group, patients in the abciximab group had a significant reduction in the primary combined endpoint of death, reinfarction or refractory ischemia at 30 days (11.1% versus 15.4%, $P < 0.0001$), although there was no difference in mortality rates. Major bleeding (excluding intracranial hemorrhage) was increased (4.3% versus 2.2%, $P < 0.005$) and in those over 75 years old there was an approximately threefold increase (13.3% versus 4.1% respectively, $P = 0.0002$).

The GUSTO-V (Global Use of Strategies to Open Occluded Arteries) trial randomized patients (n = 16 588) with STEMI presenting within six hours of onset to either full-dose (two 10 U bolus doses) or half-dose reteplase (two 5 U bolus doses) plus full-dose abciximab.[35] Although there was a reduction in the reinfarction rate at 30 days with combination therapy (7.4% versus 8.8% with reteplase alone, $P < 0.001$), overall mortality was similar (5.9% for reteplase alone versus 5.6% for reteplase plus abciximab, $P = 0.43$) and remained so at one year (8.4% in both groups).[36] In addition, there were again concerns over increased bleeding in those treated with combination therapy, with an increase in moderate to severe bleeding (excluding intracranial hemorrhage, 4.6% versus 2.3%; $P < 0.001$) and a trend towards an increase in intracranial

hemorrhage in those over 75 years old (2.1% versus 1.1%; $P = 0.07$).

The recently presented Facilitated Intervention with Enhanced Reperfusion to Stop Events (FINESSE) trial has helped to shed some light on the role of combining abciximab with a fibrinolytic agent. However, it is important to note that the trial was principally designed to evaluate whether facilitated PCI (with upstream delivery of abciximab with or without reteplase) was superior to primary PCI (with in-lab abciximab). Patients (n = 2452) with an estimated time to the catheterization laboratory of between one and four hours were randomized in a 1:1:1 fashion to upfront abciximab-facilitated primary PCI, half-dose reteplase/abciximab-facilitated PCI, or primary PCI with in-lab abciximab. Consistent with a recent meta-analysis,[37] the principal finding was that facilitated PCI provided no benefit and was associated with increased bleeding compared with standard primary PCI. There was no difference in the primary endpoint in the abciximab-only group compared to the combination group (9.8% versus 10.7% respectively, P = ns) but there was an increased incidence of TIMI major or minor bleeding (10.1% versus 14.5%, $P = 0.008$).

The use of abciximab in conjunction with half-dose reteplase or tenecteplase should be avoided in STEMI patients aged greater than 75 years due to an increased risk of intracranial hemorrhage (**Class III, Level B**).

Gp IIb/IIIa receptor antagonists in patients undergoing primary PCI

Primary PCI achieves TIMI-3 flow in the infarct-related artery in approximately 90% of patients. However, despite restoration of normal epicardial flow, flow within the downstream microvasculature and hence to the ischemic myocardium often remains impaired (the so-called "no reflow" phenomenon).[38–40] This may be a key determinant of long-term outcome as diminished microvascular flow is associated with increased cardiovascular complications and mortality.[40,41]

The role of Gp IIb/IIIa receptor antagonists in the setting of primary PCI has been evaluated in conjunction with ASA and UFH use. All trials referred to in the discussion below have evaluated the complementary role of Gp IIb/IIIa receptor antagonists in this context, unless otherwise stated.

Abciximab Abciximab is the most widely studied Gp IIb/IIIa receptor antagonist. It has consistently been shown to increase rates of TIMI-3 flow in the infarct-related vessel, in a time-dependent manner (Fig. 32.3).

The RAPPORT (ReoPro® and Primary PTCA Organization and Randomized Trial) study was the first substantive study to investigate the effect of abciximab on a clinical endpoint following primary PCI (n = 409).[42] It should be
Figure 32.3 TIMI-2 and -3 flow rates in patients with acute MI treated with abciximab prior to angiography in the TIMI-14,[32] Gold *et al*,[95] GRAPE,[96] ADMIRAL,[43] and SPEED[33] trials. The time intervals between administration of the abciximab bolus and angiography are shown. GRAPE, glycoprotein recepter antagonist patency evaluation.

noted that stent use in this study was restricted to "bail-out" use only (i.e. abrupt vessel closure or dissection). The trial demonstrated a reduction in the 30-day rate of death, reinfarction or target vessel revascularization (TVR) in the abciximab group compared to placebo (11.2% versus 5.8%, $P = 0.03$).

The ADMIRAL (Abciximab before Direct Angioplasty and Stenting in Myocardial Infarction Regarding Acute and Long-Term Follow-up) study evaluated the effect of abciximab in patients (n = 300) with STEMI prior to primary PCI.[43] A 41% reduction in the primary endpoint of death, reinfarction and TVR was observed at 30 days in the abciximab group (6.0% versus 14.6% in placebo group, $P = 0.01$), with a similar reduction at six months (7.4% versus 15.9%, $P = 0.02$). The investigators attributed the better outcome to higher levels of TIMI 3 flow in the target vessel before (16.8% versus 5.4%, $P = 0.01$) and after (95.1% versus 86.7%, $P = 0.04$) PCI. The association between postprocedural TIMI 3 flow and a lower incidence of major adverse cardiac event (MACE) at 30 days has also been observed in other studies.

The larger CADILLAC (Controlled Abciximab and Device Investigation to Lower Late Angioplasty Complications) trial randomized patients (n = 2082) with STEMI using a 2 × 2 factorial design to either abciximab or placebo, and either angioplasty or stenting.[44] Patients were also given ASA, UFH and either clopidogrel or ticlopidine prior to going to the catheterization laboratory. The principal finding was a halving in the incidence of the composite endpoint (death, MI, stroke or TVR) at six months with stent insertion compared to angioplasty (20.0% versus 10.2%, $P < 0.001$). There was only a small additional benefit with abciximab (11.5% after stenting alone versus 10.2% after stenting plus abciximab, P = ns) although this may

have been confounded by broad inclusion criteria and recruitment of a low-risk population coupled with relatively late administration of abciximab.

A meta-analysis of abciximab use in patients with STEMI undergoing primary PCI (n = 3266) demonstrated a reduction in the composite endpoint of death, reinfarction and need for TVR at 30 days (absolute RR 3.6%, relative RR 46%) and six months (absolute RR 3.2%, relative RR 20%).[45] A further meta-analysis of 11 trials (n = 27 115) also demonstrated a reduction in short (30-day) and long-term (6–12 months) mortality (absolute RR 1% and 1.8% respectively; relative RR 29% for both) with abciximab use in the context of primary PCI.[46] Neither demonstrated an increased incidence of intracranial hemorrhage although the latter analysis indicated an increase in the rate of major bleeding (absolute risk increase 1.2%, relative risk increase 68%, $P < 0.001$).

With regard to when best to administer a GP IIb/IIIa receptor antagonist in patients undergoing primary PCI, a meta-analysis of six small studies had suggested a greater prevalence of TIMI 2 or 3 flow in the infarct-related artery prior to PCI with early administration (41.7% versus 29.8%, $P < 0.001$).[47] However, the FINESSE study (n = 2452) demonstrated no benefit of upstream (prior to catheter laboratory) administration of abciximab (or indeed upstream abciximb in combination with half-dose reteplase) compared to in-catheter laboratory administration.[48]

Tirofiban and eptifibatide Whilst tirofiban and eptifibatide share a common mechanism of action with abciximab, there have been no substantive trials with clinical endpoints to assess their role in primary PCI, although small placebo-controlled studies suggest an increase in TIMI 2 or 3 flow in the infarct-related artery following early administration of tirofiban[49] and eptifibatide[50,51] respectively. The EVA-AMI trial, presented at the American Heart Association 2007 Scientific Sessions, randomized STEMI patients (n = 400) undergoing primary PCI to abciximab or eptifibatide. There were no significant differences in the primary endpoint (the rate of ST segment resolution 60 minutes following PCI) or the incidence of ischemic or bleeding events during the index admission. Similar results supporting the non-inferiority of tirofiban compared to abciximab were observed in the MULTISTRATEGY trial (n = 745).[52]

Patients with STEMI undergoing primary PCI should be treated with abciximab (**Class I, Level A**) as soon as possible prior to the procedure (**Class I, Level B**).

As an alternative, patients undergoing primary PCI may be treated with tirofiban or eptifibatide (**Class IIb, Level B**).

It should be emphasized that virtually all studies to date investigating the role of Gp IIb/IIIa receptor antagonists in STEMI patients undergoing primary PCI have been con-

ducted prior to the routine administration of clopidogrel. Interestingly, in the CADILLAC study, which failed to show a significant benefit of abciximab, patients *were* pretreated with a thienopyridine in addition to ASA. Whilst the study's broad entry criteria and subsequent recruitment of a relatively low-risk population may explain the lack of benefit with abciximab, it is possible that the routine administration of a thienopyridine diminished the relative efficacy of abciximab. The ON-TIME 2 study, showed a reduction in ST segment elevation at 60 minutes post-PCI (the primary endpoint) with tirofiban (initial 25 μg/kg bolus) compared with placebo.[53] Patients in this study were also pretreated with ASA and clopidogrel (600 mg) and although not powered for clinical endpoints, there were encouraging trends in MACE at 30 days.

Taken in conjunction with the results from the HORIZONS AMI trial, discussed below, it is clear that further studies are required to clarify the role of Gp IIb/IIIa receptor antagonists in STEMI patients pretreated with ASA and clopidogrel who are undergoing primary PCI.

Anticoagulant therapy

The coagulation cascade as a therapeutic target

Activation of the coagulation cascade plays an important role in thrombus formation during acute MI (see Fig. 32.1). Tissue factor, principally produced by monocytes within the plaque, binds to factor VII and initiates the extrinsic arm of the coagulation cascade, resulting in factor Xa generation. Factor Xa converts prothrombin to thrombin (factor IIa), the key enzyme responsible for the conversion of fibrinogen to its active form, fibrin. Multiple positive feedback mechanisms exist to enhance further production of factor Xa as well as promoting platelet activation and aggregation.

Under normal circumstances, the coagulation cascade is restrained by a number of mechanisms including the serine protease inhibitor antithrombin III (AT III). AT III binds to many of the activated coagulation factors, including thrombin and factor Xa, forming stable complexes that are no longer capable of proteolysis. The interaction between AT III and key coagulation factors is substantially enhanced by a number of endothelial cell proteoglycans. This catalytic function is reproduced by heparins.

Unfractionated heparin

Unfractionated heparin is the prototypical clinical anticoagulant. Despite important limitations (Table 32.1) it remains the most commonly used anticoagulant in clinical practice. It consists of a heterogenous mix of heparin mol-

Table 32.1 Clinical limitations of unfractionated heparin

Limitation	Clinical consequence
Non-specific binding to plasma proteins	Variability in anticoagulant effect
Cannot inactivate fibrin-bound thrombin	Reduced efficacy
Inhibited by platelet factor 4 and fibrin monomers	Leads to heparin resistance
Potential formation of antibodies against heparin	Can result in heparin-induced thrombocytopenia and thrombosis syndrome
Interaction with other drugs commonly used in the context of PCI	Variability in anticoagulant effect
Activates platelets	Potential for enhancing platelet aggregation

PCI, percutaneous coronary intervention.

Table 32.2 Benefits and risks associated with adjunctive delayed subcutaneous heparin in patients receiving streptokinase in the ISIS-3[22] and GISSI-2[21] studies

	Events per 1000 patients treated		
	ISIS-3	GISSI-2	Combined
Benefit			
Reduction in mortality	2.8	1.0	2.2[a]
Reduction in non-fatal MI	1.8	1.9	1.8
Risk			
Transfusions	2.6	4.5	3.2
Non-fatal strokes	0.5	0.6	0.6[b]

[a] Figures do not sum up because of rounding.
[b] Half of the patients had fully recovered by the time of discharge.

ecules, ranging in size from 5 to 35 kDa. It acts as an indirect inhibitor of factors IIa (thrombin) and Xa, exerting its effect by potentiating the action of AT III. Thrombin is the factor most sensitive to the effects of UFH, but requires "bridging" to the AT III/heparin complex by a heparin chain containing at least 18 saccharide units.

Unfractionated heparin in patients receiving fibrinolysis

Administration of fibrinolytic therapy results in a systemic prothrombotic state due to release of plasmin which activates platelets via the thrombin receptor[54] and triggers thrombin generation via activation of factor V.[55] The extent of thrombin activity induced by each agent appears to be directly related to the extent of free plasmin activity,[12] explaining why SK induces a more marked prothrombotic effect than the fibrin-specific agents alteplase, reteplase, and tenecteplase.[12] Exposure of clot-bound thrombin acts as a nidus for further thrombus formation and provides the rationale for the use of adjunctive anticoagulant therapy in patients treated with a fibrinolytic agent.

Angiographic studies A number of clinical trials have investigated the effect of UFH on vessel patency following fibrinolytic therapy.[5,56–60] Results are varied and interpretation is difficult owing to differences in use of ASA, fibrinolytic agent and regimen used and the timing of angiography. Overall, UFH does not appear to improve early (60–90 minute) infarct-related artery patency.[60] Although there may be some benefit at later time-points, no benefit was

seen when ASA was administered at a dose >100 mg which is now established clinical practice.

Clinical studies The Grupo Italiano per lo Studio della Sop-pravivvenza nell'Infarcto Miocardico (GISSI-2)[61] and the Third International Study of Infarct Survival (ISIS-3)[62] trials compared subcutaneous (SC) UFH with placebo as an adjunct to fibrinolysis in patients receiving SK, anistreplase and alteplase in addition to ASA (Table 32.2). In GISSI-2, patients (n = 20,891) were randomized to UFH or placebo 12 hours following administration of SK or alteplase. Unfractionated heparin was found to reduce mortality from 6.0% to 5.4% (relative RR 10%, P < 0.05). In ISIS-3 (n = 41 299), there was a trend towards a reduction in mortality with adjunctive UFH (7.4% versus 7.9% in the control group, P = 0.06). This may represent a benefit of four/five fewer deaths per 1000 during the treatment period, although due to substantial crossover of patients between treatment groups, it has been estimated that benefit was actually closer to seven lives per 1000 saved with UFH. At 30 days, although a similar trend remained, it was no longer statistically significant. Analysis of combined data from GISSI-2 and ISIS-3 suggested that in patients treated with SC UFH compared with control, there were two fewer deaths and two fewer non-fatal reinfarctions per 1000 patients, at the expense of three more transfusions and 0.6 more strokes (see Table 32.2).[63]

There is a paucity of data comparing the use of intravenous (IV) UFH in patients receiving fibrinolysis. Although four randomized controlled trials have addressed the issue and found no significant differences in mortality and rein-

Table 32.3 Effect of adjunctive intravenous heparin in patients treated with aspirin and fibrinolytic therapy

farction, all lacked the statistical power to appropriately evaluate these clinical outcomes (Table 32.3).[56,57,64]

A meta-analysis of patients (n = 68000) treated with various UFH regimens (93% of whom received fibrinolytic therapy) demonstrated a modest reduction in mortality (8.6% versus 9.1% in control group, relative RR 5.5%, $P = 0.03$) and reinfarction (3.0% versus 3.3%, relative RR 9%, $P = 0.04$) at 35 days. Major bleeding was higher in those receiving UFH (1.0% versus 0.7% in control group, $P = 0.001$).[65]

In summary, the balance between risk and benefit is not straightforward. Benefits appear modest and are at the expense of major bleeds including intracranial hemorrhage.

Unfractionated heparin in patients undergoing primary PCI

UFH has been used since the advent of PCI, principally to avoid thrombus formation at the site of balloon injury, at vascular access points and within guide catheters. Various advances have led to a steady reduction in the amount of intraprocedural UFH used, including the widespread use of stents, high-pressure stent deployment and co-administration of increasingly potent antiplatelet therapies. There are no large-scale data to guide the use of UFH in PCI and thus it remains relatively empiric. The data that do exist have been acquired in small-scale studies and principally in patients undergoing elective procedures. A meta-analysis of six randomized controlled trials suggested optimal benefit with an initial bolus of 70–100 U/kg aiming for an activated clotting time (ACT) of 350–375 s. In patients treated with a Gp IIb/IIIa receptor antagonist, this should be reduced to 50–70 U/kg, aiming for an ACT of 200 s.[66]

UFH is a useful anticoagulant in patients with STEMI undergoing primary PCI. Dose should be adjusted for weight and when used in conjunction with a Gp IIb/IIIa receptor antagonist (**Class I, Level C**).

Unfractionated heparin in patients not receiving reperfusion therapy

Data from 21 trials (n = 5459) performed prior to the introduction of fibrinolytic therapy or the widespread use of ASA, beta-blockers or angiotensin-converting enzyme inhibitors demonstrated a reduction in venous thromboembolic events, stroke, reinfarction and death with the use of UFH compared to placebo.[63,64] Overall, a relative reduction in mortality of 25% (95% confidence interval (CI) 10–37%) was observed although there were 10 ± 4 additional episodes of major bleeding per 1000 patients treated. Overall, however, there are no substantive randomized data to guide the use of UFH in patients managed using current recommended regimens.

Low molecular weight heparin

Low molecular weight heparins (LMWHs) are derived from UFH by chemical and enzymatic depolymerization, resulting in preparations containing shorter heparin fragments (mean molecular weight of 4–5 kDa). In a similar way to UFH, LMWHs enhance the action of AT III but as the mean length of the heparin fragments is less, they have a reduced ability to bridge AT III to thrombin. As such bridging is not necessary to inhibit factor Xa, LMWHs exert their effect predominantly through inhibition of factor Xa. They possess a number of potential advantages over UFH (Table 32.4), including a more predictable level of anticoagulation eliminating the need for mandatory

Table 32.4 Comparison of unfractionated heparin, low molecular weight heparin, bivalirudin and fondaparinux

	UFH	LMWH	Bivalirudin	Fondaparinux
Mechanism of action	Potentiates AT III – principal effect is indirect inhibition of thrombin	Potentiates AT III – principal effect is indirect inhibition of factor Xa – some indirect inhibition of thrombin	Direct thrombin inhibitor	Potentiates action of AT III – results in specific indirect inhibition of factor Xa
Inhibition of fibrin-bound thrombin	No	No	Yes	No
Non-specific binding	Yes – to plasma proteins and cells	Yes – to plasma proteins and cells	No	No
Activation of platelets	Yes	Minimal	No – inhibits thrombin-mediated platelet activation	No
Pharmacokinetics	Non-linear	Non-linear (less so than UFH)	Linear	Linear
Risk of HIT	Yes	Yes (less than UFH)	No	No
Monitoring	Mandatory using ACT or aPTT	Not usually necessary; anti-Xa levels can be monitored	Not usually necessary; ACT or aPTT can be monitored	Not usually necessary; anti-Xa levels can be monitored
Reversal with protamine	Yes	Partial	No	No

laboratory monitoring, a reduction in the incidence of thrombocytopenia, less platelet activation and an easier route of administration.

Low molecular weight heparin in patients receiving fibrinolysis

The use of LMWH with fibrinolytic therapy has been evaluated in a number of trials. Together, results suggest a modest advantage of LMWH over UFH that appears to be due to enhanced late patency of the infarct-related vessel and an associated reduction in reinfarction rate.

Dalteparin The Fragmin in Acute Myocardial Infarction (FRAMI) study[67] randomized patients (n = 776) to either dalteparin (150 IU/kg twice daily) or placebo following fibrinolysis with SK. The only significant difference in clinical endpoints was an increase in major hemorrhage in those treated with dalteparin (2.9% versus 0.3% in control group, P = 0.006). The Biochemical Markers in Acute Coronary Syndromes (BIOMACS)-II study[68] also evaluated the use of adjunctive dalteparin (100 IU/kg initially followed by 120 IU/kg at 12 hours) in patients (n = 101) following SK. There was a trend towards increased rates of TIMI 3 flow at 20–28 hours (68% versus 51% in placebo group, P = 0.10) and a reduction in the incidence of recurrent ischemia (recorded on continuous electrocardiography)

from 38% to 16% (P = 0.037). There were no differences in major bleeding or clinical events.

In the Assessment of the Safety and Efficacy of a New Thrombolytic Agent (ASSENT)-PLUS trial,[69] patients (n = 439) were given alteplase and randomized to either adjunctive dalteparin (120 IU/kg twice daily) for 4–7 days or IV UFH for 48 hours. Those treated with dalteparin had higher rates of infarct-related vessel patency between days 4 and 7 (86.6% versus 75.6%, P = 0.003). There was also a trend towards higher rates of TIMI 3 flow (69.3% versus 62.5%, P = 0.16). Although there were fewer reinfarctions at day seven in the dalteparin group (1.4% versus 5.4%, P = 0.01), there was no difference in the rate of reinfarction (6.5% versus 7.0%, P = ns) or the composite of death and reinfarction at 30 days.

Reviparin The Clinical Trial of Reviparin and Metabolic Modulation in Acute Myocardial Infarction Treatment Evaluation (CREATE),[70] performed in India and China, randomized STEMI patients (n = 15 570) to weight-adjusted reviparin or placebo for seven days. Use of concomitant therapies was high (ASA in 97%, clopidogrel in 55%, beta-blockers in 66%, ACE inhibitors in 72%, and lipid-lowering agents in 66%). Fibrinolytic therapy, principally with non-fibrin specific agents, was the method of reperfusion in 73% of patients. The primary endpoint of death, MI or stroke

was reduced in those treated with reviparin compared to placebo at seven days (9.6% versus 11.0%, $P = 0.0049$) and 30 days (11.8% versus 13.6%, $P = 0.0014$). Isolated mortality rates at seven and 30 days were also significantly reduced with reviparin. An excess in life-threatening bleeds not included in the primary endpoint was observed in those treated with reviparin (0.2% versus 0.1% with placebo, $P = 0.07$). Although its relevance to contemporary practice in the developed world is questionable (given that a greater proportion of patients are treated with primary PCI and fibrin-specific agents are more commonly used), the trial remains the only one to demonstrate a reduction in mortality with a LMWH.

Enoxaparin In the Acute Myocardial Infarction-Streptokinase (AMI-SK) trial (n = 496),[71] higher rates of vessel patency (87.6% versus 71.7%, $P < 0.001$) and TIMI 3 flow (70.3% versus 57.8%, $P = 0.01$) were observed at eight days in those treated with enoxaparin.

In the Heparin and Aspirin Reperfusion Therapy (HART)-II trial (n = 400),[72] rates of TIMI 2 or 3 flow at 90 minutes and rates of reocclusion at 5–7 days were similar in patients randomized to either UFH or enoxaparin for a minimum of three days following fibrinolysis with alteplase. There were no significant differences in rates of major bleeding in either study.

In the ASSENT-3 trial, patients (n = 6095) were randomized to full-dose tenecteplase with weight-adjusted UFH for at least 48 hours, full-dose tenecteplase with enoxaparin for seven days or reduced-dose tenecteplase with abciximab and UFH. The composite of death, reinfarction or refractory ischemia was significantly lower in those treated with enoxaparin than UFH (11.4%, RR 0.74, 95% CI 0.63–0.87, $P = 0.0002$). This advantage was driven primarily by a reduction in the rate of reinfarction. However, there was an increased incidence of bleeding complications in those treated with enoxaparin compared to UFH (Table 32.5).

The Enoxaparin and Thrombolysis Reperfusion for Acute Myocardial Infarction Treatment (ExTRACT-TIMI) 25 trial[73] randomized patients (n = 20506) with STEMI undergoing fibrinolysis to receive either enoxaparin (30 mg IV bolus followed by 1 mg/kg throughout the index hospitalization) or UFH (60 U bolus followed by 12 U/kg/h for 48 hours). Importantly, therefore, the treatment groups varied not only in the antithrombin agent given but also in the duration of treatment. In addition, the dosing regimen was reduced in patients ≥75 years and/or with a creatinine clearance ≤30 mL/min. The primary endpoint of death or reinfarction at 30 days occurred in 12.0% of patients treated with UFH and 9.9% of those treated with enoxaparin (17% relative RR, $P < 0.001$). Non-fatal reinfarction occurred in

4.5% of the patients receiving UFH and 3.0% of those receiving enoxaparin (relative RR 33%, $P < 0.001$); 7.5% of patients given UFH died versus 6.9% of those given enoxaparin (relative RR 8%, $P = 0.11$). TIMI major bleeding was increased in the enoxaparin group compared to those receiving UFH (2.1% versus 1.4%, relative risk 1.53, $P < 0.001$) whilst rates of intracranial hemorrhage were similar (0.8% versus 0.7% respectively, $P = 0.14$). The composite of death, reinfarction or intracranial hemorrhage (a measure of overall clinical benefit) occurred in 12.2% of patients given UFH and 10.1% of those given enoxaparin (relative RR 17%, $P < 0.001$). In a prespecified analysis to look at concomitant clopidogrel use, the rate of TIMI major bleeding with enoxaparin compared with UFH was numerically but not statistically significantly higher in patients treated with clopidogrel (2.7% versus 1.0%) versus those who were not (2.1% versus 1.2%) ($P_{interaction} = 0.61$).[74] Overall clinical benefit remained in favor of enoxaparin over UFH, either with clopidogrel (absolute RR 2.4%, 95% CI 0.5–5.3%) or without (absolute RR 1.7%, 95% CI 0.5–3.0%) ($P_{interaction} = 0.61$). A further prespecified subgroup analysis assessed the effect of impaired renal function. This was possible due to relatively broad entry criteria resulting in the recruitment of patients with a wide spectrum of renal function. In line with data from previous trials and registry data, impaired renal function was a powerful independent predictor of adverse outcome including bleeding irrespective of treatment group.[75] Each successive 30 mL/min decline in creatinine clearance (CrCl) increased the risk of major or minor bleeding by approximately 50%. For patients with well-preserved renal function (CrCl >90 mL/min), the incidence of major bleeding was not significantly different between treatment groups. However, excess bleeding was observed in those with CrCl <30 mL/min treated with enoxaparin despite a halving of the maintenance dose. This raises the possibility that dose adjustment of enoxaparin may be required in patients with even moderate renal dysfunction (for example, CrCl 30–90 mL/min) to achieve a reduction in ischemic events while mitigating the risk of bleeding. Until alternative dosing regimens are developed, it also suggests that enoxaparin should not be administered to patients with CrCl <30 mL/min. More broadly, the analysis emphasises the high-risk nature of ACS patients with impaired renal function and suggests that dose reduction for enoxaparin and UFH in this patient subgroup should be investigated further.

The results of the ExTRACT-TIMI-25 trial are broadly in keeping with the results of meta-analyses of enoxaparin use in STEMI patients treated with fibrinolysis that indicate a reduction in reinfarction and recurrent ischemia, no improvement in overall mortality and an increase in major bleeding, especially in elderly patients and those with renal impairment.[76,77]

LMWHs are a useful alternative to UFH in STEMI in conjunction with fibrinolytic therapy and should be administered throughout the index hospitalization (up to eight days) (**Class I, Level A**).

Low molecular weight heparin in patients treated with primary PCI

The majority of data concerning safety and efficacy of LMWHs in the catheterization laboratory comes from studies in patients undergoing elective procedures or in patients with ACS managed with an early invasive strategy. Broadly, these data suggest that enoxaparin is a useful alternative to UFH when used as the primary anticoagulant in elective procedures.[78] In ACS patients managed using a contemporary antithrombotic regimen incorporating enoxaparin, it appears efficacious to perform PCI without additional anticoagulation although there is a small but significant increased risk of bleeding which is particularly relevant in the elderly and in those with renal impairment.[79,80] There are limited data regarding the safety and efficacy of LMWHs during PCI in the context of patients with STEMI.

Reviparin In the CREATE trial, 949 patients underwent primary PCI as their reperfusion strategy, although details of whether additional UFH was used periprocedurally are not provided and this cohort represented just 6.1% of the overall population. There was a trend towards a reduction in the primary endpoint of death, MI or stroke at seven days with reviparin compared to placebo (5.8% versus 7.3%, hazard ratio (HR) 0.79, 95% CI 0.48–1.31).

Enoxaparin In the ExTRACT-TIMI-25 trial, patients in the enoxaparin treatment group who subsequently underwent PCI following initial treatment with fibrinolysis (not primary PCI) without the use of additional UFH (n = 4676) had a lower incidence of the primary endpoint of death and reinfarction at 30 days compared to those in the UFH group (10.7% versus 13.8%, relative RR 23%, $P < 0.001$).[81] There were no differences in major bleeding (1.4% vs 1.6% respectively, $P = $ ns).

In the Which Early ST Elevation Myocardial Infarction Therapy (WEST) study, patients with STEMI were randomized to fibrinolysis, protocol-specified rescue PCI and/or early angiography within 24h or primary PCI. Patients undergoing primary PCI (n = 33) were given ASA and clopidogrel at first contact and most received abciximab on arrival at the catheterization laboratory. Enoxaparin was administered at first contact (1 mg/kg SC). A supplemental dose (0.3–0.5 mg/kg IV) at the time of primary PCI was allowed in the original protocol and subsequently strongly encouraged following thrombotic complications in three of 36 patients during the early phase of the study enrolment. Use of UFH was precluded. Factor Xa levels were measured at the time of sheath insertion (prior to additional IV

enoxaparin) and also at the end of the procedure. Initial anti-Xa levels 56 min (median, interquartile range 47–77) after SC enoxaparin were below the recommended therapeutic level of 0.5 U/mL in 85% of patients. Following PCI, at 126 min (118–185) after SC enoxaparin, in those without supplemental IV dosing (8/33) the second anti-Xa level was 0.44 U/mL (0.29–0.53); six of the eight patients remained <0.5 U/mL. With additional IV enoxaparin (25/33) the second anti-Xa level was 0.96 U/mL (0.82–1.16) 97 min (82–109) after SC enoxaparin; all patients had therapeutic levels of anti-Xa. This open-label study provides limited data on the role of enoxaparin in patients undergoing primary PCI but suggests that whilst a single SC enoxaparin dose fails to achieve adequate anticoagulation in the majority of STEMI patients, a regimen combining initial additional IV enoxaparin may provide effective early antithrombotic therapy in those undergoing primary PCI.

LMWHs are a reasonable alternative to UFH in patients with STEMI undergoing primary PCI (**Class IIb, Level B**).

Direct thrombin inhibitors

In contrast to UFH and LMWH, direct thrombin inhibitors (DTIs) bind to the substrate recognition and/or catalytic site of thrombin, resulting in its direct inhibition without the involvement of AT III. Due to their relatively small size, they are able to bind and inactivate fibrin-bound as well as free thrombin. They do not interact appreciably with plasma proteins or other drugs and are not inhibited by platelet factor IV and so display linear dose–response kinetics, resulting in predictable levels of anticoagulation. Additionally, in contrast to UFH, they do not activate platelets (see Table 32.4).[82]

Direct thrombin inhibitors in patients receiving fibrinolysis

Hirudin Hirudin is the prototypical DTI. It is a naturally occurring polypeptide found in the saliva of the leech. Clinically, it is used in a recombinant form – lepirudin.

The TIMI-5 trial randomized patients to either UFH or escalating doses of hirudin prior to fibrinolysis with alteplase. There was no significant difference in TIMI 3 flow at 90 minutes (57% in UFH group versus 65% in the hirudin group, *P* = ns) but there was a trend towards a reduced rate of reocclusion at 18–36 hours in those receiving hirudin (1.6% versus 6.7%, *P* = 0.07) and a lower combined rate of death or reinfarction (6.8% versus 16.7%). Based on this pilot study, the TIMI-9B and GUSTO-IIb trials evaluated the effect of hirudin given after the start of fibrinolysis on reinfarction and mortality. When the data from these two studies were combined, there was no reduction in mortality but the incidence of reinfarction was reduced by 14% (*P* = 0.024).

The Hirudin for the Improvement of Thrombolysis (HIT)-4 study randomized patients to UFH or hirudin (0.2 mg/kg IV bolus followed by 0.5 mg/kg SC twice daily)

in addition to SK. There was no effect on the combined endpoint of death/reinfarction/stroke/rescue angioplasty/refractory angina at 30 days (22.7% with hirudin versus 24.3% with UFH, *P* = ns). Rates of intracranial hemorrhage and major bleeding (3.3% versus 3.5%) were similar in both treatment groups.

Bivalirudin Bivalirudin is a synthetic, 20 amino acid peptide analog of the carboxy-terminal end of hirudin. It binds bivalently to thrombin and, once bound, is slowly cleaved by thrombin with resulting recovery of thrombin activity. It is cleared from plasma by a combination of proteolytic degradation and renal excretion. Its principal advantage over hirudin is a reduced incidence of bleeding complications, probably related to a shorter plasma half-life (approximately 25 minutes compared with 2–3 hours for hirudin).

In the Hirulog and Early Reperfusion or Occlusion (HERO)-1 trial, patients (n = 412) were given UFH, low-dose bivalirudin (0.125 mg/kg bolus followed by a 0.25 mg/kg/h infusion for 12 h, then 0.125 mg/kg/h) or high-dose bivalirudin (0.25 mg/kg bolus followed by a 0.5 mg/kg/h infusion for 12 h, then 0.25 mg/kg/h). TIMI 3 flow at 90–120 minutes was higher following bivalirudin than UFH (48% with high-dose bivalirudin, 46% with low-dose bivalirudin and 35% with UFH, *P* = 0.024).

The larger HERO-2 trial randomized patients (n = 17 073) to receive a bolus and 48 h infusion of bivalirudin or UFH immediately prior to SK. At 30 days, mortality was similar (10.8% in bivalirudin group versus 10.9% in UFH group, OR 0.96, 95% CI 0.90–1.09). After adjustments for gender differences between the two groups and for factors identified in the GUSTO risk model, the mortality estimate was 10.5% in the bivalirudin group and 10.9% in the UFH group (OR 0.96, 95% CI 0.86–1.07). Rates of reinfarction at 96 hours (adjudicated by an independent blinded committee) were less in the bivalirudin group (1.6% versus 2.3% in UFH group, OR 0.70, 95% CI 0.56–0.88, *P* = 0.001). Similarly, the combined rate of death and investigator-reported reinfarction was lower in the bivalirudin group (12.9% versus 14.2%, OR 0.90, 95% CI 0.82–0.99, *P* = 0.023). Whilst rates of intracranial bleeding and severe bleeding were low and similar in both treatment groups, moderate and minor bleeding were more common with bivalirudin than UFH (see Table 32.5). In a *post hoc* analysis, the rates of the composite endpoint of death/reinfarction/non-fatal disabling stroke were 12.7% in the bivalirudin versus 13.8% in the UFH group (*P* = 0.049) (see Fig. 32.3).

Univalent direct thrombin inhibitors The univalent DTIs include argatroban, inogatran, efegatran and D-Phe-Pro-Arg-CH₂Cl. Phase I studies have demonstrated their ability to enhance fibrinolytic therapy.

The Antithrombin-Argatroban in Acute Myocardial Infarction (ARGAMI-2) study randomized patients (n = 1001)

to UFH or argatroban (120μg bolus followed by a 4μg/kg/min infusion for 72h) in addition to fibrinolysis with SK or alteplase. A third treatment arm consisting of half-dose argatroban was terminated prematurely due to lack of efficacy. Mortality at 30 days was similar (5.5% in the argatroban group versus 5.7% in UFH group, P = ns). There was a trend towards less bleeding in patients who had received argatroban but no other difference in clinical event rates.

Meta-analysis of direct thrombin inhibitor trials

The Direct Thrombin Inhibitor Trialists' Collaborative Group performed a meta-analysis of 11 randomized controlled studies (n = 35 970) in which DTIs (hirudin, bivalirudin, argatroban, efegatran or inogatran) were compared with UFH in patients with ST segment elevation or non-ST segment elevation ACS.[83] There was no difference in mortality in those given DTIs compared with UFH immediately at the cessation of therapy (1.9% versus 2.0%; OR 0.97; 95% CI 0.83–1.13; P = 0.69), at seven days (2.2% versus 2.3%; OR 1.00; 95% CI 0.87–1.16; P = 0.95), at 30 days (3.6% versus 3.7%; OR 1.01; 95% CI 0.9–1.12; P = 0.90) or at six months (OR 1.00; 95% CI 0.91–1.09; P = 0.92). However, there was a reduction in the incidence of reinfarction compared with UFH at the cessation of therapy (2.8% versus 3.5%; OR 0.80; 95% CI 0.71–0.90; P < 0.001), seven days (3.2% versus 3.9%; OR 0.91; 95% CI 0.72–0.91; P < 0.001) and at 30 days (4.7% versus 5.3%; OR 0.87; 95% CI 0.79–0.95; P = 0.004). The combined incidence of death/MI was also reduced compared with UFH at cessation of therapy (4.3% versus 5.1%; OR 0.85; 95% CI 0.77–0.94; P = 0.001), at seven days (5.0% versus 5.8%; OR 0.88; 95% CI 0.80–0.96; P = 0.006) and at 30 days (7.4% versus 8.2%; OR 0.91; 95% CI 0.84–0.99; P = 0.02).

Five trials from this meta-analysis involved patients with STEMI. When combined with data from HERO-2 (Fig. 32.4), the results indicate that whilst DTIs have no effect on mortality alone, they do reduce the combined risk of death/reinfarction by 5% at 30 days compared with UFH. This is due primarily to a 20% reduction in the rate of reinfarction.

Bivalirudin is a useful alternative to UFH in STEMI in conjunction with fibrinolytic therapy (**Class I, Level B**).

Direct thrombin inhibitors in patients undergoing primary PCI

There are data from small studies to suggest that hirudin and argatroban may be safe and efficacious during PCI. The role of bivalirudin in patients undergoing elective procedures has been extensively studied and the recent Acute Catheterization and Urgent Intervention Triage Strategy (ACUITY) trial,[84] despite a number of limitations, has suggested that its use in ACS is safe and efficacious, including patients who are invasively managed with PCI.

The HORIZONS AMI trial[85] is the only substantive trial to investigate the role of a DTI in STEMI patients undergo-

ing primary PCI. Patients (n = 3600) were randomized to UFH plus a glycoprotein IIb/IIIa receptor antagonist abciximab or eptifibatide) or bivalirudin monotherapy (plus glycoprotein IIb/IIIa receptor antagonist for large thrombus or refractory no flow only – used in only 7.2% of patients in the bivalirudin group). There was a reduction in overall clinical events (a composite of major bleeding and major adverse cardiovascular events) in the bivalirudin group at 30 days compared to the UFH and glycoprotein IIb/IIIa receptor antagonist group (12.1% versus 9.2% respectively, P = 0.006). Major bleeding alone at 30 days was also substantially reduced (8.3% versus 4.9%, P < 0.0001) and there was a significant reduction in cardiac death at 30 days (2.9% versus 1.8%, P = 0.035). The initial data demonstrate an excess in adverse events with bivalirudin only within the first 24 hours, probably related to an excess incidence of early stent thrombosis (1.3% versus 0.3% with UFH and glycoprotein IIb/IIIa receptor antagonist). However, the subsequent reduction in events seen in those treated with bivalirudin results in an overall benefit in favor of bivalirudin at 30 days, likely to be driven by a reduction in bleeding complications.

Bivalirudin is a reasonable alternative to the combination of UFH and a glycoprotein IIb/IIIa receptor antagonist in patients with STEMI undergoing primary PCI (**Class IIa, Level B**).

Factor Xa inhibitors

Fondaparinux is a synthetic inhibitor of factor Xa containing a key pentasaccharide moiety with structural similarity to the AT III binding site of UFH and LMWHs. It binds selectively to AT III, resulting in rapid and selective inhibition of factor Xa. It has a plasma half-life of around 15 hours and displays linear pharmacokinetics, obviating the need for routine monitoring (see Table 33.4).[86] Its role in the prevention and treatment of venous thromboembolic disease is well established.[86–88]

Factor Xa inhibitors in patients receiving fibrinolysis

The Synthetic Pentasaccharide as an Adjunct to Fibrinolysis in ST-Elevation Acute Myocardial Infarction (PENTALYSE) study compared fondaparinux with UFH in patients (n = 316) with STEMI.[89] All patients were given ASA and alteplase. Patients were randomized to receive UFH or one of three weight-adjusted doses of fondaparinux (4–6 mg, 6–10 mg or 10–12 mg) once daily for 5–7 days. The incidence of TIMI 3 flow at 90 minutes was similar in all groups (68% with UFH versus 64% in all fondaparinux groups). There was a trend towards a reduction in the rate of reocclusion at day 6 (0.9% versus 7.0% with UFH, P = 0.065) but rates of reinfarction at 30 days were similar (3.8% with fondaparinux versus 3.6% with UFH, P = 1.00). One patient who received fondaparinux (4 mg) suffered an

Figure 32.4 Thirty-day event rates in patients with ST-elevation MI, randomized to receive direct thrombin inhibitors (DTI) or unfractionated heparin in the HERO-1,[67] HERO-2,[48] TIMI-9B,[38] GUSTO-11B,[39] HIT-4,[65] and ARGAMI-2[73] trials: (a) death; (b) reinfarction; (c) death/reinfarction; (d) stroke; (e) intracranial hemorrhage; (f) major bleeding. HIT; hirudin for improvement of thrombolysis.

intracranial hemorrhage. Transfusion rates were 3.3% in those receiving fondaparinux versus 7.1% in those who received UFH ($P = 0.21$).

Data regarding the use of fondaparinux in patients with ACS have been gathered in the recent OASIS (Organization

to Assess Strategies in Acute Ischemic Syndromes) trials. Whilst OASIS-5 compared the use of fondaparinux with enoxaparin in patients with ACS with or without ST elevation,[90] the OASIS-6 trial (n = 12 092) compared the use of fondaparinux to usual care (placebo in those in whom

UFH was not indicated or UFH for up to 48 hours followed by placebo for up to eight days) in patients with STEMI.[91] The first dose of fondaparinux (2.5 mg) was administered IV, followed by daily SC injections for up to eight days. There were no differences in the effects of fondaparinux between groups treated with UFH/placebo or placebo alone. Over the entire study population, fondaparinux reduced the primary endpoint of death or reinfarction at 30 days compared to treatment with placebo or UFH (9.7% versus 11.2%, relative RR 14%; $P = 0.008$). The benefit persisted at the study end (13.4% versus 14.8%, relative RR 9%; $P = 0.008$). In the subgroup who received thrombolytic therapy and were randomized to either fondaparinux or UFH (n = 2666) there was a reduction in death or reinfarction (relative RR 23%, $P = 0.003$) in those treated with fondaparinux although this was a modest sized subgroup analysis and should be interpreted with caution. Rates of bleeding were similar between groups (1.0% in the fondaparinux group versus 1.3% in the UFH/placebo group, $P = 0.13$).

Whilst parallels exist between OASIS-6 and the ExTRACT-TIMI-25 trial (discussed earlier), differences in inclusion criteria, study design and length of anticoagulant therapy preclude direct comparison. However, taken together with the results from OASIS-5, these studies provide strong evidence that a strategy of 48 hours of anticoagulation may be insufficient following MI. The premature cessation of anticoagulant therapy may result in reocclusion of the infarct-related artery and expose patients to an increased risk of recurrent infarction.

Fondaparinux is a useful alternative to UFH in STEMI patients who have received fibrinolytic therapy (**Class I, Level B**).

Factor Xa inhibitors in patients undergoing primary PCI

The OASIS-6 trial included patients with STEMI who underwent primary PCI (n = 3789). Whilst data from the study population as a whole demonstrated a benefit of fondaparinux over UFH or placebo on the primary endpoint of death and recurrent MI, this benefit was not seen in patients undergoing primary PCI. In addition, there was a higher rate of guiding catheter thrombosis and more coronary complications (abrupt coronary artery closure, new angiographic thrombus, catheter thrombus, no reflow, dissection or perforation) with fondaparinux.

Fondaparinux should not be used as the sole anticoagulant in patients with STEMI undergoing primary PCI (**Class III, Level B**).

Factor Xa inhibitors in patients not receiving reperfusion therapy

Compared to other contemporary trials involving patients with ACS, the OASIS-6 trial was unusual in that it included patients with STEMI who did not receive reperfusion therapy (n = 2867). This subgroup formed almost a quarter of the overall cohort. Fondaparinux reduced the incidence of the primary endpoint (death or recurrent MI at 30 days) compared to UFH or placebo (relative RR 19%, $P = 0.04$).

Patients who do not receive reperfusion therapy should be treated throughout the index hospitalization (up to eight days) with fondaparinux in preference to UFH (**Class I, Level B**).

Conclusion

Antithrombotic therapy is a key component in the integrated management of patients presenting with STEMI. Optimal antithrombotic therapy requires antiplatelet and anticoagulant agents as well as consideration of the balance between efficacy and bleeding risk in each patient. The evaluation of novel agents and combination therapies continues at a phenomenal rate. All patients should be treated with ASA and a thienopyridine (currently clopidogrel) as soon as possible following diagnosis. The choice of anticoagulant therapy, in part, is dictated by the method of reperfusion undertaken. Whilst UFH is efficacious and remains widely used, evidence from recent large-scale trials favors the use of newer agents. Following fibrinolytic therapy, both fondaparinux and LMWHs improve clinical outcomes compared with UFH, although bleeding risk is increased with enoxaparin, especially in the elderly and those with renal impairment. Direct thrombin inhibitors appear to be a reasonable alternative to UFH, and preferred in settings of thrombocytopenia or prior heparin-induced thrombocytopenia. Whilst the use of a Gp IIb/IIIa receptor antagonist in conjunction with half-dose fibrinolytic may be considered in younger patients with a low risk of bleeding, it should be avoided in patients over 75 years of age given the increased risk of major bleeding, including intracranial hemorrhage.

In patients undergoing primary PCI, UFH has traditionally been administered based primarily on theoretical grounds and the experience of experts. There is evidence that the addition of a Gp IIb/IIIa receptor antagonist improves outcomes. Concern exists that fondaparinux and perhaps enoxaparin may not provide adequate periprocedural anticoagulation for patients undergoing PCI. There is now evidence from a single, moderately sized trial that bivalirudin is more efficacious than the combination of UFH plus a Gp IIb/IIIa receptor antagonist, removing the need for routine Gp IIb/IIIa receptor antagonist use. Further studies will be required to clarify whether this is applicable across the entire risk spectrum of STEMI patients.

For patients who have not undergone specific reperfusion therapy UFH appears to confer a modest benefit.

Compared to UFH, fondaparinux is efficacious, easy to administer and associated with a low incidence of bleeding. In order to further clarify the role of these newer agents, direct head-to-head trials of enoxaparin, fondaparinux and bivalirudin in STEMI patients undergoing primary PCI and fibrinolytic therapy are required. In addition, the role of novel antiplatelets[92,93] and inhibitors of tissue factor[94] remain to be defined.

Finally, bleeding complications in patients with ACS remain relatively common and may be as important to long-term outcome as ischemic events. Recent large studies have confirmed the importance of bleeding to overall outcome and helped identify patient subgroups at increased risk of bleeding. Given the strict inclusion criteria for most clinical trials, the risk of bleeding in the "real world" is likely to be higher. Central to the clinical decision-making process must be balancing the added antithrombotic effects of potent combination therapies against the accompanying increased risk of bleeding, especially in specific high-risk patient subgroups.

33 Complications after myocardial infarction

Peter L Thompson

University of Western Australia, Perth, Western Australia

Introduction

Despite major changes in treatment and prevention, myocardial infarction (MI) remains a common and lethal condition. The World Health Organization estimates that 7.6 million people died from cardiovascular disease in 2005, representing 30% of all global deaths,[1] and the global burden of coronary heart disease is projected to rise from around 47 million disability-adjusted life years (DALYs) in 1990 to 82 million DALYs in 2020.[2] The new definition of acute myocardial infarction, which has been expanded to include patients with clinical and electrocardiographic features of myocardial ischemia and an elevation of troponin outside the 99th percentile of the upper limit of the reference limit, will substantially increase the numbers of people who are diagnosed with acute myocardial infarction.[3] Reinfarction after myocardial infarction is a common complication, and mechanical complications include acute and chronic heart failure, cardiogenic shock, ventricular aneurysm, right ventricular infarction and failure, mitral regurgitation due to papillary muscle dysfunction or rupture, rupture of the interventricular septum and rupture of the free wall of the left ventricle. Electrical complications include ventricular fibrillation, ventricular tachycardia, atrial fibrillation, and atrioventricular block. Psychosocial and socioeconomic consequences are common and frequently neglected complications of myocardial infarction. Other chapters in this book cover the topics of left ventricular dysfunction and heart failure (Chapter 47), ventricular arrhythmias (Chapter 40), bradyarrhythmias (Chapter 41) and atrial fibrillation (Chapters 35–38).

The major complications of MI, such as left ventricular (LV) dysfunction, heart failure or ventricular and atrial arrhythmias, lend themselves to study with controlled clinical trials. However, for many of the acute complications of MI, clinical trials have not been performed, and clinical decision making must rely on evidence from other sources including uncontrolled trials, observational studies and inference from pathophysiologic data. The evidence base for managing the complications of MI will be discussed under the headings of clinical features and prognosis, and management.

Reinfarction, extension and expansion of infarction

The terminology of reinfarction can be confusing: the term *reinfarction* is used when there is new myocardial necrosis, *infarct extension* when an area of infarction extends to involve adjacent ischemic tissue[4] and *infarct expansion* when the infarcted tissue expands and contributes to hemodynamic deterioration. Infarct expansion does not require revascularization, but is treated by measures to control left ventricular dysfunction (see below). Reinfarction in patients with either non-ST segment elevation myocardial infarction (NSTEMI)[5] or ST elevation MI (STEMI)[6] may represent an extension of the initial necrosis or a new episode of infarction. The new universal definition of myocardial infarction recommends a diagnosis of reinfarction based on typical clinical features with a troponin elevation of >20% above earlier levels.[3] The evidence that the risk of reinfarction in NSTEMI is lessened by early angiography and revascularization is now strong. In a meta-analysis of seven trials with 8375 patients, all-cause mortality at one month was reduced by 25% at two years (relative risk (RR) 0.75, 95% confidence interval (CI) 0.63–0.90, $P = 0.001$) and the incidence of non-fatal myocardial infarction was reduced by 17% (RR 0.83, 95% CI 0.72–0.96, $P = 0.012$) in the early invasive group compared with the conservative group.[7] In STEMI treated with fibrinolysis, reinfarction can occur in 4–8% of patients. The reinfarction rate is significantly lower when primary percutaneous coronary intervention (PCI) is the initial treatment.[8]

Coronary reperfusion with fibrinolysis or PCI is strongly recommended and reduces the risk of reinfarction in STEMI (**Class I, Level A**).

In STEMI, PCI achieves better rates of reperfusion and is preferable to the use of fibrinolysis when available (**Class I, Level A**).

The risk of reinfarction in NSTEMI is reduced with early invasive investigation and revascularization where appropriate (**Class I, Level A**).

Left ventricular dysfunction and pulmonary congestion

Clinical features and prognosis

Pathophysiology

Adverse remodeling of the ventricle can occur immediately after coronary occlusion[9] and continues over the ensuing months and years, leading to an increase in end-diastolic and end-systolic volumes, an increase in the sphericity of the ventricle, and systolic bulging and thinning of the infarct zone, without necessarily any extension of the infarcted zone.[10] Results from autopsy studies suggested that MIs that involved greater than 40% of the left ventricle were usually fatal.[11] However, a more recent prospective study conducted in the reperfusion era showed that out of 16 patients with infarcts involving >40% of the myocardial mass and followed for 13 months, only one had persistent heart failure and subsequently died.[12] Extensive damage can occur as a consequence of one large infarction or multiple smaller ones. NSTEMI may also cause left ventricular dysfunction if there has been prior cumulative myocardial damage.[13]

Prognostic markers based on left ventricular dysfunction

The extent of LV dysfunction is a strong predictor of short- and long-term prognosis after MI. The Killip and Kimball[14] classification stratifies MI patients from low to very high risk based upon clinical signs of heart failure. It remains a reasonably accurate predictor of short-term survival. In patients undergoing primary percutaneous transluminal coronary angioplasty (PTCA), the in-hospital mortality was 2.4%, 7%, and 19% for Killip class I, II, and III respectively and six-month mortality was 4%, 10%, and 28% for class I, II, and III, respectively.[15] The Forrester classification, comprising four categories defined according to the presence or absence of pulmonary congestion and peripheral hypoperfusion, requires measurement of the pulmonary artery pressure using a balloon flotation catheter.[16] In postinfarction patients,[17] abnormal hemodynamic variables determined from right heart catheterization correlate strongly with a higher mortality even after adjusting for other prognostic variables. However, insertion of balloon

flotation catheters, while safe in experienced hands, has a recognized risk of adverse events, including ventricular tachyarrhythmias and pulmonary hemorrhage or infarction.[18] Meta-analyses of trials using pulmonary artery catheterization have failed to show any benefit on outcomes,[19] while increasing length of hospital stay.[20] Recent guidelines recommend the use of balloon flotation catheters only in severe or progressive congestive heart failure (CHF) or pulmonary edema, cardiogenic shock or progressive hypotension or suspected mechanical complications of acute infarction, i.e. ventricular septal defect (VSD), papillary muscle rupture or pericardial tamponade.[6]

Late (>30 days) postinfarction mortality was 3% in patients with an ejection fraction (EF) above 0.40, 12% when the EF was between 0.20 and 0.40, and 47% when it was below 0.20.[21] The presence of clinical signs of left ventricular failure is a strong indicator of a poor long-term prognosis but in most patients, more detailed assessment is necessary and the use of echocardiography or radionuclide assessment may provide information that cannot be obtained clinically.[22] Approximately two-thirds of patients with an ejection fraction low enough to indicate a poor long-term prognosis, e.g. <0.40, have no radiologic evidence of left ventricular failure.[23] The information obtained from assessing left ventricular function by echocardiography, radionuclide imaging or cardiac catheterization has been found to be of equivalent value in predicting one-year prognosis[24] and the choice of modality for assessment of left ventricular function depends on local availability and expertise. The left ventricular chamber volume has long been established as an important marker of long-term prognosis after myocardial infarction,[25] and the prevention of adverse remodeling by early coronary reperfusion is an important therapeutic aim in current treatment of myocardial infarction.[26] However, despite successful restoration of epicardial blood flow, left ventricular remodeling is still seen in a substantial number of patients, probably as a result of microvascular dysfunction in the coronary vessels.[27] Various methods of documenting this phenomenon have included measurements of the extent of recovery of ST segment elevation,[28] the myocardial blush grade on coronary angiography,[29] an index of microcirculatory resistance measured at angiography,[30] cardiac magnetic resistance imaging (MRI)[31] and myocardial contrast echocardiography.[32] The latter technique has been shown in a multicenter study to be superior to measurements of ST segment resolution and myocardial blush grade in predicting adverse remodeling.[32] Simple bedside scores based on readily available clinical data can also accurately stratify the risks of death and ischemic events in STEMI patients, as shown in large clinical trials such as the GUSTO,[33] GISSI[34] and TIMI trials,[35] in NSTEMI, as shown in the TIMI trials,[36] and in non-STE acute coronary syndromes as shown in the Global Registry of Acute Coronary Events (GRACE).[37]

Measurements of left ventricular function and diastolic volume predict short- and long-term prognosis after STEMI (**Level A**).

Clinical markers of prognosis can be used for risk stratification after STEMI and NSTEMI with a high degree of accuracy (**Level A**).

Biochemical markers

Biochemical markers of necrosis provide an index of the extent of left ventricular infarction, which in turn is correlated with the extent of left ventricular dysfunction. Creatine kinase was shown in the pre-reperfusion era to predict short- and long-term prognosis[38] but the introduction of reperfusion into routine clinical practice has reduced the utility of creatine kinase (CK) or CK-MB to reflect the extent of left ventricular dysfunction because of early, direct release of the myocardial enzymes into the plasma during reperfusion and high, early peaking of the serum levels. The use of newer markers such as troponins is now widespread. Both troponin-I[39] and troponin-T[40] correlate well with prognosis, and 96-hour troponin levels correlate well with infarct size.[41] B-type natriuretic peptide[42] and high sensitivity C-reactive protein[43] also correlate with cardiac failure and predict long-term prognosis after acute MI (AMI). A multimarker approach to using these biomarkers has been suggested, as patients with more than three abnormal biomarker levels have a worse prognosis than those with normal levels of biomarkers (hazard ratio (HR) 3.8 after correction for standard prognostic factors).[44]

Ninety-six hour troponin levels provide a quantitative index of the extent of infarction (**Level B**).

Management

Reperfusion therapy

While the role of early coronary reperfusion in improving outcomes has been well established, the relationship between improvements in left ventricular function and prognosis after reperfusion therapy has been surprisingly difficult to demonstrate. Although some of the early studies demonstrated clear benefits on left ventricular function from coronary thrombolysis,[45,46] the evidence since then has been conflicting, with some groups showing a worse left ventricular function despite an improved prognosis. In a meta-analysis of 10 studies enrolling 4088 patients treated with thrombolytic therapy versus control, only a modest improvement in left ventricular function was demonstrated after thrombolytic therapy.[47] By four days, mean LV ejection fraction was 53% versus 47% (thrombolytic versus control therapy, $P < 0.01$); by 10–28 days it was 54.1% and 51.5%, respectively. The reason for the discrepancy in the marked improvement in survival and the limited benefit on left ventricular function is not clear but is at least in part due to the fact that more patients not receiving fibrinolytic

therapy die before LV function can be assessed post MI. Patients who have had coronary reperfusion after MI may have myocardium that is stunned[48] or even hibernating,[49] phenomena that may affect the assessment of ventricular function, and the preinfarction left ventricular function obviously impacts on the LV function during and after myocardial infarction. Stunned myocardium has been successfully reperfused but has not regained its normal contractile function, but has the potential to recover without any further reperfusion or revascularization. A study of 352 patients with anterior MI found that out of the 252 patients with abnormal LV function on day 1, 22% had complete and 36% had partial recovery of function by day 90.[50] Hibernating myocardium is underperfused and non-contractile because of persisting ischemia, but is not infarcted and may gradually improve its function with revascularization. The degree of success in achieving coronary patency with thrombolysis is an obvious confounding factor.[51] A detailed analysis correcting for these confounding factors concluded that left ventricular function is improved by successful coronary reperfusion.[52]

Overall, reperfusion therapy results in a modest improvement in systolic LV function (**Level B**).

Hemodynamic therapy

Improvements in hemodynamic status after myocardial infarction have not translated into better outcomes. For example, furosemide has been shown to reduce elevated LV filling pressures without adversely affecting cardiac output[53] but there is no evidence of improvement in outcomes with diuretic therapy in AMI. Nitrates have been shown to improve the hemodynamic status and adverse remodeling post AMI[54] but large clinical trials have not shown improved prognosis.[55,56] The calcium-sensitizing agent levosimendan has been evaluated in post-MI patients with cardiac failure and showed only a non-statistically significant trend towards improved outcome.[57] Infusion of the B-type natriuretic peptide nesiritide for acutely decompensated heart failure, including some patients with acute myocardial infarction, was initially reported to be safer than inotropic agents[58] but a meta-analysis of all trials showed an apparent adverse effect on outcomes.[59] In contrast, aldosterone antagonists have been shown to be beneficial in post-MI patients with left ventricular dysfunction and pulmonary congestion. The Randomized Aldactone Evaluation Study (RALES) studied patients with New York Heart Association class III–IV heart failure, many with remote myocardial infarction. Spironolactone treatment compared with placebo was associated with an 11% absolute risk reduction and 30% relative risk reduction in all-cause mortality over 24 months of follow-up.[60] The Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS) demonstrated that in post-MI patients with an ejection fraction <0.40 and heart

failure or diabetes that compared with placebo, eplerenone significantly reduced overall mortality, cardiovascular mortality, and cardiac hospitalizations.[61]

Diuretics and nitrates can be used for relief of pulmonary congestion in acute MI, but there is no clinical trial evidence of benefit on outcomes (**Class I, Level B**).

Aldosterone antagonists (spironolactone and eplerenone) are indicated in post-MI patients with left ventricular dysfunction or pulmonary congestion (**Class I, Level A**).

Levosimendan may be considered as an alternative treatment in patients with severe cardiac failure following MI (**Class IIa, Level B**).

Nesiritide should not be used in patients with pulmonary congestion complicating myocardial infarction because of concerns about its safety profile (**Class III, Level A**).

ACE inhibitors for post-MI patients with left ventricular dysfunction

The beneficial effects of angiotensin-converting enzyme (ACE) inhibitors in the treatment of patients with left ventricular dysfunction complicating myocardial infarction have been striking. Eight large randomized, placebo-controlled trials have assessed the effect of an ACE inhibitor on mortality after MI. ACE inhibitors unequivocally reduce mortality overall, and the benefit appears to be greatest among patients with depressed LV function, overt heart failure or anterior infarction.[62–69]

In a meta-analysis of data from all the randomized trials involving more than 1000 patients in whom ACE inhibitor treatment was started within 36 hours of onset of myocardial infarction, there were results available on 98 496 patients from four eligible trials.[70] Among patients allocated to ACE inhibitors there was a 7% (95% CI 2–11%; $2P < 0.004$) proportional reduction in early mortality, an absolute reduction of five (SD, 2) deaths per 1000 patients. The absolute benefit was greatest in those patients with evidence of left ventricular dysfunction (i.e. Killip class 2–3, heart rate > = 100 bpm at entry) and in anterior MI. ACE inhibitor therapy also reduced the incidence of non-fatal manifestations of left ventricular dysfunction. During longer-term follow-up of patients enrolled in randomized controlled trials, ACE inhibitors have also been shown to be effective. In three long-term follow-up trials involving 5966 postinfarction patients, mortality was significantly lower with ACE inhibitors than with placebo (odds ratio (OR) 0.74, 95% CI 0.66–0.83).[71] Despite concerns that aspirin may blunt the effect of ACE inhibitors,[72] a detailed analysis of six long-term trials showed no adverse interaction between aspirin and ACE inhibitors.[73] The optimum timing of initiation of ACE inhibitor therapy has been studied in only a small number of direct comparative trials. In a direct comparison of early versus delayed administration, 352 patients with acute anterior myocardial infarction were randomized to early (1–14 days) or late (14–19 days) post-MI treatment with the ACE inhibitor ramipril and were followed by echocardiography. Those receiving early treatment had a greater improvement in ejection fraction, suggesting that such patients should be commenced on ACE inhibitor therapy early in their course of infarction.[74]

In considering treatment for left ventricular dysfunction, the hemodynamic benefits need to be balanced against the possible adverse effect. In the only ACE inhibitor trial that did not show a mortality benefit, CONSENSUS-II, treatment was begun early with an intravenous ACE inhibitor.[62]

All patients with post-MI LV dysfunction should be administered ACE inhibitors (**Class I, Level A**).

ACE inhibitors for post-MI patients without left ventricular dysfunction

Whether low-risk postinfarction patients without LV dysfunction derive benefit from ACE inhibitors is still controversial. The clear-cut benefits demonstrated in the HOPE[75] trial of ramipril in high-risk patients with coronary artery disease and the EUROPA trial of perindopril in post-AMI patients without left ventricular dysfunction[76] were not supported by the PEACE trial of trandolopril in lower risk patients.[77] A subsequent meta-analysis of the three trials supported the use of ACE inhibitors in the absence of LV dysfunction[78] and the totality of the evidence was examined in a meta-analysis of six trials including 16 772 patients randomized to ACE inhibitors and 16 728 patients randomized to placebo, which concluded that the benefits were favorable though modest,[79] consistent with the conclusion that the absolute benefit is proportional to the risk, with those at lowest risk benefiting least.[5]

ACE inhibitors are indicated for post-MI patients even in the absence of left ventricular dysfunction, but are more beneficial in patients at higher risk (**Class IIa, Level A**).

Cardiogenic shock

Clinical features and prognosis

Cardiogenic shock is a syndrome characterized by hypotension and peripheral hypoperfusion, usually accompanied by high LV filling pressures. The common clinical manifestations of these hemodynamic derangements include mental obtundation or confusion, cold and clammy skin, and oliguria or anuria. Cardiogenic shock is the most common cause of in-hospital mortality after MI.[80] When cardiogenic shock is not secondary to a correctable cause, such as arrhythmia, bradycardia, hypovolemia or a mechanical defect, short-term mortality is 80% or higher, depending upon the strictness of the definition. Despite the major improvements in treatment in the past two decades,

the in-hospital mortality in a recent international registry for patients with cardiogenic shock treated with modern therapy in the late 1990s was 66%.[81] Old age, diabetes, previous infarction and extensive infarction as assessed either by enzymatic or electrocardiographic criteria are factors commonly associated with cardiogenic shock. Among patients receiving fibrinolytic therapy, the risk of cardiogenic shock increased by 47% with each decade increase in age.[82] Patients who survive to 30 days after cardiogenic shock have an excellent late survival, almost as good as patients without shock.[83]

Management

Inotropic drugs have been subjected to detailed study and widespread use in cardiogenic shock, but no benefit on mortality has been demonstrated.[84]

Newer drugs such as levosimendan may improve myocardial efficiency by their calcium-sensitizing effect, but levosimendan also has vasodilating properties, which make it unsuitable for patients in cardiogenic shock with significant hypotension.[85] Nesiritide has been shown to improve pulmonary capillary wedge pressure in patients with decompensated heart failure[86] but was subsequently shown to increase mortality.[87]

Intra-aortic balloon pumping has been used to stabilize patients with cardiogenic shock. Clear-cut benefits on hemodynamic status and coronary blood flow have been shown, but benefits on survival have not; in-hospital mortality remained at 83% despite the use of balloon pumping in a co-operative clinical trial.[88] Nevertheless, intra-aortic balloon pumping has a clear place in stabilizing the unstable cardiogenic shock patient for more definitive treatment such as coronary angioplasty or bypass surgery,[89] as has been demonstrated to improve coronary patency in a randomized trial in the setting of rescue angioplasty.[90] Newer methods of circulatory support have shown highly encouraging results[91,92] but benefits on survival remain to be established.

Fibrinolysis

Although the outcome of cardiogenic shock has been shown to be dependent on the patency of the infarct-related artery, clinical trials of fibrinolytic therapy have not shown a benefit in patients with established cardiogenic shock.[93] Alternative antithrombotic strategies may improve outcomes, but data are limited to observational studies.[94]

Fibrinolysis could be considered for the patient with cardiogenic shock if access to PCI is not readily available (**Class IIb, Level B**).

Percutaneous coronary intervention or CABG

Observational studies on the use of PCI in cardiogenic shock suggest that an aggressive approach with early revascularization reduces the mortality of patients with cardiogenic shock after MI,[95] and a registry report has suggested that an aggressive approach with reperfusion therapy and intra-aortic balloon pulsation treatment of patients in cardiogenic shock due to predominant LV failure is associated with lower in-hospital mortality rates than standard medical therapy.[96] In a controlled clinical trial of an aggressive approach involving early catheterization with revascularization and intra-aortic balloon pumping, in cardiogenic shock patients (the SHOCK trial),[97] 87% of patients in the invasive arm underwent revascularization (surgical or percutaneous). There was a clear trend at 30 days towards reduced mortality in the invasive group compared with the medical therapy group (46.7% vs 56.0%); however, this difference did not reach statistical significance. There was an early hazard in the first five days after assignment to the invasive approach, which was likely associated with procedure-related complications. However, after the first five days there was a statistically significant survival benefit in favor of the revascularization group, which persisted at one year, when survival in the early revascularization group was 46.7% compared with 33.6% in those treated with early medical stabilization (RR for death 0.7, 95% CI 0.54–0.95).[98]

Evidence from clinical trials and registries supports invasive intervention in patients with cardiogenic shock post MI. These patients should undergo urgent coronary angiography with a view to coronary angioplasty or, in selected patients, coronary bypass surgery (**Class I, Level A**).

Right ventricular infarction and failure

Clinical features and prognosis

Right ventricular (RV) infarction typically occurs in association with inferior or posterior MI, as a consequence of total occlusion of the right coronary artery proximal to its marginal branches[99] or of the proximal circumflex in patients with a dominant left coronary system. RV infarction was present in 54% of patients with inferior MI in one series, although clinical manifestations are usually evident in only 10–15%.[100] Right ventricular involvement in inferior infarction has been reported to increase the mortality by fivefold. A meta-analysis of six studies including 1198 patients confirmed that RV myocardial involvement was associated with an increased risk of death (OR 3.2, 95% CI 2.4–4.1), shock (OR 3.2, 95% CI 2.4–3.5), and arrhythmic complications.[101] Patients in the SHOCK trial registry with cardiogenic shock due to RV infarction had the same serious prognosis (hospital mortality in excess of 50%) as patients with shock due to predominant LV infarction.[102] Early reperfusion may improve the prognosis: in patients who have primary PCI for treatment of their cardiogenic shock, those with right

ventricular infarction fared better than patients with cardiogenic shock due to left ventricular infarction.[103,104]

The clinical features of RV infarction complicating inferior MI include hypotension, an elevated jugular venous pressure and clear lung fields. Jugular venous distension on inspiration (Kussmaul's sign) has been reported to be a sensitive and specific sign of RV infarction.[105] The hemodynamic features of RV infarction may disappear with volume depletion or may emerge only after volume loading, making the clinical diagnosis elusive in some cases.

ST segment elevation in a right precordial lead (V_{4R}) has been reported to have a sensitivity of 70% and a specificity of nearly 100% for the diagnosis of RV infarction when the electrocardiogram is recorded within the first hours after the onset of symptoms. Echocardiography commonly reveals wall motion abnormalities of the right ventricle and interventricular septum. Bowing of the interatrial septum toward the left atrium indicates that the right atrial pressure exceeds the left atrial pressure,[106] and bowing of the interventricular septum into the right ventricle, compounding the dysfunction of the right ventricle,[107] both indicate a poor prognosis. Detection of a low RV EF and a segmental wall motion abnormality by radionuclide right ventriculography had a sensitivity of 92% and a specificity of 82% for identifying hemodynamically significant RV infarction in one study.[105] Assessment of RV function can help assess long-term prognosis, with patients with right ventricular ejection fraction having a risk of death four times that of patients with normal RV function.[108]

Patients with RV infarction complicating inferior MI have three times the risk of death of patients without RV infarction (**Level A**).

Patients with cardiogenic shock due to RV infarction have the same poor prognosis (>50% hospital mortality) as patients with LV infarction (**Level A**).

Management

Volume loading can normalize blood pressure and increase cardiac output.[109] Earlier studies of RV infarction demonstrated a marked response to volume loading.[110] Many of these patients were volume depleted secondary to aggressive diuresis in response to a raised venous pressure.

Volume loading can achieve hemodynamic improvement but has not been shown to improve outcomes (**Class I, Level B**).

Inotropic agents are often used in the treatment of right ventricular infarction when volume loading fails to improve cardiac output, but the effect of this on prognosis is unclear. The maintenance of atrioventricular synchrony is often critical to the maintenance of a satisfactory cardiac output; atrioventricular pacing has been shown to improve hemodynamics.[111] Successful reperfusion with fibrinolysis[112] or PCI[113] appears to reduce the incidence of RV infarction and

is associated with dramatic recovery of right ventricular function and reduced mortality. In contrast, unsuccessful right coronary artery reperfusion was associated with a high mortality.[114]

Reperfusion therapy in right ventricular infarction has not been studied in randomized trials but appears to be effective (**Level B**).

Left ventricular aneurysm

Clinical features and prognosis

Left ventricular aneurysms develop most commonly after large transmural anterior MIs, although in 5–15% of cases the site is inferior or posterior.[115] The diagnosis of aneurysm is less frequent in the reperfusion era, although documented trends have not been published. The coronary anatomy is an important determinant of the development of left ventricular aneurysm. Total occlusion of the left anterior descending artery in association with poor collateral blood supply is a significant determinant of aneurysm formation in anterior MI. Multivessel disease with either good collateral circulation or a patent left anterior descending artery is uncommonly associated with the development of left ventricular aneurysm.[116] Coronary patency also determines the likelihood of developing aneurysm.[117] A ventricular aneurysm can often be palpated as a dyskinetic region adjacent to the apical impulse. A third heart sound and signs of heart failure may also be detected. A non-specific marker of an aneurysm is ST segment elevation that persists weeks after the acute phase of infarction. Echocardiography can delineate LV aneurysms as well as left ventriculography and has a higher sensitivity in the detection of thrombus.[118] A left ventricular aneurysm may cause no problems, but may be associated with heart failure because the left ventricle functions at a mechanical disadvantage. Ventricular tachycardia late after infarction is commonly associated with an aneurysm, but its incidence may be reduced in patients receiving thrombolysis. In a non-randomized study of patients who developed a ventricular aneurysm after myocardial infarction, inducible ventricular tachycardia was less likely in patients who had received fibrinolytic therapy than those who had not (8% vs 88%; $P = 0.0008$) and there was a reduced incidence of sudden death on subsequent follow-up (0% vs 50%; $P = 0.002$).[119] A ventricular aneurysm also provides a nidus for the development of an intracavitary thrombus. The risk of a clinical embolic event, based on four observational studies, is approximately 5%[120] and is greatest within the first few weeks post infarction.

Management

Surgical removal of a left ventricular aneurysm is indicated in patients with heart failure that is difficult to control

medically, in patients with recurrent ventricular tachycardia not controlled by other means, and in patients with embolic episodes in spite of adequate anticoagulation.[121] The earlier technique of linear excision of the aneurysm was associated with a high mortality, and has been supplanted by geometric reconstruction surgery in which the aneurysm is excluded from the left ventricular cavity, first described by Vincent Dor.[122] An overview of the reported results of the newer approach suggested substantially better outcomes,[123] but recent RCT revealed no benefit.[123a]

Surgical treatment of post-MI left ventricular aneurysms can help in the control of intractable cardiac failure (**Class IIB, Level C**).

A pseudoaneurysm is a rare complication of MI that develops when a myocardial rupture is sealed off by surrounding adherent pericardium. The aneurysmal sac may progressively enlarge but maintains a narrow neck, in contrast to a true ventricular aneurysm. In a series of 290 patients with LV pseudoaneurysms, congestive heart failure, chest pain and dyspnea were the most frequently reported symptoms, but >10% of patients were asymptomatic.[124] Physical examination revealed a murmur in 70% of patients. Almost all patients had electrocardiographic abnormalities, but only 20% of patients had ST segment elevation. Radiographic findings were frequently nonspecific but a mass was detected in more than one half of patients. Differentiation of left ventricular pseudoaneurysms from true aneurysms may be difficult, and can be enhanced with echocardiography[125] or magnetic resonance imaging.[126] Regardless of treatment, patients with LV pseudoaneurysms have a high mortality rate, but especially those who are managed non-surgically.[127] Surgical repair can be achieved, albeit with a high mortality.[128]

Surgery should be considered in all patients with LV pseudoaneurysms (**Class IIB, Level B**).

Free wall rupture

Clinical features and prognosis

Rupture of the free wall of the left ventricle is an almost uniformly fatal complication of MI that now probably accounts for 10–20% of in-hospital deaths.[129] In the GISSI trial, cardiac rupture was the cause of 19% of the deaths among patients aged 60 years or younger and 86% of deaths among those more than 70 years old.[130] Rupture occurs most frequently in elderly women.[131] Anterior infarctions, hypertension on admission and marked or persistent ST elevation are also risk factors for rupture.[132] The usual presentation is sudden collapse, associated electrical-mechanical dissociation, and failure to respond to cardiopulmonary resuscitation, although in some patients

ventricular rupture is subacute, allowing time for antemortem diagnosis.[133] This clinical entity is probably underrecognized and may be amenable to surgical repair. Premonitory symptoms of chest discomfort, a sense of impending doom and intermittent bradycardia signal impending myocardial rupture in many cases[134] and, if recognized, can lead to life-saving surgery[135] although, in one report[136] of 81 consecutive patients presenting with acute hypotension with electrical–mechanical dissociation, 19 survived with medical management alone. Urgent echocardiography is invaluable in the assessment of a patient who develops the above clinical features.[137]

Overall, reperfusion reduces the frequency of rupture[138] but a meta-analysis of 58 cases of rupture involving 1638 patients from four trials showed that the odds ratio (treated/control) of cardiac rupture was directly correlated with time to treatment ($P = 0.01$); late administration of fibrinolytic therapy may increase the risk of cardiac rupture.[139]

Management

Urgent surgical repair is mandatory for acute rupture[140] (**Class I, Level B**).

Pericarditis

Clinical features and prognosis

Pericarditis occurs in approximately 25% of patients with Q-wave infarctions and 9% of patients with non-Q wave infarctions;[141] it usually occurs within the first week.[142] A pericardial friction rub may be present but is not found in half of patients with typical symptoms and is not required for diagnosis or treatment. On the other hand, the only evidence of pericarditis in many patients is a transient pericardial rub, with no symptoms. Pericarditis following myocardial infarction is associated with a higher risk of death in the year post infarction, possibly due to the associated large effusion.[141]

Management

High-dose aspirin and non-steroidal anti-inflammatory drugs (NSAIDs) are recommended to treat the symptoms of postinfarction pericarditis, although no randomized studies have been done to document their efficacy. Prolonged administration of NSAIDs should be avoided. A serial echocardiographic study of patients with postinfarction pericarditis showed that patients treated with indomethacin or ibuprofen showed a greater tendency for infarct expansion, but it was not clear if the infarct expansion was due to the NSAIDs or to the selection for treat-

ment of those with larger infarctions.[143] There is evidence that the adverse effects of the COX-2 inhibitors may affect endothelial function and enhance thrombosis by inhibiting the production of prostacyclin.[144] Recent reports indicate that the risks may be as high with all NSAIDs.[145,146] Until more observations become available, limited use of COX-2 inhibitors and NSAIDs in acute coronary syndromes is a sensible precaution.

A single dose or short-term treatment with a non-steroidal agent may be very effective for postinfarction pericarditis, but long-term therapy should be avoided (**Class IIb, Level B**).

Pericardial effusion and tamponade

A pericardial effusion can be detected by echocardiography in one-quarter of patients with acute Q-wave MI.[147] This finding correlates with the presence of heart failure and a poor prognosis. Cardiac tamponade is a rare complication of fibrinolytic therapy for acute MI, being reported in four of 392 consecutively treated patients in one series.[148] A large effusion and persistent pericarditis may be a sign of subacute rupture and should initiate consideration of surgical repair.

Dressler's syndrome

A form of postinfarction pericarditis, occurring 2–11 weeks after the acute event, was described in 1956 by Dressler.[149] The full syndrome includes prolonged or recurrent pleuritic chest pain, a pericardial friction rub, fever, pulmonary infiltrates or a small pulmonary effusion, and an increased sedimentation rate. There has been a striking reduction in the incidence of this postinfarction complication since the introduction of reperfusion into clinical practice.[150]

Non-steroidal anti-inflammatory drugs may be required for control of Dressler's syndrome, but there are no randomized trials to confirm their efficacy (**Class IIb, Level B**).

Cardiac thromboembolism

Clinical features and prognosis

The overall risk of stroke after MI estimated from published community-based studies is 11.1 ischemic strokes during hospitalization per 1000 MI, 12.2 at 30 days and 21.4 at one year.[151] In patients with large anterior STEMIs, left ventricular thrombi develop in up to 40%.[152] If left untreated, up to 15% of thrombi will dislodge and result in a symptomatic embolic event[153] This risk is higher in patients with large anterior infarctions[154,155] and patients with atrial fibrillation.[156] Emboli are more common within the first few months after infarction than later, and with large, irregular shaped thrombi, particularly those with frond-like appendages.[157]

When thrombus is visualized by echocardiography, the risk ratio for embolization is 5.45 (95% CI 3.0–9.8) according to a meta-analysis.[158] In NSTEMI, stroke is relatively uncommon but carries a high mortality. In a pooled analysis from six trials (n = 31 402) which included patients randomized to Gp IIb/IIIa inhibitors, there were 228 (0.7%) strokes: 155 (0.5%) non-hemorrhagic, 20 (0.06%) hemorrhagic, and 53 without computed tomography (CT) confirmation.[159] Older age, prior stroke and elevated heart rate were the strongest predictors of 30-day all-cause stroke. The risk of dying after a post-STEMI stroke is approximately 40%[160] and 25% after a NSTEMI stroke.[161] Fibrinolytic therapy is associated with an excess of stroke of four extra strokes on day one compared with placebo.[162] This risk is reduced if angioplasty is used instead of fibrinolytic therapy. In a meta-analysis comparing the effects of angioplasty with fibrinolysis, angioplasty was associated with a significant reduction in total stroke (0.7% vs 2.0%; $P = 0.007$) primarily due to a reduction in hemorrhagic stroke (0.1% vs 1.1%; $P < 0.001$).[163] In a Cochrane meta-analysis, the use of PCI compared with fibrinolysis significantly decreased the frequency of strokes of any cause by 66% (95% CI 28–84%) and no significant difference was observed for the incidence of major bleeding (RR 1.18, 95% CI 0.73–1.90) but the confidence intervals were large.[164]

PCI results in a lower risk of post-MI stroke compared with fibrinolysis (**Level B**).

Management

Anticoagulation with heparin followed by warfarin for six months has been shown to reduce the incidence of thromboembolism in patients with documented intracavitary thrombus (OR 0.14, 95% CI 0.04–0.52).[165] Meta-analysis of trials of anticoagulant therapy to prevent thrombus formation confirmed a benefit (OR 0.32, 95% CI 0.20–0.52) but no effect for antiplatelet drugs.[165] In a meta-analysis of all trials involving heparin administration in over 70 000 patients with acute myocardial infarction,[166] in the *absence* of aspirin, anticoagulant therapy reduced the risk of stroke to 1.1% from 2.1% (2P = 0.01), equivalent to 10 (95% CI 4) fewer strokes per 1000 (2P = 0.01). In the *presence* of aspirin, however, heparin was associated with a small non-significant excess of stroke and a definite excess of three major bleeds per 1000 (2P < 0.0001). An algorithm proposed by the STEMI guideline of the AHA and ACC of 2004 recommends the use of aspirin and warfarin for proven cardiogenic emboli, and aggressive investigation for other causes of stroke if there is no proof of a cardiac source of embolism.[6]

In post-MI patients, anticoagulation with aspirin and warfarin is recommended for proven cardiogenic emboli (**Class IIB, Level B**).

Acute mitral regurgitation

Clinical features and prognosis

Mitral regurgitation (MR) complicating acute myocardial infarction is usually due to dysfunction of the papillary muscles.[167] The milder form of mitral regurgitation is a relatively common complication of myocardial infarction, found in 19% of postinfarction patients who undergo left ventriculography[168] and 39% of those who undergo Doppler echocardiography.[169] Mitral regurgitation is an independent predictor of cardiovascular mortality in postinfarction patients; in patients studied with Doppler echocardiography, the hazard ratio for one-year mortality after adjustment for other prognostic variables was 2.31 (95% CI 1.03–5.20) for mild MR and 2.85 (95% CI 0.95–8.51) for moderate or severe MR.[170] The most severe form of mitral regurgitation results from complete rupture of the head of a papillary muscle and usually leads quickly to severe heart failure or cardiogenic shock. In the SHOCK trial registry, cardiogenic shock was associated with severe mitral regurgitation in 98 of 1190 patients.[171] The mitral regurgitation patients were more likely to be female and to have non-STEMI at the time of presentation, and to have inferior or posterior rather than anterior infarction.

Early diagnosis of mitral regurgitation complicating MI is important because mitral valve surgery can be life saving. Usually the diagnosis is evident clinically with a loud pansystolic murmur, maximal at the apex, and radiation to the axilla; however, if LV function is severely impaired or if left atrial pressure is very high, the murmur may be of low intensity or entirely absent. Echocardiographic examination is invaluable in confirming the diagnosis.[172] However, in some cases transthoracic echocardiography is non-diagnostic and transoesophageal echocardiography is required to assess the extent of the regurgitation. The presence of cardiogenic shock or severe failure with preserved LV function usually indicates that an important mechanical complication is present, and further investigation should be urgently pursued. If the mitral regurgitation is acute in its onset, the left atrium may not be greatly enlarged, and the pulmonary capillary wedge pressure tracing should exhibit large v waves. Large v waves are neither highly sensitive nor highly specific for severe chronic mitral regurgitation[173] but the correlation between giant v waves and severe acute mitral regurgitation is stronger.[174]

Management

Urgent mitral valve repair for severe post.infarction mitral regurgitation can give excellent long-term results[175] There is evidence from the SHOCK trial registry that transfer to a center skilled in mitral valve surgery for early operation

may be helpful.[171] The perioperative mortality associated with mitral valve surgery for postinfarction papillary muscle rupture is high, 27% in one series, but two-thirds of the survivors were still alive at seven years.[176] Patients with a low preoperative EF had the highest short-term and long-term mortality. Early reperfusion[177] has been shown to reduce the frequency of mitral regurgitation after myocardial infarction.[178] There have been reports of striking improvement in mitral regurgitation after emergency coronary angioplasty in patients with acute myocardial infarction.[179]

Urgent mitral valve repair is recommended for severe post-MI mitral regurgitation (**Class IIB, Level B**).

Ventricular septal rupture

Clinical features and prognosis

Rupture of the interventricular septum occurs in approximately 2% of patients with acute myocardial infarction.[180] The pathology of septal rupture is determined by the location of the associated myocardial infarction and has implications for surgical repair. Septal rupture complicating anterior infarction is usually apical and involves one direct perforation; septal rupture complicating inferior infarction often involves the posterior or basal septum with complex, serpiginous defects.[181] In the SHOCK trial registry of cardiogenic shock patients,[182] ventricular septal rupture occurred a median of 16h after infarction. The patients tended to be older ($P = 0.053$), were more often female ($P = 0.002$) and less often had previous infarction ($P < 0.001$), diabetes mellitus ($P = 0.015$) or smoking history ($P = 0.033$). The in-hospital mortality was higher in the shock patients with septal rupture (87% vs 61%, $P < 0.001$). Even when most patients undergo surgical repair, in-hospital or 30-day mortality remains high: 43–59%.[183,184] Early diagnosis may offer some hope of early repair. Most patients with septal rupture develop signs of acute right- and left-sided heart failure and a loud pansystolic murmur at the left sternal border. This may be difficult to distinguish from the murmur of acute mitral regurgitation. The murmur may be unimpressive or even absent when cardiac contractility is depressed. A large proportion of patients have a systolic thrill at the left sternal border. Echocardiography with Doppler color flow mapping is very sensitive and specific in the diagnosis of this condition; this technique also localizes the defect accurately and provides important prognostic information.[185]

Management

Early closure is now recognized to yield better results than attempting to wait for days or weeks until the conditions for surgery improve. Although early surgical intervention

may increase operative mortality, overall mortality is reduced. In the SHOCK trial register, surgical repair was performed in 31 patients with rupture, of whom six (19%) survived. Of the 24 patients managed medically, only one survived.[182] Technical advances in repair have led to better outcomes, but mortality remains high.[186] Transcatheter closure has been described and in a report from a national register, there was success in deploying a device across the VSD in 16 of 18 patients. The 30-day mortality was 28%.[187,188]

Early surgical closure of post-MI septal rupture is recommended but there are no clinical trials to guide therapy (**Class IIB, Level C**).

Transcatheter closure is a feasible alternative to surgical closure of post-MI septal rupture (**Class IIB, Level C**).

Ventricular fibrillation and sustained ventricular tachycardia

Clinical features and prognosis

Sustained monomorphic ventricular tachycardia is not common in the early postinfarction period but the GISSI-3 database showed it is a marker of adverse prognosis, and a strong independent predictor of six-week mortality (HR 6.13, 95%CI 4.56–8.25).[189] Ventricular fibrillation (VF) occurring in the absence of cardiogenic shock, severe heart failure or hypotension (primary VF) has a good short-term prognosis[190] although one major study of primary VF showed higher hospital mortality.[191] Patients surviving early in-hospital VF complicating myocardial infarction experience no adverse effect on long-term survival following hospital discharge.[192] The frequency of VF has declined over the past 20 years, as noted by Antman and co-workers, who demonstrated from the randomized trials of prevention of ventricular fibrillation that the frequency in the 1970s was 5–10%, dropping through the 1980s to less than 2%.[193,194] The reasons for this may include admission of lower risk patients to coronary care units, wider use of beta-blocking drugs and more effective treatment of ventricular dysfunction and electrolyte imbalances in the coronary care unit. The prognosis of ventricular fibrillation depends on the associated clinical state. VF occurring in the presence of hemodynamic compromise has a high hospital mortality of 80%.[195]

Management

Meta-analyses of the clinical trials have shown that prophylactic lignocaine was effective in reducing the frequency of ventricular fibrillation, but paradoxically did not improve mortality and was associated with a possible adverse effect.[196,197] For this reason the use of intravenous lignocaine as prophylaxis against ventricular fibrillation has been virtually abandoned.

Intravenous beta-blockers have been shown to reduce mortality, particularly in high-risk patients, with an apparent benefit in reduction of ventricular fibrillation[198,199] (**Class IIB, Level B**).

Low serum potassium is associated with a higher risk of VF[200] especially in patients on diuretic therapy prior to their infarction.[201] The use of intravenous magnesium may reduce the risk of ventricular fibrillation but no benefit on outcome has been demonstrated. Clinical trials have demonstrated a benefit in selected patients.[202]

Postinfarction ventricular premature beats and non-sustained ventricular tachycardia

Clinical features and prognosis

While frequent ventricular premature beats (more than 10 per hour) in the postinfarction patient are an independent risk factor for subsequent mortality (both total mortality and sudden death), the significance of non-sustained ventricular tachycardia in this setting is controversial.[203] The suppression of these ventricular arrhythmias has consistently failed to improve survival.

Management

Antiarrhythmic drugs

Trials of prophylactic antiarrhythmic therapy have provided no support for this practice, which has been widespread in the past. A meta-analysis of 138 randomized trials of prophylactic antiarrhythmic drug therapy involving 98 000 postinfarction patients, reported by Teo *et al* in 1993,[204] showed that the mortality of patients randomized to receive class I agents was increased (OR 1.14, 95% CI 1.01–1.28, $P = 0.03$). Clinical trials have shown some support for the use of the predominantly class III drug amiodarone. Two randomized clinical trials, each with more than 1000 postinfarction patients with either frequent or repetitive ventricular extrasystoles (CAMIAT)[205] or an EF of 0.40 or less (EMIAT),[206] have compared amiodarone to placebo. EMIAT reported no difference in mortality between treatment groups but CAMIAT reported a decrease in the primary endpoint, a composite of resuscitated ventricular fibrillation or arrhythmic death (3.3% vs 6.0%, RR 48%, 95% CI 4–72%), and a trend toward decreased all-cause mortality. A subsequent analysis indicated that a beneficial interaction between amiodarone and beta-adrenergic blocker drugs may have contributed to the benefit of amiodarone in these trials.[207] A limitation of amiodarone therapy is the high incidence of serious adverse effects seen with long-term therapy. The clinical trial evidence that is now available does not appear to be strong enough to recommend

amiodarone therapy to MI survivors with asymptomatic ventricular extrasystoles or a depressed EF. However, patients with symptomatic ventricular tachycardia as a long-term complication of MI often benefit from amiodarone therapy.

Implantable defibrillator

The implanted defibrillator reduced total mortality over 27 months in MADIT, a small randomized clinical trial in a specific high-risk subgroup of postinfarction patients.[208] Eligible patients had an EF of 0.35 or less, a documented episode of unsustained ventricular tachycardia, and inducible, non-suppressible ventricular tachyarrhythmia during electrophysiologic study. The risk ratio for total mortality was 0.46 (95% CI 0.26–0.82). The MADIT II trial of 1200 post-MI patients with impaired left ventricular function was terminated early after observing a 30% reduction in mortality in patients randomized to receive an implantable defibrillator device compared to those receiving conventional treatment.[209] There is no evidence that early implantation of an implanted cardiac defibrillator (ICD) will improve prognosis.[210] The evidence supports a policy of implantation of an ICD in patients with LV dysfunction due to prior MI who are at least 40 days post MI, have an LVEF less than or equal to 30–40%, are NYHA functional class II or III, are receiving chronic optimal medical therapy, and who have reasonable expectation of survival with a good functional status for more than one year.[211]

The AVID (Amiodarone Versus Implantable Defibrillators) study included a group of patients with ventricular fibrillation or ventricular tachycardia associated with a low EF or hemodynamic compromise.[212] The effect of an implanted cardiac defibrillator was compared to therapy with amiodarone or sotalol, the treatment decision guided by Holter or electrophysiologic study. There was a statistically significant benefit of defibrillator therapy compared to drug therapy. Similar results have been reported in two smaller randomized trials: the Canadian Implantable Defibrillator Study[213] and the Cardiac Arrest Study Hamburg.[214] In a subgroup analysis of the AVID database, patients with better-preserved left ventricular function with ejection fractions in the range of 35–40%, cardioverter-defibrillator therapy had no advantage over drug therapy.[215] In a meta-analysis of the defibrillator secondary prevention trials (AVID, CASH and SIDS), there was a 28% reduction in the relative risk of death in favor of defibrillator therapy over amiodarone therapy.[216]

Overall, the evidence indicates that class I antiarrhythmic drugs should not be used to treat ventricular extrasystoles or unsustained ventricular tachycardia post infarction (**Class III, Level B**).

Amiodarone may be effective in some high-risk patients, but has a risk of side effects with long-term use (**Class IIb, Level B**).

Beta-blockers reduce total mortality and the incidence of reinfarction by one-quarter in postinfarction patients, and should be commenced early (**Class I, Level A**).

Patients with LV dysfunction due to MI and are at least 40 days post MI, have an LVEF less than or equal to 30–40%, are NYHA functional class II or III, are receiving chronic optimal medical therapy, and who have reasonable expectation of survival with a good functional status for more than one year should receive an ICD (**Class I, Level A**).

Atrial fibrillation

Clinical features and prognosis

Atrial fibrillation is a relatively common complication of myocardial infarction. In patients with MI treated with thrombolytic therapy in the GUSTO 1 trial, atrial fibrillation was present on admission in 2.5% and developed during hospitalization in an additional 7.9% of cases.[217] Patients with atrial fibrillation more often had underlying three-vessel disease and an incompletely patent infarct-related artery. In-hospital stroke developed more often (3.1%) in patients with atrial fibrillation compared to those without (1.3%) ($P = 0.0001$). Atrial fibrillation was more likely to complicate the in-hospital course of older patients with larger infarctions, worse Killip class and higher heart rates. The unadjusted mortality was higher at 30 days (14.3% vs 6.2%, $P = 0.0001$) and at one year (21.5% vs 8.6%, $P = 0.0001$) in patients with atrial fibrillation. The adjusted 30-day mortality ratio was 1.3 (95% CI 1.2–1.4). In a study from the GISSI trial, the incidence of in-hospital atrial fibrillation or flutter was 7.8%, and was associated with a worse prognosis.[218] After adjustment for other prognostic factors, atrial fibrillation remained an independent predictor of increased in-hospital mortality (adjusted RR 1.98, 95% CI 1.67–2.34). Four years after acute myocardial infarction, the negative influence of atrial fibrillation persisted (RR 1.78, 95% CI 1.60–1.99).

The onset of atrial fibrillation is usually after the first hospital day, and the usual underlying causes are heart failure, pericarditis and atrial ischemia, with heart failure being by far the most common.[219] In a study based on 106 780 US Medicare beneficiaries ≥65 years of age, patients were categorized on the basis of the presence of AF, and those with AF were further subdivided by timing of AF (present on arrival versus developing during hospitalization).[220] Of the AF patients, 11 510 presented with AF and 12 055 developed AF during hospitalization. Patients developing AF during hospitalization had a worse prognosis than patients who presented with AF. In another study, detailed analysis of the prognosis of AF in AMI showed that AF was an independent predictor of cardiac death

when it developed within 24 hours (OR 2.5, 95% CI 1.2–5.0, $P = 0.0012$) and later (OR 3.7, 95% CI 1.8–7.5, $P = 0.0005$), but not when AF preceded the onset of AMI.[221]

Atrial fibrillation complicating acute myocardial infarction increases the incidence of mortality and stroke (**Level A**).

Management

Heart rate slowing is usually achieved with intravenous beta-blockers.[6] Amiodarone has been shown to be more effective than digoxin in achieving reversion to sinus rhythm.[222] In a prospective but not randomized study, the combination of amiodarone and digoxin was superior to amiodarone alone in restoring sinus rhythm faster, maintaining sinus rhythm longer, and allowing the use of a lower cumulative amount of amiodarone.[223] Studies comparing the effect of different treatment regimens on postinfarction atrial fibrillation have not addressed their effect on major outcomes.

Heart block and conduction disturbances

Clinical features and prognosis

Complete atrioventricular block occurred in 7.7% of patients with inferior MI in one large series.[224] In one series the in-hospital mortality rate was significantly higher (24.2% vs 6.3%, $P < 0.001$), but at hospital discharge the survivors had similar clinical characteristics to patients without complete atrioventricular block, and a similar mortality rate during the next year.[225] In a study of elderly patients who had suffered an acute MI, heart block was associated with increased in-hospital mortality but had no effect on prognosis at one year among hospital survivors.[226] There is some evidence that the widespread adoption of reperfusion therapy may have reduced the incidence of this complication of MI.[227] However, even in the "reperfusion era", among patients with inferior MI treated with fibrinolytic therapy, the development of complete atrioventricular block is associated with a relative risk of 4.5 for 21-day mortality.[228]

Management

In patients with inferior infarction, pacing is indicated if there is persistent high-grade atrioventricular block and hemodynamic instability.[229] In anterior infarction, the prognostic significance of atrioventricular block is even greater than for inferior MI. Patients with anterior MI and complete atrioventricular block had a 63% in-hospital mortality rate, compared with a 19% mortality rate in those without complete heart block.[224]

Transvenous pacing is required urgently for complete atrioventricular block complicating anterior infarction (**Class IIb, Level B**).

When right bundle branch block and left anterior hemiblock develop within the first few hours of infarction, prophylactic pacing may be considered but this practice remains controversial. If the patient survives, this type of heart block usually regresses, but there is a risk of complete heart block causing death after hospital discharge.[230] A small randomized trial showed no benefit of prophylactic placement of a permanent pacemaker.[231] The development of left or right bundle branch block, as a complication of MI is a marker of a larger infarct size and a higher mortality after hospital discharge[232] but is not an indication for prophylactic pacing. A randomized trial of pacing for bundle branch block complicating MI showed no advantage.[233] Left anterior hemiblock denotes neither a larger infarct size nor a worse prognosis.[234]

There is no clear indication for prophylactic pacing in post-MI conduction disturbance (**Class III, Level A**).

Psychosocial complications

Clinical features and prognosis

An estimated 20–50% of postinfarction patients have high levels of psychosocial stress, including anxiety, depression, denial, hostility, and social isolation.[235] A major depressive disorder may occur in as many as 15–20% of patients hospitalized with myocardial infarction[236] and depression has been shown to have a significantly adverse effect on outcome.[237] A meta-analysis of 16 cohorts involving 6367 MI patients showed that post-MI depression was significantly associated with an increased risk of all-cause mortality (OR 2.38, 95% CI 1.76–3.22, $P < 0.00001$) and cardiac mortality (OR 2.59, 95% CI 1.77–3.77, $P < 0.00001$).[238] The effects of depression are compounded by lifestyle factors, including isolation, which themselves have been shown to have an adverse effect.[239] Poor adherence to postinfarction therapies has been shown to be a possible mechanism for the adverse outcome of depressed postinfarction patients.[240]

Management

Cardiac rehabilitation programs provide psychologic and social support to patients after MI, in addition to education about risk factors and their modification. Randomized clinical trials of formal exercise programs post infarction have shown benefits on quality of life, but have not yielded definitive results individually on prognosis. In an overview that included 36 trials involving 4554 patients, after an average follow-up of three years, the OR was 0.80 for total mortality (95% CI 0.66–0.96), although the rate of non-

fatal reinfarction was not reduced.[241] An overview of randomized trials of disease management programs in patients with known coronary disease (including myocardial infarction) showed improvements in processes of care, quality of life and functional status and admissions to hospital (RR 0.84, 95% CI 0.76–0.94), but no reductions in all-cause mortality (RR 0.91, 95% CI 0.79–1.04)) or recurrent myocardial infarction (RR 0.94, 95% CI 0.80–1.10).[242]

The effect of a specific nursing intervention designed to improve the psychologic and social status of postinfarction patients was assessed in the Montreal Heart Attack Readjustment Trial (M-HART). The 1376 patients were randomized to usual care or to a treatment plan consisting of nurse visits and telephone calls to patients exhibiting high levels of psychologic stress. The intervention had no effect on mortality in men, and was associated with an increased mortality in women that was of borderline statistical significance ($P = 0.069$).[243] The use of psychosocial intervention was compared to usual care in a study of 2481 post-MI patients who were depressed and with a low level of social support.[244] The intervention included cognitive behavioral therapy and pharmacotherapy for non-responders with severe depression. There was no significant difference between the two groups with regard to the primary endpoint of death and MI over a period of 48 months. A clinical trial of sertraline showed benefits on mood without any adverse effects on left ventricular function, QT interval or major cardiovascular outcomes.[245] Overall, while trials of psychosocial interventions have yielded inconsistent results with regard to hard cardiovascular endpoints such as death and MI, there is some evidence that these interventions improve functional status and quality of life.

Cardiac rehabilitation and support programs may improve quality of life but have not been shown to improve major cardiovascular outcomes (**Level B**).

If postinfarction depression is severe enough to require treatment, sertraline may be effective without adverse cardiac effects (**Class II, Level B**).

34 An integrated approach to the management of patients after the early phase of ST segment elevation myocardial infarction

Pedro L Sánchez and Francisco Fernández-Avilés

Hospital General Universitario Gregorio Marañón, Madrid, Spain

Introduction

Regardless of the initial and immediate reperfusion management of patients with ST segment elevation acute myocardial infarction (STEMI), the main objective of the management of STEMI patients after the early phase should be to avoid early ischemic complications and long-term cardiac death. Thus, the therapeutic approach to prevention of these events depends upon the identification of those patients who are at the greatest risk of coronary instability and non-arrhythmic or arrhythmic death and the effectiveness of the available preventive measures and therapy. In addition, we also provide an overview of secondary prevention applicable not only to STEMI but also to the complete spectrum of the acute coronary syndrome. Mechanical or acute electrical complications are covered in Chapter 33. The evidence base for managing patients with STEMI and no clinical instability is discussed under the heading of risk stratification and management.

Invasive evaluation after the early phase of STEMI

Invasive evaluation is considered both after fibrinolytic therapy and in patients who did not undergo primary percutaneous coronary intervention (PCI) to minimize short-term ischemic complications. Furthermore, complete revascularization should also be considered in STEMI patients who undergo primary PCI of the culprit artery but with other severe stenosis. Cardiac catheterization and revascularization should always be considered in patients with recurrent ischemic chest discomfort or with poor left ventricular function.[1–3]

Ischemia-driven PCI after fibrinolysis

The DANAMI-1 trial[4] was the first and only prospective randomized study comparing an invasive strategy (PCI or coronary bypass surgery) with a conservative strategy in 1008 patients with a first STEMI and predischarge inducible myocardial ischemia after fibrinolysis. The primary combined endpoint (mortality, reinfarction, and admission with unstable angina) was significantly reduced even after long-term follow-up. Thus, patients who have received treatment with fibrinolysis and have inducible ischemia before discharge should undergo coronary angiography and be revascularized as appropriate.

Routine invasive evaluation and PCI early after fibrinolysis

Theoretically, in STEMI patients successfully reperfused with thrombolytics, routine mechanical repair of the infarct-related artery could eliminate residual stenosis, thus reducing reocclusion and related events. In the late 1980s studies of systematic cardiac catheterization and percutaneous procedures in STEMI patients with prior fibrinolytic therapy yielded disappointing results.[5–7] However, current interventional practice, including the use of stents, thienopyridines, and IIb/IIIa inhibitors, has led to studies that support the role of early routine angioplasty in the management of STEMI patients treated with fibrinolysis.

Six randomized studies (a total of 1835 patients) support routine coronary angiography and, if applicable, PCI shortly after fibrinolysis (SIAM III,[8] GRACIA-1,[9] CAPITAL-AMI,[10] the Leipzig Prehospital Fibrinolysis Study,[11] WEST[12] and CARESS-in-AMI.[12a] In the present era of stents and glycoprotein IIb/IIIa inhibitors, early elective stenting following fibrinolysis is feasible and safe. Moreover, it permits rapid patient risk stratification, substantially reduces hospitalization, improves left ventricular outcome, prevents reocclusion and, consequently, reduces the incidence of adverse coronary events at one year. Early routine PCI is

defined as a planned early percutaneous repair of the culprit artery in patients with STEMI who have been successfully reperfused with fibrinolytics. It should be distinguished from facilitated and rescue PCI,[3] both examined elsewhere in this book as reperfusion strategies in STEMI.

Completeness of revascularization for multivessel coronary artery disease after primary PCI

Multivessel coronary disease is present in approximately 50% of patients with STEMI. Both the American College of Cardiology/American Heart Association (ACC/AHA) guidelines[1,13] and the European Society of Cardiology (ESC) guidelines[2,3] recommend that, in patients with multivessel disease, primary PCI should be directed only at the infarct-related artery, with no clear statement about PCI of non-culprit lesions. One exception may be a patient with severe multivessel disease and persistent shock after PCI of the infarct-related vessel, for whom same-procedure revascularization (or bypass surgery) may be considered to reduce the ischemic burden. However, PCI of non-culprit vessels simultaneously or soon after primary PCI in stabilized patients has seldom been studied in randomized controlled trials, and observational studies provide contradictory findings.

Two observational studies reported that multivessel PCI, although feasible, was associated with a higher incidence of major adverse cardiovascular events (MACE) than infarct-related artery revascularization.[14,15] Other observational studies have shown the opposite, with significantly improved clinical outcomes when complementary multivessel disease revascularization is performed,[16–18] even simultaneously.[17]

Two randomized trials (PRIMA,[19] HELP AMI[20]) evaluating the impact of complete revascularization in patients with STEMI also failed to give an answer. Although the hypothesis that complete and simultaneous revascularization could improve ejection fraction was supported by the PRIMA study, in HELP AMI (69 patients), the one-year incidence of repeat revascularization was similar between patients randomized to culprit lesion treatment only or to complete multivessel revascularization. Therefore, there is no evidence to recommend complete revascularization for multivessel coronary disease after primary PCI.

Invasive evaluation and PCI for patients initially not undergoing primary reperfusion

Patients often seek medical attention too late and either do not receive reperfusion therapy or reperfusion therapy fails to successfully recanalize the artery. Thus, it was suggested that achieving coronary patency in either of these situations might have a beneficial effect by preventing adverse left ventricular remodeling, improving left ventricular

function,[21–23] increasing electrical stability, and providing collateral vessels to other coronary beds for protection against future events (the open artery hypothesis).

Two contemporary trials have recently re-evaluated this hypothesis: OAT (Occluded Artery Trial)[24] and TOSCA (Total Occlusion Study of Canada-2).[25] In the OAT,[24,26] 2166 stable high-risk (ejection fraction of <50% or proximal occlusion) patients with an occluded infarct artery 3–28 days after myocardial infarction (20% of whom received fibrinolytic therapy for the index event) were randomized to medical therapy or PCI. Exclusion criteria included NYHA class III or IV heart failure, rest angina, serum creatinine greater than 2.5 mg/dL, left main or three-vessel disease, clinical instability, or severe inducible ischemia on stress testing if the infarct zone was not akinetic or dyskinetic. PCI did not reduce the occurrence of death, reinfarction, or heart failure. Furthermore, there was a trend toward excess reinfarction during four years of follow-up in the invasive group compared with the medical therapy group.

In the TOSCA-2 trial,[25] 381 patients with an occluded native infarct-related artery (IRA) 3–28 days after myocardial infarction were randomized to PCI with stenting or optimal medical therapy alone. At one year, although patency of the infarct-related artery was significantly higher in the PCI group (83% vs 25%), left ventricular ejection fraction did not differ between the groups. These studies demonstrate that elective PCI of an occluded infarct-related artery 3–28 days after myocardial infarction in stable patients has no incremental benefit beyond optimal medical therapy in preserving ventricular function and preventing cardiovascular events.

Preventing cardiac remodeling

Although the mortality of patients with STEMI has decreased in recent years because of faster and more frequent administration of reperfusion treatment, some patients still experience poor clinical outcomes, which are closely linked to infarct size and onset of heart failure, among other factors. One of the main risks faced by patients with extensive infarctions who survive the hospitalization phase is the development of progressive ventricular dilation and dysfunction in the following months. Determinants of ventricular remodeling include large infarct size, anterior location, lack of patency of the infarct artery, use of thrombolytic agents, and lack of negative T-wave resolution. Although this left ventricular remodeling process could have a compensatory purpose, it often occurs in association with the development or worsening of heart failure and leads to greater mortality. In fact, heart failure is the main cause of cardiac mortality after the acute phase of STEMI;[27,28] therefore, treatments aimed at avoiding or

reversing remodeling have been recognized as a goal of therapy and include pharmacologic interventions, stem cell transplantation, and mechanical interventions.

Pharmacologic therapy

Several trials have established that angiotensin-converting enzyme (ACE) inhibition, started in the early phase of STEMI with captopril, enalapril, ramipril, trandolapril, fosinopril or zofenopril, reduces adverse cardiac remodeling and mortality after STEMI.[29–36] The benefit is greater in high-risk patients such as those with depressed ejection fraction (SAVE,[29] TRACE[31]), those who develop heart failure after myocardial infarction (AIRE[30]), and those with anterior myocardial infarction (SMILE,[33] FAMIS[34]), although it can be extended to all STEMI patients (ISIS-4[35] and GISSI-3[36]).

Several meta-analyses of ACE inhibitors have confirmed their beneficial effects in patients with STEMI regardless of whether administration is early (within 48 hours of infarction) or late (>48 hours to 16 days).[32,37–39] The administration of an ACE inhibitor is associated with a significant reduction in mortality (50 lives saved per 1000 patients treated in high-risk patients and five lives saved in low-risk patients), a significant reduction in heart failure (absolute reduction of 3.5%), and significant reduction in the incidence of reinfarction (absolute reduction of 2.4%).

Angiotensin II receptor blockers have also been tested in patients with STEMI. Initial studies (OPTIMAAL[40] and VALIANT[41]) found that the angiotensin II receptor blockers losartan and valsartan, respectively, were not superior to captopril in high-risk patients after STEMI. Furthermore, the VALIANT study did not show any additional benefit with the combination of valsartan and captopril. Thus, angiotensin II receptor blockers should not be administered in addition to an ACE inhibitor immediately after myocardial infarction, although they are recommended as a substitute in patients who cannot tolerate ACE inhibitors.

Atrial natriuretic peptide has also been examined as a pharmacologic approach to preventing adverse remodeling early after STEMI. Atrial natriuretic peptide suppresses the renin-angiotensin-aldosterone system and endothelin-1, which stimulate left ventricular remodeling. Compared to nitroglycerin, atrial natriuretic peptide improved left ventricular ejection fraction and prevented left ventricular hypertrophy.[42] However, recent concerns about the possible adverse effects of infusing B-type natriuretic peptides have discouraged further studies.[43]

In addition to their antiarrhythmic properties, beta-blockers have beneficial effects on left ventricular remodeling after acute myocardial infarction and are associated with an improvement in left ventricular ejection fraction (LVEF), reduction in volume indexes, and incremental fractional shortening. They should be given early after STEMI, and are more effective when combined with ACE inhibitors and as continued therapy.[44–46]

Stem cell therapy

The evidence that stem cells may reconstitute necrotic myocardium and improve cardiac function in animals[47] has led to clinical studies that initially examined the feasibility and safety of this therapy and later evaluated its efficacy in reversing adverse cardiac remodeling.[48] Pharmacologic mobilization of bone marrow stem cells with growth factors and catheter-based percutaneous intracoronary infusion of bone marrow-derived cells are the only methods that have been used to date for stem cell administration in patients with recent myocardial infarction.

Six Phase II randomized trials have evaluated the intracoronary administration of mononuclear bone marrow stem cells in patients with STEMI early after revascularization of the culprit artery; three studies failed to demonstrate a beneficial effect on improvement of ejection fraction,[49–51] and three showed an initial mid-term benefit.[52–54] The REPAIR-AMI trial,[53] also designed as a double-blind study, including 204 patients from 17 European centers, is the largest study performed to date. It showed a significant increase in the LVEF ($5.5 \pm 0.7\%$ versus $3.0 \pm 0.7\%$; $P = 0.014$) between stem cell recipients and patients who received placebo. Technical differences in the characteristics or handling of the infused stem cells might explain the different outcomes observed between trials.[55] A meta-analysis of 10 studies (Phase I and II) of intracoronary stem cell therapy involving 698 patients with recent acute myocardial infarction (within 14 days of the event) showed that stem cell therapy was associated with a significant increase in LVEF (3.0%), reduction in infarct size (−5.6%), reduction in end-systolic volume (−7.4 mL), and a trend toward reduced end-diastolic volume (−4.6 mL).[56] Intracoronary stem cell therapy was also associated with a significant reduction in recurrent AMI ($P = 0.04$) and with trends toward reduced death, rehospitalization for heart failure, and repeat revascularization. Thus, intracoronary stem cell therapy following PCI for STEMI appears to provide benefits for cardiac function and remodeling.

More conflicting results are observed in patients with acute myocardial infarction receiving granulocyte colony-stimulating factor (G-CSF). Although initial randomized studies showed a significant benefit in left ventricular remodeling,[57] four further studies did not find any differences in the left ventricular function among patients treated with the factor or placebo.[58–61] The divergent results may have been due to the absence of homing signals, timing of drug administration (in the study which showed a benefit, G-CSF was administered immediately after myocardial infarction, while in others administration was delayed for

3–5 days after revascularization), subpopulations of stem cells that were mobilized but not effective, and poorly defined study objectives. A meta-analysis including seven studies (Phase I and II) of G-CSF mobilized stem cells involving 318 patients with recent acute myocardial infarction (within 14 days of the event) showed that mobilization was associated with a significant increase in LVEF (2.9%) during follow-up, similar to that observed with intracoronary delivery of bone marrow-derived stem cells.

Mechanical interventions

Ventricular remodeling has been attributed to the segmental loss of viable myocardium due to myocardial infarction, which results in a redistribution of cardiac workload, with increased regional stress in the susceptible infarct and peri-infarct zones. Therefore, a reduction in wall stress early after an MI may help attenuate remodeling. Such a reduction in wall stress can be achieved by appropriate cardiac resynchronization therapy with biventricular pacing. The first reports on the feasibility and safety of this approach early after STEMI have recently been published.[62]

Preventing arrhythmic complications

All STEMI patients are at increased risk of sudden cardiac death, most often due to ventricular arrhythmias and especially in the first months after the episode of infarction.[63] Thus, identification of patients at risk is essential. Determinants of arrhythmic complications include reduced LVEF,[63–69] ventricular premature beats and non-sustained ventricular tachycardia,[64,65,70–72] late potentials,[73–75] QRS duration,[76] reduced heart variability,[77–81] and T-wave alternans.[75,82] Which risk factor to select and in which context is difficult to determine due to the limited amount of data directly comparing multiple risk factors. The most important initial parameter is probably LVEF, as most studies determining whether or not a patient who has had a myocardial infarction will require an implantable cardioverter defibrillator for primary prevention are based upon this parameter.[83–88]

Apart from LVEF, major scientific societies do not strongly recommend a routine non-invasive assessment of the risk of ventricular arrhythmias (including signal-averaged ECG, 24-hour ambulatory monitoring, heart rate variability, evoked potentials, or T-wave alternans) in patients recovering from STEMI.[1,2] Thus, the therapeutic approach to prevention of arrhythmic death depends upon the identification of high-risk patients and the implementation of proven therapeutic and preventive measures. Several large-scale studies have demonstrated that treatment with beta-blockers, ACE inhibitors, aldosterone antagonists, and statins results in reduction of all-cause mortality but also

of sudden cardiac death. In addition to optimal pharmacologic therapy, implantable cardioverter defibrillators (ICD) further decrease the risk of arrhythmic death.

Pharmacologic therapy

Beta-blockers
Several trials and meta-analyses from the pre-reperfusion era demonstrated that beta-blockers reduce mortality and reinfarction in patients recovering from acute myocardial infarction.[89,90] In the era of reperfusion therapy, convincing randomized data have shown that beta-blocker therapy improves survival during the acute phase of myocardial infarction. The CAPRICORN trial randomized 1959 patients with a LVEF of 40% or less to carvedilol or placebo 3–21 days after myocardial infarction.[91] There was a significant reduction in all-cause mortality from 15% to 12%. Furthermore, sustained ventricular tachyarrhythmic events were reduced by more than 70%,[92] confirming that treatment with beta-blockers (in addition to fibrinolysis or primary angioplasty, aspirin, and ACE inhibitors) reduces all-cause mortality and arrhythmic death.

ACE inhibitors
As pointed out previously, ACE inhibitors are one of the mainstay treatments for myocardial infarction and have been shown to improve survival. The best available data on the effect of ACE inhibitors on preventing sudden cardiac death come from a review of 15 randomized trials of ACE inhibitors which included 15 104 patients.[93] Overall mortality was reduced by 17%, with a significant reduction of 20% for sudden cardiac death. This beneficial effect on sudden cardiac death of reducing ventricular remodeling has been recently confirmed in patients with non-STEMI without clinical heart failure or overt left ventricular systolic dysfunction enrolled in the HOPE trial.[94]

Aldosterone antagonists
Two trials (RALES[95] and EPHESUS[96]) of aldosterone antagonists found significant reductions of all-cause mortality and sudden cardiac death. The RALES trial evaluated the effect of spironolactone in patients with congestive heart failure, half of whom had a history of ischemic disease. The risk for sudden cardiac death was reduced by 29%. In the EPHESUS trial, eplerenone administered 3–14 days after myocardial infarction reduced the risk of sudden cardiac death by 21%.

Statins
There is no information available from randomized trials to indicate a benefit of statins for prevention of arrhythmia in patients with STEMI. However, two observational studies in patients with ICD noted a potential benefit of statins in preventing ventricular arrhythmias.[97,98]

Implantable cardioverter-defibrillator for primary prevention after the early phase of STEMI

The incidence of ventricular arrhythmias is higher during the first hours of an infarction, declines after the event, but remains elevated indefinitely in high-risk patients. The best approach to the selection of myocardial infarction patients to receive ICD therapy for primary prevention of sudden death has been explored in randomized trials in patients with left ventricular dysfunction and chronic myocardial infarction (MADIT 1,[83] MADIT 2,[85] CABG-Patch,[87] MUSTT,[84] and SCD-Heft[88]) and in patients with left ventricular dysfunction early after the infarction event (DINAMIT[86]).

Prophylactic use of an ICD has been shown to prolong life in patients with chronic myocardial infarction or ischemia and reduced left ventricular function[83–85,88] (see Chapter 40). However, as these studies have enrolled few patients with a recent myocardial infarction, the value of early ICD therapy is still uncertain. The DINAMIT trial is the only prospective randomized study comparing the role of prophylactic ICD compared with placebo in patients experiencing acute myocardial infarction within the preceding 6–40 days (average time from myocardial infarction to randomization was 18 days).[86] Inclusion criteria included LVEF ≤35% and reduced heart rate variability or elevated resting heart rate. The ICD group had a larger reduction (>50%) than the control group in risk of death due to arrhythmia; however, this effect was offset by a similarly large increase in the risk of death from non-arrhythmic causes. The unexpected increase in mortality from causes other than arrhythmia may have been due to subsequent heart failure, of which ventricular arrhythmias were a harbinger. Consequently, prophylactic ICD therapy is not currently recommended less than 40 days after myocardial infarction. In addition, a recent substudy of MADIT 2 demonstrated no survival benefit for patients in whom the time interval from the index infarction to ICD implantation was less than 18 months, creating uncertainty about the benefit of prophylactic ICD therapy early after myocardial infarction in patients with left ventricular dysfunction.[99]

Secondary prevention

After the initial phase, patients with STEMI carry a high risk of recurrence of ischemic events. Therefore, active secondary prevention is an essential element of long-term management.[100–102] A detailed review of all the measures available for secondary prevention is beyond the remit of this chapter; therefore, emphasis will be placed on the most important.

Discharge

Low-risk STEMI patients (age ≤70 years, LVEF >45%, one- or two-vessel disease, successful PCI, no persistent arrhythmias, early reperfusion from clinical onset) can be safely discharged on day 3 after STEMI.[103,104] Wide application of this management strategy may result in substantial cost savings.

Lifestyle

Although smoking cessation is difficult to achieve in the long term, observational studies show that the mortality rate of those who quit smoking in the following years is less than half that of those who continue to smoke.[105] This is, therefore, potentially one of the most effective of all secondary prevention measures. Active counseling with programs in which specially trained nurses maintain contact with patients over several months,[106] in addition to adjuvant therapy with nicotine replacement, bupropion and varenicline are necessary.[100–102] Physical activity is strongly encouraged. Regular, moderate, daily aerobic activity is preferred.[100–102] A healthy diet based on low salt intake and reduced intake of saturated fats is essential. Regular intake of fruit and vegetables should be encouraged. Moderate alcohol consumption may be beneficial.

Weight reduction

Obesity, particularly central or abdominal obesity, is often associated with other risk factors for cardiovascular disease (hypertension, dyslipidemia and insulin resistance). The theoretic goal is to achieve a body mass index (BMI) <25 kg/m^2 or a waist circumference <102 cm (40 inches) in men and <89 cm (35 inches) in women.[102] Although these are the long-term goals, an initial weight loss of 10% from baseline is a first step. Further weight reduction can be attempted if the initial 10% weight loss is successfully achieved and maintained. A multimodality approach including diet, increased physical activity, and possible pharmacologic therapy is recommended.

Blood pressure control

The goal for blood pressure is <140/<90 mmHg in almost all patients, including those with cardiovascular disease alone.[107] A lower goal (<130/<80 mmHg) is recommended only in patients with diabetes and/or chronic renal failure. Lifestyle interventions, particularly physical activity, weight loss, and pharmacotherapy are essential to achieve blood pressure control.

Management of diabetes

Glycemic balance abnormalities should be actively sought in every patient with acute coronary syndrome. In post-

myocardial infarction diabetics, the 2006 ACC/AHA guidelines recommended an HbA1c goal of <7%, and ideally ≤6.5%.[102] Among patients with type 2 diabetes, aggressive management of lipids (LDL <70 mg/dL (1.8 mmol/L), HDL >40 mg/dL (1.1 mmol/L)), triglycerides <150 mg/dL (1.7 mmol/L)), and blood pressure (<130/<80 mmHg) appear to be at least as important as glycemic control. Lifestyle measures, in addition to weight loss in obese patients, and adapted pharmacotherapy are of great importance. In patients with impaired fasting glucose level or impaired glucose tolerance, no specific hypoglycemic treatment has been recommended except for lifestyle changes.

Interventions on lipid profile

Interventions on low-density lipoprotein cholesterol (LDL-c), high-density lipoprotein cholesterol (HDL-c), and triglycerides are an important component of the long-term management of STEMI. Most of the evidence has been obtained in the field of LDL-c reduction, which is best achieved with statins or a combination of statins and other lipid-lowering agents.

The use of statins, irrespective of cholesterol levels, has been addressed in the 4S,[108] CARE,[109] LIPID,[110] and HPS[111] trials, which compared statin therapy to placebo across a wide range of LDL-c. The concept that lower is better was tested in the PROVE IT,[112] IDEAL,[113] TNT,[114] and Phase A to Z trials,[115] which randomly assigned patients to more or less intense statin therapy. The last four trials showed greater clinical improvement with a more intense regimen and demonstrated a reduction in the incidence of stroke.

The ATP III guidelines recommended that the LDL-c goal should be less than 100 mg/dL (2.6 mmol/L) in all patients with myocardial infarction.[116] This goal is also recommended by the American guidelines for secondary prevention.[102] The modified ATP guidelines published in 2004,[117] and the American[118] and European[119] guidelines on the management of non-ST elevation acute coronary syndrome recommend an optional LDL goal of less than 70 mg/dL (1.8 mmol/L) for high-risk patients. Statins are therefore recommended for all STEMI patients irrespective of cholesterol levels and should be initiated early after admission to achieve LDL levels <100 mg/dL (2.6 mmol/L).

Antiplatelet agents and anticoagulants

Long-term aspirin therapy reduces the risk of reinfarction, stroke, and vascular death in STEMI patients by approximately 25%.[120] American and European guidelines[3,102] recommend indefinite daily oral aspirin therapy of 75–162 mg. Clopidogrel should be administered to all patients for whom aspirin is contraindicated. According to recently published recommendations for NSTEMI,[119] after PCI revasculariza-

tion, clopidogrel (75 mg) must be continued for at least one month and ideally one year if a bare metal stent has been used or at least 12 months in the case of drug-eluting stents.

Although there is evidence of clinical benefit from warfarin plus aspirin compared with aspirin alone,[1] the applicability of this evidence to current practice is unclear, in part because most patients with STEMI are treated with dual antiplatelet therapy (aspirin and clopidogrel), and in part due to unproven applicability to current practice.[121] Thus warfarin should be considered for long-term use in patients with STEMI and persistent or paroxysmal atrial fibrillation, for at least three months in patients with left ventricular thrombus observed on an imaging study, and ideally indefinitely and at a lower dose in patients with left ventricular dysfunction and extensive regional wall motion abnormalities.[1]

Beta-blockers

Beta-blockers should be initiated in all STEMI patients and maintained indefinitely in the case of reduced left ventricular function, with or without symptoms of heart failure.[102] In other patients, beta-blockers may be useful, but evidence of their long-term benefit is not fully established. Low doses are generally recommended initially in patients with heart failure to minimize the risk of an acute worsening of cardiac function.

ACE inhibitors and angiotensin-II receptor blockers

ACE inhibitors and angiotensin receptor blockers decrease cardiovascular mortality and prevent cardiac adverse remodeling after myocardial infarction. For patients with reduced left ventricular function, an oral ACE inhibitor should be started on the first day after admission, in the absence of contraindications. For other patients, treatment should be initiated during hospitalization.

Influenza vaccination

Individuals with established cardiovascular disease and those at high risk are susceptible to the complications of influenza infection. Two randomized controlled trials have demonstrated a reduction in cardiovascular events as a result of influenza vaccination in this patient population.[122,123] The 2006 ACC/AHA guidelines recommended annual influenza vaccination using the inactivated preparation for all persons with atherosclerotic cardiovascular disease.[124]

Rehabilitation and return to physical activity

Two systematic reviews of exercise-based rehabilitation trials concluded that rehabilitation programs reduced

mortality after infarction by 20–25%.[125,126] A Cochrane review of 8440 patients with coronary heart disease showed a 31% reduction in mortality.[127] However, these results must be viewed with caution as the studies were undertaken before the widespread use of aspirin, beta-blockers, and ACE inhibitors in postinfarction patients. After STEMI, patients should probably undergo an ECG-guided exercise test or an equivalent non-invasive test for ischemia within 4–7 weeks after discharge following the recommendations of NSTEMI patients.[119] However, applicability to current practice appears difficult. This approach could also help when giving patients advice on the level of physical activity including leisure, work, and sexual activity.

Evidence-based integrated approach to management of patients after the early phase of STEMI

Management of patients after the early phase of STEMI attempts to avoid early ischemic complications and late cardiac death (principally due to heart failure and arrhythmias).

Invasive evaluation after the early phase of STEMI

• Patients with recurrent ischemic chest discomfort or with left ventricular dysfunction should undergo coronary angiography and PCI or CABG as dictated by coronary anatomy (**Class I, Level B**).
• Patients who have received successful treatment with fibrinolysis should undergo routine coronary angiography and, if applicable, PCI after fibrinolysis (**Class I, Level A**).
• Patients who have received treatment with fibrinolysis and have inducible ischemia before discharge should be referred to coronary angiography and revascularized (**Class I, Level B**).
• Elective angiography and PCI of an occluded infarct artery 3–28 days after myocardial infarction should not be performed in stable patients (**Class III, Level B**).

Preventing cardiac remodeling

• ACE inhibitors should be prescribed following STEMI, because of confirmed beneficial effects on avoiding cardiac remodeling and mortality, whether they are begun early (within 48 hours of infarction) or later (more than 48 hours to 16 days) (**Class I, Level A**).
• Angiotensin II receptor blockers should not be combined with an ACE inhibitor in the immediate postinfarction setting. They are recommended in patients who cannot tolerate ACE inhibitors (**Class I, Level A**).
• Beta-blockers, especially when combined with ACE inhibitors, should be administered after acute myocardial

infarction because of their beneficial effects on left ventricular remodeling and recurrent coronary events (**Class I, Level A**).
• Intracoronary stem cell therapy following PCI and mobilization of stem cells with G-CSF appears to provide benefits on cardiac function and remodeling (**Level B**).

Preventing arrhythmic complications

• Pharmacologic treatment with beta-blockers (**Class I, Level A**), ACE inhibitors (**Class I, Level A**), aldosterone antagonists (**Class I, Level A**), and statins (**Class I, Level B**) should be implemented to reduce the probability of sudden cardiac death.
• Prophylactic ICD therapy in patients with STEMI and severe left ventricular dysfunction is recommended but not less than 40 days after myocardial infarction (**Class I, Level A**).

Secondary prevention

• Lifestyle modification, smoking cessation (**Class I, Level B**), weight reduction (**Class I, Level B**), and physical activity (**Class I, Level B**) are recommended.
• Lipid-lowering diet (**Class I, Level B**) and statins (**Class I, Level A**) are recommended.
• Aspirin is recommended for all patients without contraindications (**Class I, Level A**). Clopidogrel in addition of aspirin is recommended in patients who have undergone coronary stenting (duration at least one month for bare metal stents and 12 months for drug-eluting stents) (**Class I, Level A**).
• Warfarin is recommended for patients with STEMI and persistent or paroxysmal atrial fibrillation (**Class I, Level A**), for patients with STEMI and left ventricular thrombus (**Class I, Level C**) and, ideally, indefinitely and at a lower dose in patients with left ventricular dysfunction and extensive regional wall motion abnormalities (Class IIa, Level A).
• Beta-blockers (**Class IIa, Level B**) and ACE inhibitors are recommended for all patients with STEMI (**Class IIa, Level B**).
• Annual influenza vaccination is recommended for all patients with STEMI (**Class I, Level B**).

Introduction

The Framingham Study in the US and the Rotterdam Study in Europe have estimated lifetime risk for development of atrial fibrillation (AF) to be 1 in 4 for men and women 40 years of age and older.[1,2] Projected data from two population-based studies in the US predict a 2.5 to 3-fold increase in the number of patients with AF by 2050.[3,4] The high lifetime risk for AF and increased longevity underscore the important public health burden posed by this arrhythmia across the world. Because AF has multiple etiologies and a broad variety of presentations it demands a range of therapeutic responses. The primary pathologies underlying or promoting the occurrence of AF vary more than for any other cardiac arrhythmia, ranging from autonomic imbalance through organic heart disease to metabolic disorders, such as diabetes mellitus, metabolic syndrome, and hyperthyroidism. A rational approach to management of the individual case depends on careful assessment of the temporal pattern of the arrhythmia, associated cardiovascular disease, and any particular features suggesting the advisability or risks of any particular treatment regimen. The nature of AF and of individual patient factors change over time, requiring a flexible approach to long-term management.

AF usually tends to recur and may follow a predictable pattern. Paroxysmal AF generally progresses to persistent and/or permanent over time. In the Canadian Registry of AF (CARAF) 8–9% of patients with new-onset paroxysmal AF developed a sustained arrhythmia by the end of the first year; about 25% were in permanent AF by 5 years.[5] Rates appear to be higher for those with a persistent variety, with 35–40% developing the permanent arrhythmia by the end

of the first year since diagnosis.[6,7] Between two-thirds and three-quarters of patients had documented recurrence of AF within 5 years, despite continuous antiarrhythmic drug therapy.[5] However, even these projections may represent conservative estimates because of undiscovered silent arrhythmias.[8] Progression of AF relates to progression of the underlying disease and to continuous structural remodeling of the atria, including changes associated with ageing (e.g. fatty metamorphosis, myocyte degeneration, and fibrosis). As the arrhythmia becomes more sustained, restoration and maintenance of sinus rhythm become more challenging.

Principles of therapy

The fundamental principles of therapy for AF include primary prevention (i.e. treating the conditions that are commonly associated with the development of the arrhythmia); cardioversion of first-onset or recurrent AF which fails to self-terminate; secondary prevention (i.e. specific antiarrhythmic drugs or catheter ablation to suppress recurrence of paroxysmal or persistent AF once the arrhythmia has occurred); control of ventricular rates during recurrent or permanent AF; and anticoagulation to prevent thromboembolism. Treatment of underlying heart disease, such as hypertension and heart failure may *per se* deter the occurrence of new AF by alleviating and/or delaying remodeling of the atria (primary prevention). Although secondary prevention usually implies the use of specific antiarrhythmic agents to prevent recurrent AF, continuous treatment of underlying heart disease (e.g. stringent blood pressure control in hypertension) is likely to contribute to the reduction of recurrence and also to delay the progression to permanent AF. Treatment of the underlying heart disease to prevent AF is often referred as "upstream" therapy.[9] There is evidence that beta-blockers, which have very modest antiarrhythmic properties, and traditionally

non-antiarrhythmic drugs, such as angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, and statins, may have the antiarrhythmic potential, additional to any treatment effect on the underlying disease. This is discussed in Chapter 36.

Non-pharmacologic rhythm control therapy with catheter-based pulmonary vein isolation and left atrial ablation can be used to treat some forms of AF. However, the eventual impact of catheter-based techniques, particularly for long-term rhythm control and in patients with significant underlying heart disease, is not yet known.[10] Drug therapy remains, therefore, the mainstream for management of AF. Rate control is the primary treatment strategy in permanent AF and it is also relevant to all forms of the arrhythmia.

Studies of rate and rhythm control strategies

Two prime treatment strategies are rhythm control and rate control. Intuitively, rhythm control is a more attractive treatment strategy as sinus rhythm offers physiologic control of heart rate and regularity, normal atrial activation and contraction, the correct sequence of atrioventricular activation, and normal valve function. It might be an ideal approach for both stroke prevention and symptom alleviation. Nevertheless, during the 1980s and 1990s, the potential downside of available antiarrhythmic drug therapy became clear. A series of studies showed that under certain conditions, antiarrhythmic drugs could become proarrhythmic and, thereby, potentially lethal.[11,12] And for amiodarone, although proarrhythmia uniquely was an infrequent clinical problem, pulmonary fibrosis, a potentially lethal adverse effect, could develop.[13]

The difficulties in rhythm control management, principally the high AF recurrence rate, and the concern for serious adverse effects associated with antiarrhythmic drug therapy finally led to rate versus rhythm control studies. The major studies were the Atrial Fibrillation Follow up Investigation of Rhythm Management (AFFIRM) trial[14], the RAte Control versus Electrical Cardioversion (RACE) trial[15] and, most recently, the Atrial Fibrillation Congestive Heart Failure (AF CHF) trial[16] (Table 35.1). There were also a series of pilot studies performed, including the Pharmacological Intervention in Atrial Fibrillation (PIAF),[17] Strategies of Treatment of Atrial Fibrillation (STAF),[18] and How to Treat Chronic Atrial Fibrillation (HOT CAFÉ),[19] among others. They all directly and prospectively compared the effect of rhythm control treatment strategies versus rate control strategies on patient outcomes. It should be emphasized that it is likely none of these studies would have been performed if an antiarrhythmic drug or drugs were available which suppressed AF with >90% efficacy and an acceptable adverse effect profile.

AFFIRM

AFFIRM was a randomized clinical trial that compared two treatment strategies for AF in 4060 patients with paroxysmal or persistent AF and one or more risk factors (age ≥65, hypertension, diabetes, poor left ventricular function, congestive heart failure, or a prior stroke or transient ischemic attack) associated with a high risk of stroke and death, with at least 6 hours of AF in the last 6 months (with one episode in the previous 12 weeks).[14] The primary endpoint was all-cause mortality. A combined secondary endpoint consisted of death, disabling stroke or anoxic encephalopathy, major bleed or cardiac arrest. Quality of life and functional capacity were also assessed in a subset of patients. Throughout the study, the prevalence of sinus rhythm was high in the rhythm control arm, although it declined with time (82.4% at 1 year, 73.3% at 3 years, and 62.6% at 5 years). The prevalence of sinus rhythm in the rate control arm was higher than anticipated (42.9% at 1 year, 38.5% at 3 years, and 34.6% at 5 years).

A total of 356 patients in the rhythm control arm and 306 patients in the rate control arm died during this study. Overall survival at 1, 3, and 5 years was 96%, 87%, and 76% in the rhythm control arm, and 96%, 89%, and 79% in the rate control arm (Fig. 35.1).[14] Although there was no significant difference between the two groups ($P = 0.08$), a trend towards better survival in the rate control arm appeared after the first 1½ years. The secondary combined endpoint (death, disabling stroke or anoxic encephalopathy, major bleed or cardiac arrest) was not significantly different between the arms ($P = 0.33$) (Fig. 35.2).[20] No major differences were noted in functional status or quality of life.

A total of 77 ischemic strokes occurred in the rate control arm compared with 80 in the rhythm control arm ($P = 0.79$).[14] Most strokes in both arms occurred in patients who were either not taking warfarin or who had an INR <2.0. In the rhythm control arm, 22% of strokes occurred in patients whose INR was <2, and more than one-half (57%) occurred in patients not taking warfarin. Thus, 79% of patients in the

Time (y)	0	1	2	3	4	5
Rate (n)	2027	1925	1825	1328	774	236
Rhythm (n)	2033	1932	1807	1316	780	255
Figure 35.1 Cumulative mortality from any cause in the rate control and rhythm control arms of the AFFIRM study. Time zero is the day of randomization. Data have been truncated at 5 years. (From Wyse et al.[14], with permission.)
Figure 35.2 Cumulative events for the secondary endpoint of death, disabling stroke or anoxic encephalopathy, major bleed or cardiac arrest in the AFFIRM trial. Time zero is the day of randomization. Data have been truncated at 5 years. (From Waldo[20], with permission.)

rhythm control arm who had a stroke either were not taking warfarin or the INR was subtherapeutic. These stroke outcomes probably should not be surprising in patients with stroke risk factors because of the likely recurrence of AF in a large percentage of patients and the fact that there is an important incidence of asymptomatic AF.

RACE

RACE was a multicenter, randomized trial in 522 patients.[15] It tested the hypothesis that rate control is not inferior to the maintenance of sinus rhythm for the treatment of persistent AF. The primary endpoint was a composite of cardiovascular death, hospital admission for heart failure, thromboembolic complications, severe bleeding, pacemaker implantation, and severe adverse effects of therapy. Rate control was achieved by keeping the ventricular response rates <100 beats per minute with control of symptoms. Rhythm control consisted of serial use of antiarrhythmic drug therapy and electrical cardioversion, if required, to maintain sinus rhythm.

At 3-year follow-up, only 40% of rhythm control patients and 10% of rate control patients were in sinus rhythm. In this trial, 17.2% of patients achieved the primary endpoint in the rate control arm, versus 22.6% of patients in the rhythm control arm (absolute difference 5.4%; 90% confidence interval (CI) –11% to 0.4%). Therefore, the RACE trial demonstrated that rate control met the criteria for non-inferiority to rhythm control, indicating that rate control is an acceptable primary treatment option for patients with AF.

PIAF

The PIAF pilot study[17] compared rate control using diltiazem with rhythm control using amiodarone. Other atrioventricular node blocking drugs could be used if diltiazem failed to control the ventricular rate. The trial enrolled 252 patients with persistent AF. The primary endpoint was improvement in AF-related symptoms. At follow-up, 56%

of patients in the rhythm control arm and 10% of patients in the rate control arm were in sinus rhythm ($P < 0.001$). At 1 year, a similar proportion of patients in both groups reported improved symptoms (76 patients in the rate control arm vs 70 patients in the rhythm control arm, $P = 0.317$). Amiodarone restored sinus rhythm in 23% of patients. The distance walked in 6 minutes was greater in the rhythm control arm, but quality of life measures did not differ. Hospital admission rates were higher in the rhythm control arm (87/127 (69%) vs 30/125 (24%), $P = 0.001$), and adverse drug effects caused more frequent therapy changes in this arm as well (31 (25%) vs 17 (14%), $P = 0.036$). Overall, although the two groups in the PIAF study had similar clinical results, exercise tolerance was better with rhythm control. However, this advantage in favor of rhythm control was offset by more frequent hospital admissions.

STAF

In this pilot study, 200 patients with persistent AF were randomized to rate control or rhythm control, and followed for a mean of 19.6 ± 8.9 months.[18] There was no difference between the two strategies for the primary combined endpoint of death, cardiopulmonary resuscitation, stroke or transient ischemic attack, and systemic embolism. Hospitalization was significantly more frequent in the rhythm control arm, explained by the need to perform multiple cardioversions and to change antiarrhythmic drug therapy. In short, the data showed similar outcomes in both arms, supporting the concept that rate control is a legitimate primary treatment option. Moreover, the study suggested there was no benefit in attempting rhythm control in patients at high risk for recurrence of AF. A limitation of this study was that two-thirds of the patients had AF for more than 6 months at the time of entry into the study, and only 23% of the patients in the rhythm control arm were in sinus rhythm after 36 months of follow-up.

HOT CAFÉ

The HOT CAFÉ study was a randomized, multicenter, prospective trial in 205 patients with a clinically overt, persistent first episode of AF.[19] The primary endpoint was a composite of death from any cause, thromboembolic complications (especially disabling ischemic stroke), and intracranial or other major hemorrhage. Secondary endpoints included rate control, sinus rhythm maintenance, and discontinuation of therapy, especially if due to a potential proarrhythmic effect, hemorrhage, hospitalization, new or worsening congestive heart failure, or change in exercise tolerance. Patients were followed for a mean of 1.7 ± 0.4 years (maximum follow-up, 2.5 years). Antiarrhythmic drugs used included disopyramide, propafenone, sotalol, and amiodarone. At the end of the study, 63.5% of patients in the rhythm control arm remained in sinus rhythm.

Table 35.1 Studies of rate versus rhythm control in atrial fibrillation

Study	PIAF	STAF	HOT CAFÉ	RACE
No. of patients	252	200	205	522
Follow-up, years	1	1.6	1.7	2.3
Primary endpoint	Symptom improvement	Composite of ACM, cardiovascular events, CPR, TE	Composite of ACM, TE, bleeding	Composite of CVD, hospitalizations for CHF, TE, bleeding, pacemaker, AAD adverse effects
Difference in primary endpoint	Symptom improved in 70 RhyC vs 76 RC patients ($P = 0.317$)	5.54%/yr vs 6.09%/yr RhyC vs RC ($P = 0.99$)	No difference (OR, 10.98; 95% CI, 0.28–22.3; $P > 0.71$)	22.6% vs 17.2% RhyC vs RC (HR, 0.73; 90% CI, 0.53–1.01; $P = 0.11$)
Mortality	N/A	2.5%/year vs 4.9%/year RhyC vs RC	3 (2.9%) vs 1 (1%) RhyC vs RC	6.8% vs 7% (n.s.)
Thromboembolic event	N/A	3.1%/year vs 0.6%/year RhyC vs RC	3 (2.9%) vs 1 (1%) RhyC vs RC	Trend towards more TE in RhyC 7.9% vs 5.5% RhyC vs RC
Heart failure	N/A	Improved: 16 vs 26; worsened: 39 vs 29 RhyC vs RC patients ($P = 0.18$)	No difference	4.5% vs 3.5% RhyC vs RC
Hospitalizations	69% vs 24% RhyC vs RC ($P = 0.001$)*	54% vs 26% RhyC vs RC ($P < 0.01$)	74% vs 12% RhyC vs RC ($P < 0.001$); excluding DCC, 1.03 vs 0.05 per patient RhyC vs RC	More in RhyC*
Quality of life	No difference, but better functional capacity in RhyC	No difference	Not assessed, but better functional capacity in RhyC	No difference
Other findings	Better exercise tolerance but more AAD adverse effects in RhyC (25% vs 14%; $P = 0.036$)	18 out of total 19 primary endpoint events occurred during AF	Better exercise tolerance ($P < 0.001$), smaller LA and LV sizes, better LV systolic function in RhyC	On-treatment analysis: more CHF in RC; Echo substudy: smaller LA and LV sizes, better LV systolic function in RhyC

AAD, antiarrhythmic drugs; ACM, all-cause mortality; AF, atrial fibrillation; AF CHF, Atrial Fibrillation and Congestive Heart Failure; AFFIRM, Atrial Fibrillation Follow-up Investigation of Rhythm Management; CHF, congestive heart failure; CI, confidence intervals; CPR, cardiopulmonary resuscitation; CRRAFT, Control of Rate versus Rhythm in rheumatic study in rheumatic Atrial Fibrillation Trial; CVD, cardiovascular death; HOT CAFÉ, HOw to Treat Chronic Atrial Fibrillation; HR, hazard ratio; J-RHYTHM, Japanese Rhythm management trial for atrial fibrillation; LA, left atrium; LV, left ventricle; OR, odds ratio; PAF, Paroxysmal Atrial Fibrillation 2; PIAF, Pharmacological Intervention in Atrial Fibrillation; RACE, Rate Control versus Electrical Cardioversion; RC, rate control; RhyC, rhythm control; SE, systemic embolism; STAF, Strategies of Treatment of Atrial Fibrillation; TE, thromboembolic event; TIA, transient ischemic attack. *, including cardioversion; [†], reported as an adverse event

Although it was not reported, it is likely that very few, if any, patients in the rate control arm were in sinus rhythm because patients had to be in AF for at least 7 days at entry into the study. There were no significant differences in the primary endpoint between rate and rhythm control patients (odds ratio (OR) 1.98; 95% CI 0.28–22.3; $P > 0.71$), nor were there significant differences in secondary endpoints, except that the incidence of hospital admissions was much lower in the rate control than the rhythm control arm (12% vs 74%, respectively; $P < 0.001$).

AFFIRM	AF-CHF	J-RHYTHM	CRRAFT	PAF 2
4060	1376	823	144 (rheumatic AF, 73% had valvular intervention)	137 (after atrioventricular node ablation and pacing)
3.5	3.1	1.6	1	1.3
All-cause mortality	Cardiovascular mortality	Composite of ACM, stroke, SE, major bleeding, CHF hospitalization, adverse effects	Improvement in exercise tolerance, functional class, and quality of life	Prevention of permanent AF
23.8% vs 21.3% RhyC vs RC (HR, 1.15; 95% CI, 0.99–1.34; P = 0.08)	27% vs 25% RhyC vs RC (HR, 1.06; 95% CI, 0.86–1.3; P = 0.59)	15.3% vs 22% RhyC vs RC (P = 0.0128)	Significant improvement in all outcomes with RhyC	Permanent AF: 21% vs 37% RhyC vs RC (OR, 0.43; 95% CI, 0.18–0.98; P = 0.027)
As above	32% vs 33% RhyC vs RC (P = 0.68)	4 (1%) vs 3 (0.7%) RhyC vs RC	0 vs 5 events RhyC vs RC (P = 0.023)	N/A
Stroke: 7.1% vs 5.5% RhyC vs RC (P = 0.79) SE: 0.4% vs 0.5% RhyC vs RC (P = 0.62)	3% vs 4% RhyC vs RC (P = 0.32)	2.39% vs 2.97% RhyC vs RC	1 TIA in RhyC vs 0 events in RC	3 (4%) vs 1 (1%) RhyC vs RC (P = 0.30)
2.7% vs 2.1% RhyC vs RC (P = 0.58)	28% vs 31% RhyC vs RC (P = 0.17)	0.5% vs 1.5% RhyC vs RC	CHF functional class improved: 60% vs 17.5% RhyC vs RC; worsened: 4.4% vs 10% (P = 0.0014)	22% vs 10% RhyC vs RC (P = 0.05)
80% vs 73% RhyC vs RC (P < 0.001)	During the first year 46% vs 39% RhyC vs RC (P = 0.0063)	N/A	8.9% vs 15% RhyC vs RC (P = 0.51)	For CHF, 18% vs 7% RhyC vs RC (P = 0.05)
No difference, but trend towards better functional capacity in RhyC	Not yet available	Symptom frequency was lower with RhyC (P = 0.0027)	Improved by ³1 score: 86.7% vs 50% RhyC vs RC (P = 0.033)	No difference
On-treatment analysis: maintenance of sinus rhythm was associated with lower mortality (HR, 0.53; 95% CI, 0.39–0.72; P < 0.0001)	On-treatment analysis: no survival benefit from maintenance of sinus rhythm (HR, 1.11; 95% CI, 0.78–1.58; P = 0.568)	Symptoms or adverse effects leading to crossover occurred in 11% RhyC vs 16.6% RC patients (P = 0.0142)	N/A	N/A

Meta-analysis of these studies has demonstrated no significant excess or reduced mortality with either strategy but hinted at a trend towards better survival when rate control was the primary treatment approach (OR 0.87; 95% CI 0.74–1.02; P = 0.09).[21]

Following these publications, there has been a general movement away from rhythm control in patients who are able to tolerate the arrhythmia when the ventricular rate is adequately controlled. The major limitation of the studies which compared two strategies was inability to achieve a clear difference with respect to rhythm and rate status in the two arms as a significant proportion of patients in the rhythm control arm failed to maintain sinus rhythm and many patients in the rate control arm were in sinus rhythm at the end of the study. A subsequent, retrospective, on-treatment analysis of time-dependent covariates on outcome in the AFFIRM trial has shown that the presence of sinus rhythm conferred a considerable reduction of 47% in the risk of death irrespective of the treatment strategy.[22] However, antiarrhythmic drug use was associated with a 42% increase in the risk of death. This has been interpreted as showing that when sinus rhythm is included as

a separate factor, the sinus rhythm variable expresses the beneficial effect and the antiarrhythmic drug variable expresses the detrimental effects. Thus, use of antiarrhythmic drugs is associated with increased mortality. However, when sinus rhythm was removed as a separate factor from the analysis, antiarrhythmic drugs were not associated with mortality, presumably because the beneficial antiarrhythmic effects of antiarrhythmic drugs offset their adverse effects. In short, it suggested that in patients with AF, if one could achieve sinus rhythm safely and effectively, sinus rhythm would confer a favorable outcome.

AF CHF

Retrospective studies in patients with left ventricular dysfunction and AF previously showed that there is as high as a twofold increased mortality compared with patients in sinus rhythm.[23,24] These and similar observations triggered a large randomized, open-label trial, AF CHF. The AF CHF investigators compared rate and rhythm control strategies specifically in 1376 patients with an ejection fraction of 35% or less and NYHA II–IV heart failure who were followed for a mean of 37 months.[15] For patients randomized to the rhythm control arm, aggressive therapy to prevent AF and maintain sinus rhythm was recommended. Amiodarone was the drug of choice for AF suppression and sinus rhythm maintenance, but sotalol and dofetilide were used in selected cases. For patients randomized to the rate control arm, beta-blockers with digitalis were used to achieve the target heart rate of <80 beats per minute at rest and <110 beats per minute during a 6-minute walk test. Atrioventricular node ablation and pacemaker therapy were recommended for patients who were otherwise unable to meet rate control targets.

The study showed no benefit of rhythm control on top of optimal medical therapy with regard to the primary endpoint (cardiovascular mortality) as well as prespecified secondary endpoints including total mortality, worsening heart failure, stroke, and hospitalization. Cardiovascular death occurred in 182 (26.7%) of the patients in the rhythm control group compared with 175 (25.2%) in the rate control arm (hazard ratio (HR) 1.058, 95% CI 0.86–1.30; $P = 0.59$) (Fig. 35.3).[15] During the course of the study, 21% of patients crossed over from rhythm to rate control, primarily because of the inability to maintain sinus rhythm, but 10% crossed from the rate control arm to rhythm control, primarily because of worsening heart failure. Similar to the AFFIRM trial, the AF CHF trial conducted a retrospective on-treatment analysis of outcomes and showed that AF does not predict cardiovascular or all-cause mortality once the severity of clinical symptoms and mitral regurgitation is known.[24a] These results further indicate that rate control is a legitimate primary treatment option for patients with heart failure.
Figure 35.3 Kaplan–Meier estimates of death from cardiovascular causes (primary outcome) in the AF CHF study. AF CHF, Atrial Fibrillation in Congestive Heart Failure. (From Roy *et al*[16], with permission.)

The results of the AF CHF trial likely reflect the considerable improvement in the management of heart failure as well as the management of stroke prevention in patients with AF. In the years since the publication of the retrospective studies which identified a twofold increase in mortality in patients with AF and heart failure compared to patients with sinus rhythm and heart failure, therapy with beta-blockers, afterload reducers, statins, and aldosterone antagonists has considerably improved outcome. We learn once again from the AF CHF trial that because of new, improved and better applied therapies which produce better outcomes, historic controls are often an invalid comparator. A contemporary comparator will reflect the changes, usually the improvements, in patient care that occur over time, which, in turn, will change (usually improve) patient outcomes.

Importantly, the results of rate versus rhythm control studies highlighted the limitations of current therapies to achieve and maintain sinus rhythm. Long-term maintenance of sinus rhythm has proven difficult to achieve in patients with persistent AF, and the method is time-consuming and expensive due to the costs of the antiarrhythmic drugs and the increased need for hospitalization. Thus, the unmet need for safer and more effective antiarrhythmic agents to reverse this trend is clear.

Pharmacologic cardioversion for atrial fibrillation

Pharmacologic cardioversion is considered to be most effective if initiated within 7 days after the onset of the arrhythmia in which case restoration of sinus rhythm can

be achieved in nearly 70% of patients, but the success rate decreases significantly as AF persists beyond this limit. The likelihood of spontaneous conversion varies greatly, but is mainly determined by the nature of the arrhythmia (paroxysmal or persistent), the duration of the index episode, the overall duration of AF, the number of recurrences, and the severity of underlying heart disease.[25] Systematic analysis of placebo-controlled studies of pharmacologic cardioversion for AF has shown that among patients with AF of less than 24 hours, 66% spontaneously converted to sinus rhythm compared with only 17% of those with the arrhythmia of longer duration (OR 1.8).[26]

The choice of an antiarrhythmic drug for cardioversion of AF depends on the underlying heart disease.[5] Class IC antiarrhythmic agents (propafenone and flecainide), sotalol, and ibutilide are recommended for cardioversion of AF in patients with moderate structural heart disease or hypertension without left ventricular hypertrophy and are contraindicated in patients with a history of heart failure, myocardial infarction with left ventricular dysfunction, and significant left ventricular hypertrophy (>1.4 cm). Amiodarone and dofetilide can be used in patients presenting with symptoms of heart failure and known advanced heart disease. Propafenone, flecainide and sotalol are less effective for cardioversion with increased duration of the arrhythmia, and in such patients the choice of drugs is limited to dofetilide, ibutilide and amiodarone. Intravenous formulations of antiarrhythmic drugs are typically used for cardioversion, particularly when the AF is of short duration; however, oral forms of propafenone, flecainide, sotalol and amiodarone are available and may be used in loading doses. Although oral quinidine and oral or intravenous procainamide (class IA antiarrhythmic agents) are available in some countries, there has been a significant decrease in their use worldwide. Antiarrhythmic drugs recommended by the ACC/AHA/ESC guidelines are listed in Table 35.2.

Propafenone and flecainide

In placebo-controlled, randomized studies, intravenous propafenone and flecainide were effective in cardioversion of recent (usually 1–72 h)-onset AF, with conversion rates as high as 80–90% within an hour after the start of infusion.[27–29] The advantage of propafenone and flecainide is the possibility of oral administration for cardioversion of AF; the conversion rates are comparable to those achieved with intravenous formulations, although the effect is usually delayed.[30–36] In a meta-analysis of 1843 patients from 27 studies, intravenous or oral propafenone demonstrated a placebo-subtracted efficacy of 31.5% at 4 hours and 32.9% at 8 hours.[30] Thus, after administration of a loading single oral dose of propafenone (usually 450–600 mg) or flecainide (usually 200–300 mg), sinus rhythm

was restored in, respectively, 51–59% at 3 hours and 72–78% at 8 hours, compared with respective conversion rates of 18% and 39% on placebo.[31] Across the studies, the success rates ranged from 56% to 83% for propafenone and from 57% to 68% for flecainide. The conversion times ranged from 110 ± 59 to 287 ± 352 minutes and 110 ± 82 to 190 ± 147 minutes for propafenone and flecainide, respectively.[32–34] Both drugs have been given a **Class I** recommendation for cardioversion of recent-onset (less than 7 days) AF in patients without significant structural heart disease (**Level A**). The drugs are considered relatively ineffective for termination of AF of longer duration (**Class IIb, Level B**).

"Pill in the pocket" approach

The high efficacies of oral propafenone and flecainide in cardioversion of AF have formed the basis for the use of these drugs for termination of the arrhythmia outside the hospital setting. In patients with no or minimal structural heart disease and relatively infrequent (perhaps less than 12 per year) paroxysms of AF of distinct onset which, although symptomatic, do not cause significant hemodynamic compromise (e.g. hypotension), a loading single dose of either drug has proven safe and effective for expedient cardioversion to sinus rhythm.[37] In a key feasibility study, a selected cohort of 210 patients who had been successfully treated in hospital with either oral flecainide or propafenone for paroxysmal AF were given a supply of the relevant drug and asked to take a single oral dose within 5 minutes of noticing palpitations. In comparison with their own historic control data, as a result of the "pill in the pocket" strategy, the number of visits to emergency departments fell to 4.9 a month (from 45.6 visits a month during the previous period, $P < 0.001$), despite the same frequency of arrhythmia episodes.[38]

However, the experience with this strategy is limited, neither propafenone nor flecainide is licensed for patients to use for self-treating single attacks, and it is mandatory that the efficacy and safety of this strategy are first tested in hospital. It is unknown how valuable the "pill in the pocket" approach will be in the long term because AF tends to progress to sustained over time. Long-term anticoagulation will be needed in high-risk individuals. It is generally recommended that patients should not be taking a prophylactic antiarrhythmic drug. There is always the danger of development of atrial flutter with 1:1 atrioventricular conduction due to slowing of the atrial rate, associated with dangerous widening of the QRS complex (due to the enhanced (use-dependent) sodium channel blocking effect) and rarely left ventricular dysfunction secondary to the negative inotropic effect. Atrial flutter was reported in 2.5–20% of patients who received oral loading doses of propafenone or flecainide for conversion of AF (5–7% on average), and 2–14% of patients developed hypotension.[34] Therefore, concomitant administration of an atrioventricular node-blocking agent (a beta-blocker, verapamil or

Table 35.2 Antiarrhythmic drugs for pharmacologic cardioversion of atrial fibrillation

Drug	Route	Dose	AF ≤7 days		AF >7 days		Potential adverse effects
			Class	LOE	Class	LOE	
Flecainide	Oral or intravenous	Loading dose 200–300 mg or 1.5–3.0 mg/kg over 10–20 min	I	A	IIb	B	Rapidly conducted atrial flutter; ventricular proarrhythmia in patients with myocardial ischemia; possible deterioration of ventricular function in the presence of organic heart disease
Propafenone	Oral or intravenous	Loading dose 450–600 mg or 1.5–2.0 mg/kg over 10–20 min	I	A	IIb	B	
Ibutilide	Intravenous	1 mg over 10 min; repeat 1 mg if necessary	IIa	A	IIa	A	QT prolongation; torsades de pointes; hypotension
Sotalol	Intravenous	80 mg initial dose; then 160–320 mg in divided doses	III	A	III	B	QT prolongation; torsades de pointes; bradycardia; hypotension
	Oral	80 mg initial dose; then 160–320 mg in divided doses	IIb	B	III	B	
Dofetilide	Oral	125–500 mg twice daily*	I	A	I	I	QT prolongation; torsades de pointes; contraindicated if creatinine clearance < 20 mL/min
Amiodarone	Oral or intravenous	Inpatient: 1200–1800 mg daily in divided doses until 10 g total; then 200–400 mg daily Outpatient: 600–800 mg daily until 10 g total; then 200–400 mg daily 5–7 mg/kg over 30–60 min intravenously; then 1200–1800 mg daily oral until 10 g total; then 200–400 mg daily	IIa	A	IIa	A	Hypotension; bradycardia; QT prolongation; torsades de pointes (risk <1%); phlebitis (intravenous) gastrointestinal upset; constipation (oral); multiorgan toxicity in the long term
Quinidine†	Oral	750–1500 mg in divided doses over 6–12 hours + rate-slowing drug (e.g. verapamil)	IIb	B	IIb	B	QT prolongation; torsades de pointes; QRS widening; rapid atrial flutter; hypotension; gastrointestinal upset
Procainamide†	Intravenous	1000 mg over 30 min (33 mg/min) followed by 2 mg/min infusion	IIb	B	IIb	C	QRS widening; torsades de pointes; rapid atrial flutter

AF, atrial fibrillation; LOE, level of evidence;

*dose depends on creatinine clearance: >60 mL/min – 500 mg; 40–60 mL/min – 250 mg; 20–40 mL/min – 125 mg twice daily; contraindicated if creatinine clearance <20 mL/min;

†limited use or withdrawn agents.

diltiazem) is warranted. Transient atrioventricular block, QRS widening, and left bundle branch block occurred in approximately 2–8%. Class IC drugs usually are ineffective for conversion of atrial flutter. They slow conduction within the re-entrant circuit and prolong the atrial flutter cycle length, but rarely interrupt the circuit and there is greater risk of 1:1 atrioventricular conduction. The efficacy rates have been reported to be as low as 13–40%.[39]

Sotalol

Intravenous sotalol generally is ineffective for acute cardioversion of AF of any duration (**Class III, Level A**). The conversion rate in one study was 11–13% with sotalol vs 14% on placebo in the double-blind phase and 30% in the open-label phase.[40] In a direct comparison study with ibutilide in 308 patients with AF or flutter of 3 hours to 45 days, sotalol 1.5mg/kg (n = 103) restored sinus rhythm in only 11% of patients with AF and 19% of patients with flutter and was significantly inferior to ibutilide.[41] Even among patients with very recent onset AF (<48 hours), only 12% converted to sinus rhythm at 3 hours with oral sotalol 80–160mg and a further 12% converted to sinus rhythm at 8 hours after receiving a cumulative dose of 160–240mg.[42] In this study, the conversion rates for sotalol were significantly lower than for oral quinidine in combination with digoxin (36% and 71% at 3 and 8 hours, respectively). In the Sotalol Amiodarone Atrial Fibrillation Efficacy Trial (SAFE-T), 24.2% of patients with persistent AF treated with sotalol converted to sinus rhythm within 28 days, compared with 27.1% on amiodarone and only 0.8% on placebo.[43] Sotalol may offer a modest benefit of facilitating spontaneous conversion to sinus rhythm and, in addition, can ensure ventricular rate control in patients awaiting electrical cardioversion (**Class IIb, Level B**).

The antifibrillatory effect of sotalol is limited by reverse use dependency of its effect on atrial refractoriness: sotalol prolongs the atrial effective refractory period at normal and slow atrial rates, but not during rapid AF. The adverse effects of sotalol include hypotension, bradycardia, QT interval prolongation and associated ventricular proarrhythmia (torsades de pointes). Bradycardia and hypotension were the most common with intravenous sotalol, with an incidence of 6.5% and 3.7%, respectively.[43] Polymorphic ventricular tachycardia or torsades de pointes was reported in 1% of men and 4.1% of women who received sotalol for ventricular tachyarrhythmias.[44] The risk of proarrhythmia is increased in the presence of left ventricular hypertrophy because of increased duration and inhomogeneity of repolarization in the hypertrophied myocardium, increased transmural dispersion of repolarization, disruption of gap junction coupling, and a greater likelihood of ischemia and fibrosis. Sotalol levels are also increased in renal failure and torsades de pointes is more likely under these conditions.

Ibutilide

In randomized, placebo-controlled studies and direct comparisons with procainamide and sotalol, the class III drug ibutilide has proven more effective for cardioversion of atrial flutter than AF.[41,45–47] The overall conversion rates for atrial flutter were reported to be almost twofold higher than for AF (56–70% vs 31–44%).[41,46] In direct comparison studies, ibutilide 2mg cardioverted 70% of atrial flutter compared with only 19% on sotalol[41] and 14% on procainamide.[47] Higher doses of ibutilide administered as a single bolus of 2mg or two successive infusions of 1mg are usually required for termination of AF. Thus, in the Ibutilide/Sotalol Comparator Study, patients with AF were twice as likely to convert to sinus rhythm after receiving a 2mg infusion than those who received a 1mg infusion (44% vs 20%).[41] The antiarrhythmic effect of ibutilide decreased if the arrhythmia had persisted for more than 7 days – from 71% to 57% for atrial flutter and from 46% to 18% for AF. Nevertheless, ibutilide is recommended for cardioversion of AF (**Class IIa, Level A**).

Unlike sotalol and procainamide (a class IA agent), ibutilide does not produce significant hypotension but like many of the class III antiarrhythmic drugs, it may cause QT interval prolongation and ventricular proarrhythmia. In the ibutilide trials, the incidence of polymorphic ventricular tachycardia or torsades de pointes requiring electrical cardioversion was 0.5–1.7% and the incidence of self-terminating polymorphic ventricular tachycardia was 2.6–6.7%.[48] There are insufficient data to support the use of ibutilide in patients with significant structural heart disease as many controlled studies of ibutilide have only enrolled patients with mild or moderate underlying heart disease. Ibutilide 2mg administered intravenously on top of long-term therapy with oral amiodarone in patients referred for electrical cardioversion terminated AF in 39% of patients and flutter in 54%.[49] The QT interval was significantly prolonged, but there was only one case of non-sustained polymorphic tachycardia.

Dofetilide

In small (less than 100 patients) randomized, double-blind, placebo-controlled studies, dofetilide administered intravenously at 8μg/kg restored sinus rhythm in about one-third of patients presenting with atrial flutter or AF compared with 0–3.3% on placebo.[50,51] As with ibutilide, the conversion rates were significantly higher for atrial flutter than for AF (54–64% vs 14.5–24%).[50,51] In a double-blind, dose-ranging, pharmacokinetic study, dofetilide 8μg/kg was confirmed as the most effective dose with an acceptable rate of adverse events: 39% of patients in the dofetilide group converted to sinus rhythm compared with 6% in the placebo group.[52] In line with the conversion rates observed

with other antiarrhythmic agents, the likelihood of pharmacologic conversion on dofetilide decreased as the duration of AF increased: the drug was effective in 67% of patients with arrhythmia onset within 24 hours of treatment, 36% of patients with AF of 1–7 days, and 24% of patients with AF of more than 7 days.

Two medium-size prospective studies, SAFIRE-D (Symptomatic Atrial Fibrillation Investigative Research on Dofetilide) and EMERALD (European and Australian Multicenter Evaluative Research on Dofetilide), reported a modest 30% cardioversion rate of persistent AF with high-dose (1000 μg daily) oral dofetilide compared with 1.2% of spontaneous conversion on placebo[53] and 5% on sotalol.[54] In the pooled analysis from the DIAMOND (Danish Investigations of Arrhythmia and Mortality ON Dofetilide) studies in patients with symptomatic heart failure and an ejection fraction ≤35% (DIAMOND-CHF) or myocardial infarction with left ventricular dysfunction (DIAMOND-MI), oral dofetilide had a neutral effect on mortality and also demonstrated a greater rate of conversion to sinus rhythm (44% vs 14%).[24]

Oral dofetilide is considered safe and relatively effective for pharmacologic cardioversion of AF including arrhythmia duration of more than 7 days (**Class I, Level A**). Intravenous dofetilide is rarely used for pharmacologic cardioversion. However, dofetilide has been reported to prolong the QT interval and cause torsades de pointes. This effect is dose related. Therefore, it is mandatory that dofetilide be initiated in hospital and that patients should be monitored for 3 days. In addition, the dose of dofetilide requires adjustment to creatinine clearance.

Amiodarone

Amiodarone is currently assigned a **Class IIa, Level A** indication for cardioversion of AF of any duration. Meta-analysis of 13 randomized controlled studies in 1174 patients has shown that IV amiodarone was 44% more effective in converting AF compared with placebo, but its antiarrhythmic effect was delayed by 24 hours.[55] At 8 hours, the probability of restoration of sinus rhythm was 65% higher with flecainide or propafenone than with amiodarone. In a double-blind direct comparison with dofetilide, amiodarone cardioverted only 4% of patients with AF compared with 35% on dofetilide and 4% on placebo.[56] In one study, amiodarone administered intravenously as a bolus of 300 mg for 1 hour followed by infusion of 20 mg/kg for 24 hours and oral treatment for 4 weeks cardioverted 80% of AF.[57] However, spontaneous conversion rates in this study were also high (40%). Amiodarone given at a high single loading oral dose of 30 mg/kg (approx. 2.4 g) was less effective than oral propafenone 600 mg at 4 hours (16% vs 37%) and comparable with propafenone at 24 hours (56% vs 47%), but the median time to conversion to

sinus rhythm was significantly shorter with propafenone than amiodarone (2.4 vs 6.9 hours).[58]

Intravenous amiodarone has a modest effect on atrial refractoriness and therefore is moderately effective in terminating the arrhythmia in the emergency setting, but unlike class IC agents, amiodarone does not have any negative inotropic effect, controls the ventricular rate, and is associated with a low incidence of torsades de pointes. All this makes it safe to use in patients with advanced structural heart disease. Amiodarone prolongs the QT interval but, unlike pure class III agents, exhibits a low arrhythmogenic potential (less than 1%).[59] The most common effects of intravenous amiodarone are hypotension and relative bradycardia. There is limited experience with the use of intravenous amiodarone for termination of AF in critically ill patients.[60]

The mortality and morbidity study CHF-STAT (Congestive Heart Failure Survival Trial of Antiarrhythmic Therapy) in 667 patients with a mean ejection fraction of 25% has shown that long-term treatment with oral amiodarone 400 mg daily for the first year and 300 mg daily for the remainder of the 4.5-year trial had a neutral effect on survival but was associated with greater rates of conversion to sinus rhythm compared with placebo (31% vs 7.7%).[61] The SAFE-T study randomized 665 patients with persistent AF (74–80% less than 1 year) to therapy with amiodarone, sotalol or placebo for 28 days prior to carrying out electrical cardioversion.[43] The amiodarone regimen for this period was 800 mg for the first 2 weeks and 600 mg for the next 2 weeks. Of 267 patients who received amiodarone, 27.1% converted to sinus rhythm compared with 0.8% out of 137 in the placebo group. In a study of 95 patients with a mean AF of almost 2 years, amiodarone prescribed 600 mg daily for 4 weeks restored sinus rhythm in 34% of patients compared with 0% in the placebo group.[62]

Procainamide, quinidine, and disopyramide

The class IA drug procainamide has been shown to facilitate conversion of AF of less than 48 hours, but its efficacy is limited in AF of longer duration.[47,63–65] The conversion rates with procainamide administered intravenously at a dose 1000–1200 mg over 30 minutes ranged from 21% to 70%. In direct comparison studies, the efficacy of procainamide was comparable to that of propafenone (69.5% vs 48.7%)[64] and flecainide (65% vs 92%).[65] In a randomized, single-blind, placebo-controlled study in 362 patients with AF of less than 48 hours, the conversion rates with IV procainamide, propafenone, and amiodarone were 68.5%, 80.2%, and 89.1%, respectively.[66] Propafenone produced the most rapid effect, with a median time to conversion of 1 h, followed by procainamide (3 h) and amiodarone (9 h). The non-target effects of procainamide are vasodilation and hypotension due to the alpha-adrenergic properties, anticholinergic action, atrioventricular node blockade, worsening heart

failure, and lupus erythematosus. The drug is no longer used routinely for cardioversion of AF (**Class IIb, Level B**).

Quinidine given orally in a cumulative dose of up to 1200–2400 mg over 24 hours has been shown to cardiovert 60–80% of recent-onset AF; it is more effective than sotalol[67] and in some studies it was as effective as intravenous amiodarone.[68] The effect usually occurs within 12 hours of treatment. Quinidine poses increased risk of torsades de pointes which is observed at a rate of 6%; it widens the QRS complex, causes gastrointestinal side effects in a significant proportion of patients, and is contraindicated in individuals with structural heart disease. The poor safety profile of quinidine has led to a decrease in its use for acute cardioversion of AF (**Class IIb, Level B**).

There is limited evidence for the efficacy of intravenous disopyramide for acute pharmacologic cardioversion in patients with AF. In one study, disopyramide administered as a bolus of 2 mg/kg over 5 minutes restored sinus rhythm in 10 of 14 (71%) patients with self-limiting lone AF and 3 of 7 (43%) patients with atrial flutter.[69] There are concerns, however, that the adverse effects such as proarrhythmia, hypotension, asystole, and non-target effects resulting from anticholinergic activity of disopyramide may offset its modest antiarrhythmic potential (**Class IIb, Level B**).[5]

Other agents

One-quarter to one-half of patients with AF have low serum magnesium levels.[70] The electrophysiologic effects of magnesium include prolongation of the atrial and atrioventricular node refractory periods which are essential determinants of ventricular rates and maintenance of AF. Meta-analysis of eight studies in 476 patients showed that magnesium sulfate, administered intravenously at an initial dose of 1200–5000 mg over 1–30 minutes (in some studies followed by a second dose or continuous infusion for 2–6 hours), was superior to placebo or the active comparator in cardioverting AF with an odds ratio of 1.6 (95% CI 1.07–2.39).[70] Time to conversion was 3.8–14.9 hours and the most common side effects were sensations of warmth and flushing. In addition to its antifibrillatory action, magnesium produced effective ventricular rate control. There was no correlation between serum magnesium levels and the response. However, magnesium is not routinely used for pharmacologic cardioversion of AF (**Class IIb, Level B**), but it may potentiate the effect of other antiarrhythmic agents, e.g. in patients with refractory AF.

Digitalis, beta-blockers, and calcium antagonists usually are ineffective for acute conversion of AF (**Class III**).[27,71,72] The DAAF (Digitalis in Acute Atrial Fibrillation) study has shown no difference in cardioversion rates at 16 hours between intravenous digoxin and placebo (51% vs 46%).[73] Moreover, the drug has been shown to have a profibrillatory effect due to its cholinergic effects which may cause a non-uniform reduction in conduction velocity and effective refractory periods of the atria, and to delay the reversal of remodeling after restoration of sinus rhythm.[74] Digoxin is not indicated for pharmacologic cardioversion of AF (**Class III, Level A**). Short-acting intravenous beta-blockers (e.g. esmolol) and non-dihydropyridine calcium antagonists (verapamil and diltiazem) are more commonly used for rate control than for restoration of sinus rhythm.

Antiarrhythmic drugs and electrical cardioversion

Antiarrhythmic drugs can be used to facilitate electrical cardioversion and to prevent immediate or early recurrence of AF (**Class IIa, Level B**). Synergistic action of antiarrhythmic drugs may be due to prolongation of atrial refractoriness, conversion of AF to a more organized atrial rhythm (e.g. flutter) which may be cardioverted with less energy, the suppression of atrial premature beats that may re-initiate AF, and prevention of atrial remodeling. The disadvantages are increased risk of ventricular proarrhythmia and bradycardia.

Pretreatment with ibutilide lowered the energy requirement by approximately 30% and improved the success rate of cardioversion, including those who previously had failed electrical cardioversion.[75] Flecainide administered intravenously increased the likelihood of converting to sinus rhythm by 16% and significantly reduced the energy requirement.[76] Intravenous sotalol was synergistic with internal electrical cardioversion by preventing reinitiation of AF. Sotalol suppressed atrial premature beats and prolonged the coupling interval of atrial premature beats, thus reducing risk of early recurrence.[77] Higher success rates of electrical cardioversion for persistent AF were reported in patients pretreated with oral amiodarone compared with diltiazem (88% vs 56%).[78] The results with calcium antagonists were controversial. Thus, in the VEPARAF (VErapamil Plus Antiarrhythmic drugs Reduce Atrial Fibrillation) trial, adjunctive treatment with verapamil reduced the AF recurrence rate from 35% to 20%.[79] In the VERDICT (Verapamil versus Digoxin Cardioversion Trial), only 47% of patients in the verapamil-treated group and 53% of those in the digoxin-treated group remained free from recurrence of the arrhythmia during the first month after cardioversion.[80]

New agents for pharmacologic cardioversion

Vernakalant

Vernakalant is a new arrhythmic drug agent with an affinity for ion channels specifically involved in the repolarization

processes in atrial tissue, in particular, the ultrarapid potassium repolarization current I_{Kur}. Although I_{Kur} current is the main target of vernakalant, its mechanism of action involves blockade of several ion channels such as I_{to}, and I_{Na}, but there is little impact on major currents responsible for ventricular repolarization, such as I_{Kr} and I_{Ks} currents. The intravenous formulation of vernakalant is under regulatory body review for pharmacologic cardioversion of AF.

The efficacy of vernakalant was investigated in one dose-finding study, three medium-size randomized clinical studies, and a phase IV open-label study (Table 35.3).[81–84] In the randomized, double-blind, placebo-controlled Atrial arrhythmia Conversion Trials (ACT I and II), vernakalant was significantly more effective than placebo in converting AF of less than 7 days (51.7% and 51.2% compared with 4% and 3.6%, respectively, $P < 0.001$).[82,83] Vernakalant was administered as a 10-minute infusion of 3 mg/kg and if AF persisted after 15 minutes, a second infusion of 2 mg/kg was given. The median time to conversion was 8–11 minutes and the majority of patients (75–82%) converted after the first dose. The highest efficacy was observed for AF of up to 72 hours (70–80%). The results were reproduced in the open-label ACT IV study in which vernakalant restored sinus rhythm in 50.9% within 14 minutes after the start of treatment. Vernakalant was significantly less effective in converting AF of more than 7 days and did not convert atrial flutter.

The drug was well tolerated, with no significant QT prolongation or drug-related torsades de pointes. However, in the ACT I study, the QTc values after infusion were greater in the vernakalant group than in the placebo group, and 24% of patients in the vernakalant group had QTc >500 ms as opposed to 15% in the placebo group, but no torsades de pointes was reported during the first 24 hours after

Table 35.3 Summary of clinical studies of vernakalant in atrial fibrillation

Study	Number of patients	Patient characteristics	Dose of vernakalant	Placebo controlled	Primary endpoint	Outcome vs placebo/control
CRAFT	56	AF 3–72 h	IV 0.5 mg/kg +1 mg/kg or IV 2 mg/kg + 3 mg/kg	Yes	Conversion to SR during infusion or within 30 minutes after the last infusion	Converted to SR: 61% vs 5%, $P < 0.001$; patients in SR at 30 minutes 56% vs 5%, $P = 0.016$; only higher dose was effective
ACT I	336	AF 3 h–45 days (3 h–7 days, n = 220; 8–45 days, n = 116)	IV 3 mg/kg + 2 mg/kg	Yes	Conversion to SR within 90 minutes of drug initiation in AF 3 h–7 days	Converted to SR: 51.7% vs 4%, $P < 0.001$
ACT II	150	AF 3–72 h between 24 h and 7 days after cardiac surgery	IV 3 mg/kg + 2 mg/kg	Yes	Conversion to SR within 90 minutes of drug initiation in AF 3 h–7 days	Converted to SR: 47% vs 14%, $P < 0.001$
ACT III	262	AF 3 h–45 days (3 h–7 days, n = 170; 8–45 days, n = 69)	IV 3 mg/kg + 2 mg/kg	Yes	Conversion to SR within 90 minutes of drug initiation in AF 3 h–7 days	Converted to SR: 51.2% vs 3.6%, $P < 0.001$
ACT IV	167	AF 3 h–45 days (3 h–7 days, n = 170; 8–45 days, n = 69)	IV 3 mg/kg + 2 mg/kg	No	Conversion to SR within 90 minutes of drug initiation in AF 3 h–7 days	Converted to SR: 50.9%
Prevention, phase IIa	159	After pharmacologic (vernakalant) or electrical cardioversion for persistent AF	Oral 300 or 600 mg bid	Yes	SR at 1 month	Maintained SR at 1 month: 61% (each group) vs 43% on placebo, $P = 0.028$
Prevention, phase IIb	446	Persistent AF after pharmacologic (vernakalant) or electrical cardioversion	Oral 150, 300 or 500 mg bid	Yes	SR at 3 months	Maintained SR at 3 months on 500 mg bid: 51% vs 37% on placebo, $P < 0.05$; lower doses reduced AF rates, but not significant vs placebo

infusion.[82] The most common (>5%) side effects of vernakalant were dysgeusia, sneezing, and nausea.

Prevention of atrial fibrillation

Prophylactic antiarrhythmic drug therapy generally is not recommended after a first episode of AF, either self-terminating or after pharmacologic or electrical cardioversion.[5] However, this approach can be appropriate in a small proportion of patients as paroxysmal AF tends to become persistent or permanent. After cardioversion, approximately 25–50% patients will have recurrence of AF within the first 1–2 months (early recurrence).[85] Thereafter, the recurrence rate is about 10% per year (late recurrence). Prophylactic antiarrhythmic drug therapy is recommended for the vast majority of patients with paroxysmal AF when paroxysms occur frequently and are associated with significant symptoms or lead to worsening left ventricular function, and for patients with persistent AF when the likelihood of maintenance of sinus rhythm is uncertain, especially in the presence of risk factors for recurrence such as left atrial enlargement, evidence for depressed atrial function, left ventricular dysfunction, underlying cardiovascular pathology, long duration of the arrhythmia, advanced age, and female gender) (**Class I, Level A**).

The choice of antiarrhythmic drug for prevention of AF is dictated by the presence and nature of underlying heart disease (Fig. 35.4).

A systematic review of 44 studies in 11 322 patients has shown that antiarrhythmic drugs significantly reduced AF recurrence after cardioversion; the number of patients needed to treat to prevent a recurrence ranged from two to nine depending on the agent used.[86] Antiarrhythmic drugs may also render AF less symptomatic, less frequent, and less sustained or may promote conversion to sinus rhythm. The majority of large, high-quality studies were conducted in patients with persistent AF, i.e. AF requiring electrical or pharmacologic therapy to terminate. This was probably because the recurrence of a persistent episode is more "predictable," is likely to occur during the first year, and is easier to recognize and document, especially when the time to first symptomatic recurrence is used as an endpoint. Hence, the results of many trials of the efficacy of antiarrhythmic drugs for the prevention of recurrences of persistent AF were extrapolated on the patient populations with a paroxysmal (self-terminating) arrhythmia.

Beta-blockers

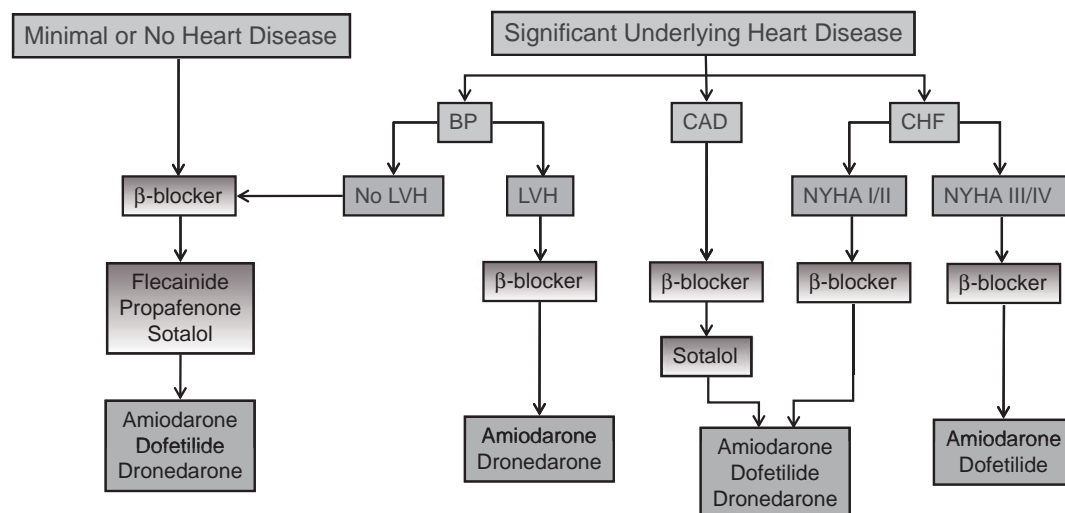
Beta-blockers generally are modestly effective in preventing AF (**Class IIb, Level B**) and are mainly used for rate control. An exception is AF caused by thyrotoxicosis or, rarely, lone adrenergically mediated AF when beta-blockers may be a first-line therapy (**Class I**).[87,88] In anecdotal reports beta-blockers were superior to placebo or were as effective as sotalol for prevention of persistent AF.[89,90] In a medium-size (n = 394), double-blind, placebo-controlled study, treatment with metoprolol 100 mg daily was associated with a modest reduction in arrhythmia recurrence at 3 months after electrical cardioversion from 60% in the placebo arm to 48% in the metoprolol arm.[89] Patients who received metoprolol had slower ventricular rates during the recurrence of AF and were probably less symptomatic. In another study, 58% of


Figure 35.4 Selection of antiarrhythmic drugs for prevention of atrial fibrillation.

patients treated with bisoprolol 5 mg daily and 59% of patients treated with sotalol 160 mg daily maintained sinus rhythm at 1 year after cardioversion.[90]

Some beta-blockers such as carvedilol may be more potent antiarrhythmics because of their direct effects on cardiac ion channels beyond their antiadrenergic action. In addition, carvedilol has antioxidant activity and may protect the atrial myocardium from oxidative injury caused by fast atrial rates and ischemia. In direct comparisons, carvedilol demonstrated no benefit over bisoprolol, although a higher proportion of patients treated with carvedilol completed the 1-year study in sinus rhythm (68% v 54%)[91] although this trend was not significant and the number of patients was small (n = 90). Beta-blockers may, however, prevent AF associated with congestive heart failure: a meta-analysis of seven studies in 11 952 patients has shown that therapy with beta-blockers, on background therapy with ACE inhibitors and diuretics, was associated with a statistically significant reduction in the incidence of new-onset AF from 39 to 28 per 1000 patient-years (a 27% reduction in relative risk) during mean follow-up of 1.35 years (**Class I, Level A**).[92]

Quinidine

Quinidine has been used for treatment of AF since the discovery of its antiarrhythmic properties in early 1920s. In a meta-analysis of six randomized controlled trials in 808 patients, published in 1990, the proportions of patients remaining in sinus rhythm at 3, 6, and 12 months were 69%, 58%, and 50% in the quinidine group compared with 45%, 33%, and 25% in the control group.[93] In a 2006 analysis which included two recent large-scale studies of quinidine, PAFAC (Prevention of Atrial Fibrillation After Cardioversion) and SOPAT (Suppression Of Paroxysmal Atrial Tachyarrhythmias), quinidine reduced the incidence of recurrent AF by 49%.[86] The antiarrhythmic effect of quinidine was offset by high all-cause mortality and sudden death in the quinidine-treated patients compared with controls (2.9% vs 0.8%; OR 2.98).[93] The foremost safety issue for quinidine is its propensity to cause ventricular proarrhythmia including torsades de pointes, even at low or subtherapeutic doses. In earlier studies, the incidence of quinidine-induced ventricular proarrhythmias was reported to be 15%.[12]

Following the reports of increased mortality associated with quinidine and the development of newer antiarrhythmic drugs which are better tolerated, the use of quinidine has significantly decreased worldwide. However, the PAFAC[94] and SOPAT[95] trials showed no adverse effect on mortality, probably because in these studies, quinidine was used at lower doses (320–480 mg as opposed to 1000–1800 g daily in the previous trials[93]), in combination with verapamil, and in patients with less significant structural heart disease. The number of patients with previous myocardial

infarction (2.9–5%) and coronary artery disease (17–21%) was low.

In the PAFAC (848 patients with persistent AF) and SOPAT studies (1012 patients with similar clinical characteristics), which both employed daily transtelephonic ECG monitoring for arrhythmia detection, quinidine was superior to placebo and was as effective as sotalol in maintenance of sinus rhythm after cardioversion. The overall efficacy of antiarrhythmic drug therapy was modest: at 1 year, only about 30–35% of patients had no AF recurrence (including asymptomatic episodes detected during daily transtelephonic ECG transmissions) compared with 20–23% in the placebo arm. As for the safety concerns, there were five reports of ventricular tachycardia of more than 10 beats in patients treated with quinidine, four in the PAFAC study and one in the SOPAT study, but no torsades de pointes, which did occur in the sotalol arm of the PAFAC study. Nevertheless, the modest efficacy of quinidine and concerns about its safety have led to the withdrawal of quinidine from the list of drugs available for treatment of AF (**Class III, Level A**).

Disopyramide

Disopyramide is rarely used for treatment of AF because of its negative inotropic effect, the torsadogenic potential, and poor tolerance due to antimuscarinic properties. However, the use of disopyramide is advocated in patients with lone, vagally mediated AF (**Class IIa, Level B**). Although it was commonly prescribed for ventricular arrhythmias, data on the efficacy of disopyramide in AF are sparse. In a randomized, double-blind placebo-controlled study of 90 patients, disopyramide maintained sinus rhythm in 70% of patients at 1 month and 54% of patients at 1 year after cardioversion; the corresponding values for placebo were 39% and 30%, respectively.[96] In a small, double-blind study of 56 patients, disopyramide 250 mg tid was not significantly different from propafenone 300 mg tid in maintaining sinus rhythm at 6 months after cardioversion (67% vs 55%) but was associated with a significantly higher withdrawal rate due to adverse events, including two cases of heart failure and fast ventricular rates during AF in one patient.[97]

Propafenone and flecainide

Propafenone and flecainide are recommended as first-line therapy (**Class I, Level A**) for AF in patients without significant structural heart disease, i.e. patients without congestive heart failure, left ventricular dysfunction, hypertrophy, previous myocardial infarction or coronary artery disease. Both propafenone and flecainide reduced the recurrence rate by two-thirds, with no advantage of one drug over the other.[86] A number of randomized, controlled

studies addressed the long-term efficacy of class IC antiar-rhythmic drugs in AF.[98–104] In the Propafenone Atrial Fibril-lation Trial (PAFT) of 102 patients, the likelihood of maintenance of sinus rhythm at 6 months after cardiover-sion was 67% with low-dose propafenone (450 mg) com-pared with 35% on placebo, with no increase in drug-related side effects (10% on propafenone vs 14% on placebo).[99] The UK PSVT (Paroxysmal Supraventricular Tachycardia) study evaluated the safety and efficacy of propafenone, 600 mg and 900 mg daily, and showed that both regimens were effective but a dose of 900 mg was associated with a less favorable adverse events profile.[100] In a meta-analysis of propafenone, the incidence of recurrent AF was 55.4% (51.3–59.7%) at 6 months and 56.8% (52.3–61.3%) at 1 year.[101] All-cause mortality associated with propafenone was 0.3%.

The efficacy of a sustained-release (SR) propafenone for-mulation which allows twice-daily dosing has been studied in the North American Recurrence of Atrial Fibrillation Trial (RAFT)[103] and its European equivalent, ERAFT.[104] Both studies have shown that propafenone SR is superior to placebo in prolonging time to first symptomatic recur-rence of paroxysmal AF in patients with minor structural heart disease. In the RAFT study, which included 523 patients with onset of AF within 1–1.5 years prior to enrol-ment, time to AF recurrence was prolonged from 41 days on placebo to 112, 291, and >300 days on propafenone SR 225, 325, and 425 mg twice daily. Sixty-five percent of patients treated with the highest dose of 425 mg twice daily were free of symptomatic AF at the end of follow-up com-pared with only 20% in the placebo group, although the adverse effect rate was higher than with low-dose regimens.[103] The ERAFT study randomized 293 patients with paroxysmal AF of longer duration (approximately 5 years) and more frequent paroxysms to propafenone SR 325 mg or 425 mg twice daily or placebo. The time to the first recurrence of the arrhythmia was shorter than in the RAFT study, but still was prolonged from 5 days on placebo to 19 and 24 days on lower and high-dose propafenone.[104]

Several placebo-controlled and comparator trials of another class IC antiarrhythmic drug, flecainide, including the Flecainide Multicenter Atrial Fibrillation Study, have consistently reported a 70–80% likelihood of maintaining sinus rhythm after 1 year with an acceptable risk–benefit relationship.[105–108] In direct comparisons, flecainide and propafenone prevented AF in 77% and 75% patients, respec-tively.[106] In 239 patients, the antiarrhythmic effect of fle-cainide at a maximum dose of 300 mg daily was comparable to that of quinidine given at a maximum dose of 1500 mg daily, but 30% in the quinidine group withdrew from the 1-year study because of the side effects compared with 18% in the flecainide group.[107] In the Flecainide Atrial Fibrilla-tion study in 123 patients with paroxysmal AF or flutter, flecainide demonstrated a linear dose–response, with only

7.7% and 9.4% of patients remaining free from the arrhyth-mia on the lowest doses (25 mg and 50 mg twice daily, respectively) compared with 39.4% of patients who received a standard therapeutic dose of 100 mg twice daily.[108]

Other class IC drugs

Drugs with class IC mode of action other than flecainide and propafenone are available in some countries, e.g. pil-sicainide is available in Japan; cibenzoline is used in Japan and France. Pilsicainide is modestly effective in cardiover-sion of recent-onset AF (45% vs 8.6% on placebo) but is ineffective in AF of longer duration.[109] The drug showed no superiority over other members of its class in maintain-ing sinus rhythm in the long term and exhibited a similar adverse event profile to other class IC agents. In direct comparisons with cibenzoline which, in addition to sodium channels, also blocks potassium repolarization currents (I_{Kr} and I_{Ks}) and the acetylcholine-activated potassium current (I_{KAch}), the efficacy of pilsicainide was 8–59% at 6 months and 3–41% at 1 year.[110] The corresponding values for ciben-zoline were 29–59% at 6 months and 16–50% at 1 year.

Sotalol

Selected randomized trials of the efficacy of class III antiar-rhythmic drugs for conversion of AF and maintenance of sinus rhythm are summarized in Table 35.4. Several ran-domized, placebo-controlled and comparator studies have reported that sotalol is an effective and safe prophylactic antiarrhythmic drug for AF in the absence of heart failure, myocardial infarction or hypertension with significant left ventricular hypertrophy (**Class I, Level A**) (Table 35.4, Fig. 35.5).[111–113] Because of its beta-blocking effect, sotalol offers the additional benefit of ventricular rate slowing during recurrences. In the d,l-Sotalol Atrial Fibrillation/Flutter dose efficacy study of 253 patients, sotalol significantly pro-longed the median time to first symptomatic recurrence of the arrhythmia documented by transtelephonic monitoring from 27 days on placebo to 106, 229, and 175 days (for 80, 120, and 160 mg twice-daily regimens, respectively).[111] In this study, sotalol 120 mg twice daily was found to be both safe and effective compared with lower and higher dose regimens. In direct comparisons, sotalol was as effective as propafenone (73% vs 63%)[112] and quinidine (74% vs 68%)[113] or quinidine plus verapamil (50% in each group)[95] in main-taining sinus rhythm after 1 year. Sotalol 160 mg twice daily was superior to an investigational class III antiarrhythmic agent azimilide in 658 patients with persistent AF.[114] Sotalol prolonged the median time to recurrence of sustained AF after electrical cardioversion to 28 days compared with 14 days for azimilide and 12 days for placebo. In a meta-analysis of nine randomized controlled studies in 1538 patients, sotalol reduced the recurrence rate by 47%.[86]

Table 35.4 Selected studies of class III antiarrhythmic drugs for conversion and/or maintenance of sinus rhythm in patients with atrial fibrillation

Study	Drug	No of patients	Follow-up
Ibutilide Repeat Dose Study[46]	Ibutilide 1.5 mg or 2 mg IV vs placebo	266; 50% AFL	24 hours
Randomized study of Ibutilide[47] vs Procainamide[40]	Ibutilide 1–2 mg IV vs procainamide 1.2 g IV	127; 33% AFL	24 hours
Ibutilide/Sotalol Comparator Study (ISCS)[41]	Ibutilide 1 mg or 2 mg IV vs d,l-sotalol 1.5 mg/kg IV	319; 18.5% AFL	72 hours
d,l-Sotalol Atrial Fibrillation/ Flutter Study Group[111]	d,l-Sotalol 160, 240, 320 mg	253; 20% AFL	1 year
SOCESP[113]	Sotalol 160–320 mg vs quinidine 600–800 mg	121	6 months
Bellandi[112]	Sotalol 240 mg vs propafenone 450–900 mg vs placebo	300	1 year
PAFAC[94]	Sotalol 320 mg vs quinidine + verapamil 320/160 mg vs placebo	848	1 year
SOPAT[95]	Sotalol 320 mg vs quinidine + verapamil 480/240 mg, 320/160 mg vs placebo	1012	1 year
CTAF[115]	Amiodarone 200 mg vs sotalol 160–320 mg or propafenone 450–600 mg	403	1.3 year
CHF-STAT[50,61]	Amiodarone 800 mg for 2 weeks; 400 mg for 50 weeks; maintenance dose 300 mg vs placebo	667; 103 with AF at baseline	4.5 years
SAFE-T[43]	Amiodarone 300 mg for the 1st year, 200 mg thereafter vs sotalol 320 mg vs placebo	665	4.5 years
DDAFFS[51]	Dofetilide 8 μg/kg IV vs placebo	96; 18% AFL	24 hours
DIAMOND-AF[24]	Dofetilide 500 μg vs placebo	506	1.5 years
SAFIRE-D[53]	Dofetilide 250, 500, 1000 μg vs placebo	225	1 year
EMERALD[54]	Dofetilide 250, 500, 1000 μg vs sotalol 160 mg vs placebo	671	Phase 1: 72 h; Phase 2: 2 years

AF, atrial fibrillation; AFL, atrial flutter; CHF-STAT, Congestive Heart Failure Survival Trial of Antiarrhythmic Therapy; CTAF, Canadian Trial of Atrial Fibrillation; DDAFS, Danish Dofetilide in Atrial Fibrillation and Flutter Study; DIAMOND-AF, Danish Investigations of Arrhythmia and Mortality ON Dofetilide; EMERALD, European and Australian Multicenter Evaluative Research on Dofetilide; PAFAC, Prevention of Atrial Fibrillation After Cardioversion; SAFE-T, Sotalol Amiodarone Atrial Fibrillation Efficacy Trial; SAFIRE-D, Symptomatic Atrial Fibrillation Investigative Research on Dofetilide; SOCESP, Cardiology Society of São Paulo Investigators; SOPAT, Suppression Of Paroxysmal Atrial Tachyarrhythmias.

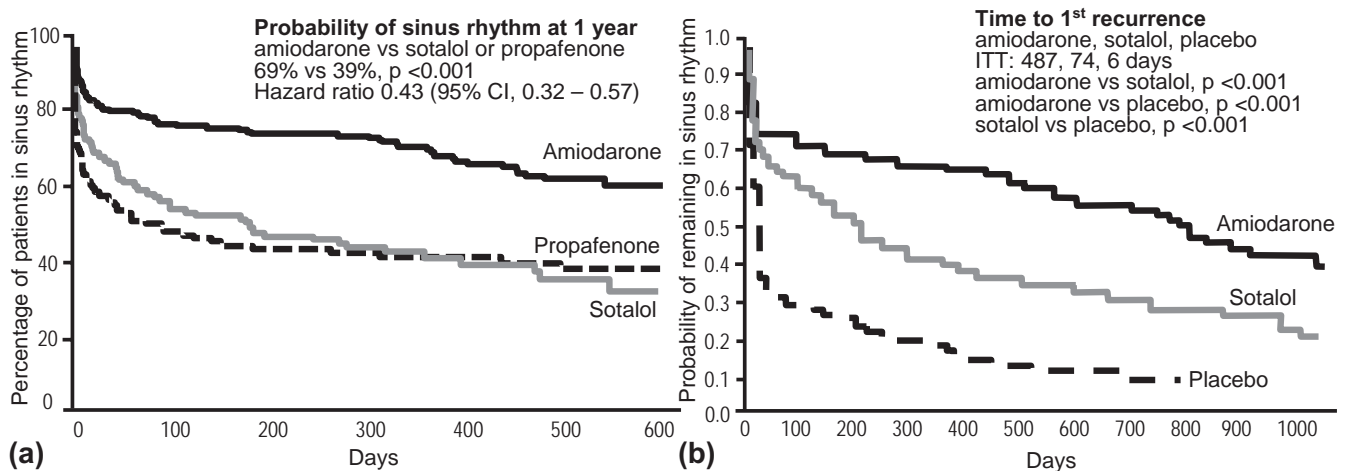
Conversion rate	Maintenance of sinus rhythm	Torsade de pointes
47% converted on ibutilide vs 2% on placebo ($P < 0.0001$); 63% AFL vs 31% AF ($P < 0.0001$)	N/A	8.3% on ibutilide; 1.7% required electrical cardioversion
58.3% converted on ibutilide vs 18.3% on procainamide ($P < 0.0001$)	N/A	0.8% on ibutilide
AFL: 76% converted on ibutilide vs 14% on placebo ($P = 0.001$)		
AF: 51% converted on ibutilide vs 21% on placebo ($P = 0.005$)		
AFL: 70% converted on ibutilide 1.5 mg vs 56% on ibutilide 1 mg vs 19% on sotalol ($P < 0.05$ vs sotalol)	N/A	0.9% on ibutilide 2 mg; 0.5% required electrical cardioversion; none on sotalol
AF: 44% converted on ibutilide 1.5 mg vs 20% on ibutilide 1 mg vs 11% on sotalol ($P < 0.05$ for ibutilide 1.5 mg vs sotalol)		
N/A	Free from AF: 30%, 40%, 45% on sotalol 160, 240, 320 mg vs 28% on placebo	None
	Time to 1st AF recurrence: 106, 229, 175 days on sotalol 160 ($P = 0.111$), 240 ($P = 0.001$), 320 mg ($P = 0.012$) vs 27 days on placebo	
N/A	74% on sotalol vs 68% on quinidine ($P = 0.43$)	5% on sotalol vs 2% on quinidine
	Time to 1st AF recurrence 69 vs 10 days ($P < 0.05$); AF ≤72 h: 93% in sinus rhythm on sotalol vs 64% on quinidine ($P = 0.01$); AF > 72 h: 33% in sinus rhythm relapsed on sotalol vs 68% on quinidine ($P < 0.05$)	
N/A	73% in sinus rhythm on sotalol vs 63% on propafenone vs 35% on placebo ($P = 0.001$)	4% on sotalol; 2% required cardioversion
N/A	33% in sinus rhythm on sotalol vs 35% on quinidine and 17% on placebo	2.3% on sotalol; ventricular tachycardia 0.5% on sotalol vs 1.1% on quinidine
N/A	~50% in sinus rhythm on sotalol and quinidine vs 38% on placebo	Ventricular tachycardia 0.4% on quinidine high dose
	Time to 1st AF recurrence: 146 days on sotalol ($P = 0.0007$) vs 149 (low dose; $P = 0.0006$) and 150 (high dose; $P = 0.0061$) on quinidine vs 106 on placebo	
N/A	65% in sinus rhythm on amiodarone vs 37% on sotalol or propafenone ($P < 0.001$)	1 (1%) on propafenone
31.3% on amiodarone vs 7.7% on placebo ($P = 0.002$)	New-onset AF: 4% on amiodarone vs 8% on placebo ($P = 0.005$)	Not stated
27.1% converted on amiodarone, 24.2% on sotalol vs 0.8% on placebo ($P < 0.001$ for both drugs)	63% in sinus rhythm on amiodarone vs 49% on sotalol vs 18% on placebo ($P < 0.001$)	1 (0.4%) on sotalol
	Time to 1st AF recurrence: 487 days on amiodarone, 74 days on sotalol vs 6 days on placebo ($P < 0.001$ for both drugs)	
30.3% converted on dofetilide vs 3.3% on placebo ($P < 0.006$)	N/A	3% on dofetilide
44% on dofetilide vs 14% on placebo ($P < 0.001$)	79% in sinus rhythm on dofetilide vs 46% on placebo ($P < 0.001$)	3.3% on dofetilide
6.1% ($P = 0.015$), 9.8% ($P = 0.015$), 19.9% ($P < 0.001$) on dofetilide 250, 500, 100 µg vs 1.2% on placebo	40%, 37%, 58% on dofetilide vs 25% on placebo	0.8% on dofetilide 1 (0.4%) proarrhythmic death
6%, 11%, 29% on dofetilide vs 5% on sotalol at 72 hours	66% in sinus rhythm on dofetilide 1000 µg vs 21% on placebo at 1 year	3 (0.45%) torsades de pointes 1 (0.15%) sudden death
Figure 35.5 Efficacy of sotalol in comparison with other antiarrhythmic drugs for maintenance of sunus rhythm in patients with atrial fibrillation. A-COMET II, Azimilide CardiOversion MaintEnance Trial II; AFFIRM, Atrial Fibrillation Follow-up Investigation of Rhythm Management; CTAF, Canadian Trial of Atrial Fibrillation; d,l-SAFFS, d,l-Sotalol Atrial Fibrillation/Flutter Study; PAFAC, Prevention of Atrial Fibrillation After Cardioversion; SOCESP, Cardiology Society of São Paulo Investigators; SOPAT, Suppression Of Paroxysmal Atrial Tachyarrhythmias; * at 6 months.


Figure 35.6 Probability of remaining free from recurrent atrial fibrillation with amiodarone and sotalol in the Canadian Trial of Atrial Fibrillation (CTAF) (a) and in the Sotalol Amiodarone Atrial Fibrillation Efficacy Trial (SAFE-T) (b). ITT, intention to treat. (Modified from references Singh et al.[43] and Roy et al.[115], with permission.)

However, subsequent studies reported limited efficacy of sotalol compared with amiodarone and the combination of quinidine and verapamil.[43,94,115] In the Canadian Trial of Atrial Fibrillation (CTAF), sotalol was significantly inferior to amiodarone for the long-term maintenance of sinus rhythm (Fig. 35.6).[115] The PAFAC study demonstrated a 50% recurrence rate with sotalol during 1 year of daily transtelephonic ECG monitoring compared with 38% on the combination of quinidine and verapamil.[94] In the SAFE-T study, sotalol 160 mg twice daily was superior to placebo, but less effective than amiodarone in prevention of AF recurrence after pharmacologic or electrical cardioversion (the median time to a recurrence was 6 days on placebo, 74 days on sotalol, and 487 days on amiodarone).[43] At 2 years, approximately 30% of patients treated with sotalol remained in sinus rhythm compared with 60% of patients on amiodarone and 10% of patients on placebo. However, a prespecified subgroup analysis revealed that
Figure 35.7 Prevalence of sinus rhythm at 1 year in the AFFIRM substudy.[116] Patients are included only if they were randomized 1 year or more before the termination of the substudy. Amio, amiodarone; CV, cardioversion; SR, sinus rhythm.

this difference was driven by the superiority of amiodarone and a relative inefficacy of sotalol in patients without ischemic heart disease, whereas both drugs were equally modestly effective in patients with ischemic heart disease: the proportion of patients in sinus rhythm at 2 years was approximately 40% in the amiodarone group and 35% in the sotalol group. The efficacy of sotalol was similar to that of class I antiarrhythmic drugs and inferior to that of amiodarone in the AFFIRM substudy (48%, 45%, and 66%, respectively) (Fig. 35.7).[116]

Hypotension and bradycardia were the most common cardiovascular adverse effects of sotalol with an incidence of 6–10%, while ventricular proarrhythmias associated with prolongation of the QT interval were reported in 1–4% of patients and were dose related.[112,113] In A-COMET II (Azimilide CardiOversion MaintEnance Trial-II), eight (3.5%) out of 223 patients treated with sotalol 320 mg daily withdrew from the study because of a significant QT interval prolongation compared with two (0.9%) of 224 patients in the placebo group.[114] In the SAFE-T trial, only one patient (0.4%) in the sotalol group had an episode of torsades.[43]

Dofetilide

Unlike class IC agents and sotalol, dofetilide is safe to use in patients with previous myocardial infarction and/or congestive heart failure (**Class I, Level A**). In the DIAMOND AF substudy of DIAMOND-CHF and DIAMOND-MI trials, 506 patients with AF at baseline were more likely to remain in sinus rhythm on treatment with

dofetilide 500 µg twice daily compared with placebo (79% vs 42%).[24] Dofetilide had no effect on mortality in patients in whom AF persisted during the study, but restoration and maintenance of sinus rhythm were associated with a 56% reduction in death. In the DIAMOND-CHF (n = 1518) and DIAMOND MI (n = 1510) studies, patients treated with dofetilide had a lower incidence of new-onset AF than those on placebo (1.23% vs 3.78%)[117,118]; this effect was more pronounced in patients with NYHA class III and IV heart failure enrolled in DIAMOND-CHF (1.98% vs 6.55%).[117]

In the dose-ranging SAFIRE-D study of 325 patients with persistent AF or flutter for 2–26 weeks, dofetilide exhibited a dose-related effect: 40%, 37%, and 58% patients receiving 250, 500, and 1000 µg of dofetilide, respectively, were in sinus rhythm after 1 year compared with 25% in the placebo group.[53] The median time to relapse was 31, 179, and more than 365 days for dofetilide groups and 27 days for placebo. Dofetilide was almost twice as effective for the long-term prevention of atrial flutter than of AF (73% vs 40%).

The major safety concern about dofetilide is its torsadogenic potential which is dose related. For instance, the incidence of torsades de pointes with dofetilide ranges from almost "zero" at doses below 250 µg bid to 10% or greater at doses higher than 500 µg bid.[12] In the randomized controlled studies, the incidence of torsades de pointes varied between 0.6% and 3.3%, with more than three-quarters of episodes occurring during the first 3–4 days of drug initiation. Dofetilide is excreted predominantly via the kidneys and its dose should be adjusted for creatinine clearance (see Table 35.2); the drug should not be prescribed in patients with significantly impaired renal function (creatinine clearance less than 20), hypokalemia, hypomagnesemia or a QT interval of longer than 500 ms. If the QT interval is prolonged to >500 ms or by >15% versus baseline, the dose should be reduced.

Azimilide

Although initial reports on azimilide were encouraging,[119] the recent A-STAR (Supraventricular TachyArrhythmia Reduction) and A-COMET II trials, in patients with persistent AF, have failed to show any antiarrhythmic benefit of azimilide.[114,120] The ALIVE (AzimiLide PostInfarct SurviVal Evaluation) trial of 3717 patients with a recent myocardial infarction and left ventricular dysfunction has shown a neutral effect of azimilide on all-cause mortality, including in patients with a significantly reduced ejection fraction.[121] Fewer patients who started the trial in sinus rhythm developed AF on azimilide and there was a trend to higher pharmacologic conversion rates in the azimilide arm than in the placebo arm (26.8% vs 10.8%); ($P = 0.076$).[122] The

marginal efficacy and unacceptably high rates of torsade de pointes proarrhythmia prevent the use of azimilide for treatment of AF.

Amiodarone

The potential of amiodarone to maintain sinus rhythm in patients with AF and a relative cardiac safety in patients with significant structural heart disease has been repeatedly shown in observational and prospective, randomized, controlled studies. The CTAF trial randomized 403 patients with mixed paroxysmal and persistent AF to amiodarone 10 mg/kg for 2 weeks, followed by 300 mg per day for 4 weeks and a maintenance dose of 200 mg and either sotalol 160–320 mg per day (depending on gender, body mass, and creatinine clearance) or propafenone 450–600 mg (depending on age and body weight).[115] The incidence of recurrent AF lasting more than 10 minutes was reduced by 57% in the amiodarone group compared with the sotalol or propafenone group (31% vs 61%) (see Fig. 35.6). Data from the CHF-STAT substudy showed that patients who received amiodarone at a maintenance dose of 300 mg per day converted to sinus rhythm more frequently (31.3% vs 7.7% on placebo), had fewer recurrences, and were half as likely to develop new AF compared with placebo.[61]

Despite prolonging cardiac repolarization, amiodarone has a low torsadogenic potential.[12] For instance, a literature review reported that the incidence of torsades de pointes was only 0.7% in 2878 patients treated with amiodarone in 17 uncontrolled studies, while no proarrhythmic effects were described among 1464 patients treated in seven controlled studies.[59] The residual risk of torsades de pointes with amiodarone occurs chiefly in patients with other risk factors, such as bradycardia or hypokalemia. The reason for the low propensity of amiodarone to cause torsades de pointes is not clear, but is presumably related to its complex mode of action which involves class I, II and IV effects alongside its class III properties. It has also been suggested that amiodarone does not increase the heterogeneity of refractoriness in the myocardial layers and does not increase transmural dispersion of repolarization.[123]

Given its neutral effect on all-cause mortality, amiodarone should be considered a drug of choice for management of AF in patients with congestive heart failure, hypertrophic cardiomyopathy and hypertension with significant left ventricular hypertrophy (**Class I, Level A**). However, although several studies besides the CHF-STAT have reported on the relative safety of amiodarone,[124,125] recent subgroup analyses from the Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT) suggested that amiodarone was associated with excess mortality in patients with NYHA III heart failure.[126]

Amiodarone may cause multiple non-target effects, which range from transient and relatively trivial (e.g. gastrointestinal disturbances) to partially preventable (e.g. skin toxicity) and medically correctable (e.g. underactive thyroid) to serious such as pulmonary toxicity, liver damage, hyperthyroidism, bradycardia, significant or irreversible neurologic symptoms (e.g. peripheral neuropathy), and visual disturbances (e.g. optic neuritis). The adverse effects of amiodarone seem to occur less frequently at low doses (100–200 mg daily) than with higher maintenance doses (300–400 mg daily), but idiosyncratic reactions can arise. Amiodarone is not therefore recommended as first-line therapy in patients with little or no structural heart disease for whom therapy with class IC drugs or sotalol is more appropriate.

Dronedarone

Dronedarone is an investigational agent with multiple electrophysiologic effects which are similar to those of amiodarone, but it is devoid of iodine atoms and is believed to have a better side-effect profile with significantly less reporting of pulmonary fibrosis, ocular adverse effects, and skin photosensitivity. Dronedarone does not significantly prolong the QT interval and, like amiodarone, probably has a low potential for causing torsades de pointes.

The antiarrhythmic potential of dronedarone and the effects on mortality and morbidity have been studied in a dose-finding study, two high-quality, medium-size efficacy and safety trials, and a recently completed large-scale survival trial (Table 35.5).[127–129] The efficacy of dronedarone in preventing AF recurrences after electrical cardioversion was clearly demonstrated in a dose-ranging study where 400 mg bid proved to be the most effective dose.[127] The EURIDIS (EURopean trial In atrial fibrillation or flutter patients receiving Dronedarone for the maintenance of Sinus rhythm) and its American-Australian-African equivalent ADONIS have shown that dronedarone 400 mg twice daily (n = 828) was superior to placebo (n = 409) in prevention of recurrent AF and was also effective in controling ventricular rates.[128] In the European trial, the median time to the recurrence of arrhythmia (the primary endpoint) was 41 days in the placebo group and 96 days in the dronedarone group (P = 0.01). In the American-Australian-African counterpart, the corresponding time was 59 and 158 days (P = 0.002). Figure 35.8 shows the probability of recurrent AF on dronedarone and placebo based in the pooled EURIDIS and ADONIS studies.

The efficacy and safety of dronedarone were directly compared to that of amiodarone in the DIONYSOS (Efficacy and Safety of Dronedarone versus Amiodarone for the Maintenance of Sinus Rhythm in Patients with Atrial Fibrillation) study in 504 patients with persistent AF who underwent electrical cardioversion (data on file). The primary

Table 35.5 Summary of clinical studies of dronedarone in atrial fibrillation

Study	Number of patients	Patient characteristics	Dose of dronedarone	Placebo controlled	Primary endpoint	Follow-up, months	Outcome
DAFNE	199	Post cardioversion	400 mg bid 600 mg bid 800 mg bid	Yes	Time to first AF recurrence	6	Dronedarone 400 mg bid significantly prolonged median time to first AF recurrence v placebo: 60 vs 5.3 days. Relative risk reduction, 55%; (95% CI, 28–72% $P = 0.001$)
EURIDIS	615	Persistent or paroxysmal AF	400 mg bid	Yes	Time to first AF recurrence	12	Median time to first AF recurrence was 41 days on dronedarone v 96 days on placebo, $P = 0.01$
ADONIS	630	Persistent or paroxysmal AF	400 mg bid	Yes	Time to first AF recurrence	12	Median time to first AF recurrence was 59 days on dronedarone vs 158 days on placebo, $P = 0.002$
EURIDIS and ADONIS pooled	1237	Persistent or paroxysmal AF	400 mg bid	Yes, n = 409	All-cause mortality and hospitalizations *post hoc* analysis	12	Reduced on dronedarone vs placebo: 22.8% vs 30.9% (HR, 0.73; 95% CI, 0.57–0.93; $P = 0.01$)
ERATO	630	Permanent AF with ventricular rates >80 bpm on rate-controlling therapy	400 mg bid	Yes	Mean 24-hour ventricular rate at 2 weeks	1	Ventricular rates were 12 bpm lower on dronedarone v placebo; $P < 0.0001$
ANDROMEDA	617	Congestive heart failure; EF <0.35; 38% had a history of AF; 25% in AF at randomization	400 mg bid	Yes	All-cause mortality and hospitalization for heart failure	Median, 2	Stopped early because of increased mortality in the dronedarone arm: 8% vs 3.8% on placebo (HR, 2.3; 95% CI, 1.07–4.25; $P = 0.03$) Primary endpoint: 17.1% on dronedarone vs 12.6% on placebo (HR, 1.38; 95% CI, 0.92–2.09; $P = 0.12$)
ATHENA	4628	Paroxysmal or persistent AF with risk factors	400 mg bid	Yes	All-cause mortality and hospitalizations for cardiac causes	21	Dronedarone reduced the primary endpoint vs placebo by 24% ($P < 0.001$)
DIONYSOS	504	Persistent AF	400 mg bid	No, amiodarone is used as an active comparator	AF recurrence and premature drug discontinuation for side effects or lack of efficacy	7	Primary endpoint events on dronedarone vs amiodarone: 184 (73.9%) vs 141 (55.3%); p < 0.01 AF recurrence: 36.5% vs 24.3% Drug discontinuation: 26 (10.4%) vs 34 (13.3%)

ACE, angiotensin-converting enzyme; ADONIS, American-Australian-African trial with DronedarONe In atrial fibrillation or flutter for the maintenance of Sinus rhythm; AF, atrial fibrillation; ANDROMEDA, ANtiarrhythmic trial with DROnedarone in Moderate to severe heart failure Evaluating morbidity DecreAse; ATHENA, A placebo-controlled, double-blind, parallel arm Trial to assess the efficacy of dronedarone 400 mg bid for the prevention of cardiovascular Hospitalization or death from any cause in patiENts with Atrial fibrillation/atrial flutter; bpm, beats per minute; DAFNE, Dronedarone Atrial FibrillatioN study after Electrical cardioversion; DIONYSOS, Efficacy and Safety of Dronedarone vs Amiodarone for the Maintenance of Sinus Rhythm in patients with Atrial Fibrillation; EF, ejection fraction; ERATO, Efficacy and Safety of Dronedarone for the Control of Ventricular Rate; EURIDIS, EURopean trial In atrial fibrillation or flutter patients receiving Dronedarone for the maintenance of Sinus rhythm.

Figure 35.9 Time to first cardiovascular hospitalization or death in the ATHENA trial. ATHENA = A placebo controlled, double blind Trial to assess the efficacy of dronedarone for the prevention of cardiovascular Hospitalization or death from any cause in patiENts with Atrial fibrillation and flutter. Reproduced from Hohnloser et al.[129], with permission.

endpoint was recurrence of AF or premature drug discontinuation secondary to adverse effects or lack of efficacy. After a mean follow-up of 7 months, 36.5% patients in the dronedarone group and 24.3% patients in the amiodarone group had a recurrence of AF. Dronedarone was better tolerated, with fewer episodes of thyroid dysfunction (2 vs 15), neurological side effects (3 vs 17), and bradycardia (8 vs 22) compared with amiodarone. However, gastrointestinal disorders (diarrhea, vomiting, nausea) were more common with dronedarone than amiodarone (32 vs 13).

The *post hoc* analysis of the EURIDIS and ADONIS studies showed that patients treated with dronedarone had a 27% reduction in relative risk of hospitalization for cardiovascular causes and death (22.8% vs 30.9% on placebo).[128] Subsequently, a further Phase III randomized controlled study (ATHENA: A placebo controlled, double blind Trial to assess the efficacy of dronedarone for the prevention of cardiovascular Hospitalization or death from any cause in patiENts with Atrial fibrillation and flutter) has been undertaken in 4628 high-risk patients.[129] Dronedarone prolonged time to first cardiovascular hospitalization or death from any cause (the composite primary endpoint) by 24% ($P < 0.001$) compared with placebo (Fig. 35.9). This effect was driven by the reduction in cardiovascular hospitalizations (25%), particularly hospitalizations for AF (37%) and acute coronary syndromes (30%). All-cause mortality was similar in the dronedarone and placebo groups (5% and 6%, respectively); however, dronedarone significantly reduced deaths from cardiovascular causes (2.7% vs 3.9%; $P = 0.03$).

The ANDROMEDA (ANtiarrhythmic trial with DROnedarone in Moderate to severe heart failure Evaluating morbidity DecreAse) study was initiated to explore the effects of dronedarone on all-cause death and hospitalizations for heart failure in patients with NYHA class III or IV heart failure. The trial was stopped prematurely after 627 patients out of the 1000 planned were enrolled, because an interim safety analysis revealed an excess of deaths in the dronedarone arm compared with placebo (8% vs 13.8%; HR 2.13; 95% CI 1.07–4.25; $P = 0.03$).[130] The adverse outcome of ANDROMEDA appears largely explained by an increase in creatinine in the dronedarone-treated patients being misinterpreted as progressive renal failure (it was due to its effect on renal tubular excretion), prompting inappropriate discontinuation of otherwise life-saving treatment with angiotensin-converting enzyme inhibitors or angiotensin receptor-blocking drugs. Consequently, excess mortality related to dronedarone was secondary to heart failure. The risk of death was the greatest in patients with severely depressed ventricular function and there were more hospitalizations for heart failure in the dronedarone arm. In the subsequent analysis of a small proportion (n = 200) of patients with class III heart failure enrolled in the ATHENA trial, therapy with dronedarone was, in fact, associated with a lower likelihood of hospitalizations or death from cardiovascular cause as well as lower all-cause mortality compared with placebo.[130a]

Investigational antiarrhythmic agents

A raft of other amiodarone analogs is currently at various stages of development.[84] Celivarone (SSR149744C) has been studied in a Phase II dose-ranging study, MAIA (MAintenance of sinus rhythm In patients with recent

Atrial fibrillation or flutter) in 673 patients who were randomized to one of four doses (50, 100, 200 or 300 mg once daily) or placebo. As with dronedarone, the higher doses of celivarone tended to be less effective than the lower doses. The lowest incidence of the recurrence at 90 days was 52.1% in the celivarone 50 mg compared with 67.1% in the placebo group. No proarrhythmia or thyroid dysfunction was reported in this short-term study. The results of the double-blind placebo-controlled CORYFREE (COntrolled Dose Ranging studY of the eFficacy and safEty of SSR149744c 300 or 600 mg for the Conversion of Atrial Fibrillation/flutter) trial are expected. There is ongoing research into the development of an amiodarone derivative with modified bonds within the molecule allowing rapid hydrolization by esterases, resulting in a more rapid action, a shorter half-life and possibly a better risk–benefit ratio. Another amiodarone derivative, budiodarone (ATI-2042) which shares its mixed ion channel effects but has a different metabolic pathway, a shorter half-life, and low propensity to tissue accumulation, has recently proven to reduce AF burden by up to 75.5% over 12 weeks of treatment in 110 patients with paroxysmal AF (reported at the Heart Rhythm Society Late Breaking Trials Session in 2009).

An oral formulation of vernakalant has been investigated in two medium-size Phase II studies (Table 35.3).[84] In a double-blind, placebo-controlled study (n = 446), patients treated with vernakalant 600 mg twice daily were more likely to maintain sinus rhythm at 3 months after pharmacologic or electrical cardioversion compared with placebo (51% vs 37%).

There were no reports of torsade de pointes or drug-related deaths. There is evidence that an antianginal drug, ranolazine, may also produce an antiarrhythmic effect due to multiple channel blockade, particularly late sodium current blockade. Phase III studies of ranolazine in AF are presently planned.

Where to initiate antiarrhythmic drug therapy

The issue of the proper site for initiation of antiarrhythmic drug therapy for AF revolves around considerations of risk and practicality. In-hospital initiation under monitored conditions conveys benefits of accurate assessment of the efficacy and prompt recognition of adverse effects, such as bradycardia, conduction abnormalities, excessive QT interval prolongation, proarrhythmia, and intolerance or idiosyncrasy. Patients in AF in whom sinus node function or the QT interval duration during sinus rhythm are unknown and patients at anticipated high risk of developing adverse effects should not be prescribed antiarrhythmic drugs outside the hospital setting that are known to aggravate their condition. For some antiarrhythmic agents, e.g. dofetilide, there is formal mandate for in-hospital initiation.

In the absence of proarrhythmic concerns and formal labeling, convenience and cost effectiveness favor out-of-hospital initiation, e.g. oral propafenone and flecainide in patients with lone AF or AF associated with hypertension without significant left ventricular hypertrophy. The same approach is valid for amiodarone, given its long elimination half-life period and low probability of developing torsades de pointes. Dronedarone has proven a safe and well tolerated agent with an added benefit of ventricular rate control and can, therefore, be initiated on an outpatient basis. An ECG control or transtelephonic ECG monitoring should be arranged to provide surveillance of heart rate, PR and QT interval durations, QRS width, and assessment of the efficacy of treatment.

Antiarrhythmic drug use after left atrial ablation

After left atrial ablation-based therapies, the incidence of AF or atrial tachycardia has been reported to be 45% during the first 3 months despite antiarrhythmic drugs.[131] [131]. The arrhythmia recurrence is more common in patients with persistent AF, older individuals, and in patients with structural heart disease. In many cases, early recurrence of AF after ablation is transient and is thought to be secondary to inflammation after radiofrequency injury, nerve ending damage and resulting imbalance of the cardiac autonomic nervous system, and a delayed effect of ablation associated with "maturation" of lesions. Early AF often subsides after 3 months (the blanking period) upon the resolution of inflammation and restoration of autonomic regulation, without the need for reablation. Therefore antiarrhythmic drug therapy to suppress early recurrence of AF is commonly employed for the first 1–3 months after ablation or if the arrhythmia recurs after discontinuation of the antiarrhythmic drug. These are usually the same agents that have been previously ineffective, but may now be efficacious because of a synergistic effect with ablation (an example of so-called "hybrid" therapy). Amiodarone has been reported to be most commonly prescribed because of its antifibrillatory as well as atrioventricular conduction slowing properties. The use of antiarrhythmic drugs increases the probability of maintaining sinus rhythm by about 20–30% as suggested by the worldwide surveys on catheter ablation for AF conducted in 1995–2002 and 2003–2006.[132,132a]

The synergistic effect of antiarrhythmic drugs (mainly propafenone, flecainide, and sotalol) has recently been demonstrated in the 5A (AntiArrhythmics After Ablation of Atrial fibrillation) study in 110 patients randomized to receive antiarrhythmic drugs or no therapy for at least 6 weeks after ablation (presented at the Annual Sessions of the Heart Rhythm Society in 2008). The composite endpoint was the occurrence of atrial arrhythmias lasting more

than 24 hours or symptomatic arrhythmias, need for cardioversion or hospitalization for atrial arrhythmias, and intolerance of antiarrhythmic drugs. About one-quarter of patients had reablation. The recruitment for the study was terminated early because of significantly fewer events in the drug-treated group compared with patients who received no drug therapy. However, because of a short minimum follow-up period of 6 weeks that falls within the blanking period, the study has failed to show whether antiarrhythmic drug therapy can offer any benefit beyond the blanking period when the majority of patients would receive an antiarrhythmic drug anyway according to the current practice.

About 10% of patients, however, develop regular fast atrial tachycardias which are either focal or re-entrant (atypical atrial flutter), are refractory to antiarrhythmic drugs, and often require additional ablation. The incidence of late (more than 1 year) recurrence of AF after ablation is currently at 5–10%, but it is likely to be higher when long-term follow-up data become available and the procedure is more widely used.[131]

Pharmacologic rate control

Acute rate control

Beta-blockers and calcium antagonists

Randomized controlled studies have shown that intravenous verapamil, diltiazem, and beta-blockers (usually esmolol) can accomplish rapid control of the ventricular response rate (**Class I, Level B/C**) (Table 35.6).[133–139] The decrease in the ventricular rate (approximately 20–30%),

time to the maximum effect (20–30 minutes), the conversion rate (12–25%), and the adverse reactions (usually hypotension and bradycardia, although left ventricular dysfunction and high-degree heart block may occur) have been reported to be the same with both beta-blockers and calcium antagonists. Beta-blockers are preferable in patients with a history of myocardial infarction or if thyrotoxicosis is suspected as a cause of the arrhythmia, whereas verapamil and diltiazem are preferred in patients with chronic obstructive airways disease.[139] The majority of patients (70–75%) responded to the first bolus of diltiazem and verapamil with heart rate reductions to below 100 bpm.[137,138] In patients with pre-excitation syndrome and AF, agents which slow atrioventricular conduction can cause the impulse to travel in the anterograde direction via the accessory pathway rather than via the atrioventricular node. Because the accessory pathway, unlike the atrioventricular node, is capable of conducting very rapidly at a 1:1 ratio, this may lead to AF with extremely fast ventricular rates that may degenerate into ventricular fibrillation.

Digoxin

Intravenous digoxin is no longer the treatment of choice when rapid rate control is essential because of its delayed onset of the therapeutic effect (more than 60 minutes). In a direct comparison with diltiazem, the peak effect of digoxin was not observed until 3 hours, whereas diltiazem significantly decreased the ventricular rate within 5 minutes.[136] Some reported no significant effect or lack of persistent rate control with digoxin in patients with continuous AF and symptomatic bradyarrhythmias or pauses when AF converted to sinus rhythm.[140] However, because of its positive inotropic action, digoxin can be used in patients with poor

Table 35.6 Drugs for acute rate control in atrial fibrillation

Drug	Route of administration	Dose	Onset	Recommendation (Class)	Level of evidence
Esmolol	Intravenous	0.5 mg/kg over 1 min followed by 0.05–0.2 mg/kg/min infusion	5 min	I	C*
Metoprolol	Intravenous	2.5–5 mg over 2 min followed by repeat doses if necessary	5 min	I	C*
Propranolol	Intravenous	0.15 mg/kg	5 min	I	C*
Diltiazem	Intravenous	0.25 mg/kg over 2 min followed by 5–15 mg/h infusion	2–7 min	I	B
Verapamil	Intravenous	0.075–0.15 mg/kg over 2 min	3–5 min	I	B
Digoxin	Intravenous	0.25 mg each 2 h, max 1.5 mg	2 h	IIb†	B
Amiodarone	Intravenous	As for cardioversion‡	6–8 h	IIb‡	C
Sotalol	Intravenous	1–1.5 mg/kg over 5–10 min	15–30 min	III	B

*For all beta-blockers;

‡Class IIa indication in patients with poor ventricular function and moderately fast ventricular rates, level of evidence C.

ventricular function and moderately fast ventricular rates (**Class I, Level B**). One important advantage of digoxin is its ability to convert atrial flutter to AF and, thereby, make ventricular rate control easier to accomplish. However, this approach is rarely practical in the emergency setting.

Amiodarone

Amiodarone suppresses atrioventricular conduction by inhibiting the L-type calcium current ($I_{Ca,L}$), (the major determinant of the action potential of the atrioventricular nodal cells), and producing a sympatholytic effect. Amiodarone also has mild beta-blocking properties. There is anecdotal evidence that intravenous amiodarone may be effective in ventricular rate control when other agents have no effect on ventricular response or are contraindicated. Intravenous infusion of amiodarone was associated with a decrease in ventricular rates by 37 beats per minute and an increase in systolic blood pressure by 24 mmHg in 38 patients with hemodynamically unstable AF refractory to electrical cardioversion and intravenous agents, such as esmolol, diltiazem, digoxin, and procainamide.[60] The atrioventricular blocking effect of amiodarone is complemented by its antifibrillatory action. The disadvantages of IV amiodarone are slow onset of action and increased risk of phlebitis. Although amiodarone is not routinely used for acute rate control, it is given a **Class IIa, Level C** recommendation in patients with AF *and* congestive heart failure and, unlike digoxin, has the potential to restore sinus rhythm.

Sotalol

Sotalol usually is ineffective in cardioverting AF, but can slow down the ventricular rate due to its beta-blocking properties.[43] In 140 patients with recent-onset AF, intravenous infusions of either sotalol 1.5 mg/kg over 10 minutes or amiodarone 10 mg/kg in 30 minutes helped to facilitate rate control compared with IV digoxin, but the overall conversion rate within 12 hours was modest with either agent.[141] The potential negative inotropic effect of sotalol precludes its use for rate control in patients with left ventricular dysfunction and the proarrhythmic (torsadogenic) potential of sotalol due to QT interval prolongation reduces its value as a rate-controling agent (**Class III, Level B**).

Clonidine, adenosine, and magnesium

There is limited evidence on the use of clonidine and magnesium for ventricular rate control. The rationale for the use of clonidine in AF is its central sympatholytic activity of directly blocking alpha-2 adrenoreceptors in the lower brainstem region and its ability to stimulate parasympathetic outflow, resulting in prolongation of the refractoriness of the atrioventricular node. In 40 hemodynamically stable patients with new-onset (less than 24 hours) rapid AF, clonidine, given orally at a dose of 0.1 mg and repeated at 2-hour intervals if rate control was not achieved, reduced

ventricular rates by 44 beats per minute over a 6-hour follow-up. This effect was comparable to that of verapamil and digoxin, both administered intravenously (the mean heart rate reduction was 52 and 42 beats per minute, respectively).[142] Clonidine was associated with a greater reduction of systolic blood pressure compared with verapamil.

In a meta-analysis of trials in 303 patients and a rapid ventricular rate, intravenous magnesium effectively reduced the ventricular rate to below 90–100 within 5–15 minutes of infusion (OR 1.96; 95% CI 1.24–3.08).[70] Magnesium had a synergistic effect on the atrioventricular node when given with digoxin or diltiazem[139] and also produced an antifibrillatory effect. The overall response rate, including rate control and conversion to sinus rhythm, was significantly higher in patients who received the magnesium infusion compared with placebo or an active comparator (86% v 56%; OR 4.61; 95% CI 2.67–7.96).[70]

Adenosine, in its present formulation, is not suitable for rate control (**Class III, Level A**) because of its extremely short half-life, lack of the antifibrillatory effect, and the potential to induce AF, particularly in the presence of an accessory pathway. The incidence of AF after a central venous intravenous adenosine infusion for supraventricular tachycardia is about 10–15%.[143]

New agents for acute rate control

Several adenosine derivatives with a high specificity for adenosine A1 receptors, tecadenoson, selodenoson, and capadenoson, are currently under investigation. The high affinity for A1 receptors enables effective rate control without reducing the blood pressure or causing bronchospasm as a result of stimulating A2 receptors. Tecadenoson has an immediate onset of action in about 30 seconds and has a half-life of approximately 30 minutes and may prove to be a potent and safe drug for urgent rate control and possibly even cardioversion of AF. Selodenoson has an even longer half-life of 150 minutes and is available in an oral formulation. Tecadenoson has been mainly studied for cardioversion of supraventricular tachycardias.[144] Undesirable symptoms commonly reported with adenosine, such as flushing, dyspnea, and chest pain, occurred less frequently. Tecadenoson shortens atrial action potential duration and may therefore induce AF. However, in contrast to adenosine, the effect on atrial refractoriness is smaller than the blocking effect on the atrioventricular node, and risk of AF is therefore expected to be low. In the Phase III TEMPEST (Trial to Evaluate the Management of Paroxysmal supraventricular tachycardia during Electrophysiologic Study with Tecadenoson), AF as an adverse event was reported in 2% of patients.[144] Selodenoson demonstrated a statistically and clinically significant decrease in ventricular rate compared with placebo in a small double-blind Phase II trial.[145] Final results are pending from three other Phase II studies in patients with spontaneous AF with uncontrolled ventricular rates.

Rate control in paroxysmal and persistent atrial fibrillation

Beta-blockers and calcium antagonists

Rate control is an essential constituent of management of AF and is pertinent to all types of the arrhythmia. In paroxysmal and persistent AF, rate control is important during the recurrence or prior to electrical cardioversion. Non-dihydropyridine calcium antagonists and beta-blockers are drugs of choice (**Class I, Level B/C**). They are also commonly prescribed in combination with the class IC agents propafenone and flecainide to prevent fast ventricular rates due to 1:1 atrioventricular conduction when recurrent AF evolves to flutter.

Digoxin

Digoxin should be avoided if the arrhythmia is self-terminating or electrical cardioversion is planned and rhythm control is pursued. This is because digoxin abbreviates the atrial action potential by several mechanisms, including increased intracellular calcium, augmentation of the transient outward potassium I_{to} current, and a vagotonic effect which can be proarrhythmic in the atria.[146] Thus digoxin can promote the recurrence or perpetuation of atrial fibrillation and offset the effect of antiarrhythmic agents. In a randomized, double-blind, placebo-controlled, crossover study in 43 patients with frequent symptomatic paroxysms of atrial fibrillation, the median time to the occurrence of two episodes of the arrhythmia documented by patient-activated monitors was prolonged from 13.5 days in the placebo group to 18.7 days in the digoxin group during 2-month follow-up.[147] However, no significant difference was detected between digoxin and placebo in terms of the number and duration of atrial fibrillation episodes. It is likely that digoxin used as monotherapy reduced the frequency of symptomatic atrial fibrillation by lowering the ventricular rate response and increasing the regularity. The heart rate during symptomatic episodes was reduced by approximately 15 beats per minute.

Sotalol and amiodarone

Some antiarrhythmic drugs, such as sotalol, amiodarone, and dronedarone, slow atrioventricular conduction and thus offer an additional benefit of ventricular rate control during recurrences of AF. Although much of the evidence for the rate-controling effects of antiarrhythmic drugs comes from studies in permanent AF, antiarrhythmic drugs are not commonly employed for long-term rate control and therefore will be discussed in this section.

Sotalol has been relatively well studied for rate control.[148–150] In the randomized, double-blind, parallel, placebo-controlled Sotalol Atrial Fibrillation Study in 60 patients, the combination of digoxin and dl-sotalol, at either 80 or 160 mg/day, resulted in a statistically significant reduction in heart rate at rest and with exercise during both exercise testing and ambulatory monitoring.[148] In patients with AF of more than 1 month, sotalol and metoprolol on the background of digoxin were equally effective in reducing the resting heart rate, but sotalol surpassed metoprolol during exercise.[150] Although there were no reports of torsades de pointes, sotalol significantly prolonged the QT interval both at rest and during exercise. In the CHF-STAT study, amiodarone reduced the mean and maximal ventricular rates by 16–20% and 14–22%, respectively.[61] However, sotalol and amiodarone are not routinely employed for long-term rate control, e.g. in permanent or accepted AF, because of proarrhythmic and non-target side effects (**Class IIb, Level B/C**).

Dronedarone

In the EURIDIS and ADONIS studies, dronedarone was not only effective in suppressing recurrent AF, but also reduced the ventricular rate response during the recurrence of the arrhythmia by 12–15 beats per minute compared with placebo.[128] Similar reductions in ventricular rates were achieved in the ATHENA trial including patients who progressed to permanent AF. The ability of the drug to control ventricular rates was prospectively assessed in the ERATO (Efficacy and Safety of Dronedarone for the Control of Ventricular Rate) study of 174 patients with AF with a resting heart rate of more than 80 beats per minute despite standard therapy with beta-blockers, calcium antagonists, and digitalis.[151] At 2 weeks, dronedarone lowered the mean 24-hour ventricular rate (the primary endpoint) by 12 beats per minute and limited the peak heart rate during a maximal symptom-limited exercise test by 24 beats per minute compared with placebo without affecting the overall exercise capacity.

Rate control in permanent atrial fibrillation

Elements of rate control

Several questions remain to be answered about rate control therapy in AF. These include how best to measure successful therapy and what is the optimal heart rate. Current guidelines define adequate rate control as maintenance of the ventricular rate response between 60 and 80 at rest and 90 and 115 during moderate exercise.[5] Few systematic studies have explored the effect of rate-slowing drugs on chronotropic competence in AF or defined upper limits of the appropriate ventricular rate response during exercise.[152,153] Measuring the systolic velocity integral of aortic blood flow with Doppler ultrasound to assess the effect of different ventricular rates on cardiac output in 60 patients with AF, Rawles demonstrated that rates of up to 90 maintain good cardiac output at rest, while during exercise, ventricular rates of 90–140 might be necessary in order to maintain equivalent cardiac outputs to patients in sinus rhythm.[153] However, no con-

trolled clinical trials have validated these values with regard to their effects on morbidity or mortality.

Atrial contraction contributes 20–40% of the total stroke volume. Loss of atrial contraction may cause a marked decrease in cardiac output, especially in patients with impaired diastolic filling, hypertension, and left ventricular hypertrophy. Hence, although rapid ventricular rates can be detrimental, they should not be too low either. Pharmacologic ventricular rate control can have other problems, such as being associated with periods of bradycardia (usually sinus) alternating with tachycardia (usually AF) in the same patient.[154] This often requires placement of a pacemaker to prevent bradycardia and permit adequate drug therapy to control ventricular rates. It also sometimes leads to atrioventricular node ablation by radiofrequency ablation with placement of a permanent pacemaker system to control ventricular rate optimally.

Adequate rate control probably encompasses more than the mere prevention of fast ventricular rates. The effect of excessively irregular rhythm is rarely acknowledged in practice as an important constituent of effective rate control, despite some evidence that the rhythm irregularity *per se* may contribute to ventricular dysfunction.[155] Randomized studies comparing atrioventricular node ablation and atrioventricular node modification in AF provided indirect evidence that not only rate control but also regularization of the rhythm were essential for improving cardiac performance.[156]

Methods of assessment of rate control

Ventricular rate control at rest does not always translate into effective control during exercise. Few data exist that define the most robust method of assessment of rate control and explore whether different methods can provide comparable information or whether the combination of two or theoretically more tests may provide better results. In a small study in patients with permanent AF, ventricular rates assessed after 5 minutes of rest, after a 50-yard walk and after 1 minute of stair stepping exercise correlated with ventricular rates derived from 24-hour Holter recordings.[157] Thus, the heart rate at rest was slower than the mean heart rate obtained from the Holter recording, on average, by 20 beats per minute, but when combined with the heart rate after a 50-yard walk, the resulting heart rate was similar to the mean rate on Holter. The heart rate after 1 minute of stair stepping was similar to the maximum ventricular rates during Holter monitoring. Ambulatory 24-hour ECG monitoring is considered sufficient for assessment of rate control in elderly and sedentary individuals, whereas in younger individuals, an exercise stress test may be necessary.[5] The AFFIRM trial[14] used those criteria in establishing clinical ventricular rate control, but the RACE trial[15] took a more lenient approach, accepting simply a ventricular rate less than 100 beats per minute. The mean heart rate across all follow-up visits for patients in AF was lower in AFFIRM.[158] Event-free survival for the occurrence of the primary endpoint did not differ (64% in AFFIRM vs 66% in RACE). Patients with mean ventricular rates during AF within the AFFIRM (≤80 beats per minute) or RACE (<100 beats per minute) criteria had a better outcome than patients with ventricular rates ≥100 beats per minute (HR 0.69 and 0.58, respectively for ≤80 and <100 compared with ≥100 beats per minute). Perhaps the closeness to 80 beats per minute of the mean ventricular rates in these studies tells the story best. A RACE II study was instigated to assess whether maintaining strict rate control, i.e. mean resting heart rate less than 80 beats per minute and heart rate during mild exercise less than 110 beats per minute, can offer any additional benefit to standard practice.[159]

Drugs for rate control

Digoxin, beta-blockers, verapamil, and diltiazem, are commonly employed (Table 35.7).[5] Digoxin is effective in controling ventricular rates at rest by prolongation of atrioventricular node conduction and refractoriness through vagal stimulation, by direct effects on the atrioventricular node, and by increasing the amount of concealed conduction in the atrioventricular node due to the increased rate at which atria discharge (**Class I, Level B**). However, the effect of digoxin is negated during exercise when most vagal tone is lost and atrioventricular conduction is further enhanced by the increased sympathetic tone.[160] Therefore, digoxin as monotherapy can be effective in older, sedentary patients, but a combination with beta-blockers or calcium antagonists is often necessary to achieve rate control in the majority of patients.

Non-dihydropyridine calcium antagonists and beta-blockers are effective as primary pharmacologic therapy for rate control (**Class I, Level B/C**); however, multiple adjustments of drug type and dosage and a combination of two agents may be needed to achieve the desired effect.[160–164] For example, in the AFFIRM trial, only 58% of patients in the rate control group achieved adequate rate control with the first drug or combination; drug switches occurred in 37% of the patients and drug combinations were commonly used.[164] Overall, adequate rate control was ascertained in 80% of patients at 5 years (most frequently on a beta-blocker with or without digoxin), but these patients were followed carefully to assess rate control at each follow-up visit and frequent drug switches were allowed. Digoxin alone was effective in only 58% of patients.

Atrial fibrillation after cardiac surgery

Prevalence and risk factors

Pooled data from the control arms of 40 randomized clinical trials and three large observational studies have shown

Table 35.7 Drugs for long-term rate control in atrial fibrillation

Drug	Dose	Class of recommendation	Level of evidence	Potential adverse effects
Digoxin	Loading dose: 250 µg every 2 hours; up to 1500 µg; maintenance dose 125–250 µg daily	I	B	Bradycardia; atrioventricular block; atrial arrhythmias; ventricular tachycardia
Diltiazem	120–360 mg daily	I	B	Hypotension; atrioventricular block; heart failure
Verapamil	120–360 mg daily	I	B	Hypotension; atrioventricular block; heart failure
Atenolol	50–100 mg daily	I	C*	Hypotension; bradycardia; heart failure; deterioration of chronic obstructive pulmonary disease or asthma
Metoprolol	50–200 mg daily	I	C*	
Propranolol	80–240 mg daily	I	C*	
Bisoprolol	5–10 mg daily	I	C*	
Carvedilol	25–100 mg daily	I	C*	
Sotalol	80–320 mg	IIb†	C	Bradycardia; QT prolongation; torsades de pointes (risk <1%); photosensitivity; pulmonary toxicity; polyneuropathy; hepatic toxicity; thyroid dysfunction; gastrointestinal disturbances
Amiodarone	800 mg daily for 1 week, then 600 mg daily for 1 week, then 400 mg daily for 406 weeks; maintenance dose 200 mg daily	IIb†	C	Bradycardia; QT prolongation; torsades de pointes (risk <1%); photosensitivity; pulmonary toxicity; polyneuropathy; hepatic toxicity; thyroid dysfunction; gastrointestinal disturbances

*For all beta-blockers;
†useful during recurrence of atrial fibrillation.

that, in the absence of prophylactic antiarrhythmic drug therapy, AF may occur in about 30% of patients after isolated coronary artery bypass grafting, 40% of patients after valve surgery, and 50% of patients after combined coronary artery and valvular surgery.[165] Postoperative AF occurs predominantly during the first 4 days and is associated with increased morbidity and mortality, largely due to stroke and circulatory failure, and longer hospital stay. More than 90% patients present with a paroxysmal or first-onset form of the arrhythmia. Atrial flutter and atrial tachycardias, including multifocal atrial tachycardia, are also common.

Clinical factors that convey a higher risk for the development of postoperative atrial tachyarrhythmias include advanced age, male sex, a previous history of AF, hypertension, congestive heart failure, valvular heart disease, chronic obstructive pulmonary disease, chronic renal failure, previous cardiac surgery, left atrial enlargement, inadequate cardioprotection and hypothermia, right coronary artery grafting, and a longer bypass time.[166] The incidence of postoperative atrial tachyarrhythmias may be lower with minimally invasive techniques, especially for valvular surgery.[167] The pathophysiology of AF after cardiac surgery relates primarily to sterile pericarditis that accompanies the surgery. This results in perioperative changes in atrial electrophysiology, including increased dispersion of atrial refractoriness, decreased atrial conduction velocity, and changes in atrial transmembrane potential.

Rate versus rhythm control

The rhythm control strategy, including electrical or pharmacologic restoration of sinus rhythm with subsequent prophylactic antiarrhythmic therapy, should be considered in hemodynamically unstable or highly symptomatic patients with postoperative AF. If AF is well tolerated, rate control may be sufficient as AF after isolated coronary bypass surgery is often self-limiting and there is a high likelihood of spontaneous conversion to sinus rhythm, usually within 6 weeks. Although digoxin and non-dihydropyridine calcium antagonists (verapamil, diltiazem) are effective in slowing atrioventricular conduction, beta-blockers should be considered the first-line choice because of their beneficial effects on the hyperadrenergic postoperative state. In comparator studies, diltiazem pro-

duced a more rapid rate-slowing effect than digoxin (median times to a 20% or more decrease in ventricular rates were 2 minutes and more than 3.5 hours, respectively).[168] At 2 and 6 hours, the proportion of patients who achieved adequate rate control was significantly higher in the diltiazem-treated group compared with the digoxin-treated group (75% vs 35% and 85% vs 45%, respectively). Digoxin in combination with either beta-blockers or a non-dihydropyridine calcium antagonist will often provide effective therapy in otherwise difficult cases.

Pharmacologic prevention of postoperative AF

Beta-blockers

The best evidence for efficacy in prevention of postoperative AF has been accumulated for beta-blockers, sotalol, and amiodarone (Fig. 35.10).[165] Two earlier meta-analyses of randomized controlled studies have shown that treatment with beta-blockers may reduce the incidence of AF by approximately 50%.[169,170] In a meta-analysis of 27 trials in 3840 patients, therapy with beta-blockers reduced risk of postoperative AF by 61%; there was also a trend towards shorter length of stay.[165] In the large Beta-blocker Length Of Stay (BLOS) study in 1000 patients, 85% of whom had isolated coronary artery bypass grafting, therapy with metoprolol 100–150 mg per day initiated immediately after surgery was associated with a small but statistically significant reduction in the incidence of AF compared with placebo, but had no effect on the length of hospital stay.[171] Current guidelines give a **Class I, Level A** recommendation for beta-blockers for prevention of AF after heart surgery. The downside of beta-blockers is that they may increase risk of bradycardia (5–10%) and risk of longer ventilation (1–2%). In a retrospective analysis, carvedilol was reported to be superior to other beta-blockers, predominantly metoprolol or atenolol, with respect to efficacy and safety.[172] Temporary cardiac pacing using temporary epicardial wire electrodes placed at the

time of surgery in most patients should permit use of beta-blockers in the face of bradycardia.

Sotalol

In eight randomized controlled studies in 1294 patients, sotalol has been reported to reduce the incidence of postoperative AF by 65% compared with placebo, but it had no impact on length of hospital stay, strokes or mortality.[165] Sotalol may be more effective in the prevention of AF than beta-blockers because of its potential incremental benefit due to its class III antiarrhythmic property.[173] However, the use of sotalol risks bradycardia and torsades de pointes, especially in patients with electrolyte disturbances. In direct comparisons, both sotalol and amiodarone were effective and safe in reducing postoperative AF in patients undergoing isolated coronary artery bypass surgery (25% vs 17%), but sotalol was significantly inferior to amiodarone in patients who had aortic valve replacement alone or in combination with coronary surgery (82% vs 7%).[174] When the results of several studies were pooled, there were no differences between the two drugs with respect to the incidence of AF, length of stay, and adverse events.[175] Sotalol was designated **Class IIb, Level B** for prevention of postoperative AF.

Amiodarone

There is compelling evidence from randomized, controlled studies and meta-analyses that treatment with amiodarone may reduce the incidence and duration of postoperative AF, and also control the ventricular rate (**Class IIa, Level A**).[176–183] The Amiodarone Reduction in Coronary Heart (ARCH) study of 300 patients who had undergone coronary bypass surgery has shown a significant reduction in the incidence of postoperative AF with IV amiodarone compared with placebo (35% vs 47%).[181] In the Prevention of Arrhythmias that Begin Early After Revascularization (PAPABEAR) trial of 601 patients undergoing isolated coronary artery bypass surgery, treatment with amiodarone 10 mg/kg per day starting 7 days before surgery was associated with a significant decrease in the incidence of postoperative AF compared with placebo (30% vs 16%), reflecting a 52% reduction in relative risk.[182] The number of patients needed to be treated in order to prevent one episode of the arrhythmia was 7.5. However, there was no difference between amiodarone and placebo groups with respect to complications or length of hospital stay.

A meta-analysis of 19 studies which enrolled 3295 patients, among whom 1639 had received amiodarone and 1656 were in the control group, has shown that therapy with amiodarone halved the incidence of postoperative AF.[165] In addition, amiodarone reduced the occurrence of ventricular tachyarrhythmias by 61% and strokes by 47%. In contrast with other therapies, treatment with amiodarone was associated with a statistically significant shorter

Drug	Studies, n	Pts, n	RR (95% CI)
Beta-blockers	27	3840	0.39 (0.28 – 0.52)
Sotalol	8	1294	0.35 (0.26 – 0.49)
Amiodarone	17	3007	0.50 (0.42 – 0.59)
Magnesium	20	2490	0.54 (0.38 – 0.75)
Propafenone	1	293	0.62 (0.43 – 0.91)
Procainamide	2	146	0.47 (0.22 – 0.99)
Verapamil	3	432	0.94 (0.56 – 1.58)

length of hospital stay, although the difference from the control group was small (0.6 days), resulting in cost savings of marginal statistical significance (data on costs were available in six studies). Adverse events such as hypotension and bradycardia necessitating inotropic and chronotropic support or pacing may limit the routine use of amiodarone to prevent postoperative AF.

Other agents

Ibutilide and dofetilide have proven to be effective for pharmacologic cardioversion of atrial tachyarrhythmias after cardiac surgery. In 302 patients, 101 of whom presented with atrial flutter, ibutilide restored sinus rhythm in 57% compared with 15% on placebo.[184] Conversion rates at all doses were higher for atrial flutter than for AF (78% vs 44%). In 133 patients undergoing isolated coronary artery bypass grafting or combined with valvular surgery, therapy with dofetilide at doses adjusted according to glomerular filtration rates and started on the day of operation resulted in a modest decrease in the incidence of AF compared with placebo (36% vs 18%).[185] Although there were no cases of torsades de pointes in this study, the QT-prolonging effect and the proarrhythmic potential of dofetilide and ibutilide are of significant concern and the drugs are not routinely used in the early postoperative period.

Magnesium sulfate has been reported to reduce the incidence and number of episodes of AF by 46% in a pooled analysis of 20 studies in 2490 patients.[186] The effect was comparable to that of beta-blockers, sotalol, and amiodarone and no adverse events were reported. The favorable effects of magnesium may relate to restoration of electrolyte balance after surgery. Alternatively, the stimulating effects of magnesium on the sodium/potassium pump may act beneficially by inducing a calcium channel-blocking effect. However, magnesium is not commonly employed as a primary agent for prevention or treatment of AF and is usually adjunctive to beta-blockers or antiarrhythmic drugs.

Class I antiarrhythmic drugs have been shown to be moderately effective in prevention of atrial tachyarrhythmias after cardiac surgery. The results from the Clinical Outcomes from the Prevention of Post-operative Arrhythmia (COPPA) II study in 293 patients who had undergone coronary bypass have shown that treatment with propafenone 675 mg daily reduced the incidence of postoperative AF by 38% compared with placebo, but did not change length of stay.[187] Propafenone administered intravenously at a dose of 2 mg/kg produced a more rapid effect on restoration of sinus rhythm compared with intravenous procainamide given at a dose of 20 mg/kg to maximum of 1000 mg (59% vs 18% at 15 minutes) but there was no significant difference in the conversion rates at 1 hour (76% vs 61%).[188] The proarrhythmic potential and the negative inotropic effect of propafenone in patients prone to ischemia or patients with previous myocardial infarction limit the use of propafenone early after heart surgery. Procainamide was associated with a significantly higher incidence of hypotension than propafenone (27% vs 7%) which was clinically relevant and required discontinuation of the drug in 9% of cases. Procainamide does not appear to be significantly more effective than placebo in the prevention of AF and there are concerns about its negative inotropic effect in patients with depressed ventricular function.[189]

Several randomized controlled studies have suggested the beneficial role of agents with anti-inflammatory properties, such as statins, or specific anti-inflammatory drugs such as corticosteroids; these therapies are discussed in detail in Chapter 36.

Conclusion

It is important to emphasize that the rate versus rhythm control trials provide good evidence to help guide therapy. They consistently demonstrate that rate control is a legitimate primary therapeutic option. Importantly, the results of these trials should not be interpreted to mean that a rate control strategy is better than a rhythm control strategy. The strategy of choice must be decided on a patient-by-patient basis. Thus, considering presently available therapy of AF, the first decision to be made with each patient is which strategy to pursue: rate control or rhythm control. Rational antiarrhythmic treatment of AF starts with classification of AF into one of its subtypes: recent onset, paroxysmal, persistent or permanent. Only then can the goal of treatment be identified: to restore sinus rhythm with the option of prophylactic drug treatment or to accept AF as the dominant rhythm.

Antiarrhythmic treatment is further guided by the duration of the arrhythmia, the tendency for recurrence after conversion, and the potential side effects of drugs. At some stage during treatment, rate control is useful in all three subtypes of AF but especially in the permanent form. Pharmacologic cardioversion can be accomplished with intravenous or oral antiarrhythmic drugs, but it is most effective in recent-onset AF. In persistent AF of longer duration, restoration of sinus rhythm is accomplished by electrical cardioversion and antiarrhythmic drugs are employed for prevention of recurrence. Most patients cannot be cured of AF: almost all will experience recurrence of the arrhythmia sooner or later after the first attack despite drug treatment. Therefore, the primary goal of treatment is to reduce morbidity (and possibly mortality) rather than simply to suppress the arrhythmia.

In the last several decades the proarrhythmic effect of antiarrhythmic drugs has been widely recognized. In addition, negative inotropic and extracardiac side effects further limit the use of traditional antiarrhythmic agents. Furthermore, there have been surprisingly few trials designed to

demonstrate their efficacy in reducing mortality, significant morbidity or healthcare costs. There has recently been a significant effort by the pharmaceutical industry to develop new agents for the management of patients with AF and it now seems likely that several of these agents will be approved and will become available for the control of AF and flutter.

36 Atrial fibrillation: upstream therapies

Antonios Kourliouros, Irina Savelieva, Marjan Jahangiri and A John Camm
St George's University of London, London, UK

Introduction

Atrial fibrillation (AF) has been described as an "epidemic" due to its rising prevalence in our aging population. AF is a leading cause of thromboembolism and is also assosciated with impaired quality of life and increased overall mortality. Available treatment strategies consist of heart rate control, rhythm control and prevention of thromboembolism. Antiarrhythmic agents still form the mainstay of pharmacologic therapy for AF. However, despite their proven efficacy in symptom control and prevention of hemodynamic complications, they do not offer a definitive treatment. Comprehensive understanding of the mechanisms leading to AF is paramount for the development of targeted and potentially curative treatments.

Current evidence suggests that the pathogenesis of AF is multifactorial. Observations at the level of atrial cardiomyocytes and interstitium reveal cellular degeneration with hypertrophy and extracellular matrix protein proliferation leading to fibrosis. It has been described that interstitial fibrosis predisposes to tissue anisotropy by creating areas with different conduction properties, which can either block or initiate a conduction wavelet and lead to re-entry circuits and AF. Although this structural remodeling can generate an inflammatory response, inflammation may also play a direct role in the development of atrial fibrosis and act as a trigger for the development of AF in the presence of a susceptible anatomic substrate. Finally, the ionic current changes and action potential abnormalities associated with the development of AF are also accountable for the self-perpetuation of the arrhythmia.

Upstream management of AF refers to therapies that target the responsible substrate and aim to prevent the development of the arrhythmia in the first place or delay its occurrence and domestication. Experimental and clinical data have highlighted the potential effect of angiotensin-converting enzyme inhibitors (ACEI), angiotensin receptor blockers (ARB), statins, n-3 polyunsaturated fatty acids (PUFA) and corticosteroids on the prevention of AF. The proposed mechanisms by which these agents exhibit their protective effect are shown in Table 36.1.

Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers for the prevention of atrial fibrillation

In a meta-analysis of 12 published randomized controlled trials (RCT) evaluating the effect of ACEIs/ARBs on new or recurrent AF, the difference in the underlying cardiovascular pathology of the studied populations led to significant variability in outcomes.[1] Although ACEIs/ARBs conferred a statistically significant risk reduction of 28% in AF, this effect was more pronounced in high-risk heart failure patients (44% relative risk reduction), and absent in the hypertension subgroup analysis. This finding was consistent even when the meta-analysis was revisited by another group, which included data from patients with cardiovascular disease but preserved left ventricular ejection fraction (LVEF), receiving ramipril or placebo.[2] In another meta-analysis,[3] additional to their marked benefit in patients with heart failure, ACEIs/ARBs were also found to be effective in the prevention of AF in patients with hypertension and following myocardial infarction (23% and 11% risk reduction, respectively). Finally, Anand and colleagues, having identified 9 RCTs with new onset AF (and not recurrent) as a reported outcome, demonstrated that ACEIs were more efficacious in primary AF prevention than ARBs.[4] Overall, most of the studies examined did not specify AF as a primary endpoint and AF outcomes were analysed *post hoc*, which may have led to multiple testing errors. This evidence-based assessment of the efficacy of ACEIs/ARBs in AF prevention focuses on patient groups with similar underlying cardiovascular pathology.

Table 36.1 Upstream therapies for prevention of atrial fibrillation

Drugs	Mode of action	Evidence base
ACEIs and ARBs	Targeting underlying heart disease (e.g. hypertension, heart failure) and unloading the atria Preventing structural remodeling: antifibrotic, antiapoptotic, and anti-inflammatory effects Antioxidant effects via PPAR-dependent pathways Direct electrophysiologic effects on ion channels (e.g. inhibition of I_{Kur}, I_{to}) Preventing gap junctional remodeling Modulating the autonomous nervous system: antisympathetic activity Modulating thrombogenesis (e.g. antiplatelet effects, P-selectin inhibition)	Good experimental data Retrospective analyses of large RCTs Small prospective studies Three meta-analyses Ongoing RCTs
Statins	Reducing cardiovascular events and the development of underlying heart disease Preventing substrate formation: anti-inflammatory and antioxidant effects Protecting the atrial mycardium during ischemia via increased eNOS activity Preventing matrix remodeling via inhibition of MMPs Preventing electrical remodeling by reducing downregulation of the I_{Ca} Modulating thrombogenesis (e.g. improved rheology, antiplatelet effects, fibrinogen reduction)	Experimental data Retrospective analyses of RCTs and observational studies Prospective study in electrical cardioversion Prospective studies in CABG Three meta-analyses Ongoing RCTs
Corticosteroids	Anti-inflammatory effects	Indirect evidence based on CRP reduction Small prospective studies Prospective studies in CABG and aortic valve surgery
PUFA	Preventing stretch-induced electrical remodeling Direct electrophysiologic effects on ion channels (inhibition of I_{Na}, I_{Ca}) Reducing proarrhythmic eicosanoids in the myocardium Anti-inflammatory and antioxidant effects Preventing matrix remodeling via MMP-dependent mechanism	Experimental data Clinical experience: preventing ventricular fibrillation Analyses from the population-based studies Prospective study in CABG and after cardioversion Ongoing RCTs

ACEIs and ARBs for the prevention of AF in patients with heart failure

The beneficial effects of ACEI/ARB therapy in patients with heart failure are well established. Their potential anti-arrhythmic effect was initially examined in a cohort of 30 patients with congestive heart failure (CHF) and persistent AF who were randomized to lisinopril 10 mg or placebo and treated with electrical cardioversion.[5] Despite the higher rate of maintenance of sinus rhythm (SR) in the lisinopril group, the AF risk reduction was not statistically significant in this small group of patients.

The first study to demonstrate a statistically significant reduction in AF due to ACEI treatment was the TRAndolapril Cardiac Evaluation (TRACE) trial.[6] Patients admitted to hospital with acute MI and documented LVEF ≤36% were randomized to trandolapril (up to 4 mg/day) or placebo. During the follow-up period of 2–4 years, the incidence of AF was 5.3% in the plecebo group and 2.8% in the treatment group, yielding a 55% risk reduction in AF due

to trandolapril. Although the antiarrhythmic effect of trandolapril remained consistent after adjustment for progressive LVEF decline in the placebo group, it is likely that AF reduction may just reflect the distinct attenuation of LV remodeling following MI due to ACE inhibition. The results of the SOLVD (Studies Of Left Ventricular Dysfunction) trial, which examined the effect of ACE inhibition on AF in patients with LV dysfunction, supported the beneficial role of enalapril.[7] With an absolute risk reduction of 18%, enalapril use was strongly associated with maintenance of SR during the 2.9 years of follow-up. Once again, it is likely that the efficacious management of underlying cardiac disease might have been responsible for this reduction in AF rather than any potential direct antiarrhythmic effect of enalapril.

In 4395 patients with documented heart failure who were randomized to valsartan or placebo in the context of the Val-HeFT study,[8] new-onset AF occurred in 5.1% of those on valsartan versus 7.95% receiving placebo (odds ratio (OR) 0.63, 95% confidence interval (CI) 0.49–0.81).

Table 36.2 Clinical studies of ACEIs and ARBs for the prevention of atrial fibrillation

Study, date	n	Baseline rhythm	Underlying disease	Design	Drug	Groups	Add. Intervent	Endpoint	Mean follow-up	Risk reduction
Van de Berg,[5] 1995	30	Persistent AF	Congestive heart failure	Double-blind RCT	Lisinopril	Lisinopril vs placebo	DCCV	AF recurrence	84 days	No effect
CAPPP,[10] 1999	10985	Sinus rhythm & AF	Primary hypertension	Open-label RCT (AF secondary outcome)	Captopril	Captopril vs conventional antihypertensives	–	AF occurrence	6.1 years	No effect of captopril on AF prevention
STOP-H2,[11] 1999	6614	Sinus rhythm & AF	Primary hypertension	Open-label RCT (AF secondary outcome)	Enalapril or lisinopril	ACEIs vs calcium antagonists vs conventional antihypertensives	–	AF occurrence	5 years	No effect of ACEIs on AF prevention
TRACE,[6] 1999	1577	Sinus rhythm	Post-MI, LV dysfunction	Double-blind RCT with retrospective analysis	Trandolapril	Trandolapril vs placebo	–	AF occurrence	2–4 years	55%
Madrid,[18] 2002	154	Persistent AF	Any, 21% lone AF	Open-label RCT	Irbesartan	Irb+amio vs amio	DCCV	Time to 1st recurrence	254 days	65%
Ueng,[19] 2003	145	Persistent AF	Any, 20% lone AF	Open-label RCT	Enalapril	Enalapril+amio vs amio	DCCV	Time to 1st recurrence	270 days	69%
SOLVD,[7] 2003	374	Sinus rhythm	LV dysfunction	Double-blind RCT with retrospective analysis	Enalapril	Enalapril vs placebo	–	AF occurrence	2.9 years	78%
Madrid,[20] 2004	90	Persistent AF	None, lone AF	Open-label RCT	Irbesartan	Amio vs amio+irb 150 mg vs amio+irb 300 mg	DCCV	Time to 1st recurrence	220 days	53% reduction by amio+irb 300 mg
LIFE,[13] 2005	8851	Sinus rhythm	HTN, LV hypertrophy	Double-blind RCT with retrospective analysis	Losartan	Losartan-based vs atenolol-based therapy	–	New-onset AF	4.8 years	33%
Val-HeFT,[8] 2005	4395	Sinus rhythm	Congestive heart failure	Double-blind RCT with retrospective analysis	Valsartan	Valsartan vs placebo	–	AF occurrence	23 months	37%
CHARM,[9] 2006	6379	Sinus rhythm	Congestive heart failure	Double-blind RCT (AF prespecified)	Candesartan	Candesartan vs placebo	–	Time to new AF	37.7 months	20%
HOPE,[2] 2007	8335	Sinus rhythm	CAD + other cardiovascular risk factor	Double-blind RCT with retrospective analysis	Ramipril	Ramipril vs placebo	–	AF occurrence	4.5 years	No effect
CAPRAF,[21] 2007	171	Persistent AF	Any, 48% lone AF	Double-blind RCT	Candesartan	Candesartan vs. placebo	DCCV	AF recurrence	6 months	No effect
VALUE,[14] 2008	13760	Sinus rhythm	HTN, other cardiovascular risk factors	RCT (AF secondary outcome)	Valsartan	Valsartan-based vs. amlodipine-based therapy	–	AF occurrence	4.2 years	16% (unadjusted)
TRANSCEND,[15] 2008	5926	Sinus rhythm	Coronary, peripheral vascular or cerebrovascular disease	Double-blind RCT (AF secondary outcome)	Telmisartan	Telmisartn vs. placebo	–	AF occurrence	56 months	No effect
ONTARGET,[16] 2008	25620	Sinus rhythm	Coronary, peripheral vascular or cerebrovascular disease	Double-blind RCT (AF secondary outcome)	Telmisartan	Telmisartan vs telmisartan + ramipril vs. ramipril	–	AF occurrence	56 months	No effect
GISSI-AF,[22] 2009	1442	≥2 episodes of AF or successful DCCV	Cardiovascular disease, lone AF (12%)	Double-blind RCT	Valsartan	Valsartan vs. placebo	±DCCV	Time to first recurrence and proportion of patients with ≥1 recurrence	12 months	No effect

This risk reduction in AF due to valsartan was not influenced by concomitant treatment with other ACE inhibitors (93% of cases). In addition, AF occurrence was associated with a 40% increase in overall mortality. Despite the efficacy of valsartan in the prevention of AF, its capacity to reduce mortality was not proven, probably due to the relatively low rate of AF in this study population. In the CHARM study,[9] the effect of candesartan on new-onset AF was a prespecified secondary outcome in the cohort of 6379 patients with symptomatic heart failure and absence of the arrhythmia. The reduction in AF caused by candesartan (target dose 32 mg/d) versus placebo (5.55% vs 6.74%), remained significant following adjustment for prespecified co-variates that are known to influence overall prognosis and AF development (OR 0.80, 95% CI 0.65–0.99). The design of this study allowed for the analysis of subgroups with CHF but preserved LVEF (in contrast to the SOLVD and Val-HeFT studies), and CHF with or without concomitant ACEI treatment. Although no significant heterogeneity was observed in subgroup analysis, the beneficial effect of candesartan was more pronounced in patients with reduced LVEF, irrespective of ACEI treatment (adjusted OR 0.77, 95% CI 0.59–0.99).

The available data from these large-scale studies are highly suggestive of the preventive role of ACEIs/ARBs in avoiding new or recurrent AF in patients with heart failure. Although this association was often either a *post hoc* finding or a secondary endpoint, the size of the studies and the consistency of their results provide satisfactory evidence on the efficacy of ACEIs/ARBs in this setting. Therefore, the use of ACEIs/ARBs for the prevention of AF in patients with CHF is recommended (**Class I, Level A**).

ACEIs and ARBs for the prevention of AF in patients with hypertension and/or coronary artery disease

The efficacy of ACEIs/ARBs for the treatment of primary hypertension is recognized. Large studies, which aimed to identify whether their antihypertensive capacity is associated with a reduction in overall cardiovascular mortality and morbidity, included AF occurrence in their secondary endpoints. More specifically, the Captopril Prevention Project (CAPPP) was a multicenter randomized trial evaluating the effect of captopril (50–100 mg) versus conventional antihypertensive treatment with beta-blockers and/or diuretics, on fatal and non-fatal myocardial infarction and stroke and other cardiovascular deaths.[10] Cardiovascular mortality was lower in the captopril group, albeit not statistically significant. No difference was observed upon analyses of secondary outcomes with the inclusion of new AF, between the two groups. These findings were in line with its contemporary, the Swedish Trial in Old Patients with Hypertension-2 (STOP-H2) study,[11] which compared the efficacy of conventional antihypertensives (diuretics, beta-blockers), ACEIs (enalapril 10 mg, lisinopril 10 mg) and calcium antagonists (felodipine 2.5 mg, isradipine 2.5 mg) on cardiovascular morbidity and mortality in patients aged 70–84 years. All three therapies were similarly effective against these primary outcomes, and no superiority of ACEIs was observed in the prevention of AF when compared to conventional antihypertensives. However, in another multicenter trial (LIFE),[12] patients with hypertension and documented LV hypertrophy benefited from losartan-based treatments, which significantly reduced new-onset AF when compared to atenolol-based treatment (OR 0.67, 95% CI 0.55–0.83). The enhanced regression of LV hypertrophy caused by losartan, as evaluated on the echocardiographic substudy within LIFE,[13] may have led to reduced atrial overload and dilation, and therefore a reduction in AF. New-onset AF was a prespecified outcome within the VALUE trial.[14] Valsartan-based antihypertensive treatment led to a reduction in AF occurrence when compared to amlodipine in patients with hypertension and other cardiovascular risk factors. In contrast, two contemporary RCTs evaluating the role of telmisartan versus placebo,[15] and telmisartan with or without ramipril,[16] did not show any preventative effect on AF occurrence in patients with coronary, peripheral or cerebrovascular disease.

In conclusion, due to the limited number of studies, their design and significant heterogeneity, the efficacy of ACEIs/ARBs in the prevention of AF in hypertensive patients with cardiovascular risk factors, although plausible, requires further evaluation (**Class IIa, Level B**).

ACEIs and ARBs for secondary prevention of AF

The efficacy of amiodarone in the maintenance of sinus rhythm in patients with persistent AF is well documented.[17] The addition of irbesartan (150–300 mg/d) to amiodarone (400 mg) therapy before electrical cardioversion for persistent AF led to a 65% reduction in the risk of AF recurrence over a two-month follow-up.[18] This open-label randomized trial was the first to describe the possible association of ARBs and maintenance of sinus rhythm. However, it was limited by the fact that the irbesartan treatment group was more likely to receive beta-blockade, which is known to be protective for AF, and that asymptomatic recurrences that terminated spontaneously could not have been effectively captured. In a similar study evaluating the effect of enalapril on AF recurrence following electrical cardioversion and amiodarone, a 69% risk reduction was observed in patients on combined enalapril and amiodarone treatment at four weeks.[19] Finally, Madrid and colleagues[20] examined the effect of increasing doses of irbesartan in addition to amiodarone treatment on AF recurrence after electrical cardioversion in patients with "lone" persistent AF. Maintenance of SR was higher in the irbesartan 300 mg plus

amiodarone group (77%), when compared to the irbesartan 150 mg plus amiodarone group (65%) and to amiodarone alone (52%). The risk reduction conferred by high-dose irbesartan was 53% after appropriate adjustments at the two-month follow-up.

Although a combination therapy of amiodarone with ACEIs/ARBs appears superior to amiodarone alone, the efficacy of monotherapy with ACEIs/ARBs was not tested in any of those trials. In addition, their open-label design and the lack of placebo group may have influenced the accuracy of their outcomes. In an attempt to overcome these important limitations, Tveit and colleagues designed a double-blind placebo-controlled trial examining the effect of the ARB candesartan on AF recurrence following successful electrical cardioversion in patients not receiving adjunct antiarrhythmics.[21] Six-week pretreatment with candesartan (16 mg) followed by a 6-month therapy after electrical cardioversion did not influence AF recurrence rates when compared with placebo. Similarly, the more recent GISSI-AF study, which examined the role of valsartan (vs. placebo) in AF prevention in patients with documented symptomatic AF and/or successful electrical cardioversion, did not demonstrate any effect attributed to valsartan treatment.[22] The main outcome measures were time to first AF recurrence and proportion of patients with more than one AF episodes during the first year; the treatment arm received valsartan gradually adjusted to 320 mg daily, in addition to established antiarrhythmic regimens. Despite the relatively short follow-up and the underrepresentation of patients with heart failure (8%), the negative results from this study encourage the scepticism regarding the efficacy of ARBs in secondary AF prevention.

Therefore, the beneficial effect of ACEIs/ARBs in secondary prevention is not yet established and will need to be validated further (**Class IIb, Level B**). Ongoing trials aim to create a clearer picture on the antiarrhythmic potential of ACEIs/ARBs. ACTIVE I is a partial factorial placebo-controlled, double blind trial evaluating the capacity of irbesartan (titrated to 300 mg/day) to prevent AF recurrence in patients with paroxysmal or persistent AF, which is a prespecified secondary outcome.[23] The Angiotensin II antagonist in paroxysmal atrial fibrillation (ANTIPAF) trial focuses on the effect of olmesartan (40 mg/day) on reduction of episodes of paroxysmal AF as a primary endpoint, and assesses both symptomatic and asymptomatic paroxysms with the use of transtelephonic ECG monitoring.[24]

Statins for the prevention and treatment of atrial fibrillation

Several studies have suggested the possible prophylactic effect of statins on new-onset AF and on AF recurrence following successful electrical or chemical cardioversion.

A systematic review and meta-analysis evaluating the efficacy of statins on AF prevention demonstrated variability in outcomes between observational studies and RCTs.[25] Interestingly, the antiarrhythmic effect of statins was less pronounced in RCTs and did not reach statistical significance, whereas observational studies yielded a 23% relative risk reduction in patients on statins, which was statistically significant (OR 0.77, 95% CI 0.70–0.85) and associated with no apparent heterogeneity. Many reasons may account for this discrepancy, such as the potentially underpowered AF detection in a large RCT, longer mean follow-up of observational studies and variability in methods of AF detection. It is also evident that the patient populations, presence and type of AF at baseline, type of intervention performed, and primary outcome of interest differed between studies. Another meta-analysis focusing only on RCTs demonstrated that statin use was associated with a significant decrease in the incidence or recurrence of AF (OR 0.39, 95% CI 0.10–0.85). However, the variability in clinical settings and significant heterogeneity between studies is, once again, supportive but not confirmatory of the overall beneficial effect of statins on AF.[26] This is why our evidence-based analysis examines the effect of statins on patients according to their baseline heart rhythm, underlying cardiovascular pathology and type of intervention performed.

Statins for the prevention of AF in patients with coronary artery disease

The first association of statin use with prevention of AF in patients with chronic coronary artery disease (CAD) was shown by Young-Xu and colleagues in an observational longitudinal study with a five-year follow-up.[27] Patients receiving statins had a 9% incidence of new-onset AF compared with 15% in patients not on statins. Following adjustment for potential confounders, the risk reduction in AF remained statistically significant (OR 0.37, 95% CI 0.18–0.76). This effect was independent of changes in baseline and follow-up cholesterol levels, indicating that the potential antiarrhythmic effect of statins extends beyond their lipid-lowering capacity.

High-dose statin use and its possible impact on AF in patients with acute coronary syndrome (ACS) was examined *post hoc* within the Myocardial Ischemia Reduction with Aggressive Cholesterol Lowering (MIRACL) study.[28] Atorvastatin 80 mg or placebo was administered to patients with ACS within four days of admission to hospital and for a period of 16 weeks. The incidence of new-onset AF (1.6% and 1.8%, respectively) in patients without the arrhythmia prior to randomization and the rate of freedom from recurrence in patients with known AF, were not influenced by intensive statin treatment. However, the short duration of follow-up (16 weeks) with limited ECG record-

Table 36.3 Clinical studies of statins for the prevention of atrial fibrillation

Study, date	Design	N	Setting	Statin type	Mean follow-up	Risk reduction
Dotani,[46] 2000	Retrospective	323	CABG	Any brand	1 year	77%
Siu,[38] 2003	Retrospective	62	Lone persistent AF following DCCV	Simvastatin (20 ± 13 mg) Atorvastatin (10 ± 3 mg)	44 months	69%
Young-Xu,[27] 2003	Observational	449	Stable CAD	Any brand	5 years	63%
Colivicchi,[39] 2004	Observational	851	Persistent AF, HTN and electrical or chemical cardioversion	Atorvastatin (12 ± 4 mg) Simvastatin (20 ± 7 mg)	1 year	25%
Merckx,[30] 2004	Observational	667	LA dilation, LVH	Any brand	6.5 years	67%
MIRACL,[28] 2004	Prospective randomized, placebo controlled	3086	ACS	Atorvastatin 80 mg	16 weeks	No effect
Tveit,[40] 2004	Prospective randomized, open label	114	AF >48 hours, DCCV	Pravastatin 40 mg	6 weeks	No effect
Amar,[47] 2005	Observational	131	Major non-cardiac thoracic surgery	Any brand	7–9 days post-op	74%
Ozaydin,[41] 2006	Prospective randomized, open label	48	Persistent AF, DCCV	Atorvastatin 10 mg	3 months	81%
Amit,[35] 2006	Retrospective	264	Post pacemaker	Any brand	359 days	No effect
Marin,[48] 2006	Prospective, observational	234	CABG	Any brand	1 month	48%
ARMYDA,[49] 2006	Prospective randomized, double blind, placebo controlled	200	Cardiac surgery	Atorvastatin 40 mg vs placebo	1 month	61%
SCD-HeFT,[34] 2006	Prospective randomized, placebo controlled	2521	Heart failure, LVEF ≤35%	Any brand	45.5 months	28%
ADVANCENT[SM],[33] 2006	Retrospective, registry	25268	LVEF ≤40%	Any brand + other lipid-lowering agents	–	31%
García-Fernández,[42] 2006	Prospective randomized	54	Persistent AF, DCCV	Atorvastatin 80 mg	3 months	No effect
Richter,[44] 2007	Retrospective	234	Paroxysmal or persistent AF, RF ablation	Any brand	12.7 months	No effect
Al Chekakie,[45] 2007	Retrospective	177	Paroxysmal or persistent AF, RF ablation	Any brand	13.8 months	No effect
Tsai,[36] 2007	Prospective randomized, open label	106	Post pacemaker	Atorvastatin 20 mg	1 year	67%
Ramani,[29] 2007	Retrospective, registry	1526	ACS	Any brand	–	43%
Ozaydin,[51] 2007	Observational	326	CABG	Any brand	1 week post-op	53%
Mariscalco,[52] 2007	Observational	405	CABG	Any brand	Hospital stay	42%
Kourliouros,[53] 2008	Observational	623	Cardiac surgery	Any brand	Hospital stay	44%
Lertsburapa,[54] 2008	Observational	555	Cardiac surgery	Any brand	1 month	40%
Song,[50] 2008	Prospective randomised, open-label	124	Off-pump CABG	Atorvastatin 20 mg	1 month	66%
Gillis,[37] 2008	Observational	185	Post pacemaker	Any brand	1 year	67%
Almroth,[43] 2009	Prospective randomised, double-blind, placebo-controlled	234	Persistent AF, DCCV	Atorvastatin 80 mg	1 month	No effect
Pellegrini,[31] 2009	Post hoc analysis of randomised, placebo-controlled trial	2673	CAD	Any brand	4.1 years	55%

ings may be responsible for the very low incidence of new-onset AF, which potentially renders this analysis underpowered. In a retrospective study,[29] 1526 patients admitted to hospital with suspected ACS and no history of arrhythmia were evaluated by the development of new AF and statin use. A risk reduction of 43% was present in statin users following adjustment for potential confounders (OR 0.57, 95% CI 0.39–0.83).

Echocardiographic risk factors for the development of AF, such as left ventricular hypertrophy (LVH) (wall thickness ≥10 mm) and left atrial dilation (≥40 mm) were evaluated in another study by Merckx and colleagues.[30] In this cohort analysis of patients with the above echocardiographic features and CAD, but no evidence of LV failure, statin use was found to be protective for the development of future AF, especially with advanced age. Finally, in a post hoc analysis of the Heart and Estrogen/Progestin Replacement Study (HERS), including women with prior coronary disease, statins were associated with 65% lower odds of AF at baseline and with a 55% risk reduction in new-onset AF during follow-up.[31]

The efficacy of statins in reducing morbidity and coronary mortality in anginal and/or postinfarction patients is recognized and their use is therefore recommended. The possible additional effect of statins on AF prevention further supports the recommendation in this group of patients (**Class IIa, Level B**).

Statins for the prevention of AF in patients with heart failure

Congestive heart failure and AF often co-exist. The prevalence of AF in the CHF population varies from 13% to 27%. The Framingham Heart Study confirmed that new-onset AF against the background of CHF significantly increases mortality (hazard ratio (HR) 2.7, 95% CI 1.9–3.7).[32] The efficacy of statins in the prevention of AF in CHF patients has been examined in patients with LV dysfunction (LVEF ≤40%) on the ADVANCENT^SM registry.[33] The significant reduction in prevalence of AF in patients on statins was even more pronounced than that achieved from ACEIs/ARBs, and was independent of their lipid-lowering properties. This observation is in line with the findings from the Sudden Cardiac Death Heart Failure Trial (SCD-HeFT), in which statins were as efficacious as amiodarone in the prevention of atrial arrhythmias in patients with symptomatic heart failure and LVEF ≤35%.[34] However, this group included cases of atrial flutter in addition to AF, and therefore, the absolute effect of statin use on AF is not clearly specified. Overall, although statins may have a place in CHF, their potential antiarrhythmic effect is less well established in this setting and requires further investigation (**Class IIb, Level B**).

Statins for the prevention of AF in patients with permanent pacemakers

It is recognized that the incidence of supraventricular arrhythmias and AF in particular is increased in patients with conduction abnormalities and presence of permanent pacemakers. In an observational study of 264 patients with pacemakers implanted predominantly for atrioventricular block and sinus bradycardia, Amit and colleagues[35] demonstrated no impact of statin treatment on the incidence of AF. However, the heterogeneity between the groups, with patients on statins being more likely to suffer from CAD, hypertension and previous AF, was one of the main limitations of the study. A randomized open-label trial assessing the effect of atorvastatin 20 mg on paroxysmal AF or atrial high rate episodes (AHE) in patients with pacemakers demonstrated the protective effect of atorvastatin on the arrhythmia, with a 67% risk reduction in new PAF/AHEs in a one-year period.[36] Similarly, in an observational cohort study of patients with history of paroxysmal AF who underwent pacemaker implantation (>90% sinus node disease), statin use was associated with a 67% relative risk reduction in AF recurrence.[37] Overall, the available clinical evidence is still limited before any strong recommendations for statin use can be made in this setting (**Class IIb, Level B**).

Statins in patients with AF following cardioversion

The first study to evaluate the effect of statin treatment on AF recurrence following successful external electrical cardioversion (DCCV) was reported by Siu and colleagues.[38] Sixty-two patients with persistent-lone AF were retrospectively evaluated for a mean of 44 months after DCCV. AF recurrence was 40% in the statin group versus 84% in the no statin group at two years, leading to a significant reduction in AF (relative risk 0.31, 95% CI 0.103–0.905). In an observational study by Colivicchi and colleagues,[39] patients with persistent AF against a background of essential hypertension who underwent successful chemical or electrical cardioversion were examined for the development of recurrent AF for one year. Due to the non-randomized nature of the study, a propensity model was constructed and following appropriate adjustments, atorvastatin and simvastatin use was associated with a significant reduction in AF recurrence (HR 0.75, 95% CI 0.63–0.89). Four randomized trials, with primary endpoint being AF recurrence following successful DCCV, yielded controversial results. In an open-label study of 114 patients with AF >48 hours who were scheduled for DCCV, the statin group received pravastatin 40 mg for three weeks before and six weeks after the procedure.[40] Pravastatin did not confer any benefit on the immediate success of cardioversion or AF

recurrence. However, in another randomized controlled trial, atorvastatin 10 mg administered 48 hours before and for three months following DCCV, in addition to standard antiarrhythmic therapy, led to a significant reduction in AF recurrence.[41] In a similar cohort of patients, intensive atorvastatin treatment (80 mg) had no effect on recurrent AF.[42] The only double-blind placebo-controlled trial to examine the role of statins in sinus rhythm maintenance following successful electrical cardioversion showed a small (and not statistically significant) benefit in patients receiving intensive atorvastatin treatment who were not on routine antiarrhythmic therapy.[43] In conclusion, in view of certain methodological issues and conflicting results among studies, the indicated use of statins is less well established for sinus rhythm maintenance following electrical cardioversion (**Class IIb, Level B**).

Statins in AF patients following catheter ablation

In recent years, catheter ablation for the treatment of AF has become a commonly performed procedure mainly indicated for the presence of symptomatic AF refractory or intolerant to at least one class I or III antiarrhythmic medication. However, rates of AF recurrence vary considerably according to the duration of AF, presence of structural abnormalities, use of antiarrhythmic medications, and type of procedure performed. Two contemporary retrospective studies assessing catheter ablation outcomes did not show any significant reduction in AF recurrence due to statin use, with or without ACEIs/ARBs.[44,45] Differences in baseline characteristics, treatment and duration of AF are some of the inherent limitations of such studies (**Class III, Level C**).

Statins for the prevention of AF in patients undergoing cardiac surgery

The rate of AF following cardiac surgery ranges from 10% to 50%, with a peak incidence on the second and third postoperative days. The exact etiology of postoperative AF remains unknown but pre-existing structural remodeling under the influence of the augmented inflammatory response due to cardiopulmonary bypass, myocardial ischemia and cardiotomy may be contributing factors.

The first evidence of the possible preventive effect of statins on arrhythmias following cardiac surgery came from a study by Dotani and colleagues.[46] Patients on statins had a significantly lower incidence of post-CABG "new arrhythmias" requiring treatment (OR 0.23, 95% CI 0.08–0.65, P = 0.006). While statins were also found to be beneficial in AF prevention following non-cardiac thoracic surgery,[47] the first prospective study to associate statin use with a reduction in AF following CABG surgery was reported by Marin and colleagues.[48] In their cohort of 234 consecutive patients, history of AF and non-use of statins were independent risk factors for the postoperative arrhythmia. ARMYDA-3 (Atorvastatin for Reduction of Myocardial Dysrhythmia After cardiac surgery) is the only double-blind, placebo-controlled randomized trial to assess the effect of statins on postoperative AF.[49] Two hundred patients were randomized to atorvastatin 40 mg or placebo for seven days before cardiac surgery until discharge. Postoperative AF occurred in 57% of the control group compared with 35% of patients on atorvastatin (OR 0.39, 95% CI 0.18–0.85, P = 0.017). Although not statistically significant, the placebo group included more patients who received combined coronary and valve surgery, whereas beta-blocker use was also less prevalent. Since then, additional studies have supported the beneficial effect of statins on AF after CABG,[50–52] with the addition of a possible dose-dependent effect.[53,54] A meta-analysis evaluating adverse postoperative outcomes according to preoperative statin treatment, demonstrated a significant 33% relative risk reduction in postoperative AF.[55] Therefore, statin use is recommended in patients undergoing cardiac surgery for the prevention of postoperative AF (**Class I, Level A**).

N-3 polyunsaturated fatty acids for the prevention of atrial fibrillation

The role of nutritional factors in the development of AF has recently been suggested following observations of reduced risk of fatal arrhythmias in populations with high fish consumption.[56] The n-3 polyunsaturated fatty acids (PUFA) eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), the active ingredients in fish oil, were found to be protective against fatal arrhythmias in clinical and experimental studies.[57,58] The effect of PUFAs on AF was examined in a population-based cohort study of 4815 individuals ≥65 years, within the Cardiovascular Health Study (CHS).[59] Individuals consuming tuna or other fish ≥5 times per week had a significantly lower incidence of AF (19 per 1000 person-years), when compared to those who consumed fish <1 time per month (33 per 1000 person-years). Although the higher fish consumption group exhibited a more favorable cardiovascular risk profile, multivariate adjustment for possible confounders confirmed the significant risk reduction in new AF (HR 0.65, 95% CI 0.51–0.87, P = 0.001). These beneficial effects were attributable to tuna/other broiled or baked fish and not to fried fish or fish sandwich, the frequent consumption of which was positively associated with the development of AF. Aside from the possible confounding of other lifestyle determinants and increased cardiovascular risk factors, this finding may also be explained by the fact that frying increases the content of n-6 fatty acids, *trans* fatty acids and oxidation

Table 36.4 Clinical studies on PUFAs for the prevention of atrial fibrillation

Study, year	n	Design	Groups	Mean age (years)	Mean follow-up	AF incidence	Risk reduction
Cardiovascular Health Study,[59] 2004	4815	Prospective cohort study	Quartiles according to baked/broiled fish consumption (<1/mo, 1–3/mo, 1–4/wk, ≥5/wk)	72.8	12 years	20%	35% between highest and lowest quartile
Danish Diet, Cancer and Health Study,[60] 2005	47949	Prospective cohort study	Quintiles according to average daily PUFA intake from fish (0.16 g, 0.36 g, 0.52 g, 0.74 g, 1.29 g)	56	5.7 years	1%	No effect
Calò,[64] 2005	160	Randomized, open label	PUFAs 2 g/day vs control for ≥5 days before CABG until hospital discharge	65.6	28 days	15% PUFA, 33% controls	68%
Phycisians' Health Study,[61] 2006	17679	Prospective cohort study	Quintiles according to dietary fish intake (<1/mo, 1–3/mo, 1–2/wk, 2–5/wk, ≥5/wk)	Unknown	15 years	7%	Increased AF risk in highest vs lowest quintile
Rotterdam Study,[62] 2006	5184	Prospective cohort study	Tertiles of EPA + DHA daily intake (≤43 mg, 43–144 mg, ≥144 mg)	67.4	6.4 years	6%	No effect
Erdogan,[65] 2007	108	Randomized, placebo-controlled trial	PUFA vs placebo for 4 wks before and 1 year after DCCV for persistent AF	66.5	1 year	80% recurrence	No effect
Women's Health Initiative,[63] 2008	46704	Cohort analysis	Quartiles according to estimated dietary fish and omega-3 intake	Unknown	6 years	0.8%	No effect

Table 36.5 Clinical studies on corticosteroids for the prevention of atrial fibrillation

Study, year	Design	N	Setting	Drug	Follow-up	Risk reduction
Yared,[68] 2000	Randomized, double-blind, placebo-controlled trial, *post hoc* analysis	235	Cardiac surgery, any	DEX 0.6 mg/kg IV after induction of anesthesia	Hospital discharge	DEX reduced post-op AF from 32% to 19%
Halvorsen,[69] 2003	Randomized, double-blind, placebo-controlled trial	300	CABG	DEX 4 mg IV after induction and same dose morning after surgery	Hospital discharge	No effect
Dernellis,[75] 2004	Randomized, placebo-controlled trial	104	Persistent AF after chemical ± electrical cardioversion	Methylprednisolone 16 mg for 4 weeks tapered to 4 mg for 4 months (+ propafenone 450 mg/day to all patients)	23.6 months	9.6% recurrent AF in steroid group vs 50% in placebo
Huerta,[77] 2005	Population-based cohort study	5710	Asthma and/or COPD	Respiratory drugs, including oral and inhaled steroids	–	2.7 times increased risk of AF with oral steroids
Rubens,[70] 2005	Prospective randomized	68	Cardiac surgery	CPB control, SMA-CPB, SMA-CPB-MPSS, MPSS alone	Hospital discharge	AF reduction from 38% without MPSS to 12% with MPSS
Prasongsukarn,[71] 2005	Randomized, double-blind, placebo-controlled trial	88	CABG	Methylprednisolone 1 g IV before CPB followed by DEX 4 mg IV/6 h for first 24 h post-op	Hospital discharge	50%
Rotterdam Study,[76] 2006	Population-based cohort study	385	New-onset AF	Any oral or parenteral steroids administered 1 month before AF diagnosis	–	Increased AF in steroid users
Yared,[72] 2007	Randomized, double-blind, placebo-controlled trial	78	CABG + valve surgery	DEX 0.6 mg/kg IV after induction of anesthesia	Hospital discharge	No effect
Halonen,[73] 2007	Randomized, double-blind, placebo-controlled trial	241	CABG and/or AVR	Hydrocortisone 100 mg, 1 dose pre-op, then 1 dose/8 h for 3 days post-op	Hospital discharge	46%

products, which are associated with adverse cardiac outcomes.

The Danish Diet, Cancer, and Health Study was a large cohort analysis of 47949 individuals, assessing, amongst others, the effect of n-3 fatty acids on AF.[60] With a mean follow-up of 5.7 years and a cohort of patients with no history of cardiac disease, increased consumption of fish oil did not influence the incidence of AF. The authors suggest that apart from other methodologic issues that may have affected outcomes such as additional intake of fish oil capsules, patients on the top quintile of fish oil consumption were likely to be older and suffer from hypertension, factors which are known to be associated with AF. Moreover, findings from the Physicians' Health Study of 17679 men during a 15-year follow-up demonstrated that high estimated omega-3 fatty acid consumption is positively associated with AF (OR 1.37, 95% CI 0.90–2.28) and that there is a statistically significant trend for AF occurrence with increasing fish consumption.[61] In another prospective population-based study (The Rotterdam Study),[62] no effect on AF was observed between patients on the highest and the lowest tertiles according to fish intake (relative risk 1.25, 95% CI 0.95–1.67). Similarly, estimated dietary omega-3 fatty acid intake did not influence the development of AF during follow-up in a cohort analysis of Women's Health Initiative Study.[63]

Many factors may be responsible for the variability in outcomes seen in these population-based studies. Differences in mean age (72.8 years in CHS, 67.4 in Rotterdam and 56 in Danish studies) could explain the lower incidence of observed AF in the "no benefit" studies (20% CHS vs 6% in Rotterdam and 1% in Danish studies), as well as dietary changes and new cardiac conditions during follow-up, which may have contributed to inconsistent results.

The possible prophylactic effect of PUFAs on AF occurrence following CABG was examined in an open-label randomized study of 160 patients.[64] PUFAs (850–882 mg EPA and DHA in a 1:2 ratio) were administered for a minimum of five days before surgery until discharge. Patient characteristics and perioperative variables were not significantly different between treatment and control groups. The incidence of postoperative AF was reduced in patients on PUFAs (15.2%), compared to controls (33.3%) (OR 0.35, 95% CI 0.16–0.76) and, along with age, PUFA use remained an independent predictor for postoperative AF (OR 0.32, 95% CI 0.10–0.98, P = 0.013). In addition, the treatment group had a significantly shorter length of hospital stay (7.3 ± 2.1 days vs 8.2 ± 2.6 days).

A recent randomized placebo-controlled study of 108 patients with persistent AF, who underwent successful electrical cardioversion, did not demonstrate differences in AF recurrence between those on PUFAs and the placebo group.[65]

The antiarrhythmic effects of PUFAs on AF are not confirmed since large epidemiologic studies yielded contro-

versial results. The two randomized trials on the effect of PUFAs on postoperative AF and AF recurrence following successful electrical cardioversion were also inconsistent.

These findings may indicate a differential effect according to underlying medical conditions, cardiovascular risk factors and types of intervention performed. Further controlled studies are necessary to delineate the possible antiarrhythmic effect of PUFAs on AF (**Class IIb, Level B**).

Corticosteroids for the prevention of atrial fibrillation

The first evidence to associate AF with inflammation was reported in 1997, when Frustaci and colleagues demonstrated histologic changes consistent with myocarditis in atrial tissue of patients with lone AF.[66] The increased rate of AF following cardiac surgery highlights the role of inflammation in the development of the arrhythmia.

Elevated plasma C-reactive protein (CRP) levels have been associated with an increased risk of cardiovascular events and its predictive value has been validated in various prospective epidemiologic studies.[67] Corticosteroids exhibit a potent anti-inflammatory capacity and their role in AF prevention has been examined mainly within the context of cardiothoracic surgery.[68–73] A recent meta-analysis of clinical trials assessing the efficacy of corticosteroids on postoperative AF demonstrated a 45% reduction in the arrhythmia with an associated statistically significant reduction in length of hospital stay by 1.6 days.[74] With insignificant heterogeneity between studies or publication bias, this meta-analysis also suggests that only intermediate doses confer a statistically significant protective effect. Finally, the odds of postoperative pneumonia, urinary tract infections and gastrointestinal bleeding were increased, albeit not significantly, whereas overall mortality was decreased.

In patients with persistent AF, the use of low-dose glucocorticoid treatment in addition to prophylactic propafenone was associated with a significant reduction in the rate of recurrence after chemical or electrical cardioversion.[75] Patients who received 16 mg methylprednisolone for four weeks tapered to 4 mg for four months had a 9.6% incidence of recurrent AF compared with 50% of the placebo group without any severe side effects. Methylprednisolone significantly reduced CRP by 80% in the first month. Follow-up CRP levels were also correlated significantly with the risk of recurrent AF. This preventive capacity of corticosteroids in AF was not validated in a later nested-cohort analysis within the Rotterdam Study.[76] In contrast, the risk of new-onset AF was significantly increased with corticosteroid use (OR 3.75, 95% CI 2.38–5.87) and, moreover, this effect was more pronounced with high-dose steroids, independent of their indication, suggesting a potential direct arrhythmo-

genic effect of steroids. Due to the nature of this study, a possible diagnosis bias, with patients using steroids receiving more ECGs and rendering AF diagnosis more likely, cannot be eliminated. In addition, the case population consisted of older people with hypertension, heart failure and previous MI, and despite appropriate adjustment with multivariate regression, a selection bias may also be present. However, the observation that steroids may lack any antiarrhythmic effect, but that they may induce AF instead, was further supported by another nested-cohort study from the UK General Practice Research Database.[77] Upon comparison of the case group, with documented arrhythmia and asthma and/or chronic obstructive pulmonary disease, to controls with the same respiratory conditions, oral steroids, especially short-term use, were associated with an increased risk of AF (OR 2.7, 95% CI 1.9–3.8).

The impact of corticosteroids in the prevention of AF remains controversial. Although intermediate-dose steroids appear to confer a relative reduction in AF post cardiac surgery (**Class IIa, Level B**), high-dose steroids may be arrhythmogenic in this setting as well as in the background of asthma and COPD. More trials are required to establish the efficacy of corticosteroids in AF and, more importantly, to delineate their safety if used for arrhythmia prevention alone.

Conclusion

Atrial fibrillation is an important health problem due to the associated risk of stroke, all-cause mortality and its rising prevalence in our aging population. The objective of available treatment modalities for AF is to reduce morbidity (and possibly mortality) through restoration of sinus rhythm, heart rate control when rhythm conversion is not feasible, and prevention of thromboembolism. However, most patients with a first-detected episode of AF, symptomatic or not, will experience recurrence and possibly domestication of the arrhythmia despite treatment. It is evident that available antiarrhythmic regimens, although potentially efficacious in symptom control and prevention of hemodynamic complications, do not offer a definitive treatment or cure.

Upstream therapies refer to pharmacologic agents that target and modulate the substrate responsible for the development and perpetuation of AF. The use of angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, statins, n-3 polyunsaturated fatty acids and corticosteroids in the context of AF prevention, which is beyond their recommended conventional indications, has delivered promising results. Although their efficacy is dependent on the nature of underlying cardiovascular pathology, type and chronicity of AF, and other therapeutic interventions performed, most studies concur in the beneficial impact of upstream therapies in AF prevention.

Experimental data suggest that this effect is predominantly achieved by amelioration of atrial structural changes and inflammatory response associated with the arrhythmia, as well as modulating risk factors for cardiovascular disease, which eventually lead to AF. Further evaluation of upstream therapies through well-defined clinical trials and experimental studies will provide additional evidence for their use as adjuncts to antiarrhythmic treatments or as stand-alone therapy for the prevention of AF.

37 Atrial fibrillation: antithrombotic therapy

John A Cairns[1] and Stuart Connolly[2]
[1] University of British Columbia, Vancouver, Canada
[2] McMaster University, Hamilton, Ontario, Canada

Definitions, incidence and natural history

Stroke and non-central nervous system (CNS) embolism have long been known to be important complications of atrial fibrillation (AF). In several case series, 50–70% of embolic strokes were found to result in either death or severe neurologic deficit.[1] The Framingham Study[2,3] documented an annual 4.5% incidence of stroke among individuals with rheumatic AF, although those with AF in the absence of other disease and whose age is under 60 years (so-called "lone atrial fibrillation") have an extremely low risk of stroke.[4,5] The terms "non-rheumatic atrial fibrillation" and "non-valvular atrial fibrillation" (NVAF) are not entirely synonymous, although they are often used interchangeably. Non-valvular atrial fibrillation has become the preferred term for patients with AF in the absence of mitral valve disease, a prosthetic valve or mitral valve repair.[6] Paroxysmal AF is defined as an episode lasting up to seven days, whereas persistent AF is defined as a duration beyond seven days. Both paroxysmal and persistent AF are designated as recurrent AF if they resolve spontaneously or in response to treatment and then recur. Persistent AF is defined as permanent if cardioversion fails or AF lasts for more than one year and cardioversion has not been attempted.

Data from the placebo groups of five landmark randomized clinical trials among patients with non-valvular AF[7–12] found a mean 4.5% annual incidence of stroke (range 3–7%) and a mean 5.0% annual incidence of stroke plus other systemic emboli (range 3–7.4%); over half the strokes resulted in death or permanent disability.[13] Patients were selected for entry into these trials according to a variety of criteria, including the absence of contraindications to warfarin and in some instances to aspirin, willingness to participate in a clinical trial and the echocardiographic exclusion of rheumatic valvular disease. Although generalizations to a wider population must be made cautiously, the observed rates of stroke and other systemic embolism are similar to those reported in earlier cohorts and likely are representative of those in the general population.

Antithrombotic management

Oral anticoagulant therapy

Prior to 1990, anticoagulation was usually prescribed for AF patients who had mitral stenosis, a prosthetic heart valve, prior arterial embolism or who were to undergo electrical cardioversion. Anticoagulation was generally not prescribed long-term for patients with non-rheumatic AF. In the late 1980s, the observations of the Framingham Study, together with evidence for the efficacy and increased safety of regimens of lower-dose warfarin, prompted the initiation of five randomized controlled trials of warfarin versus control or placebo for the primary prevention of thromboembolism among patients with non-rheumatic (non-valvular) AF (Table 37.1).[13] The trials enrolled patients with AF detected on a routine or screening electrocardiogram, whose mean age was 69 years. AFASAK[10] and SPINAF[9] excluded patients with intermittent AF, whereas the proportion of intermittent AF in CAFA[8] was 7%, in BAATAF[7] 16% and in SPAF[12] 34%. Previous stroke or transient ischemic attack was infrequent. Treatment allocation was randomized in all trials; the international normalized ratio (INR) ranges varied from a lower limit of 1.4 to an upper limit of 4.5. There was a double-blind comparison of warfarin to placebo in CAFA and SPINAF, and an open-label comparison in BAATAF. AFASAK compared warfarin, aspirin and aspirin placebo. SPAF allocated patients as being warfarin eligible (group 1) or warfarin ineligible (group 2). Group 1 patients were randomized to open-label warfarin, aspirin 325 mg/day or aspirin placebo; group 2 patients were randomized to aspirin or aspirin placebo.

* INRs estimated by investigators from prothrombin time ratios.

Four of the trials[7,9,10,12] were stopped early by their Data and Safety Monitoring Boards (DSMB) because interim analyses were strongly positive, whereas the fifth[8] was stopped early because of the strongly positive results from two other trials. The primary outcomes varied somewhat among the trials. However, it is possible to determine the rates of ischemic stroke and major bleeding (intracranial, transfusion of two or more units, hospitalization) from each trial, to make comparisons and to pool the results. The Atrial Fibrillation Investigators overview[13] was a collaborative prospective meta-analysis which provides reliable summary data based on individual patient information. The overall risk of ischemic stroke of 4.5% per year (identical to that documented in the Framingham Study) was reduced to 1.4% per year with warfarin, a relative risk reduction (RRR) of 68% (95% confidence interval (CI) 50–79%) and an absolute reduction of 31 strokes for every 1000 patients treated ($P < 0.001$). A major concern with warfarin is hemorrhage, which was carefully documented in each trial. The rate of major hemorrhage with warfarin was 1.3% per year versus 1% per year in controls, an increase of three major hemorrhages per 1000 patients treated, including an excess of intracranial hemorrhage of two per year for every 1000 patients treated. A more recent meta-analysis[14] of these five trials calculated a RRR of 66% for ischemic stroke, and 61% for ischemic stroke or intracranial hemorrhage. This overview calculated a significant 31% RRR of all-cause mortality. Hence, the overall picture is one of major benefit from warfarin, with only a modest and statistically insignificant increase in the risk of major extracranial hemorrhage and cerebral hemorrhage (**Level A**).

The European Atrial Fibrillation Trial (EAFT) compared oral anticoagulants, aspirin and placebo in patients with non-rheumatic AF who had experienced a transient ischemic attack (TIA) or stroke within the preceding three months.[15] The annual risk of recurrence was 12% among the placebo patients, dramatically higher than the 4.5% annual risk in the overall population of patients with non-rheumatic AF. The relative risk reduction by anticoagulants was 66% ($P < 0.001$), virtually identical to that calculated in the overview of the five major randomized controlled trials, but the absolute reduction of strokes was much greater (84 per year per 1000 patients) because of the high baseline risk of stroke in this population. Major extracranial bleeding was more frequent on anticoagulants versus placebo (excess of 21 per year per 1000), but this adverse event was far outweighed by the reduction of major or moderately disabling strokes by anticoagulants (**Level A**).

A recent meta-anlysis[16] of primary and secondary prevention trials has assessed the outcome of all stroke (ischemic plus hemorrhagic), providing a more clinically meaningful summary than the outcome of ischemic stroke only. The relative risk reduction was 64% overall, about 60% in primary prevention trials (absolute risk reduction [ARR] was 27/1000 patients/year) (Table 37.2) and about 68% for secondary prevention (ARR 84/1000 patients/year). There was an excess of major extracranial bleeding of 3/1000 patients/year with adjusted dose oral anticoagulation versus control.

Aspirin therapy

Comparisons of aspirin and placebo resulted in a somewhat less impressive risk reduction for stroke of about 16% (NS) in AFASAK,[10] 44% ($P = 0.02$) in SPAF[12] and 17% (NS) in the European Atrial Fibrillation Trial (EAFT)[15] (Table 37.3). A recently updated meta-analysis[16] which included the Low Dose Aspirin, Stroke and Atrial Fibrillation pilot study (LASAF),[17] the Japan Atrial Fibrillation Stroke Trial,[18] atrial fibrillation patients from the European Stroke Prevention Study 2 (ESPS-2)[19] and the United Kingdom TIA Study (UK-TIA)[20] found a statistically significant 22% RRR (95% CI 2–39%) of all strokes (ischemic plus hemorrhagic) in five trials of aspirin versus placebo, and a 19% RRR (95% CI 1–35%) when two trials of aspirin versus no treatment were included. The ARR was 0.8%/year in primary prevention trials and 2.5%/year in secondary prevention trials. Hence, aspirin can be expected to reduce the risk of ischemic stroke and all strokes, with an ARR of about one half that of warfarin and with a somewhat lower risk of major extracranial bleeding of 0.2%/year versus 0.3%/year (**Level A**).

Aspirin versus oral anticoagulants

Direct comparisons of oral anticoagulants and aspirin have been undertaken in nine trials[16,21] (Table 37.4). AFASAK[10] included 671 patients who were randomized to warfarin (INR 2.8–4.2) or aspirin 75 mg/day. SPAF-II[22] studied 715 patients aged 75 years or less and 385 patients aged over 75 years, with each group randomly allocated to either

warfarin (INR 2.0–4.5) or aspirin (325 mg/day). EAFT[15] randomized 455 anticoagulation-eligible patients with recent TIA or minor ischemic stroke to oral anticoagulant (INR 2.5–4.0) or aspirin (300 mg/day). AFASAK-2[23] randomized 339 patients into a primary prevention trial which compared warfarin (INR 2–3) to aspirin (300 mg/day). PATAF[24] randomized 272 patients into a primary prevention trial which compared warfarin (INR 2.5–3.5) to aspirin (150 mg/day). A meta-analysis[16] and an update[21] found a statistically significant 39% (95% CI 19–53) RRR of all strokes (ischemic plus hemorrhagic) with anticoagulants, equivalent to an ARR of about 9 events/1000 patients/year for primary prevention and 70 events/1000 patients/year

for secondary prevention (**Level A**). Major extracranial hemorrhage occurred with an excess of about 2/1000/year on warfarin.[16]

In SPAF II warfarin was superior to aspirin for reducing ischemic stroke, but the risk of intracranial hemorrhage was increased with warfarin, particularly in patients >75 years of age. When patients of all ages were considered, there was an ARR of 0.8%/year (P = NS) in ischemic stroke or systemic embolus with warfarin, but when all strokes were compared, the ARR was only 0.3%/year (P = NS). The relatively high rates of intracranial bleeding may be attributable to the use of prothrombin time monitoring, the high INR range chosen and the very elderly population. If the

SPAF II results were to be excluded from the meta-analysis, the RRR of all strokes (ischemic and hemorrhagic) with anticoagulation would be greater than 39%.

The Birmingham Atrial Fibrillation Treatment of the Aged (BAFTA) Trial[25] was a randomized, open-label study of warfarin (INR 2.0–3.0) versus aspirin (75 mg/day) which is particularly relevant to several areas of uncertainty in current practice, because the patients were aged 75 years and greater (mean 81.5 years). They were recruited from and managed within general practices in England and Wales and the primary outcome included fatal or disabling stroke (ischemic and hemorrhagic), intracranial hemorrhage, and clinically significant arterial embolism. Warfarin reduced the annual risk of the primary outcome from 3.8% to 1.8%, a RRR of 52% (*P* = 0.003), and an ARR of 2% per year. The annual risk of extracranial hemorrhage was 1.4% (warfarin) versus 1.6% (aspirin). It should be noted that 40% of patients were on warfarin prior to study entry and that the study subjects represented only an estimated 10% of those with AF in the geographic region. Nevertheless, the results provide powerful evidence for the relative efficacy and safety of warfarin over aspirin for the treatment of NVAF in carefully selected elderly patients in real-life clinical practice settings.

Adjusted Dose Anticoagulation compared to warfarin/aspirin combinations, low or fixed dose anticoagulation, and to alternative antiplatelet regimens

The SPAF III trial[26] was undertaken in an attempt to reduce the rates of major hemorrhage with warfarin, while improving on the stroke prevention achievable by aspirin alone. Patients at high risk of embolic stroke (at least one of impaired LV function, systolic hypertension, prior thromboembolism, or female gender plus age over 75 years) were randomly allocated warfarin 1–3 mg/day plus aspirin 325 mg/day or warfarin (INR 2–3). The trial was discontinued early after a mean follow-up of 1.2 years, because the rate of the composite primary outcome of ischemic stroke or systemic embolus was significantly higher in those given combination therapy than in those given adjusted-dose warfarin (7.9% vs 1.9% per year, *P* < 0.0001). Rates of disabling stroke and of the composite of ischemic stroke, systemic embolus or vascular death were also significantly and markedly increased. The rates of major bleeding were similar in the two treatment groups.

AFASAK 2[22] was designed to compare regimens of aspirin 300 mg/day, fixed-dose warfarin (1.25 mg/day) plus aspirin 300 mg/day and fixed-dose warfarin 1.25 mg/day to warfarin (INR 2.0–3.0). The trial was stopped early when the results of SPAF III became available. Adjusted-dose warfarin was superior to each of the three comparison regimens at this point. It is clear that in high-risk patients, regimens of low fixed-dose warfarin in combination with aspirin do not provide adequate protection against thromboembolism (**Level A**).

Three trials (AFASAK 2,[22] MWNAF[27] and PATAF[23]) compared low or fixed doses of warfarin with standard warfarin (INR 2.0–3.0 or 2.5–3.5) but none showed a benefit. A meta-analysis[24] calculated a statistically insignificant 38% RRR for all strokes with the adjusted-dose warfarin (**Level A**).

The SIFA study[28] compared the antiplatelet agent indo-bufen to warfarin (INR 2.0–3.5), randomizing 916 patients with recent ischemic stroke or TIA. During a one-year follow-up, the RRR by warfarin was 21% (95% CI 54–60%) (**Level A**).

The FFAACS[29] study compared the oral anticoagulant fluindione (INR 2.0–2.6) to fluindione plus aspirin 100 mg/day in high-risk patients with AF, but was stopped early because of excess hemorrhage in the combination group. The NAS-PAEF study[30] randomized 495 high-risk AF patients to acencoumarol (INR 2.0–3.0) or acencoumarol (INR 1.4–2.4) plus the cyclo-oxygenase inhibitor triflusal (600 mg/day). There were 714 lower risk patients randomized to acencoumarol (INR 2.0–3.0), triflusal or triflusal plus acencoumarol (INR 1.25–2.0). The achieved INRs differed less than was intended between the acencoumarol alone group (mean INR 2.5) and the combination therapy groups (mean INRs 1.93 and 2.17 in the low- and high-risk strata, respectively). The hazard ratio (HR) of the combination versus acencoumarol alone for the outcome of ischemic stroke or systemic embolus was 0.44 in both groups. When severe bleeding was combined with the primary outcome of vascular death, TIA or non-fatal stroke, there was an ARR of 2.3%/year ($P < 0.05$) with the combination in the intermediate risk group and an ARR of 1.74%/year (P = NS) in the high-risk group (**Level B**). These results suggest that it may yet be possible to find a regimen of antiplatelet agent and lower dose anticoagulant, but the appropriate INR range is likely to be only marginally less than the standard 2.0–3.0.

The ACTIVE program comprised three separate inter-related trials, including ACTIVE-W,[31] which used a non-inferiority design to compare the combination of clopidogrel (75 mg/day) plus aspirin (recommended at 75–100 mg/day) to anticoagulation (INR 2.0–3.0), among patients with AF who were eligible and willing to take anticoagulation. The trial was stopped early (only 27% of expected events had occurred) at the recommendation of the DSMB, because of an extremely low likelihood of eventually concluding non-inferiority of the clopidogrel/aspirin combination. Among the 6706 patients enrolled and followed for a median of 1.28 years, the risk ratio with the combination for the composite outcome of stroke, non-CNS embolus, myocardial infarction and vascular death was 1.44 (95% CI 1.18–1.76, P = 0.0003), and for all stroke was 1.72 (95% CI 1.24–4.37, P = 0.002) (**Level A**). Somewhat surprisingly, the risk ratio for major bleeding was 1.10 (95% CI 0.83–1.45) with the combination.

The ACTIVE-A trial[31a] compared the combination of clopidogrel (75 mg/day) plus aspirin to aspirin alone among 7554 patients with AF at increased risk of stroke and for whom vitamin K antagonist therapy was unsuitable. After a mean 3.6 years the risk of major vascular events was reduced by the combination (RR 0.89; 95% CI 0.81, 0.98; P = 0.01). However, major bleeding was increased (2.0% vs 1.3%/year, RR 1.57; 95% CI 1.29, 1.92; $P < 0.001$).

Other anticoagulants

Warfarin and other vitamin K antagonists are very effective in reducing the incidence of stroke and systemic embolus. However, the narrow therapeutic margin and the interactions with many other drugs and foods necessitate frequent monitoring and patient diligence. There is a substantial risk of major hemorrhage, particularly in elderly patients. Ximelagatran is an oral direct thrombin inhibitor, with predictable and stable pharmacokinetics and relatively low potential for interactions with other drugs and with foods. Coagulation monitoring and dose adjustments are not required. This agent was evaluated in two large trials employing non-inferiority designs.[32,33] In both, it was concluded that ximelagatran was non-inferior (i.e. not unacceptably inferior) to warfarin.

SPORTIF III[32] randomized 3410 patients with AF and one or more stroke risk factors to open-label warfarin (INR 2.0–3.0) or ximelagatran (36 mg bid). During a mean 17.4-month follow-up, the incidence of the primary outcome (all stroke or systemic embolus) by intention to treat was reduced to 1.6%/year with ximelagatran from 2.3%/year with warfarin (ARR 0.7%/year, 95% CI –0.1–1.4 %, P = 0.10 and RRR 29%, 95% CI –6.5–52%). The incidence of major bleeding was similar in the two groups, but the total of minor or major bleeding was less frequent with ximelagatran (25.8%/year vs 29.8%/year, RRR 14%, 95% CI 4–22%, P = 0.007). The authors concluded that ximelagatran was "at least as effective" as warfarin for the prevention of stroke and systemic embolism.

SPORTIF V[33] compared ximelagatran to warfarin among 3922 patients in a study of almost identical design, except that it was double blind. During a mean follow-up of 20 months, the incidence of the primary outcome was 1.6%/year with ximelagatran and 1.2%/year with warfarin (ARR –0.45%/year, 95% CI –1.0–0.13%/year, but $P < 0.001$ for the predefined non-inferiority margin). The incidence of major bleeding was similar in the two groups, whereas major or minor bleeding was less frequent with ximelagatran (37% vs 47%/year, 95% CI –14% to –6.0%/year, $P < 0.001$). The authors concluded that "ximelagatran was non-inferior to well-controlled warfarin".

Both studies found an excess of patients with elevations of alanine transaminase (ALT) to greater than three times the upper limit of normal, usually within the first six months (6.0% vs 1% in SPORTIF III and 6.0% vs 0.8% in SPORTIF V). Furthermore, the claim of non-inferiority was based on the choice of non-inferiority margins that were excessive.[34] The commonly accepted approach is to estimate the efficacy of the currently accepted therapy (in this

case warfarin vs placebo) from a meta-analysis and then to choose a non-inferiority margin which would represent preservation of at least 50% of the benefit of the accepted therapy compared to placebo. If the non-inferiority margin had been chosen according to the FDA recommendations, SPORTIF III would still have reached a conclusion of non-inferiority, but SPORTIF V would not, nor would a meta-analysis of the two studies. The FDA did not approve the new agent, having concluded that the more convenient dose and monitoring regimens and less total bleeding did not outweigh their concerns about hepatic toxicity and the appropriateness of the chosen non-inferiority margins (**Level B**).

Dabigatran is another oral direct thrombin inhibitor which is being compared to warfarin (INR 2-3) among patients with AF with at least one additional risk factor for stoke in the RE-LY trial. Enrollment is complete (18 113 patients) and results are expected in 2009.

There are several available oral, direct acting Factor Xa inhibitor drugs which have proven effective and safe in studies of deep venous thrombosis and offer promise in the setting of AF. In the AVERROES trial, apixaban (5 mg bid) is being compared to aspirin (81–324 mg daily) among patients with AF at more than very low risk of stroke in whom vitamin K antagonist therapy is unsuitable. The expected enrollment is 5600 patients with completion in 2010. In the ARISTOTLE trial, apixaban (5 mg bid) is being compared to warfarin (INR 2.5) among patients with AF at somewhat higher risk of stroke. The expected enrollment is 15 000 patients with completion in 2010. In the ROCKET AF trial, rivaroxaban (20 mg/day) is being compared to warfarin (INR 2.5) among patients with AF at risk of stroke and suitable for warfarin therapy. The expected enrollment is 14 000 patients with completion in 2010. In the ENGAGE AF TIMI 48 trial, DU-176b (high and low dose regimens) is being compared to warfarin among patients with AF at risk of stroke and suitable for warfarin therapy. The expected enrollment is 16 500 patients with completion in 2011.

Risk stratification (stroke or systemic embolus)

Rigorous and current data for stroke risk come from analyses of the placebo patients in large clinical trials of antithrombotic therapy. The Atrial Fibrillation Investigators overview[13] calculated the annual risk of stroke to be 4.5% among the total group of control patients in the five major primary prevention randomized trials of anticoagulation. The statistically significant multivariate predictors of stroke were previous stroke or TIA, increasing age, history of hypertension, and diabetes. Annual stroke risk ranged from 0 (112 patients <60 years age) to 1.3% (patients <80 years age with no other risk factors), to 11.7% (patients with prior stroke or TIA). A recent systematic review[35] examined the evidence identifying independent risk factors for stroke as reported in seven studies (including the AFI overview[13]) selected according to rigorously defined criteria. The absolute annual risk of stroke varied 20-fold among patients grouped by various risk factors. Independent risk factors for stroke (Table 37.5) were the same as those previously identified[13]: stroke/TIA (RR 2.5), age (RR 1.5/decade), history of hypertension (RR 2.0) and diabetes mellitus (RR 1.7). Female sex was an independent risk factor in three of six cohorts, but coronary artery disease and clinical congestive heart failure were not found to be independent risk factors in any of the studies which met the inclusion criteria. Congestive heart failure and reduced ejection fraction have been identified as univariant risk factors[13,36,37] and are included in current risk classification schemes.[6,38] The review emphasized a variety of shortcomings of the studies, including inconsistencies in definitions of some of the risk factors, the use of antiplatelet therapies, and the stroke outcomes (ischemic strokes only, all strokes, strokes plus other systemic emboli and strokes plus TIAs) (**Level A**).

The data from the Atrial Fibrillation Investigators overview[13] and the SPAF group[35] were combined to create the

Table 37.5 Risk factors for stroke in patients with non-vascular atrial fibrillation*

Risk factor	Multivariate RR (%)	95% CI (%)	Prevalence of risk factor in patient cohorts (% and range)	Observed range of absolute stroke rate/year with only this risk factor (%)
Stroke/TIA	2.5	1.8–3.5	7 (0–14)	6–9
Age	1.5/decade	1.3–1.7	Mean age range 62–79 yrs	1.5–3.0 for age >75 yr.
History of hypertension	2.0	1.6–2.5	48 (42–53)	1.5–3.0
Diabetes mellitus	1.7	1.4–2.0	15 (14–18)	2.0–3.5

*Data from Stroke Risk in Atrial Fibrillation Working Group[35]
RR, relative risk; CI, confidence interval

CHADS$_2$ index[38] which assigns 1 point each for congestive heart failure, hypertension, age 75 years or older and diabetes mellitus and 2 points for a history of stroke or TIA. The scheme was validated and compared to the other two schemes among 1733 Medicare beneficiaries aged 65–95 years, who had been discharged from hospital with non-rheumatic AF and not prescribed warfarin. The CHADS$_2$ index was the most accurate predictor of stroke, with the annual stroke rate increasing by about 1.5% for each 1-point increase in CHADS$_2$ score (from 1.9 with a score of 0 to 18.2% with a score of 6). This scheme was also evaluated in comparison to several others among 2580 patients receiving aspirin in six prospective trials.[39] The CHADS$_2$ index identified increments in stroke risk similar to those identified in the prior validation, and was better at discriminating medium- and high-risk patients than the other schema. The CHADS$_2$ index has become the favored choice for determining risk of stroke and guiding choice of antithrombotic therapy.[6]

Several cohort studies[1] have demonstrated a more consistent lower annual stroke risk in patients with paroxysmal (transient) AF than in those with persistent (chronic or sustained) AF. On the other hand, the SPAF trial found similar annual rates of ischemic stroke in patients with "recurrent" (3.2%) and "chronic" (3.3%) AF,[40] and a meta-analysis of the control groups in five large trials showed no difference.[13] Current practice guidelines do not differentiate between paroxysmal and persistent AF (**Class I, Level A**). However, it is possible that the risk of stroke is less in patients whose episodes of AF are brief (<1 day) and self-terminating.[41]

The short-term risk of stroke appears to be higher in patients with recent-onset atrial fibrillation than in those with atrial fibrillation for more than 1–2 years.[42,43] In the European Atrial Fibrillation Trial,[15] among patients with prior stroke, the annual recurrence rate was 12% without treatment. Several case series reported recurrence rates of 0.1–1.3%/day during the first two weeks following a cardioembolic stroke.[44] The high rate of recurrence, although not observed in every study, suggested that there is some urgency in initiating anticoagulation following the occurrence of embolic stroke in patients with AF. The International Stroke Trial Collaborative Group addressed this concern with a large randomized trial of 18 451 patients with ischemic stroke who were randomized within 24 hours of onset to SC unfractionated heparin (5000 IU bid or 12 500 IU bid), aspirin 300 mg/day, both or neither and maintained for 14 days or until prior hospital discharge.[44] CT scan was performed to exclude intracranial hemorrhage when possible and was mandatory in comatose patients. Among the 3169 patients with AF, both doses of heparin were significantly more effective for the prevention of recurrent stroke of ischemic or unknown type. However, both heparin regimens resulted in significantly more symptomatic intracranial hemorrhage, and there was no significant difference among the regimens in the rate of the composite outcome of recurrent stroke or symptomatic intracranial hemorrhage, nor of all-cause mortality. Patients with AF had a higher mortality than patients without AF (16.9% vs 7.5%), probably due to greater mean age and larger cerebral infarcts. The rate of recurrence within 14 days, of stroke of ischemic or unknown type, was 3.9% among patients with AF, considerably lower than reported in earlier studies, but still higher than in patients without AF in this study. The results indicate that heparin is not indicated in the acute management of embolic stroke among patients with AF (**Level A**). Based upon their study and a combined analysis with the Chinese Acute Stroke Trial,[45] the authors recommend that AF patients who experience ischemic stroke should be given aspirin 300 mg/day with conversion to warfarin (INR 2.0–3.0) after 14 days[44] (**Class IIa, Level A**). When stroke occurs in AF patients receiving warfarin, subsequent management should be guided by the INR measured at the time of onset of the stroke. If the INR was below the conventional therapeutic range it is probably sufficient to reinstitute warfarin with meticulous attention to maintaining INR in the range of 2.0–3.0. If the INR was in the therapeutic range, it is reasonable to raise the intensity of warfarin to an INR range of 2.5–3.5 (**Class IIb, Level C**).

The risk of stroke in patients with thyrotoxic AF is substantial, although the mechanism and the relative role of congestive heart failure are uncertain. The risk of stroke is also substantial among patients with hypertrophic cardiomyopathy and AF. These risks have not been rigorously evaluated, and antithrombotic therapies for patients with AF and thyrotoxicosis or hypertrophic cardiomyopathy should be based upon the presence of validated stroke risk factors[46] (**Class I, Level C**).

Risk of hemorrhage

The efficacy of warfarin for the prevention of ischemic stroke must be balanced against the risk of major hemorrhage, particularly cerebral hemorrhage, which is usually fatal. The risk of major hemorrhage is increased by the intensity of anticoagulation, advanced age, and hypertension.[47,48] It is likely to be higher in clinical practice than in the rigorous setting of a clinical trial. The 3.1% absolute reduction of ischemic stroke observed in the initial five randomized controlled trials was accompanied by an absolute excess risk of major hemorrhage of only 0.3%. The INR ranges chosen varied from a low of 1.4 to a high of 4.5. In SPAF II[21] the greater efficacy of warfarin over aspirin for the prevention of ischemic stroke was outweighed by excess cerebral hemorrhage in patients over age 75 years (mean 80 years), likely related to the chosen INR of 2.0–4.5.

The HEMORR$_2$HAGES scheme was developed from three previously published prediction rules and all four approaches were then evaluated in a population of elderly patients with AF.[49] The scheme allotted points for hepatic or renal disease, ethanol abuse, malignancy, age >75 years, reduced platelets, prior bleed, hypertension, anemia, excessive falls or neuropsychiatric disease and prior stroke. The scheme provided good discrimination among patients with an annual risk of hospitalization for hemorrhage which ranged from 1.9% to 12.3% (**Level C**).

Recent practice guidelines[6,46] stress the importance of appropriate antithrombotic therapy for AF, and yet practice surveys indicate that rates of compliance range from rather low[50–54] to reasonably high.[55] Hylek et al[56] point out that randomized trials and most observational cohorts underestimate the risks of major hemorrhage because they include few patients over 80 years of age, and infrequently include patients in the initial phase of warfarin therapy when the risk of major hemorrhage is highest. They enrolled 472 patients age ≥65 years (153 ≥80 years), with ECG-verified AF, who were new to warfarin and whose care was established at the study institution and whose warfarin was managed by the on-site anticoagulation clinic. The patients were enrolled on the first day of warfarin and followed for one year between 2001 and 2003 (complete follow-up in 100%). A total of 90% of patients ≥80 years of age had a CHADS$_2$ score ≥2, and of the patients ≥80 years, 95.3% had at least an intermediate risk of major hemorrhage. Anticoagulation control was very good, with 56% of person time within the INR range of 2.0–3.0, 29% below 2.0, 11% within 3.0–<4.0, and only 2% ≥4.0. Even within this optimized setting, the rate of major hemorrhage was 7.2 per 100 patient-years (intracranial hemorrhage was 2.5 per 100 patient-years). The incidence of major hemorrhage was 13.08% for patients ≥80 years versus 4.75% for those <80 years. The risk during the first 90 days of therapy was three times that of the remainder of the year. The risk of major hemorrhage was increased 20 times among patients with an INR >4.0. Most of the intracranial bleeds occurred in patients ≥75 years of age. The rate of major hemorrhage was higher in patients with higher CHADS$_2$ scores.

In contrast, the BAFTA study[25] found that in patients aged >75 years, warfarin was more efficacious than aspirin in preventing all strokes (ischemic plus hemorrhagic) and did not cause more extracranial hemorrhage (1.4%/year with warfarin vs 1.6%/year with aspirin). The lower bleeding risk may be attributable to more restrictive patient selection for a clinical trial than for the Hylek survey and the fact that 40% of them had been taking warfarin safely prior to entering the trial.

These observations point to the challenges in choosing the optimal antithrombotic therapy for very elderly patients to ensure a favorable risk–benefit ratio.[57] For those with no stroke risk factors other than age ≥75 years, it is reasonable to consider aspirin in preference to warfarin.[6] Nevertheless, ischemic stroke with its dire consequences is relatively frequent, and the competing risk of intracranial hemorrhage with warfarin may be acceptable. If warfarin is to be used, great care must be taken to rigorously maintain the selected therapeutic INR with frequent monitoring in the first three months and more often than the "standard" monthly interval subsequently (**Class I, Level C**).

For most patients who are candidates for warfarin, an INR range of 2.0–3.0 with a target of 2.5 appears optimal.[6, 46] In a large cohort of patients the risk of ischemic stroke, severity of stroke and mortality rose sharply when INR fell to 1.5–1.9, but the risk of intracranial hemorrhage did not rise until INR values exceeded 3.9.[58] A recent meta-analysis[59] of studies which assigned hemorrhagic and thromboembolic events in patients taking anticoagulants to discrete INR ranges found that 44% of hemorrhages occurred when INRs were above the therapeutic range, 48% of thromboembolic events took place when below it and that the mean proportion of events that occurred when the patient's INR was outside the therapeutic range was higher in the studies of shorter follow-up. Patients with a previous TIA or minor stroke may benefit from a somewhat higher INR of 2.0–3.9 with a target of 3.0.[6,60] Patients at higher risk of cerebral hemorrhage, particularly those over the age of 75, may benefit from a somewhat lower INR range of 1.6–2.5 with a target of 2.0,[6] although protection against ischemic stroke drops off sharply when INRs fall below this target (**Class IIa, Level C**).

Rate versus rhythm control

Management strategies for AF have generally been focused on rhythm control (attempting to establish and sustain normal sinus rhythm by the use of various proven pharmacologic agents and appropriate electrical cardioversion) or rate control (attempting to maintain resting and exercise heart rates below optimal levels, without specific attempts to establish or maintain sinus rhythm). An overview[61,62] of the five trials which compared the strategies of rhythm with rate control in AF found a mortality of 13.0% with rate control versus 14.6% with rhythm control (OR 0.87, $P = 0.09$). The rates of ischemic stroke and major hemorrhage were similar. The AFFIRM trial,[63] by far the largest, randomized 4060 patients of mean age 69.7 years and found a trend toward lower survival in the rhythm control group, which also had significantly more hospitalizations and adverse drug effects. Anticoagulation (INR 2.0–3.0) was mandated in the rate control group (85% maintained warfarin) and strongly encouraged in the rhythm control group, but could be stopped at the physician's discretion

if sustained sinus rhythm was achieved (70% maintained warfarin). Ischemic stroke occurred at an annual rate of about 1% in each group, and in most instances the patient was either off warfarin or the INR was <2.0. The authors concluded that continuous anticoagulation is warranted in all patients with AF and one or more risk factors for stroke, whether or not sinus rhythm appears to be restored and maintained, and this approach is recommended by consensus groups[6,46] (**Class I, Level A**).

Choice of antithrombotic therapy

Table 37.6 is derived from the practice guidelines of the AHA/ACC/ESC consensus process[6] and incorporates concepts of varying risks of thromboembolism with age and other risk factors, and embodies concepts of varying hemorrhagic risk with increasing age. The schema differs somewhat from that developed by the ACCP consensus process[46] which recommends aspirin in a dose of 325 mg/day, definite warfarin for patients ≥75 years even with no other risk

factors, not differentiating between moderate- and high-risk factors, and not considering weak or less validated risk factors. The Atrial Fibrillation Working Group has recently published a comparison of 12 risk stratification schemes.[64] They conclude that additional research is required to "identify and strengthen a single scheme around which standard recommendations could be developed".

For the present, tables such as Table 37.6 can provide broad guidance to the clinician in decisionmaking about antithrombotic therapy for AF. However, experienced clinical judgment is required to decide optimal therapy depending on the competing risks (ischemic stroke/other systemic embolus versus cerebral and other major hemorrhage); anticoagulant monitoring (quality and availability of monitoring and the willingness/ability of the patient to maintain a safe regimen); and individual patient preferences (perspectives on the competing risks of ischemic stroke and major hemorrhage and the inconvenience and complexity of warfarin therapy). Eventually, pharmacogenomic algorithms may allow more rapid and safe determinations of initial warfarin dosage, particularly among

Table 37.6 Choice of antithrombotic therapies for patients with non-rheumatic atrial fibrillation (based on AHA/ACC/ESC Guidelines 2006[6])

Clinical risk factors*	Age (years)		
	<65	65–74	≥75
No	Aspirin (81–325 mg/day) (**Class I, Level A**) *Consider no antithrombotic therapy* (**Class IIb, Level C**) *Consider warfarin (INR 2.0–3.0, target 2.5) for females or coronary artery disease* (**Class IIa, Level B**)	Aspirin (81–325 mg/day) (**Class I, Level A**) or Warfarin (INR 2.0–3.0, target 2.5) (**Class I, Level A**)	Aspirin (81–325 mg/day) (**Class I, Level A**) or Warfarin (INR 2.0–3.0, target 2.5) (**Class I, Level A**) *Consider INR 1.6–2.5, target 2.0* (**Class IIb, Level C**)
1 moderate risk factor# in addition to age ≥75 yr	Aspirin (75–325 mg/day) or Warfarin (INR 2.0–3.0, target 2.5) (**Class IIa, Level B**)	Aspirin (75–325 mg/day) or Warfarin (INR 2.0–3.0, target 2.5) (**Class IIa, Level B**)	Warfarin (INR 2.0–3.0, target 2.5) (**Class I, Level A**) *Consider INR 1.6–2.5, target 2.0* (**Class IIb, Level C**)

patients whose warfarin requirements are particularly low or high.[64a]

Cardioversion

Although the randomized trials have shown no improvement in major outcomes including thromboembolism with a rhythm control strategy versus rate control, individual patients may gain symptomatic benefit and even long-term freedom from AF following electrical or pharmacologic cardioversion. The strongest predictor of initial and persistent success with cardioversion is short duration of the atrial fibrillation before cardioversion. In general, it may be expected that atrial fibrillation occurring in conjunction with surgery, viral illness, alcohol or other pharmacologic excess, or in association with thyrotoxicosis or pulmonary embolus, has a high likelihood of reversion with persistence of sinus rhythm if there has been resolution of the precipitating cause. Successful and sustained reversion to sinus rhythm is associated with relatively young age and freedom from underlying heart disease. Some patients have intolerable symptoms and poor exercise tolerance during AF and may prefer attempted rhythm control to rate control. The rate of initial success in restoring sinus rhythm is high but in the contemporary AFFIRM trial, vigorous efforts to establish and sustain sinus rhythm resulted in prevalences of 82.5%, 73.3% and 62.6% at one, three and five years, respectively.[63]

Although no study has rigorously documented the incidence of systemic embolism following electrical, pharmacologic or spontaneous cardioversion, it is widely believed that in many patients cardioversion acutely increases the risk of stroke. This perception forms the rationale for anticoagulation of patients prior to cardioversion. The best available study used a prospective cohort design to detect a reduction of postcardioversion systemic embolism from 5.3% to 0.8% among anticoagulated patients.[65] It is generally believed that a newly formed thrombus will become organized and adherent to the left atrial wall within two weeks of formation. Transesophageal echocardiography (TEE) reveals that in the majority of patients thrombus resolves, rather than simply becoming firmly adherent to the wall of the left atrium or left atrial appendage.[66] Accordingly, anticoagulation is usually recommended for about three weeks before cardioversion[6,46] (**Class I, Level C**). A study that pooled data from 32 studies found that 98% of thromboembolic events occurred within 10 days of cardioversion of atrial fibrillation or flutter.[67] However, evidence exists that even after successful electroversion, atrial contraction may not normalize for some weeks,[68,69] and therefore maintenance of anticoagulation for about four weeks following cardioversion seems prudent[6,46] (**Class I, Level C**). There is a lack of evidence that the incidence of throm-

boembolism is less with pharmacologic than with electrical cardioversion, and accordingly anticoagulant management should not differ[6] (**Class I, Level C**). New-onset atrial fibrillation is generally not thought to warrant anticoagulation if cardioversion is undertaken within 48 hours of its onset.[6,46] If cardioversion is unsuccessful or if AF has been recurrent, anticoagulation may be commenced subsequently.

Emergency cardioversion may be required because of ischemia or hemodynamic compromise in some situations, and should not be delayed even if the AF has been present for more than 48 hours and the patient is not already anticoagulated. In such a situation, concomitant heparinization may offer some benefit (**Class I, Level C**).

The potential role of TEE for the detection of atrial thrombi and the simplification and shortening of the anticoagulation regimen in association with cardioversion was studied in a consecutive series of 230 patients.[70] Atrial thrombi were detected in 15%. Of 196 patients without thrombi, 95% were successfully cardioverted without prolonged anticoagulation, and none had a clinical thromboembolic event. However, a subsequent study[71] and a meta-analysis of several clinical studies[72] indicate that the absence of thrombi on TEE does not mean that a period of four weeks of anticoagulation following cardioversion may be safely omitted (**Class I, Level C**).

The Assessment of Cardioversion Utilizing Echocardiography (ACUTE) pilot study[73] was followed by a multicenter randomized prospective of trial of 1222 patients with atrial fibrillation of more than two days' duration.[74] All patients were anticoagulated and assigned to therapy guided by the findings on TEE or to conventional therapy. If TEE showed no thrombus, the patient underwent cardioversion and continued on anticoagulant therapy for four weeks. If thrombus was detected, warfarin was given for three weeks, TEE was repeated and, if the thrombus had resolved, cardioversion was performed and warfarin continued for four weeks. If thrombus was still detected after three weeks of anticoagulation, no cardioversion was attempted but warfarin was continued for four weeks further. The patients randomized to no TEE received warfarin for three weeks and then underwent cardioversion followed by a further four weeks of warfarin. At eight weeks after the assignment of management strategy, there was no significant difference between the two therapeutic groups (TEE vs no TEE) in the rate of embolic events or the prevalence of sinus rhythm. The TEE strategy resulted in fewer total hemorrhagic events, most of them minor. Right or left heart thrombi were identified in 13.8% of patients who underwent TEE. Of those patients with thrombi detected, 88.2% had a thrombus in the left atrial appendage. Patients may be anticoagulated and screened by TEE and cardioversion performed immediately if no thrombus is detected, and then receive at least four further weeks of anticoagulation.

If thrombus is detected, patients should undergo at least three weeks of anticoagulation prior to cardioversion, followed by a further four weeks of anticoagulation. Among those patients with atrial thrombi detected, the value of repeat TEE after the initial three weeks of anticoagulation is uncertain. In centers where TEE is readily available and the interpretations reliable, a TEE-guided management strategy may safely shorten the time to cardioversion by comparison with standard anticoagulant regimens (**Class I, Level A**). The cost-effectiveness of such an approach depends very much on local and national patterns of practice and cost structures.

Left atrial radiofrequency ablation is increasingly used to treat AF, raising questions about the role of warfarin in such patients. In general, the procedure should be conducted with the patient off warfarin and the INR in the normal range. Warfarin should then be restarted with INR 2.0–3.0 for at least the next several months, and continued indefinitely in patients with a CHADS$_2$ of 3 or more,[41] with consideration given to discontinuing warfarin in young patients with very low CHADS$_2$ scores and who are free of even asymptomatic AF after several months (**Class IIb, Level B**).

Atrial flutter

There is a widespread perception that the risk of stroke is less with atrial flutter than with atrial fibrillation. A retrospective analysis of a large database of elderly hospitalized patients confirmed this perception, calculating a stroke risk ratio of 1.4 with atrial flutter and 1.6 with AF.[75] By eight years of follow-up more than half the patients with atrial flutter had developed AF, and these patients were more likely to experience a stroke. The development of AF was more likely among patients with congestive heart failure, rheumatic heart disease, hypertension and diabetes mellitus. Although there are no rigorous prospective data on the incidence of stroke among patients with atrial flutter, nor randomized trials of the value of anticoagulation, it is generally recommended that patients with atrial flutter be risk stratified and treated in the same manner as patients with AF[6,46] (**Class I, Level C**).

Retrospective studies of patients with atrial flutter undergoing cardioversion suggest that the risk of thromboembolism is less than that for patients with AF, but nevertheless clinically important.[76] Case series note a very low incidence of thromboemboli when patients with atrial flutter are adequately anticoagulated prior to cardioversion.[77] It is generally recommended that patients with atrial flutter who are to be cardioverted receive an anticoagulant regimen identical to that for patients with AF[6,46] (**Class I, Level C**).

Atrial fibrillation and coronary artery disease

There are extensive data available on the efficacy of warfarin at various intensities, combinations of warfarin and aspirin, aspirin alone and clopidogrel among survivors of acute myocardial infraction (AMI).[78,79] Practice guidelines favor the use of aspirin 75–162 mg/day, and the substitution of clopidogrel 75 mg/day or warfarin (INR 2.5–3.5) for patients allergic to aspirin.[78,79] However, when AF is present following AMI, warfarin therapy is usually required for stroke prophylaxis. An INR range of 2.5–3.5 may be appropriate for the first few months post AMI, followed by the standard range of 2.0–3.0 long term.[6,46,78] Aspirin should generally not be given concurrently (**Class I, Level B**). A prospective cohort study based on Swedish coronary care unit admissions of patients discharged with AF following AMI found that oral anticoagulants were given to only 30% of such patients, and yet this therapy was associated with a 7% reduction of one-year mortality after adjustment for confounding variables[80] (**Level C**).

For patients undergoing percutaneous coronary intervention (PCI), maintenance aspirin is supplemented by clopidogrel which is begun prior to PCI and maintained for several months subsequently, the duration being longer for drug-eluting than bare metal stents.[78,79,81] AF patients who are receiving warfarin monotherapy, and who undergo PCI, may have the warfarin interrupted for 48 hours prior to PCI and reinstituted as soon as possible after the procedure, with the substitution of aspirin (75–81 mg/day) during the period off warfarin. Clopidogrel should be administered according to the same approaches as for patients without AF[46,78,79,81] (**Class I, Level C**). In patients at particularly high risk of stent thrombosis, triple therapy with warfarin, clopidogrel and aspirin may be appropriate[78,81] (**Class IIb, Level C**). The risk of bleeding is increased when warfarin is given in conjunction with aspirin and/or clopidogrel, and careful monitoring with INR 2.0–2.5 is recommended (**Class I, Level C**).

Interruption of warfarin therapy in relation to surgical procedures

Warfarin should generally be discontinued prior to surgical or diagnostic procedures which have a risk of bleeding. Given that the risk of stroke among patients with AF ranges from <1% to >20%/year, it is generally recommended that warfarin may be safely discontinued for up to a week (four days prior to and three days after surgery) in most patients with AF[82] (**Class IIa, Level C**). For those at particularly high risk of stroke (mechanical valve prosthesis or recent stroke), IV unfractionated heparin or SC

LMWH may be given preoperatively. It is likely that most potentially hemorrhagic dental procedures, if undertaken with appropriate surgical skill and the use of hemostatic mouthwash, can be done without discontinuing warfarin, provided the preoperative INR is under 3.0[83] (**Class IIa, Level B**).

Conclusion and recommendations

Patients with persistent or paroxysmal atrial fibrillation should generally receive chronic antithrombotic therapy with warfarin or aspirin regardless of whether a strategy of rate control or rhythm control has been selected (see Table 38.6) (**Class I, Level A**). Antithrombotic therapy should generally be sustained indefinitely, unless a clearly reversible cause of atrial fibrillation (e.g. pulmonary embolism, thyrotoxicosis, viral infection, perioperative, alcohol excess) has resolved and sinus rhythm has resumed (**Class I, Level C**).

Major risk factors for thromboembolism include the presence of mitral stenosis, a prosthetic heart and a history of prior stroke, TIA or non-CNS systemic embolism; moderate risk factors include age ≥75 year, history of hypertension, heart failure or moderate to severe LV dysfunction and diabetes mellitus. Warfarin is more effective than aspirin in preventing thromboemboli, but carries a higher risk of hemorrhage. The choice of agent is governed by the perceived balance between the risk of thromboembolism and the risk of hemorrhage in each individual patient and should include appropriate consideration of patient preferences (**Class I, Level A**).

Among patients with persistent or paroxysmal AF, age is an important determinant of the risk of thromboembolism even in the absence of other moderate or major risk factors. When the patient is <65 years and is free of any moderate or major risk factors for thromboembolic events (CHADS$_2$ = 0), the risk of thromboembolism is very low and aspirin therapy is preferable to warfarin (**Class I, Level A**). Consideration should be given even to no antithrombotic therapy (**Class IIb, Level C**). In the age range 65–74 years (CHADS$_2$ = 0), the risk of thromboembolism is increased and either aspirin or warfarin may be indicated. Patient preferences and risk factors for hemorrhage should influence the choice (**Class IIa, Level A**). When the patient is aged ≥75 years the risk of thromboembolism is further increased, even in the absence of other risk factors (CHADS$_2$ = 1). However, the risk of major hemorrhage, and particularly intracranial hemorrhage, also rises. Either aspirin or warfarin may be appropriate (**Class I, Level A**). If warfarin is to be used, consideration should be given to a reduced intensity of anticoagulation (INR 1.6–2.5, target 2.0), recognizing that maintaining an adequate intensity of anticoagulation with a target of 2.0 is difficult and requires frequent monitoring (**Class IIb, Level C**).

Patients aged 74 or less with one moderate risk factor for thromboembolism (CHADS$_2$ = 1) should receive either aspirin or warfarin. Risks of thromboembolism and hemorrhage as well as patient preferences should influence the choice (**Class I, Level A**).

Patients with more than one moderate risk factor or one major risk factor for thromboembolism (CHADS$_2$ ≥ 2) should receive warfarin (**Class I, Level A**).

Patients with AF who experience an episode of thromboembolism with an INR below the therapeutic range should continue on oral anticoagulation with more meticulous monitoring and dose adherence. If the episode occurs at an INR in the therapeutic range, consideration should be given to maintaining a higher range (INR 2.5–3.5), with intensive monitoring to avoid any levels over 4.0 (**Class IIb, Level C**).

Patients undergoing cardioversion (electrical or pharmacologic) for AF of uncertain or known duration of 48 hours or longer should generally receive oral anticoagulation for about three weeks prior to the procedure and for at least four weeks afterwards (**Class I, Level C**). Patients with more than one episode of AF or who are at high risk of thromboembolism should have oral anticoagulation continued indefinitely even if sinus rhythm persists at four weeks (**Class I, Level C**). If cardioversion is required on an urgent basis because of hemodynamic instability in patients with AF of uncertain or greater than 48 hours duration, cardioversion should not be delayed. Concomitant anticoagulation should be established using IV unfractionated heparin (activated partial thromboplastin time (APTT) 1.5–2.0 times reference control) and maintained until oral anticoagulation can be achieved and sustained for at least four weeks (**Class I, Level C**).

New-onset AF does not require anticoagulation if cardioversion is undertaken within 48 hours of its onset.[6,46] If cardioversion is unsuccessful or if AF has been recurrent, anticoagulation may be commenced subsequently (**Class I, Level C**).

In appropriate centers TEE-guided management can offer a safe, cost-effective and convenient alternative to standard anticoagulant regimens. If AF is of uncertain or known duration of 48 hours or longer, TEE may be performed. If there is no LA thrombus, IV heparin may be commenced, cardioversion undertaken, and oral anticoagulation maintained for at least four weeks. (An alternative would be to administer oral anticoagulation initially for at least five days and then to perform TEE.) If thrombus is detected on TEE, anticoagulation should be continued for a total of three weeks, followed by cardioversion and sustained oral anticoagulation for at least four weeks further (**Class I, Level B**).

Patients undergoing LA radiofrequency ablation should have warfarin stopped and INR in the normal range. Warfarin should then be restarted and maintained indefinitely

for patients with a CHADS$_2$ score of 3 or less, with consideration given to discontinuing warfarin in young patients with very low CHADS$_2$ scores and who are free of even asymptomatic AF after several months (**Class IIb, Level B**).

The antithrombotic management of patients with atrial flutter should be generally be similar to that for patients with AF (**Class I, Level C**).

Patients with AF following myocardial infarction should receive warfarin (INR 2.5–3.5 for the first few months and 2.0–3.0 long term) and aspirin should generally not be given concurrently (**Class IIb, Level C**).

AF patients who are to undergo PCI should have the warfarin interrupted for 48 hours prior to PCI and reinstituted as soon as possible after the procedure, with the substitution of aspirin (75–81 mg/day) during the period off warfarin. Clopidogrel should be administered according to the same approaches as for patients without AF, with triple therapy reserved for patients at particularly high risk of stent thrombosis. The INR should be kept in the range 2.0–2.5 in such patients[46,78,79,81](**Class IIb, Level C**).

In patients about to undergo surgical or diagnostic procedures that carry a risk of bleeding, if the INR is 2.0–3.0, oral anticoagulation may be safely discontinued for up to four days before and three days after the procedure. With expert management, most potentially hemorrhagic dental procedures do not require cessation of anticoagulation if the INR is 2.0–3.0 (**Class IIa, Level B**).

Introduction

The past decade has witnessed major advances in the treatment of atrial fibrillation (AF). Following the seminal observations of Haissaguerre *et al*[1] who recognized the importance of the role of ectopic beats from the pulmonary veins (PVs) in the initiation of AF, percutaneous catheter ablation has evolved as a curative therapy and has been effective in maintaining sinus rhythm in patients with paroxysmal AF. The purpose of this chapter is to discuss the role of ablative therapy and those trials which compare ablation to pharmacologic therapy or to the "ablate and pace" strategy. Because of its necessarily invasive nature, a description is also given of reported complications and studies which have applied strategies to quantify and prevent them.

Advantages of rhythm control

The main advantage in maintaining sinus rhythm is the relief of symptoms. A significant number of patients with AF complain of palpitations, dizziness, fatigue or dyspnea. Contributory factors include lack of atrial contraction, a rapid ventricular rate, an irregular ventricular rhythm and a reduced cardiac output. In patients with poor ventricular rate control in atrial fibrillation, symptoms of congestive heart failure may result from tachycardia-mediated cardiomyopathy.

In patients with valvular disease (for example, mitral stenosis) or those with a less compliant left ventricle (for example, those with left ventricular hypertrophy), the absence of co-ordinated atrial mechanical activity may result in a reduction in ventricular preload and a consequent reduction in cardiac output. The more rapid heart rates further impair ventricular filling by shortening diastolic filling time. Even in patients with controlled ventricular rates, irregular R-R intervals are associated with a 15% reduction in cardiac output.[2] Effective rhythm control thus aims to restore normal atrial function, increase ventricular preload and slow the ventricular rate, thereby enhancing cardiac output. These improvements in hemodynamics lead to increased exercise tolerance.[3] Other benefits of the maintenance of sinus rhythm include avoidance of tachycardia-induced cardiomyopathy,[4] a possible reduction of embolic risk and a potential decrease in mortality.

A few large clinical trials have been published comparing treatment strategies for AF. In particular, the AF Follow-up Investigation of Rhythm Management (AFFIRM),[5] Rate Control versus Electrical cardioversion for AF (RACE)[6] and Strategies for Treatment of AF (STAF)[7] trials compared rate control and rhythm control approaches using antiarrhythmic drugs (AADs). For a full discussion of these trials see Chapter 35. Adopting an intention-to-treat analysis, these trials concluded that there was no mortality difference between the two approaches. Hence, for the type of patients enrolled, a rate control approach may be adequate treatment for AF when compared with a rhythm control strategy with AADs.

However, it would be incorrect to extrapolate that sinus rhythm offers no benefit over AF. The aforementioned trials were not comparisons of sinus rhythm with AF. They compared a rate control strategy to a pharmacologic rhythm control strategy with AADs which was only poorly effective. When the data in the AFFIRM trial were analyzed according to the patient's actual rhythm, the benefit of sinus rhythm over AF became apparent. In a subgroup analysis by Scott *et al*, the presence of sinus rhythm was one of the most powerful independent predictors of survival, along with the use of warfarin, even after adjustment for all other relevant clinical variables.[8] Patients in sinus rhythm were almost half as likely to die compared with those with AF (adjusted hazard ratio 0.53; 99% confidence interval (CI) 0.39–0.72; $P < 0.0001$). This benefit was offset

apparently by the use of AAD therapy, which may have increased the risk of death. Of note, these trials largely excluded highly symptomatic patients who might benefit most from sinus rhythm.

Inadequacy of non-ablative rhythm control

The failure of AFFIRM, RACE or STAF trials to show any difference between rate and rhythm control strategies is perhaps a testament to the ineffectiveness of the rhythm control strategies that were used. The main modalities for non-ablative rhythm control are AADs and device-based therapy. Meta-analysis of randomized trials looking at the efficacy of AADs showed that up to 32% of the placebo arm patients were in sinus rhythm, compared to 55% of the patients who were assigned to receive ADD therapy.[9]

Evidently, AADs do not reliably cure AF but serve to reduce the burden of AF in some patients. Even in patients who were able to maintain sinus rhythm while on AADs, debilitating side effects were not uncommon in the published trials. Of the AADs, amiodarone had the highest success rate in maintaining sinus rhythm. However, the side-effect profile of amiodarone led to its discontinuation in up to 30% of patients due to intolerable skin discoloration, pulmonary fibrosis, thyroid dysfunction, neurologic or ophthalmic disorders.[10]

Device-based therapy has demonstrated poor efficacy for the treatment of AF. Antitachycardia devices can deliver burst atrial pacing and may convert atrial tachycardia or atrial flutter to sinus rhythm but such rapid pacing usually fails to terminate AF.[11] Atrial defibrillators can terminate AF with a high success rate.[12] However, repeated shocks lead to patient discomfort, making this option intolerable for the majority of patients. Dual site and overdrive atrial pacing,[13] which were expected to be beneficial, have failed to demonstrate consistent reduction in AF burden or improvement in AF symptoms.

Another option for patients who have AF with ventricular rates that are uncontrolled despite maximum tolerated AV nodal blocking agents is the so-called "ablate and pace strategy." The PABA-CHF trial (Pulmonary vein antrum isolation vs AV Node ABlation with Bi-ventricular pacing for Atrial Fibrillation in Congestive Heart Failure), which is currently in press, compared such a strategy to pulmonary vein isolation. This trial is discussed below in the section on randomized controlled trials.

Catheter ablation of atrial fibrillation

Pulmonary vein isolation (PVI), or radiofrequency (RF) ablation for AF directly eliminates or isolates the initiating factors for AF and offers the possibility of a "cure" without

subjecting the patient to the side effects of AADs. It is well established that the pulmonary veins play a major role in triggering and maintaining AF. Haissaguerre *et al*[1,14] demonstrated that up to 94% of patients had triggers in one or more pulmonary vein (PV). Sites outside the pulmonary veins may trigger AF in 6–10% of patients.[15,16]

AF has also been reported to be maintained by micro re-entrant circuits ("rotors") that exhibit high frequency and periodic activity, from which spiral wavefronts of activation radiate into the surrounding atrial tissue.[17] Of interest, the dominant rotors in AF are localized primarily in the pulmonary vein-left atrium (PV-LA) region.[18] Vagal inputs may also be important in both triggering and maintaining AF; many of these inputs are clustered close to the PV-LA junction.[19]

The primary goal of radiofrequency catheter ablation for AF is to electrically disconnect the PVs from the rest of the atrium by ablating around the atrial aspect of the veins. Most centers worldwide, regardless of further adjunctive ablation strategies, recognize that PVI is of the foremost importance in AF ablation. The inhomogeneity of left atrial and LA antral anatomy poses significant challenges in PV isolation. The PV is a "funnel-shaped" structure with a large proximal end, known as the antrum. The antrum of each PV blends into the posterior wall of the LA. In order to maximize success and minimize the complication of PV stenosis it is advisable for ablation to be performed around the entire antrum at the posterior left atrial wall.

Most centers performing AF ablation are ablating at the PV antrum and not at the true PV ostium, thus minimizing the risk of PV stenosis. Different centers may refer to ablation at the antrum by various names such as LA catheter ablation, circumferential PV antrum isolation or extraostial isolation. The lesion sets produced by these various approaches are very similar. A typical PV isolation RF ablation lesion set is shown in Plate 38.1.

Randomized controlled trials of catheter ablation for atrial fibrillation

There are five published randomized controlled trials comparing RF ablation with pharmacologic treatment. The sixth published randomized controlled trial compared ablation with no other treatment after patients had undergone prior treatment with amiodarone and direct current (DC) cardioversion. These six published trials are summarized in Table 38.1. Another trial was presented in 2006 but is not yet published. One further trial (in press) compared outcomes in patients with refractory AF who underwent ablation with those who underwent an "ablate and BiV-pace" procedure. At least four further multicenter, randomized trials are in the recruitment stages: AATAC-HF (Ablation v Amiodarone for Treatment of Atrial Fibrilla-

tion in patients with Congestive Heart Failure and an implanted ICD/CRTD), CASTLE-AF (Catheter Ablation versus STandard conventional treatment in heart failure patients with Left ventricular dysfunction and Atrial Fibrillation), RAAFT-2 (first line Radiofrequency Ablation versus Antiarrhythmic drugs for Atrial Fibrillation Treatment) and CABANA (Catheter ABlation versus ANtiarrhythmic drug therapy for Atrial Fibrillation – pilot trial).

In a study published in 2003, Krittayaphong et al[20] reported on 30 patients with long-standing AF who did not respond satisfactorily to drug treatment. These patients were randomized to treatment with amiodarone (n = 15) or RF ablation (n = 15) and were followed up for 1 year. In the ablation arm, the patients underwent PVI and further ablation in the right atrium. The study reported that freedom from AF was better in the RF ablation group (78.6%) as compared to the amiodarone group (40%) (P = 0.018). There was also a difference in favor of the RF ablation group in terms of subjective measurements of symptoms relating to AF and quality of life. Amiodarone was not observed to have a significant effect on symptoms of AF or quality of life in this study. In the RF ablation group, one patient suffered a stroke. Amiodarone was associated with adverse effects in 47% of patients, necessitating discontinuation in one patient. The authors concluded that RF ablation was an effective alternative treatment in patients with long-standing AF refractory to medical therapy.

Wazni et al[21] studied 70 patients (RAAFT pilot study), 67 with paroxysmal and three with persistent AF. None of the included patients had previously been treated for AF; therefore each patient's allotted treatment was the first-line treatment for that individual. Patients were randomized to receive either PVI using RF ablation (n = 33) or antiarrhythmic drug treatment (n = 37), with a 1-year follow-up. At the end of 1-year follow-up, 63% of patients who received antiarrhythmic drugs had at least one recurrence of symptomatic AF compared with 13% of patients who received PVI (P < 0.001). There were significantly decreased hospitalization rates and improved quality of life measurements in the PVI group. In the antiarrhythmic drug group, the mean number of AF episodes decreased from 12 to six, after initiating therapy. In the ablation group there was one asymptomatic PV stenosis and no severe PV stenosis. There was no thromboembolic event in either group. There was a higher rate of documented bradycardia in the AAD group, occurring in 9% of patients. Overall, the authors concluded that PVI may be a feasible first-line approach for treating patients with symptomatic AF. This is the only published trial to date comparing outcomes in patients who were AAD naïve at the time of recruitment.

Stabile et al[22] (CACAF, Catheter Ablation for the Cure of Atrial Fibrillation study) studied 137 patients with both paroxysmal and persistent AF in whom treatment with AAD had already been unsuccessful. Patients were randomized to continue their current drug regimen (n = 69) or to continue medications and additionally undergo RF ablation (n = 68). RF ablation involved PVI, ablation of the cavotricuspid isthmus and ablation from the left inferior pulmonary vein to the mitral valve (mitral isthmus). The follow-up period was 13 months, including a 1-month blanking period. The primary endpoint of the study was the absence of any documented recurrence of atrial arrhythmia lasting >30s in the 1-year follow-up period, following the blanking period. After completion of follow-up, 91% of patients in the non-ablation group had at least one recurrence compared to 44% (P < 0.001) of patients in the ablation group. Of the recurrences in the ablation group, four patients developed an atrial flutter and 26 had recurrence of atrial fibrillation. The success observed in the ablation group must, of course, be viewed in terms of observed complications. In the ablation group there was a major complication rate of 4.4%. Complications were due to a stroke in one patient, a pericardial effusion requiring pericardiocentesis in one patient and transient diaphragmatic paralysis in one further patient. No pulmonary vein stenosis was reported. In the AAD group one patient suffered sudden death, one patient had a transient ischemic attack and two died from cancer. Comparing the median per patient number of hospitalizations in the 1 year of follow-up between the two groups, no statistically significant difference was observed between the ablation and control groups. It was concluded that ablation therapy combined with antiarrhythmic drug therapy is superior to antiarrhythmic drug therapy alone in preventing atrial arrhythmia recurrences in patients with paroxysmal or persistent AF in whom antiarrhythmic drug therapy had already failed.

Pappone et al[23] (APAF, Ablation for Paroxysmal Atrial Fibrillation trial) randomized 198 patients with paroxysmal AF who had previously failed AAD therapy. The patients included in this study had a longer history of paroxysmal AF with a mean of 6 ± 5 years. These patients were randomized to circumferential PV ablation (n = 99) or to medical treatment (n = 99) with the maximum tolerated dose of amiodarone, flecainide or sotalol, either as single drug or in combination. Analysis was performed according to the intention-to-treat principle. Of note, 42 of 99 patients who were randomized to drug treatment crossed over and received catheter ablation, which was permitted under the study protocol after 3 months of therapy. All patients received warfarin and were followed for 12 months. In the RF ablation group, a repeat ablation was performed in 9% of patients; this was for atrial tachycardia (3%) and AF (6%). At the completion of follow-up, 86% of patients in the RF ablation group and 22% in the AAD group who did not require a second AAD were free from recurrent AF or atrial tachycardia (P < 0.001). Amiodarone was, overall,

administered to 61 patients in the group, either alone or in combination with flecainide. Based on intention-to-treat analysis, after 1 year of follow-up, 93% of the RF ablation group and 35% of the AAD group were free of all atrial tachyarrhythmias ($P < 0.01$). However, there was a high rate of crossover from the AAD arm to the RF ablation arm, with 42% of patients crossing over to the RF ablation arm. One transient ischemic attack and one pericardial effusion occurred in the RF ablation group. Side effects leading to drug withdrawal were observed in 23 patients in the AAD group; they included thyroid dysfunction (seven patients receiving amiodarone), 1:1 atrial flutter or a wide complex tachycardia (three patients receiving flecainide), and sexual dysfunction (11 patients receiving sotalol). The authors concluded that RF ablation was more successful than AADs for prevention of paroxysmal AF, with an observed low complication rate in the RF ablation group.

Oral et al[24] reported on 146 patients with persistent AF who were randomized to either RF ablation or medical management. The study was designed such that all patients, regardless of randomized group, received amiodarone for the initial 6 weeks after recruitment. Patients assigned to RF ablation then underwent PVI and had amiodarone continued for a further 3 months following ablation. Patients in the control group, who did not convert to SR on amiodarone therapy, underwent up to two direct current cardioversions in the first 3 months and continued amiodarone for 3 months following cardioversion. Those who reverted to AF after this time in the control group were permitted to resume therapy with amiodarone or cross over to RF ablation. Analysis was by the intention-to-treat principle. There were 77 patients included in the RF ablation arm and 69 in the control arm. A second ablation procedure was performed in 32% of patients in the RF group because of recurrence of AF (26%) or emergence of an atypical atrial flutter (6%) following the initial RF ablation procedure. By the intention-to-treat analysis at the end of 1-year follow-up, 74% of patients in the RF ablation group and 58% of those in the non-ablation group were free of atrial tachyarrhythmias in the absence of AAD therapy. There was, however, a very high crossover rate observed. Of the 69 patients in the non-ablation group, 77% (53 patients) crossed over to undergo RF ablation for recurrent AF within 1 year. Of those in the control group who were not on AAD therapy or did not undergo RF ablation at the end of 1 year, only 4% were in sinus rhythm. The authors reported no observed procedure- or AAD-related complications, with the exception of the 6% of patients who developed atrial flutter following RF ablation. The authors concluded that RF ablation offers a good strategy for maintenance of sinus rhythm for the majority of patients with symptomatic persistent AF, independent of long-term AAD use.

The results of these six trials were pooled in a recent meta-analysis,[25] giving a total of 578 randomized patients.

This analysis has to be viewed with the knowledge that there was heterogeneity in patients included, AF patterns and treatment strategies among the different published trials. Nonetheless, it was observed that compared to presence or absence of AAD therapy, RF ablation was more effective in preventing AF recurrence. Following 1-year follow-up, AF was present in 72 of the 291 patients (25%) who underwent RF ablation. This compared to 193 of 287 patients (67%) in those who were not assigned to undergo RF ablation. It is noteworthy that RF ablation was the better treatment in all six studies, whether they included patients with paroxysmal, persistent or "permanent" atrial fibrillation. Also, RF ablation resulted in better rates of sinus rhythm at 1 year in those patients who had previously failed AAD and in those who had not undergone prior treatment with AAD therapy.

Another trial, the Ablation versus AntiArrhythmic drugs for Atrial fibrillation [A4] trial, was presented in 2006.[26] This multicenter, international trial randomized 59 patients to AAD therapy and 53 patients to RF ablation, after having failed treatment with at least one class I or class III AAD. All patients had symptomatic paroxysmal AF of at least 6 months' duration. Follow-up entailed ambulatory ECG monitoring at 2, 3, 6 and 12 months, as well as monitoring for patient symptoms. The primary endpoint of this study was recurrence of AF of a duration greater than 3 minutes, after a 3-month blanking period from initiation of AAD therapy or ablation. After 3 months, crossover was permitted and in fact 37 patients in the AAD arm crossed over to the RF arm by the end of the study. Repeat ablation and multiple AAD trials were permitted in the first 3 months. Patients randomized to the ablation arm underwent a mean of 1.8 ablations. At the completion of the study, after 1 year of follow-up, 75% of patients in the RF ablation group and 7% of patients in the AAD therapy group were free of atrial arrhythmia. The best outcomes in the AAD group were observed in those patients who received amiodarone for the first time, with 25% being free of AF at 1 year. This still was inferior to the observed results in the RF ablation group. Complications referable to RF ablation included cardiac tamponade (n = 2), pulmonary vein stenosis (n = 1), and groin hematomas (n = 2). In patients treated with AADs, one patient developed hyperthyroidism and one died unrelated to therapy, due to cancer. This trial, in similarity to the published trials, supported the use of RF ablation for patients with symptomatic AF over the use of AADs.

Another strategy (the "ablate and pace" strategy) has been used in patients with symptomatic AF in whom it has not been possible to control ventricular rates. The procedure involves ablation of the AV junction and implantation of a pacemaker, thus avoiding rapid ventricular rates in atrial fibrillation. This historically has involved implantation of a right ventricular pacemaker lead with or without

(for patients with "permanent" atrial fibrillation) implantation of an atrial lead. Such patients, following successful AV junction ablation, will become pacemaker dependent with chronic right ventricular pacing. This can have a deleterious effect; in patients in SR this has been shown to increase the likelihood of hospitalization for heart failure and death.[27]

The OPSITE trial (Optimal Pacing SITE) examined the role of RV, LV and BiV pacing in patients who had undergone AV junction ablation for permanent AF after failure of drug treatment.[28] The primary endpoints were exercise capacity and quality of life. Compared to RV pacing, this study demonstrated no significant improvement with LV-only pacing and a modest improvement with BiV pacing.

Subsequent to this, the PAVE trial (left ventricular-based cardiac stimulation Post AV nodal Ablation Evaluation) was published by Doshi et al.[29] This was a prospective, randomized, multicenter, patient-blinded trial comparing RV pacing with BiV pacing in patients who had undergone AV junction ablation for persistent AF which was refractory to medical management. The primary endpoints were change in quality of life, change in the 6-minute walk test and change in LV ejection fraction (LVEF) at the end of 6 months' follow-up. At the end of the study there was no significant difference in quality of life, but there were modest but significant differences in LVEF and 6-minute walk distance. The largest benefit in terms of change in the 6-minute walk distance was observed in patients who had pre-existing LVEF <45% or NYHA class II–III symptoms as compared to those with normal LVEF or NYHA class I symptoms.

Following publication of these trials, the question arose as to whether RF ablation for AF (PVI) would prove superior to the best available "ablate and pace" strategy in patients with pre-existing heart failure and LV systolic dysfunction. The PABA-CHF trial was a prospective, international multicenter study which included patients with systolic heart failure (LVEF ≤ 40% and NYHA class II–III) and symptomatic AF which had proven to be drug unresponsive. Patients with both paroxysmal and persistent AF were included and were then randomized to undergo either PVI or AV junction ablation with biventricular pacing (AVJA-BiV). Patients in the PVI group who were still in AF at 3 months underwent a further RF ablation procedure. Patients were followed up over 6 months with clinical measurements, echocardiograms and monitoring for both symptomatic and asymptomatic episodes of AF recurrence. The primary endpoint was a composite of LVEF, 6-minute walk distance and the Minnesota Living with Heart Failure (MLWHF) score at 6 months.[30]

Of the 81 patients included, 41 underwent PVI (49% paroxysmal), 40 underwent AVJA-BiV (54% paroxysmal) and follow-up data were available on all. The trial reached its primary composite endpoint favoring the PVI group as compared to the AVJA-BiV group. There were improvements favoring the PVI group in the prespecified composites at 6 months, including the MLWHF score (61 v 79, $P < 0.0001$), longer 6-minute walk distances (340 v 297 m, $P = 0.0002$) and higher LVEF (35% v 28%, $P = 0.0001$). After 6 months of follow-up of patients who had undergone PVI, 88% were free of AF while maintained on AADs and 71% were free of AF without AAD therapy. Other relative measures of improvement in the PVI group, as compared to the AVJA-BiV group, included improvement in LA size (4.5 v 4.9 cm, $P = 0.003$) and less progression of AF severity (0% v 32%, $P < 0.0001$). There were no major complications or mortalities in either group. In the RF ablation group, there were three groin hematomas, one pericardial effusion, two asymptomatic mild PV stenoses and one incidence of pulmonary edema. In the AVJA-BiV group there were two cases of generator pocket hematoma, one pneumothorax, two LV lead dislodgments and two cases of high LV lead capture thresholds at follow-up. The authors concluded that, in patients with heart failure and depressed LVEF who have atrial fibrillation, treatment with PVI as compared to AVJA-BiV resulted in improvements in quality of life (as measured by the MLWHF tool), 6-minute walk test, LVEF and LA dimensions. This was achieved without the inherent pacemaker dependence which follows AV junction ablation. The PABA-CHF study adds support to the use of PVI for systolic heart failure patients with drug-refractory AF.

Non-randomized trials of atrial fibrillation ablation in patient subgroups

Apart from the PABA-CHF trial, there are no randomized trials in the cardiomyopathy subpopulations of patients with AF. However, there are some published data which do offer some insight and are at least hypothesis generating. In patients with congestive heart failure, studies have been published which suggest that PVI has a positive effect on LVEF, with an improvement from 42 ± 9% to 56 ± 8% observed in one study.[31] Tondo et al also noted significant improvement in LVEF (from 33 ± 2% to 47 ± 3%) following RF ablation for AF.[32] Significant improvements in quality of life measures were observed in another study as reported by Chen et al.[33] A non-significant improvement in LVEF was observed in this study. Hsu et al first reported significant improvements in LVEF (of 21 ± 13%), symptoms, quality of life measures and exercise capacity in patients with congestive heart failure and documented depressed LV systolic function.[34] Similar findings have also been reported in a smaller study[35] (Table 38.1).

Another well-recognized group of patients who are susceptible to the development of AF are those with hypertrophic cardiomyopathy (HCM). Medical treatment of AF in

Table 38.1 Randomized controlled trials of ablation

Trial	AF type	Prior AAD treatment	Number of patients	RF ablation patients	Control patients	Control	Follow-up (months)	AF free RFA (%)	AF free control (%)	P value
Krittayaphong et al[20]	Persistent	Yes	30	15	15	AAD	12	78.6	40	0.018
Wazni et al[21]*	Paroxysmal	No	70	33	37	AAD	12	87	13	<0.001
Stabile et al[22]**	All	Yes	137	68	69	AAD	13	55.9	8.7	<0.001
Pappone et al[23]	Paroxysmal	Yes	198	99	99	AAD	12	93	35	<0.01
Oral et al[24]***	Persistent	Yes	146	77	69	AAD/none	12	74	58	0.05

*There were 63 patients with paroxysmal AF and 3 with persistent AF.

**Patients in the RF group also continued AAD treatment throughout the study.

***Crossover to RF from the control arm was permitted after 3 months. There was a high rate of crossover; 77% of patients crossed over by the end of the study. The tabulated results are an intention-to-treat analysis. In the control arm, 3 (4%) patients were in SR in the absence of AAD therapy or RF ablation.

****Crossover to RF from the control arm was permitted after 3 months.

AF, atrial fibrillation; AAD, antiarrhythmic drug (see text for details); RF, radiofrequency.

this population can be quite difficult. Again, no randomized data are available in this subpopulation but results of two studies suggest a promising role for catheter ablation in this group of patients. It is not surprising that the reported success rates are not as high as those reported in patients without HCM. In one series of 27 patients with HCM undergoing RF ablation for AF, a success rate of 70% was observed, seven of the patients having required a second ablation procedure.[36] Another study, in 33 patients, observed a success rate of 62% in returning patients to SR following RF ablation in patients with AF and HCM.[37]

All of these studies have several limitations including the small sample size, the enrollment of selected groups of patients, being performed either in a single center or in institutions with highly experienced operators. In addition, many of the consecutive series originated from centers with exceptional experience and the observed success and complication rates might not reflect what could be achieved in less specialized institutions.

Complications of catheter ablation of atrial fibrillation

Extensive ablation within the atria coupled with instrumentation with various catheters in the setting of aggressive anticoagulation during RF ablation sets the stage for potential complications. Nonetheless, overall complication rates are relatively low. A variety of these complications have been reported. While the majority occurred during or within 48 hours of the procedure, some are known to have an insidious course with a relatively late presentation. This

section reviews the published literature on these complications so that they can be prevented or diagnosed accurately and treated appropriately if they do occur.

Cerebrovascular events

The incidence of thromboembolism in AF ablation ranges from 0.5% to 2.8%.[38] A worldwide survey reported cerebral thromboembolism in 67 patients (20 strokes and 47 transient ischemic attacks) out of 7154 patients who underwent left atrial instrumentation for ablation of AF.[39] Prevention remains the best strategy for reducing thromboembolic events during AF ablation. Continuation of warfarin in its therapeutic range throughout the periprocedural period has recently proved to be a safe alternative to bridging with enoxaparin or heparin, which have been demonstrated to increase the risk of procedure-related bleeding.[40]

PV stenosis

The incidence of PV stenosis, defined as >70% narrowing, was reported to occur in 3.4% of patients in one series.[41] The pathogenesis of PV stenosis is probably due to initial ablation too close to the true PV ostium, which precipitates a healing reaction culminating in proliferation of the elastic lamina/intima. The incidence of PV stenosis has decreased as a result of PV isolation at the antrum, which is a considerable distance from the true PV ostia. With this technique in one study, the incidence of PV stenosis was found to be 0.9% (16 out of 1780 patients).[42] The clinical presentation of these patients was variable and included no symptoms, mild dyspnea to severe dyspnea with hemoptysis, fever, and pleuritic chest pain. An algorithm was devised to cal-

culate the cumulative stenosis index (CSI) which is the sum of percentage stenosis of the ipsilateral veins divided by the total number of ipsilateral veins. The study concluded that patients with a CSI ≥75% and a relative lung perfusion of ≤25% have the greatest risk of severe symptoms and lung diseases. In these patients, early and, when required, repeated PV intervention (with venoplasty and/or stenting) should be considered for improvement of pulmonary blood flow and prevention of associated lung disease.

Esophageal injury and fistula

The posterior wall of the LA is adjacent to the esophagus. RF ablation procedures may substantially elevate the temperature at the LA–esophageal interface and may be observed within the esophageal lumen.[43] Atrio-esophageal fistulas may then result from thermal injury leading to tissue necrosis and fistula formation between the posterior LA and esophagus. A report of three patients with this complication after percutaneous RF ablation in experienced centers was published in 2004 [44,45]

Via an anonymous volunteer reporting method, a series of nine patients who had this complication was later reported.[46] A variety of clinical presentations occurred within 2 weeks of the ablation procedures, including neurologic findings consistent with multiple embolic strokes (with intravascular gas on CT), endocarditis, chest pain associated with ST segment elevation, and gastrointestinal bleeding. All nine patients developed septic shock and died; autopsy confirmed the presence of atrio-esophageal fistula.

Although the incidence of atrio-esophageal fistula is rare, it is almost always fatal. Recently, a case of successful temporary esophageal stenting to seal off an esophageal perforation following LA catheter ablation was reported.[47]

Continuous monitoring of esophageal temperature may be an option to enhance safety during posterior LA wall ablation. Alternative strategies in avoiding esophageal injury during AF ablation include empirically decreasing the power delivered and duration of lesions when ablating on the posterior LA wall, pre-procedure ingestion of Gastrograffin dye, tagging the esophagus on a three-dimensional electroanatomic mapping system and merging a three-dimensional recreated image of the esophagus with an electroanatomic map of the LA.

Organized atrial tachyarrhythmias

Organized left atrial tachyarrhythmia (OLAT) following segmental or wide area circumferential PVI and LA circumferential ablation with additional linear ablation has been variably reported as ranging from 2.5% to 27%. The mechanism of these OLATs has been described as macro re-entry, micro re-entry and "focal." The macro re-entry OLATs are most often due to re-entry mediated by gaps in linear ablation lines. Such a gap functions as a slowly conducting isthmus in the re-entry circuit, commonly located at the LA roof, posterior wall or mitral isthmus.

These macro re-entry OLATs are often symptomatic, necessitating a repeat ablation. On the other hand, focal OLATs typically originate from PV ostial or antral regions that have partially recovered conduction to the LA. Of note, centers that adopt a strategy of wide area circumferential PV ablation and linear LA ablations[48,49] appear to experience an increased prevalence of OLATs. This demonstrates that the inability to create contiguous linear lesions and/or recovery of partial conduction along such lesions can be proarrhythmic. An example of an OLAT (later shown to be due to macro re-entry) and the electroanatomic map are shown in Figure 38.1 and Plates 38.2 and 38.3.
Figure 38.1 Atypical flutter in a patient following previous RF ablation for atrial fibrillation. A 12-lead ECG of a patient who was highly symptomatic of an atypical atrial flutter which occurred months following a PVI procedure.

Phrenic nerve injury

During RF ablation for AF, phrenic nerve (PN) injury may occur when isolating the superior vena cava (SVC) from the right atrium or the right superior pulmonary vein from the left atrium. A series of 17 patients who sustained PN injury following catheter ablation or AF, inappropriate sinus tachycardia or ventricular tachycardia with a variety of energy sources including RF ablation (13 patients), cryo-ablation (one patient), ultrasound balloon ablation (two patients) and laser balloon ablation (one patient) has been reported.[50] All patients recovered within a median time of 6 months.

Needless to say, the most effective way to prevent PNI is to deliver RF energy away from the PN. Too close a proximity to the PN can be demonstrated by high-output pacing at the proposed region of ablation where PN capture occurs. Ablation at these regions is not advisable. Preablation pacing at the level of the PV antrum (as far as feasible from the PV ostia) or the SVC–RA junction when performing isolation of these veins for AF could represent a potential strategy to minimize the risk of PN injury. A novel method of protecting the PN during epicardial catheter ablation, by using a balloon catheter in the pericardial space to mechanically separate the left PN from the ablation catheter, has been recently reported.[51] Early recognition of transient PN injury by fluoroscopy during RF ablation may result in fewer cases of persistent injury.

Other complications

Other complications include air embolism, cardiac tamponade, mitral valve damage and rare instances of acute pyloric spasm and gastric hypomotility observed following posterior LA lesions.[52] In summary, the short-term safety with newer ablation techniques has improved, but serious and potentially life-threatening complications persist.

Conclusion

Ablation of atrial fibrillation is appropriate in symptomatic patients who have failed medical therapy (**Class I, Level A**).

Ablation of atrial fibrillation should be considered in patients with congestive heart failure who are unresponsive to AAD (**Class I, Level B**). The benefits of ablation of atrial fibrillation in congestive heart failure have been demonstrated by one randomized trial and several consecutive series.

Ablation of atrial fibrillation may be considered for first-line therapy in patients with recurrent atrial fibrillation (**Class IIb, Level B**).

Several larger ongoing trials are comparing AAD therapy with ablation for AF (AATAC-HF, CASTLE-AF, RAAFT-2 and CABANA trials). These studies will be important in deciding whether catheter ablation for AF can be adopted as a reasonable first-line strategy compared to the current strategy of initiating AAD, thus negating the inherent dangers associated with long-term AAD therapy. If the results of these trials concur with the pilot RAAFT study, ablation as first-line therapy may then become a Class I recommendation.

39 Supraventricular tachycardia

Erica D Penny-Peterson and Gerald V Naccarelli

Penn State University College of Medicine, Hershey, PA, USA

Introduction

Supraventricular arrhythmias encompass tachycardias that require atrial or atrioventricular (AV) nodal tissue for initiation and maintenance (Box 39.1). The duration of symptoms may be paroxysmal or incessant. Origins include atrial musculature, AV nodal tissue, sinus node and pulmonary veins.[1–4] There are several forms which can be categorized as AV node dependent or AV node independent (Box 39.2).

Paroxysmal supraventricular tachycardia (PSVT) is generally a narrow complex tachycardia that excludes atrial flutter, atrial fibrillation and multifocal atrial tachycardia. Its incidence is 35 per 100 000 persons and higher in females.[1,2] PSVTs associated with cardiovascular disease typically occur in older males and often originate in atrial tissue.[5] More than 50% of these patients also have associated atrial fibrillation.[6]

Typical symptoms from PSVT include palpitations, light-headedness, and chest pain. Overt syncope is rare.[1,7] However, some patients are minimally symptomatic. PSVTs are prognostically benign rhythms and often well tolerated. Hemodynamic compromise is uncommon but is more likely to occur in patients with significant structural heart disease. Incessant forms of PSVT can cause a tachycardia-mediated cardiomyopathy. Tachycardia-mediated cardiomyopathy can be reversed by either preventing the arrhythmia or control of the ventricular response either by pharmacologic or ablative treatments. Several studies have documented an improvement in left ventricular ejection fraction after catheter ablation in patients who had PSVT with rapid rates.[8,9]

SVT mechanisms include re-entry, automaticity, and triggered activity.[4,10] Automaticity is a disorder of impulse initiation. It occurs when the sinus node impulse is blocked or slowed. This allows ectopic pacemakers located in the atria, coronary sinus, pulmonary veins or AV junction to reach threshold and overdrive the sinus node. Impulse formation may also occur when the sinus node is exposed to excessive adrenergic stimulation or reduced vagal input, resulting in inappropriate sinus tachycardia.[11]

Rarely, SVTs may be secondary to triggered activity.[10] Triggered activity is a disorder of impulse conduction, mainly repolarization, in which the previous action potential or summation of action potentials creates depolarizing oscillations in the membrane potential. Early afterdepolarizations (EAD) occur during phase 2 or phase 3 of the action potential. Late or delayed afterdepolarizations (DAD) occur during phase 4 of the action potential. These afterdepolarizations are capable of reaching the membrane potential threshold and initiating a new action potential. An example of a triggered arrhythmia is non-paroxysmal atrial tachycardia with block secondary to digitalis toxicity.[12] Steinbeck *et al* demonstrated an increase in rate secondary to a shift of the dominant pacemaker cells to a group of cells near the sinoatrial border in rabbit atrial preparations exposed to ouabain, suggesting that these triggered foci are not in the SA node but in the perisinus atrium.[13] DAD is associated with calcium overload.

Re-entry is the most common mechanism for SVT.[1,2,4,10,14] Sixty percent of re-entry is AV nodal, 30% is atrioventricular re-entry, 10% is atrial or sinoatrial re-entry tachycardia. If the tachycardia is secondary to re-entry, initiation and termination of the tachycardia are reproducible with programmed electrical stimulation.[10]

History and physical examination are important and can give clues to mechanism and type of arrhythmia. If there is a gradual increase in rate with initiation or decrease with termination, automaticity is likely. Abrupt initiation and termination favor re-entry. An irregular rhythm may be more suggestive of atrial fibrillation, atrial flutter or multifocal atrial tachycardia.

Sinoatrial reentrant tachycardia	SANRT
Non-paroxysmal junctional tachycardia	NPJT
Junctional ectopic tachycardia	JET
Atrial fibrillation	AF
Atrial flutter	AFL
Multifocal atrial tachycardia	MAT

BOX 39.2 Classification of supraventricular tachycardias

AV node independent
- Sinus tachycardia
- Inappropriate sinus tachycardia
- Sinus node re-entrant tachycardia
- Atrial tachycardia
- Atrial flutter
- Atrial fibrillation
- Multifocal atrial tachycardia
- Junctional ectopic tachycardia

AV node dependent
- Slow-fast AVNRT
- Fast-slow AVNRT
- Orthodromic AVRT (WPW)
- Antidromic AVRT (WPW) – pre-existed
- PJRT (slow conducting CBT)

QRS (PR or RP) are helpful in making a more specific diagnosis and allow the diagnosis of atrioventricular nodal re-entrant tachycardia (AVNRT) or atrioventricular re-entrant tachycardia (AVRT) in 80–85% of cases.[15] Once the rhythm has been terminated, the tachycardia should be compared to a resting 12-lead electrocardiogram. However, 20% of ECG interpretations may incorrectly characterize PSVT. Therefore, a 12-lead ECG should not be the sole diagnostic test to determine mechanism.[16]

Vagal maneuvers such as Valsalva, the diving reflex, breath holding, and carotid sinus massage can be helpful in terminating tachycardia or in revealing clues to the etiology of the arrhythmia (**Class I, Level B**).[1,16] Intravenous adenosine can also be used to aid in the diagnosis. AVNRT and AVRT are excluded if tachycardia persists with block in the AV node. If the tachycardia is not terminated by vagal maneuvers and IV adenosine, the most likely etiology is an AV node-independent tachycardia. Intravenous AV node blocking agents, such as IV verapamil or diltiazem, may be attempted if adenosine fails to help therapeutically and/or clarify the mechanistic diagnosis.

An echocardiogram may be useful if there is a suspicion of structural heart disease. Findings are useful in determining if patients can be treated with class IC agents or help in defining anatomy and/or congenital defects in patients prior to an ablation procedure.[1,7] Thyroid function and electrolytes should be evaluated. Electrophysiology study is helpful in patients in whom the mechanism and etiology cannot be determined with the above information and also in those patients with a history of tachycardia but no documented tachycardia on 12-lead ECG or Holter monitor. Patients with continued symptoms despite AV nodal blocking agents and those who desire to maintain normal rhythm with an antiarrhythmic agent are appropriate to refer for an electrophysiology study. Patients with hemodynamically unstable SVT, patients who do not wish to take medications but are interested in invasive catheter ablation, patients with evidence of pre-excitation, and those with a wide complex tachycardia requiring differentiation of SVT from VT are also candidates for an electrophysiology study.[1–3]

Acute management of SVT focuses on termination or conversion of SVT to sinus rhythm or control of ventricular rate. Intravenous L-type calcium channel antagonists have proven efficacious for acute management of narrow complex hemodynamically stable SVT[1,17–20] (**Class I, Level A**). Verapamil and diltiazem are calcium channel antagonists which slow or depress the effects of sinus node and AVN function by inhibiting membrane transport of calcium. Sung *et al* studied the conversion rate of SVT to sinus rhythm in 20 patients with re-entrant SVT randomized to verapamil or placebo. Fifteen of 19 patients converted to sinus versus 1/16 patients with placebo.[18] Waxman *et al* confirmed in a double-blind randomized trial that IV low- and high-dose verapamil were superior to placebo in slowing the ventricular rate and converting PSVT to sinus rhythm.[19] The IV Diltiazem Study Group determined that the conversion rate by IV diltiazem (0.05 mg/kg) was 84%. The limitation of diltiazem and verapamil therapy is hypotension.[20]

Adenosine is an alpha-1 receptor inhibitor in cardiac muscle cells. It prevents the influx of calcium into the cell and thus depresses conduction of the SA node and AVN.[21] It has been proven through double-blind randomized placebo-controlled trials to be as efficacious and safe as verapamil.[22,23] Glatter *et al* evaluated 229 patients with SVT during an electrophysiology study and determined that the rate of conversion to sinus rhythm with adenosine was 85% for AVRT and 86% for AVNRT.[22] This is comparable to the conversion rate with verapamil.[20] DiMarco *et al* evaluated the efficacy and safety of adenosine in two prospective, randomized trials. Results of this study determined that the rate of adverse events/side effects was 36%, were typically mild and lasted less than 1 minute. Also, when compared to verapamil, time to termination was much faster,

occurring in 30 seconds.[23] Adenosine is an effective treatment for the acute termination of narrow complex SVT (**Class I, Level A**).[1] However, recurrence rate of SVT after adenosine was found to be 57% within 5 minutes of adenosine.[24]

There are no large randomized double-blinded placebo-controlled trials evaluating the efficacy and safety of selective beta-1 adrenergic blockers, digoxin or amiodarone (**Class IIb, Level C**).[1] Evidence is based on small clinical trials, expert opinion and clinical experience. Intravenous esmolol and metoprolol were proven to decrease ventricular rate by 15% in patients with SVT.[25,26] Patients were also able to be switched to oral digoxin, propranolol, verapamil, metoprolol and quinidine successfully without losing therapeutic effect.[25] Short-term intravenous amiodarone has a high rate of conversion of SVT to sinus rhythm with low risk of toxicity.[27,28] Vietti-Ramus *et al* demonstrated that high-dose IV amiodarone had an 88% conversion rate and 100% conversion if atrial flutter and atrial fibrillation were excluded. Time to conversion was between 30 minutes and up to 20 hours.[27] Given safer and better options as noted above, intravenous amiodarone for acute symptoms of SVT is a **Class IIb, Level C** recommendation.[1]

The goals of long-term management of PSVT are arrhythmia suppression or significant decrease in frequency and duration of symptomatic episodes. If PSVT recurrence rates are high, long-term management with an antiarrhythmic or catheter-based ablation should be considered. Flecainide is a class IC antiarrhythmic that is proven efficacious and safe in the treatment of PSVT (**Class IIa, Level B**). Henthorn *et al* performed a double-blind placebo-controlled trial evaluating time to first recurrence in 34 patients with PSVT.[29] The time to first recurrence in the flecainide group was 55 days compared to 11 days with placebo. Freedom from symptoms during 60 days was 70% of the flecainide group and 15% of the placebo group. Anderson *et al* performed a similar double-blind placebo-controlled trial evaluating chronic therapy with flecainide to increase the time to recurrent SVT.[30] Of patients on flecainide, 82% were symptom free versus 24% on placebo. There were no proarrhythmic events or deaths during treatment with flecainide. In a multicenter trial evaluating the safety and efficacy of oral flecainide (100–200 mg bid), 87% of patients improved symptomatically.[31] Minor subjective side effects such as headache, dizziness and abnormal vision occurred but these were rarely severe enough to necessitate discontinuation of flecainide.

Propafenone, a class IC agent with beta-adrenergic blocker properties, has also been proven efficacious and safe in the long-term management of PSVT[1,32] (**Class IIa, Level B**). A 6-month randomized placebo-controlled trial evaluating recurrence rates after treatment with 300 mg tid, 300 mg bid, and 150 mg bid of propafenone compared with placebo revealed that the recurrence rate in the propafe-

none group was one-fifth of that seen in the placebo group.[33] In the UK Propafenone PSVT Study Group, 100 patients with PSVT, paroxysmal atrial fibrillation or atrial flutter were evaluated comparing propafenone 300 mg bid or tid and placebo. This therapy was proven efficacious and safe for the prophylaxis of recurrent PSVT. Patients who could tolerate higher doses of propafenone had a trend towards fewer episodes compared to when treated with lower doses.[34]

Multiple class III antiarrhythmics have been evaluated in the long-term treatment of PSVT. A multicenter randomized, double-blind placebo-controlled trial has been performed with sotalol to evaluate its efficacy and safety (**Class IIa, Level C**). Recurrent SVT was less frequent in the sotalol group versus placebo. There were no adverse events of cardiac death, heart failure or proarrhythmia in patients receiving either 160 mg or 80 mg bid.[35]

Amiodarone was assessed in 121 patients with atrial tachyarrhythmias refractory to digoxin, beta-blockers, and other antiarrhythmics over 27 months and 81% did not have recurrent episodes.[36] Amiodarone was discontinued in 6% because of adverse side effects.[36] Therefore, amiodarone can be used as long-term management of PSVT for pharmacologic control but is generally not used due to long-term end-organ toxicity (**Class IIa, Level C**).

The efficacy of dofetilide was compared to propafenone and placebo in 122 patients over 6 months. The endpoints were episode-free periods and reduction in the frequency of symptomatic PSVT, assessed using diaries and event recorders. Episode-free rates were 50% in the dofetilide group, 54% in the propafenone group and 6% in the placebo group.[37] The results of this study confirmed that dofetilide, a class III antiarrhythmic agent, was as efficacious as propafenone in preventing recurrence and in decreasing frequency of PSVT (**Class IIa, Level C**). Although an effective alternative, the use of dofetilide is usually limited to the treatment of AF/atrial flutter due to its proarrhythmia potential (**Class IIa, Level C**).

The pill-in-the-pocket method has been evaluated in the management of PSVT that occurs infrequently.[38] This approach can effectively terminate SVT and reduce hospitalizations and cost of care. Alboni *et al* evaluated the conversion rate within 2 hours and the safety profile of a single oral dose of flecainide, diltiazem and propranolol, and placebo in 33 patients with inducible SVT during electrophysiology studies.[39] The conversion rate was 52% for placebo, 61% with flecainide and 94% with combination diltiazem and propranolol.[39] Patients were discharged on the most effective medication for conversion based on results of electrophysiology study. At 1 year, the rate of emergency room consultation decreased from 100% at baseline to 9%. Adverse events included hypotension, bradycardia and an episode of syncope.[39]

Catheter ablation for the treatment of PSVT is a first-line acceptable alternative to pharmacologic therapy in very symptomatic patients or in patients with high-risk professions seeking a definitive cure (**Class I, Level B**).[1,40] Cure rates for AVNRT and AVRT are greater than 95% with low risks of heart block, tamponade, and vascular complications.[7] Catheter ablation improves quality of life and reduces healthcare costs in symptomatic patients compared to pharmacologic management.[40]

Sinus tachycardia

Sinus tachycardia is usually a response to physiologic stimulus such as fever, infection, anemia, exercise, hypotension or pain and is corrected by treating the underlying etiology. Acute myocardial infarction is an indication to treat sinus tachycardia with medications (e.g. beta-blockers). Sinus tachycardia in this setting is consistent with higher 30-day mortality and poor outcomes.[41,42]

Inappropriate sinus tachycardia

Inappropriate or non-physiologic sinus tachycardia is a tachycardia out of proportion to metabolic demands.[1,4] The exact mechanism has not been well defined. It is hypothesized that there is abnormal automaticity, enhanced automaticity or an abnormal response to autonomic tone.[43,44] The prognosis is usually benign unless the tachycardia is rapid and incessant such that a tachycardia-mediated cardiomyopathy is induced. There are no randomized trials of treatment of inappropriate sinus tachycardia. Treatment is empiric and if the tachycardia is due to excessive sympathetic tone, beta-blockers may be helpful and are considered first-line treatment (**Class I, Level C**). Calcium antagonists have a more limited role (**Class IIa, Level C**).[45] If vagal suppression is the underlying etiology, heart rate control may be more difficult. Catheter ablation or modification of the sinus node has been performed but long-term success is limited and based only on several small studies (**Class IIb, Level C**).[46,47] Although heart rate is slower with modification, symptoms do not improve consistently. Common complications of sinus node ablation include the need for permanent pacemaker, phrenic nerve damage and trauma to the superior vena cava leading to superior vena cava syndrome.

Sinus node re-entry

Mapping during tachycardia demonstrates superior to inferior and right to left activation,[47,48] similar to normal sinus rhythm. Sinus node reentrant tachycardia terminates abruptly with vagal maneuvers and adenosine unlike physiologic and inappropriate sinus tachycardia. There are no randomized, double-blind placebo-controlled trials for the therapy of sinus node reentrant tachycardia. Patients are generally managed with beta-blockers or calcium channel antagonists (**Class I, Level C**). Catheter ablation can be used in patients with persistent symptoms despite medication, but complications such as phrenic nerve damage and intra-atrial block limit the use of this technique (**Class IIb, Level C**).[3,48,49]

Atrial tachycardia

In 2001 the Joint Expert Group from the Working Group on Arrhythmias of European Society of Cardiology and North American Society of Pacing and Electrophysiology classified atrial tachycardias according to mechanism and anatomy.[50] Focal and intra-atrial tachycardias have been described. Associated clinical scenarios in which atrial tachycardia may be sustained include acute myocardial infarction, infection, electrolyte abnormalities, hypoxia, and cardiac stimulants such as theophylline and cocaine.[1,4,51] Formerly, it was generally accepted that the mechanism of focal atrial tachycardia was enhanced automaticity, but three mechanisms are currently recognized (enhanced automaticity, triggered activity, and micro re-entry) and can be difficult to discriminate clinically. There is variable response to Valsalva maneuvers and adenosine.[11,52–54] In a study performed by Engelstein *et al*, adenosine was used to distinguish different mechanisms of atrial tachycardia during electrophysiologic study. There was no effect on intra-atrial re-entrant or macro re-entrant atrial tachycardias.[53] Triggered activity may respond to adenosine due to its ability to shorten the action potential and reduce the time available for early afterdepolarizations.[53] In automatic atrial tachycardias varying degrees of heart block may develop in response to adenosine. P-wave morphology may assist in locating the focus and planning of catheter ablation. Kristler *et al* developed an algorithm determining location of focal atrial tachycardias based on P-wave morphology.[55,56]

Acute treatment focuses on control of ventricular rate and management of symptoms. Atrial tachycardia is rarely terminated with adenosine (**Class IIa, Level C**).[52–54] Direct current cardioversion seldom terminates automatic focal atrial tachycardia but may terminate atrial tachycardia resulting from micro re-entry or triggered activity.[1,4] It is used in hemodynamically unstable atrial tachycardia (**Class I, Level B**). Clinical trials evaluating the efficacy and safety of pharmacologic agents in the acute treatment of atrial tachycardia are lacking. Guidelines are based on clinical experience. Intravenous verapamil (**Class IIa, Level C**) and beta-blockers (**Class I, Level C**) may be beneficial in cases where slow conduction is a critical component of the re-entry circuit or to control the ventricular rate through slowing of the AV node without affecting the atrial

rate.[57] Intravenous amiodarone may also be an alternative for rate control acutely, especially in patients with left ventricular dysfunction (**Class IIa, Level C**). Digoxin is typically not used acutely due to its delayed onset of action (**Class III, Level C**).

Long-term management is based on symptoms and prevention of tachycardia-induced cardiomyopathy.[58] Beta-blockers or non-dihydropyridine calcium channel antagonists may be beneficial for rate control (**Class I, Level C**).[19,25,26] Class IA, class IC, and class III agents may be used for suppression (**Class IIa, Level C**).[1,59,60] Flecainide achieves complete suppression in 56%, reduced symptoms or frequency in 8% and no response 36% of patients with either atrial tachycardia or atrial fibrillation.[59]

Catheter ablation may be attempted for recurrent symptoms or failed pharmacologic treatment (**Class I, Level B**).[61] The success rate is approximately 86% with an 8% recurrence. Complications are related to the origin of the tachycardia and the site of ablation.[1,2,61] Cardiac perforation can occur, ablating both right- and left-sided focal atrial tachycardias. Heart block is possible near areas of the septum and coronary sinus ostium.

Paroxysmal atrial tachycardia with AV block or variable conduction is classified as a focal tachycardia. Its mechanism is generally accepted as being triggered activity with characteristics similar to enhanced automaticity.[3,4] Paroxysmal atrial tachycardia is associated with acute pulmonary disease and digoxin toxicity.[3] Efforts at rhythm control with antiarrhythmics have been suboptimal. Treatment involves treating the underlying pathologic disease state, discontinuing digoxin and in rare instances giving digoxin antibody (Digibind).[1,62,63]

Intra-atrial re-entrant tachycardia, also known as re-entrant atrial tachycardia, is a macro re-entrant arrhythmia. It may be extremely difficult to differentiate between intra-atrial and focal atrial tachycardia without electrophysiologic techniques. Intra-atrial re-entrant tachycardia is the mechanism of 6% of atrial tachycardias referred to electrophysiology studies.[64] It is generally associated with structural heart disease and congenital heart disease with atrial surgical scars. The response to vagal maneuvers is approximately less than 25% due to reduced autonomic innervation of atrial tissue compared to the sinus and AV node.[16] The treatment is empiric based on case reports or small studies. Class IC agents may be attempted if the patient has no known structural heart disease. Amiodarone is an acceptable alternative because of its efficacy but is limited by its side-effect profile with long-term use. Calcium channel antagonists and beta-blockers (**Class I, Level C**) are useful for rate control but rarely resolve symptoms except in combination with a membrane-active antiarrhythmic.[1,3,4] Drug resistance, adverse effects of drugs and persistent symptoms are indications for catheter ablation

(**Class I, Level B**). There is a high recurrence rate with catheter ablation. Collins *et al* studied congenital heart disease patients with atrial arrhythmias and acute success rates with catheter ablation.[65]

Multifocal atrial tachycardia

Multifocal atrial tachycardia is described as an atrial tachycardia with variable PR intervals and at least three distinct P-wave morphologies.[3,66] The mechanism is thought to be either triggered activity or abnormal automaticity. Multifocal atrial tachycardia is seen in less than 1% of PSVT.[66] It is associated with chronically and severely ill patients. Disease states that are common to this arrhythmia are pulmonary disease, cardiac disease, and sepsis. More than 60% will have associated pulmonary disease which can be exacerbated by theophylline and beta-adrenergic agonists used in these patients.[67,68] Associated arrhythmias include atrial flutter, atrial fibrillation and atrial tachycardias.[69] The overall prognosis of a patient with multifocal atrial tachycardia is poor, with mortality rates of up to 30–60%.[69] Interestingly, death is usually not secondary to the arrhythmia but due to the underlying disease. Therapy is aimed at treating the underlying disease state.[1,66] However, ventricular rates of 150 and rarely over 200 may require treatment if causing significant symptoms or hemodynamic instability. Pharmacologic therapy is aimed at decreasing the ventricular rate with AV nodal blocking agents. Membrane-active antiarrhythmics and cardioversion tend to be less effective and recurrence of multifocal atrial tachycardia is common. Digoxin is not of proven efficacy and may increase the risk of paroxysmal atrial tachycardia with variable conduction because of digoxin toxicity.[69] Given the high rate of chronic obstructive lung disease, verapamil and diltiazem in a continuous intravenous infusion are commonly used to control ventricular rates.[70,71] The use of verapamil or diltiazem is limited by the occurrence of hypotension. Beta-blockers can also be used if tolerated.[72] Magnesium supplementation has also been studied.[73] Drug-resistant patients may be referred for radiofrequency ablation of the AV junction.[74,75] This is not curative but does decrease the ventricular response. Given the limited options, the best choice is treatment of the underlying disease state and control of ventricular rates as needed.[1,66]

Atrial flutter

Atrial flutter is a macro re-entrant atrial tachycardia typically associated with organic heart disease.[1] It is more common in males and the elderly, can co-exist with atrial fibrillation and is common after cardiac surgery.[1,6,50] Long-term sequelae may include tachycardia-mediated cardiomyopathy and thromboembolic events.[76]

In 2001 the Working Group on Arrhythmias of the European Society of Cardiology and North American Society of Pacing and Electrophysiology attempted to develop a standardized classification.[50] Typical atrial flutter is a macro re-entrant tachycardia circulating around the tricuspid annulus with an area of slow conduction in the cavotricuspid region. Therefore, these atrial flutters were designated as cavotricuspid-dependent atrial flutter and all others were designated as cavotricuspid-independent atrial flutter.[50] Vagal maneuvers or adenosine may be helpful to slow ventricular conduction through the AV node to reveal the flutter waves and exclude other forms of paroxysmal supraventricular tachycardias[1,16] (**Class I, Level C**).

Acute treatment is based on symptoms and hemodynamics of the patient.[1,76] If there is hemodynamic instability, emergency cardioversion is performed (**Class I, Level C**). Cardioversion in hemodynamically stable patients can be accomplished with direct current cardioversion with 50–100 J biphasic (**Class I, Level C**) or with ibutilide 1 mg over 10 minutes (**Class IIa, Level A**). Ibutilide has an acceptable rate of conversion to sinus rhythm of approximately 50–60%.[1,77–81] Stambler *et al* performed a multicenter randomized placebo-controlled trial evaluating the efficacy and safety of ibutilide in the conversion of atrial fibrillation and atrial flutter to sinus rhythm in 266 patients. The rate of conversion of atrial flutter was 63% and dosing regimens of ibutilide (1 mg × 2 or 1 mg and 0.5 mg) did not affect the efficacy.[77] Trials comparing ibutilide to other class III or class IC agents have proven it to be superior in pharmacologic conversion of atrial flutter to sinus rhythm.[79–81] Non-sustained polymorphic ventricular tachycardia and torsades de pointes requiring cardioversion may occur up to 4 hours post infusion with a reported incidence of 0.9–8.3% in clinical trials[77–81]; therefore, ibutilide must be given in a monitored setting. Intravenous magnesium prior to infusion of ibutilide, ruling out hypokalemia and avoiding use in patients with prolonged QT intervals may prevent polymorphic VT/torsades de pointes. Intravenous class IC antiarrhythmic agents are not highly effective at the acute conversion of atrial flutter to sinus rhythm[82] (**Class IIb, Level A**).

In postsurgical patients with an epicardial wire, pacing the atrium at a cycle length 10 ms less than the tachycardia cycle length may terminate atrial flutter or convert the flutter to atrial fibrillation. Prospective, randomized clinical trials have demonstrated that transesophageal atrial pacing is as efficacious as direct current cardioversion for atrial flutter.[83] In the asymptomatic patient, rate control is the goal and can be achieved with AV nodal blocking agents.[84–88] IV diltiazem (**Class I, Level C**) and IV digoxin (**Class IIb, Level C**) were compared in a prospective, randomized open-label trial in the emergency room and diltiazem was superior in controling ventricular rates.[84] A similar randomized, double-blind trial was performed in post coronary bypass patients. Diltiazem controlled rates more rapidly than digoxin but overall rate control after 12–24 hours was similar.[85] Rate control may be difficult and warrant conversion to sinus rhythm.

If a patient has symptomatic atrial flutter, long-term treatment is focused on maintaining sinus rhythm, maintaining control of ventricular rates or curing the patient with catheter-based ablation. For symptomatic patients it is important to convert to sinus with direct current cardioversion, an antiarrhythmic agent or both.[1,76,89] A 3-year study demonstrated that only 42% of patients maintained sinus rhythm after direct cardioversion without an antiarrhythmic.[89] Predictors of failure to convert to sinus rhythm include severe left atrial dilation, dilated cardiomyopathy and chronic atrial flutter of prolonged duration. Pharmacologic control with antiarrhythmic drugs is reasonable and if there is no evidence of coronary artery disease or cardiomyopathy, class IC agents may be used.[29–34] It is important to give an AV nodal blocking agent with these antiarrhythmic drugs due to the risk of 1:1 conduction and sudden cardiac death.

The risk of thromboembolic events is comparable or slightly lower than with atrial fibrillation.[89–92] Post cardioversion the risk is approximately 1%.[89] In patients with atrial flutter and risk factors for stroke or who require cardioversion of atrial flutter of more than 48 hours duration, therapeutic anticoagulation with warfarin is warranted, as with atrial fibrillation.

Catheter ablation techniques to cure atrial flutter are highly effective and have low complication rates. Success rates acutely are 95–100% with chronic success rates of 85–95%.[1,93] This is now an acceptable first-line therapy for atrial flutter.[93–96] The Loire-Ardeche-Drome-Isere-Puy-de-Dome (LADIP) trial demonstrated that long-term success in suppressing atrial flutter was greater in first-time patients with atrial flutter ablation (**Class I, Level B**) versus patients treated with cardioversion and oral amiodarone (**Class IIb, Level C**). Rates of subsequent atrial fibrillation were not significantly different between the two groups.[94] Another prospective randomized trial comparing ablation versus pharmacologic rhythm control as first-line therapy proved that ablation of atrial flutter improved quality of life, reduced recurrent atrial flutter rates, reduced future hospitalizations, and reduced the incidence of atrial fibrillation in follow-up.[96]

However, most studies have demonstrated that atrial flutter ablations have no impact on the incidence of atrial fibrillation.[94,97] In patients receiving antiarrhythmic drugs for atrial fibrillation with subsequent drug-induced atrial flutter, treatment with atrial flutter ablation and continuing pharmacologic control of atrial fibrillation is efficacious and safe.[98,99] Despite the claim of long-term success, approximately 60% of patients will be diagnosed

with atrial fibrillation within a 5-year period.[95,97] The risk of the procedure is low but complete heart block, perforation with tamponade, coronary artery damage, and thromboembolic events may occur.[1,93] Patients who cannot be converted to sinus rhythm or who fail anatomic ablation may be referred for palliative ablation of the AV junction.

AV nodal re-entrant tachycardia

AV nodal re-entrant tachycardia (AVNRT) is the most common form of PSVT in adults, accounting for more than 50% of cases.[1–4,10] It is more common in females. There are rare cases in young children and infants. On physical exam, neck pulsations may be evident from simultaneous contraction of the atria and ventricles.[2,100]

The anatomy of the AV junction is important to understand the mechanism of AVNRT. The AV node has right and left posterior extensions. It is hypothesized that there are atrial inputs superiorly, posteriorly and from the left atrium.[101] The superior inputs are near the apex of the triangle of Koch and the posterior or inferior inputs are near the coronary sinus ostium.[101] One hypothesis is that the transitional cells or atrial inputs involve the slow and fast pathways. The fast pathway is located superiorly and posteriorly to the apex of the triangle of Koch. The slow pathway is made of multiple strands anteriorly and inferior to the coronary sinus ostium[102] and there may be multiple slow pathways present in a single individual.[103] The fast pathway has faster conduction and a longer effective refractory period compared to the slow pathway and is more responsive to adrenergic stimuli, such as catecholamines and isoproterenol. Slow-fast AVNRT is the most common form,[3–4,102] present in 75% of cases. The atypical fast-slow variant occurs in about 5–10% of cases. A slow-slow variant occurs in about 5–10% of cases.[3–4,102]

Normal conduction through the AV node is via a single AV nodal pathway. However, dual AV nodal pathways are commonly noted in patients during electrophysiologic testing.[104,105] Although dual AV nodal pathways are common, only a small percentage will support clinical tachycardia.

Acute treatment is determined by how well the arrhythmia is tolerated.[1–3] If there is hemodynamic instability, direct current cardioversion is favored. Termination may occur with intravenous adenosine 6 mg or 12 mg.[21–24] The rate of termination of AVNRT after intravenous adenosine is approximately 86–95% (**Class I, Level A**), and adenosine is as effective as verapamil based on various clinical trials.[21–24,106] Vagal maneuvers may also be beneficial[16] (**Class I, Level B**). AV nodal blocking agents, such as beta-blockers and calcium channel antagonists and digoxin, slow antegrade pathway conduction (**Class IIa, Level C**).[17–20,25–28,107]

Curative measures versus suppression of recurrent arrhythmia through ablation or pharmacologic therapy are long-term therapy goals. Class IC agents typically affect the retrograde fast pathway and are one of the most effective pharmacologic options[20–34] (**Class IIb, Level B**). In the Flecainide Supraventricular Tachycardia Study Group, the number of symptom-free patients after chronic oral flecainide therapy increased from 24% to 82%.[30] Sotalol (**Class IIa, Level B**) and amiodarone (**Class IIb, Level C**) may have beneficial effects on both antegrade and retrograde parts of the circuit.[35,107]

In patients with recurrent episodes despite pharmacologic therapy, those not willing to take medications or patients in high-risk professions, such as commercial pilots, radiofrequency catheter ablation is a reasonable option[1,108] (**Class I, Level B**). The target is the slow pathway anterior and posterior to the CS ostium and tricuspid annulus. The target is found via an anatomic approach, characteristic electrograms or a combination of the two.[108] The anatomic approach places the ablation catheter anterior and inferior to the CS ostium near the tricuspid annulus. Endpoints include elimination of slow pathway or dual AV nodal physiology and of inducible AVRNT. The success rate is approximately 95% with low recurrence rates.[1,93,108] Complications include complete heart block requiring a permanent pacemaker in approximately 1%.[93,109]

In patients with only one documented episode or very infrequent episodes, it is reasonable to advise vagal maneuvers, pill-in-the-pocket therapy, rate control options, catheter ablation or no treatment. All of the above in this setting are considered Class I, Level C recommendations.[1]

Automatic junctional tachycardia

Automatic junctional tachycardias (AJTs) occur secondary to increased automaticity within the AV junction.[1,3,4,110] Electrophysiology studies in selected patients have demonstrated increased response to exercise and isoproterenol and decreased response to propranolol. This suggests a catecholamine-sensitive or dependent junctional focus.[111,112] There are no randomized, placebo-controlled trials for the treatment of AJT. Treatment is based on clinical experience and small case series, mainly in infants and children. Most will respond to beta-blockers (**Class IIa, Level C**) but may require class IC agents or amiodarone (**Class IIa, Level C**) in addition to AV nodal agents.[113] Ablation of the junctional focus or His bundle is reserved for incessant, drug-resistant forms and treatment recommendations are based on case reports[114–116] (**Class IIa, Level C**).

Non-paroxysmal junctional tachycardia occurs in the presence of structural heart disease. Examples include myocardial infarction, myocarditis, post surgery, and digoxin toxicity in the setting of atrial fibrillation.[117,118]

Treatment is typically not indicated. Resolution occurs with correction of underlying pathology (**Class I, Level C**).[119] Beta-blockers may be useful in some settings (**Class IIa, Level C**).[1]

Atrioventricular reciprocating tachycardia

Atrioventricular reciprocating tachycardias are re-entrant arrhythmias that involve an accessory pathway in one limb of the circuit. The prevalence of manifest pre-excitation is 0.15–0.25% in the population and of those studied in the electrophysiologic laboratory, up to 13% will have multiple pathways.[1,120] There tends to be a male predominance. Typically, structural heart disease is absent. However, 5–10% of patients with Epstein's anomaly will have Wolff–Parkinson–White syndrome with right-sided accessory pathways predominating. There have been case reports of familial occurrence of accessory pathways without and in association with dilated cardiomyopathy.[121,122]

The prognosis depends on the electrophysiologic properties of the accessory pathway.[1,122–124] Localization of the accessory pathway may be predicted based on the vector of the delta wave on ECG.[125]

Arrhythmias associated with accessory pathways or Wolff–Parkinson–White (WPW) syndrome include orthodromic AV reciprocating tachycardia, antidromic reciprocating tachycardia, atrial flutter and atrial fibrillation, and permanent junctional reciprocating tachycardia. Orthodromic AV reciprocating tachycardia is the most common paroxysmal supraventricular tachycardia in WPW syndrome.[1,3] It is a macro re-entrant tachycardia that uses the AVN as the antegrade limb and the accessory pathway as the retrograde limb. There are some patients with no ECG evidence of pre-excitation who have orthodromic tachycardia with retrograde conduction over an accessory pathway; 20–30% of patients with accessory pathways have such concealed bypass tracts.[1,3,126] Diagnosis is determined during electrophysiologic studies. Most concealed pathways are left sided.

The permanent form of junctional reciprocating tachycardia involves an accessory pathway with slow conduction and decremental properties. Typically, there is no evidence of pre-excitation during sinus rhythm and the concealed pathway participates in orthodromic tachycardia in the retrograde direction. It is typically seen in children and young adults and may become incessant and result in tachycardia-mediated cardiomyopathy.[126] The most common location of the pathway is posteroseptal near the ostium of the coronary sinus.

Antidromic tachycardia is a macro re-entrant tachycardia which occurs in 5–10% of patients with WPW syndrome.[1,3] This circuit uses the pathway as the antegrade

limb, resulting in a wide QRS complex during tachycardia. Atrial fibrillation and atrial flutter may occur in 20–30% of patients with pathways that conduct antegrade.[1,3] Accessory pathway conduction is sodium channel dependent, often resulting in short refractory periods and fast conduction; thus antegrade pathways may conduct 1:1 with atrial flutter at rates 300 bpm and faster with atrial fibrillation with a risk of ventricular fibrillation and sudden death under these conditions. The risk of sudden death is increased by the presence of a short refractory period of the antegrade pathway (<250 ms), multiple accessory pathways, and a shortest pre-excited R-R during atrial fibrillation of <220 ms.[127]

Treatment of accessory pathways is guided by symptoms or associated arrhythmias such as atrial fibrillation. Symptomatic patients are best treated with catheter ablation (**Class I, Level B**).[1] Asymptomatic patients or patients with WPW pattern are generally low risk for sudden death. Observation is usually the best option (**Class I, Level C**).[1,123,124]

Acute treatment of orthodromic SVT may be accomplished with vagal maneuvers (**Class I, Level B**), adenosine (**Class I, Level A**), diltiazem (**Class I, Level B**), verapamil (**Class I, Level A**), and intravenous beta-blockers (**Class I, Level B**) and amiodarone (**Class I, Level B**).[16–28] If there is hemodynamic compromise, direct current cardioversion is favored (**Class IIa, Level C**). The target of pharmacologic therapy is the weak limb of the circuit, usually the AV node. Adenosine has limited value in determining the mechanism of AVRNT versus AVRT in a narrow QRS tachycardia (**Class I, Level A**). Adenosine has a short duration of action, does not cause hypotension and has been proven to be as effective and safe as verapamil[23] (**Class I, Level A**). Procainamide is a class IA antiarrhythmic which slows conduction of both atrial and ventricular tissue and increases the effective refractory period of the accessory pathway, atrium and ventricle. It has been proven efficacious in treatment of orthodromic tachycardia.[128] Antidromic tachycardia or pre-excited atrial fibrillation presents with a wide QRS due to antegrade conduction via the accessory pathway. Treatment is best managed with cardioversion if there is hemodynamic instability. If the patient is hemodynamically stable the safest pharmacologic agent to terminate tachycardia or slow the ventricular response is procainamide[128] but this is not generally available nowadays. AV node blockers slow conduction of the AV node and may lead to unopposed conduction of the accessory pathway. This could result in ventricular fibrillation, especially in the setting of atrial fibrillation.[129–132] Therefore, these agents must be avoided in WPW patients with atrial fibrillation (**Class III Level B**).

Catheter ablation is preferred as a definitive cure in long-term management of symptomatic patients (**Class I, Level B**). Patients who decline an invasive approach who have low-risk pathways for sudden death may be treated with

class IC, IA or class III antiarrhythmics or AV nodal agents for rate control except digoxin and verapamil (**Class III, Level C**). There are no randomized, placebo-controlled trials to demonstrate the efficacy and safety of antiarrhythmic agents in this patient population. Most recommendations are based on small case series and expert opinion. Class IC agents have been proven to be efficacious and safe[133–135] (**Class IIa, Level C**). Vassiliadis *et al* determined that 40% of patients with WPW syndrome responded to an initial dose of oral propafenone, and 60% responded after an increase in dose without developing significant adverse reactions or proarrhythmic events.[133] In an open-label uncontrolled trial with oral flecainide, Cockrell *et al* studied 63 symptomatic patients with tachycardias involving accessory pathways during electrophysiology study.[135] Prevention or slowed inducible AVRT was demonstrated in 70%. Adverse reaction to flecainide occurred in hospitalized but not in discharged patients.[135] It is reasonable to use oral class IC antiarrhythmics for the prevention of AVRT. It may be reasonable to initiate this in a monitored setting and ensure the patient does not have structural heart disease.

Class III agents prolong the refractory period of the atria, ventricles and accessory pathway (both retrograde and antegrade).[136–138] Sotalol has been shown to be effective and safe during electrophysiology studies[136] (**Class IIa, Level C**). The success of intravenous and oral sotalol during electrophysiology study was predictive of long-term success of oral sotalol in preventing recurrent SVT.[136] There are multiple studies demonstrating that amiodarone is a reasonable option in orthodromic, antidromic and prevention of pre-excited atrial fibrillation.[137,138]

Class IA agents were the first antiarrhythmics to be used in WPW but were replaced by safer class IC agents. The use of class IA agents is limited by multiple side effects (e.g. gastrointestinal and anticholinergic effects). In patients with pre-excited atrial fibrillation, disopyramide slows the ventricular response by prolongation of the refractory period of the accessory pathway.[139]

Catheter-based ablation is a first-line therapy for symptomatic patients and patients with documented atrial fibrillation.[1,140] Ablation may be offered to patients who have high-risk professions or those who have failed medications (**Class I, Level B**). Approximately 50% of accessory pathways are located in the left lateral AV groove, 30% are posteroseptal, 20% are right free wall, and <5% are anteroseptal. The curative ablation site is at the earliest atrial electrogram or ventricular electrogram and the site of the accessory potential.[140] Difficult ablations may occur secondary to catheter instability, especially on the right, oblique pathways (the atrial insertion and ventricular insertion are not parallel). The success rate is approximately 90–95% with low recurrence, <5% with left-sided pathways and higher with right-sided pathways.[93,140] Pos-

teroseptal and anteroseptal pathway ablations have a slightly lower success rates with a risk of AV block in the paraseptal area. Some ablations may need to be performed within the CS due to an epicardial location.

40 Prevention and treatment of life-threatening ventricular arrhythmia and sudden death

Carlos A Morillo[1] and Adrian Baranchuk[2]
[1]Hamilton Health Sciences, McMaster University, Hamilton, Ontario, Canada
[2]Kingston General Hospital, Queen's University, Kingston, Ontario, Canada

Introduction

Sudden cardiac death (SCD) remains a major public health problem; however, in the last two decades a series of well-conducted randomized clinical trials have provided solid evidence that has lead to significant changes in guidelines and recommendations.[1] The incidence of SCD varies among reports. In Canada it has been estimated that 40 000 deaths annually are due to cardiovascular disease; 50% of these deaths are sudden.[2] In the United States the annual incidence of SCD is 450,000.[3,4] The global European incidence of sudden death is difficult to calculate, however, the Maastricht study reported an annual incidence of out-of-hospital sudden death of 1 in 1000 inhabitants, which is quite similar to the North American estimates.[5,6] One of the limitations in determining the true estimate of SCD is the lack of uniform criteria to define and classify the mode of death. Most studies define SCD as death occurring within an hour of initiating symptoms.

Risk stratification

Identifying subjects at risk of SCD has proven to be a complex task. Over the past two decades several methods of risk stratification have been developed and evaluated. Different methods have been used in clinical trials of anti-arrhythmic agents to select a population at high risk of SCD. The most simple and widely used markers include the degree of reduction in left ventricular ejection fraction (LVEF), and functional class as assessed by the New York Heart Association (NYHA) classification. Direct assessment of ventricular ectopy derived from the 24-hour ambulatory ECG recording and susceptibility to induced

ventricular arrhythmias by programmed electrical stimulation have also been reported.[6] Methods that identify potential triggers such as signal-averaged ECG and more recently T-wave alternans or modulators of autonomic function like heart rate variability, baroreflex sensitivity and turbulence have all been assessed individually or in combination, with disappointing results.[7] To date, LVEF reduction with a threshold around <35% continues to be the easiest and most powerful predictor of both total mortality and SCD.

Although the most prevalent cause of SCD is coronary artery disease, it is important to highlight that non-ischemic dilated cardiomyopathy with depressed LVEF and congenital cardiomyopathies and channelopathies with preserved LVEF have a significant incidence of SCD as primary manifestation.

Suppression of ventricular arrhythmias and sudden cardiac death

Ventricular ectopy is considered an electrical trigger of sustained ventricular arrhythmias and potentially SCD. Several trials evaluated the role of ventricular arrhythmia suppression and its effect on cardiac mortality in patients with coronary artery disease.

The International Mexiletine and Placebo Antiarrhythmic Coronary Trial (IMPACT)[8] included 630 patients with recent myocardial infarction who were randomly assigned to treatment with mexiletine or placebo. After an average follow up of nine months, the mortality on mexiletine was 7.6% and on placebo was 48% (*P* = NS). The Cardiac Arrhythmic Suppression Trial (CAST)[9] enrolled 1727 patients with recent onset of myocardial infarction and with asymptomatic, or mildly symptomatic, ventricular arrhythmia (≥6 ventricular premature ventricular complexes per hour), potentially suppressible by a class I antiarrhythmic drug (encainide, flecainide or moricizine), who were randomized to the active antiarrhythmic drug or placebo and followed for arrhythmic death. The trial was

halted early because of an increased incidence of arrhythmic cardiac death and non-fatal cardiac arrests in patients treated with encainide and flecainide (4.5% vs 1.2%, risk ratio (RR) 3.6, 95% confidence interval (CI) 1.7–8.5). In a meta-analysis of the results of 138 trials of antiarrhythmic prophylactic therapy in patients after myocardial infarction,[10] there were 660 deaths among 11 712 patients allocated to receive class I agents and 571 deaths among 11 517 corresponding control patients (51 trials: odds ratio (OR) 1.14; 95% CI 1.01–1.28; P = 0.03). Based on this evidence, class I antiarrhythmic agents have been abandoned for the reduction of the the risk of SCD in patients with ischemic cardiomyopathy and non-sustained ventricular arrhythmia.

Class III antiarrhythmic agents were tested in a series of randomized studies. The two largest trials using amiodarone are the Canadian Amiodarone Myocardial Infarction Arrhythmia Trial (CAMIAT)[11] and the European Myocardial Infarction Amiodarone Trial (EMIAT).[12] Both showed a reduction in arrhythmic death but no significant reduction in overall death. Meta-analysis of data from all 13 randomized controlled trials of amiodarone (89% of patients, after myocardial infarction) showed a significant reduction in total mortality (OR 0.87, 95% CI 0.78–0.99) and a significant reduction in arrhythmic death (OR 0.71, 95% CI 0.59–0.85).[13,14]

Analysis of the interaction between the treatment and baseline factors suggested an important positive relationship between beta-blocker use and amiodarone effect,[15] such that patients on beta-blockers received a significantly greater benefit from amiodarone than those not on beta-blockers. More recently, the association of amiodarone and beta-blockers has been demonstrated to markedly reduce the incidence of appropriate ICD therapy. In the Optimal Pharmacological Therapy in Cardioverter Defibrillator Patients (OPTIC) trial,[16] amiodarone plus beta-blocker significantly reduced the risk of appropriate ICD shocks compared with beta-blocker alone (HR 0.27; 95% CI 0.14–0.52; P < 0.001) or sotalol (HR 0.43; 95% CI 0.22–0.85; P = 0.02).

D-Sotalol, a pure class III agent, was evaluated for prevention of SCD in a placebo-controlled trial of 3121 patients with recent myocardial infarction and LVEF <40%, or symptomatic heart failure with a remote myocardial infarction (Survival with Oral d-sotalol, SWORD trial).[17] Among 1549 patients assigned to d-sotalol there were 78 deaths (5.0%) compared to 48 (3.1%) among the 1572 patients assigned to placebo (RR 1.65, 95% CI 1.15–2.36). Presumed arrhythmic deaths (RR 1.77, 95% CI 1.15–2.74) accounted for the excess mortality in the d-sotalol group. This proarrhythmic fatal effect of d-sotalol was greater in patients with a left ventricular ejection fraction of 31–40% than in those with lower ejection fractions (RR 4.0 vs 1.2, P = 0.007). In a multicenter double-blind randomized study, Julian *et al* reported the effect of sotalol 320 mg once daily compared

with placebo in patients surviving an AMI.[18] Treatment was started 5–14 days after infarction in 1456 patients (60% being randomized to sotalol and 40% to placebo). Patients were followed for 12 months. The mortality rate was 7.3% (64 patients) in the sotalol group and 8.9% (52 patients) in the placebo group. The mortality was 18% lower in the sotalol than in the placebo group, but this difference was not statistically significant.

Another pure class III compound, dofetilide, was tested in patients with symptomatic heart failure. In the Danish Investigations of Arrhythmia and Mortality on Dofetilide (DIAMOND), 1518 patients were randomized to dofetilide or placebo.[19,20] The study treatment was initiated in hospital and included three days of cardiac monitoring and dose adjustment. During a median follow-up of 18 months, 311 patients in the dofetilide group (41%) and 317 patients in the placebo group (42%) died (OR 0.95; 95% CI 0.81–1.11). Treatment with dofetilide significantly reduced the risk of hospitalization for worsening congestive heart failure (CHF), rate of conversion and risk of recurrence of atrial fibrillation. There were 25 cases of torsades de pointes in the dofetilide group (3.3%), compared to none in the placebo group. Dofetilide has also been tested in a randomized trial of 1510 patients with severe LVEF ≤35% after recent myocardial infarction (DIAMOND MI trial).[21] The primary endpoint was all-cause mortality. No significant difference was found between the dofetilide and placebo groups in overall mortality (31% vs 32%). The cardiac mortality (26% vs 28%) and arrhythmic mortality (17% vs 18%) were also similar. There were seven cases of torsades de pointes ventricular tachycardia, all in the dofetilide group. In the Azimilide Postinfarct Survival Evaluation (ALIVE) trial the effect of azimilide, another pure class III agent, was evaluated in 3717 patients with recent myocardial infarction, with LVEF <35% and with low heart rate variability. Azimilide had no effect on mortality (HR 1.0).[22]

Other studies have tested antiarrhythmic agents in patients with sustained ventricular arrhythmias. The endpoints were arrhythmic death, recurrence of sustained ventricular arrhythmia or reinducibility of ventricular tachycardia during programmed electrical stimulation. Steinbeck *et al*[23] conducted a prospective randomized trial in 170 patients to investigate whether electrophysiologic study (EPS)-guided antiarrhythmic therapy improved the long-term outcome of patients with spontaneous and inducible sustained ventricular arrhythmia compared with metoprolol therapy not guided by EPS. In 55 patients ventricular tachycardia was not inducible during the baseline EPS, thereby precluding further serial drug testing. These patients were treated with metoprolol. The two-year incidence of the composite outcome was the same for EPS-guided therapy compared to metoprolol (46% vs 48%).

The Electrophysiological Study Versus Electrocardiographic Monitoring (ESVEM) study[24,25] included patients

with inducible ventricular tachycardia and any of the following: (i) history of cardiac arrest, (ii) sustained ventricular tachycardia or (iii) syncope. They were randomly assigned to undergo serial testing to determine efficacy of antiarrhythmic drugs either by performing EPS or by 24-hour ambulatory ECG monitoring. Patients (n = 486) received long-term treatment with the first antiarrhythmic drug that was determined to be effective on the basis of either repeated EPS or 24-hour Holter. The ESVEM study concluded that therapies guided by EPS or Holter monitoring were comparable. The secondary outcome, related to the efficacy of individual antiarrhythmic drugs, concluded that sotalol was more effective than the class I drugs tested. The actuarial probability of a recurrence of arrhythmia after a drug was deemed efficacious by either strategy was significantly lower for patients treated with sotalol than for patients treated with other antiarrhythmic agents (RR 0.43; 95% CI 0.29–0.62). Sotalol significantly reduced the risk of all-cause mortality (RR 0.50; 95% CI 0.30–0.80), cardiac mortality (0.50; $P = 0.02$) and arrhythmic death (0.50; $P = 0.04$).

In the Cardiac Arrest in Seattle: Conventional versus Amiodarone Drug Evaluation (CASCADE) study, antiarrhythmic drug therapy was evaluated in survivors of out-of-hospital ventricular fibrillation (VF).[26] Amiodarone without EPS or Holter guidance was compared to class I antiarrhythmic agents (quinidine, procainamide, their combination, or flecainide), selected by serial EPS or Holter monitoring. Most of the 228 randomized patients had coronary artery disease with a prior myocardial infarction, and the mean LVEF was 35 ± 10%. During a mean follow-up of six years, amiodarone improved survival compared to class I agents (53% vs 40%, $P = 0.007$).

The Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT) randomly assigned 2521 patients with NYHA class II or III CHF and a LVEF of 35% or less to conventional therapy for CHF plus placebo (847 patients), conventional therapy plus amiodarone (845 patients), or conventional therapy plus a conservatively programmed, shock-only, single-lead ICD (829 patients).[27] Placebo and amiodarone were administered in a double-blind fashion. The primary endpoint was death from any cause. Mortality was 29% in the placebo group and 28% in the amiodarone group. As compared with placebo, amiodarone was associated with a similar risk of death (HR1.06; 97.5% CI 0.86–1.30; P = 0.53).

Beta-blockers and prevention of sudden cardiac death

Beta-blockers are the agent most frequently studied in postmyocardial infarction patients for the prevention of death, with more than 12 large trials reported. A meta-analysis of the beta-blocker trials, reported in 1985, showed a significant reduction in mortality during treatment after myocardial infarction.[28] This meta-analysis also indicated a highly significant 30% reduction in sudden cardiac death with beta-blockers. The risk of non-sudden death was also decreased by 12%, but this difference was not significant. Recent beta-blocker trials in CHF patients also show a reduction in both overall deaths and SCD.[29–32] Beta-blockers are effective against arrhythmic death (20–30% reduction) and non-arrhythmic deaths, and reduce overall mortality significantly. Beta-blocker therapy is indicated in all patients at high risk for SCD.

In summary, antiarrhythmic drugs have been extensively evaluated in randomized trials as prophylactic agents against death, but little tested against recurrence of arrhythmia. Class I antiarrhythmic drugs are harmful and are proscribed in patients with ischemic heart disease and reduced LVEF. Amiodarone has a moderate effect against SCD and a neutral effect on other deaths, therefore its overall effect on total mortality is modest. Pure class III agents are at best neutral and, in the case of d-sotalol, actually harmful. Pure class III antiarrhythmic agents clearly do not reduce mortality or SCD when used prophylactically in high-risk patients. The different results of d-sotalol, dofetilide and azimilide trials are probably due to differences in the design of the studies and differences in risk of torsades de pointes between the agents.

Recommendations

- Beta-blockers are indicated in patients with myocardial infarction or congestive heart failure for the prevention of death (**Class I, Level A**).
- Amiodarone, usually in combination with beta-blockers, can be useful for patients with LV dysfunction due to prior MI and symptoms due to VT unresponsive to beta-blockers (**Class IIa, Level B**).
- Sotalol is reasonable therapy to reduce symptoms resulting from ventricular tachyarrhythmia (VT) for patients with LV dysfunction due to prior MI unresponsive to beta-blockers. Amiodarone or sotalol is reasonable adjunctive therapies for patients with implantable cardioverter-defibrillators (ICD) to improve symptoms due to frequent episodes of sustained VT or VF in patients with LV dysfunction due to prior MI.
- Amiodarone is reasonable therapy to reduce symptoms due to recurrent hemodynamically stable VT for patients with LV dysfunction due to prior MI who cannot or refuse to have an ICD implanted (**Class IIb, Level C**).
- Amiodarone may be reasonable therapy for patients with LV dysfunction due to prior MI with an ICD indication, who cannot or refuse to have an ICD implanted (**Class IIb, Level C**).
- Class Ic antiarrhythmics should be avoided in patients with coronary artery disease or LV dysfunction (**Class III, Level A**).

Upstream therapy and prevention of sudden cardiac death

The effect of angiotensin-converting enzyme (ACE) inhibitors on the risk of SCD following myocardial infarction has been demonstrated in randomized trials.[33–35] A recent meta-analysis incorporated data from 15 trials that included 15 104 patients having 900 SCD.[35] ACE inhibitor therapy resulted in a significant reduction in total mortality (OR 0.83, 95% CI 0.71–0.97), cardiovascular death (OR 0.82, 95% CI 0.69–0.97) and SCD (OR 0.80, 95% CI 0.70–0.92). Also, the meta-analysis suggested that a reduction in SCD risk with ACE inhibitors was an important component of overall survival benefit, the magnitude of effect on SCD being the same as on overall mortality.

Interestingly, in the Heart Outcome Prevention Evaluation (HOPE) Study[36] involving cardiovascular patients without a significant decrease in left ventricular function (LVEF >40%), the ACE inhibitor ramipril significantly decreased the incidence of cardiac arrest (RR 0.62, 95% CI 0.41–0.94). The mechanism by which ACE inhibitors reduce SCD is poorly understood. In addition to attenuation of remodeling, thereby reducing the substrate for ventricular tachyarrhythmia, they provide significant neurohumoral modulation and protection from future ischemic events.

Angiotensin receptor blockers (ARB) are potentially antiarrhythmic; this effect can be explained by blockade of the angiotensin II receptor type I leading to inhibition of the proarrhythmic effects of angiotensin II.[37] Several trials of different angiotensin receptor blockers have demonstrated equivalent effects to those of ACE inhibitors on cardiac and overall mortality. However, with the exception of the CHARM trials, the addition of an ARB to an ACE inhibitor has not yielded any added benefits.[38] In summary, ARBs should be used as alternative therapy in patients intolerant to ACE inhibitors.

In the Randomized Aldactone Evaluation Study (RALES),[39] aldactone was evaluated in patients having NYHA III–IV. After a mean follow-up of 24 months, the incidence of SCD was significantly decreased (RR 0.71, 95% CI 0.54–0.95). The magnitude of this effect was similar to the effect on total mortality (RR 0.70, 95% CI 0.68–0.72). In the EPHESUS trial patients with an acute myocardial infarction complicated by symptomatic LV dysfunction were randomized to standard therapy versus standard therapy plus eplerenone.[40] Eplerenone significantly reduced all-cause mortality, cardiovascular death and the risk of cardiovascular death or hospitalization. Interestingly SCD was also significantly reduced (RR 0.79, 95% CI 0.64–0.97). Either spironolactone or eplerenone is recommended as adjunctive therapy in patients with heart failure with LV dysfunction and NYHA class III–IV.

The role of n-3 polyunsaturated fatty acids for the prevention of SCD has been assessed in a number of randomized trials. The Diet And Reinfarction Trial randomized 2033 men with recent myocardial infarction and reported a significant reduction in both cardiac and total mortality (RR 0.71, 95% CI 0.54–0.93).[41] In a larger study, the GISSI-Prevenzione Trial,[42] treatment with n-3 polyunsaturated fatty acids in 11 324 postmyocardial infarction patients significantly decreased the incidence of SCD (RR 0.74, 95% CI 0.58–0.93), also significantly decreasing total cardiac mortality and coronary mortality by a similar extent (RR 0.78 and 0.80, respectively, both significant). A recent systematic review of 48 RCTs (36 913 participants) and 41 cohort studies did not document a clear effect of omega 3 fats on total mortality, combined cardiovascular events or cancer.[43] The pooled estimate of this meta-analysis showed no strong evidence of reduced risk of total mortality (relative risk 0.87, 95% CI 0.73–1.03) or combined cardiovascular events (0.95, 0.82–1.12) in participants taking additional omega 3 fats. When data from the subgroup of studies of long-chain omega 3 fats were analyzed separately, total mortality (0.86, 0.70–1.04; 138 events) and cardiovascular events (0.93, 0.79–1.11) were not clearly reduced. Neither RCTs nor cohort studies suggested increased risk of cancer with a higher intake of omega 3 (trials: 1.07, 0.88–1.30; cohort studies: 1.02, 0.87–1.19), but clinically important harm could not be excluded.

In summary, the effects of fish oils on SCD and cardiovascular morbidity and mortality remain debated. The protective effect of fish oils may be limited to patients with a previous myocardial infarction. Current guidelines recommend that patients with documented coronary artery disease consume approximately 1 g of EPA+ DHA per day, preferably from oily fish although supplements can also be considered.[44]

Thus, accumulated evidence supports the wide use of upstream interventions in appropriate patients.

Recommendations

- ACE inhibitors and, in ACE-intolerant patients, ARBs are indicated in patients with myocardial infarction or congestive heart failure for the prevention of death (**Class I, Level A**).
- Polyunsaturated fatty acids (1 g of EPA+ DHA per day) are recommended in patients with known cardiovascular disease for the prevention of cardiovascular outcomes (**Class IIa, Level B**).

Implantable cardioverter-defibrillators for prevention of sudden cardiac death

Several studies have assessed the effectiveness of ICDs for the prevention of SCD in high-risk populations. The primary risk stratifier is a LVEF ≤35%. In some instances the presence of non-sustained VT or the induction of VT during programmed electrical stimulation have been used as inclusion criteria. These trials may be classified according to the underlying anatomic substrate:

• Coronary artery disease and depressed LVEF: MADIT,[45] CABG-Patch,[46] MUSTT,[47] MADIT II,[48] DINAMIT[49]
• Dilated non-ischemic cardiomyopathy (DCM) and depressed LVEF: CAT,[50] AMIOVIRT,[51] DEFINITE[52]
• LVEF <35% independent of the etiology of the underlying cardiomyopathy: SCD-HeFT.[27]

Primary prevention of SCD in ischemic cardiomyopathy

The rationale for the CABG-Patch trial was developed at a time when a thoracotomy was required for implantation of an ICD. Thus patients scheduled for CABG and with LVEF ≤35% were further stratified for risk of arrhythmic death by signal-averaged ECG.[46] There were 900 high-risk patients randomized to receive an ICD or not at the time of CABG. Antiarrhythmic drug use was similar between the two groups. There were 52 patients randomized to ICD who either never received a device or who had it removed. There were 198 deaths (102 in the ICD group and 96 in the control group) for an overall mortality rate of 21.8% during an average follow-up of 32 ± 16 months. The hazard ratio was 1.07 (95% CI 0.81–1.42), indicating no benefit from the ICD in this patient population. Secondary analysis showed that the ICD did reduce arrhythmic death; this potential benefit was offset by an unexplained increase in non-arrhythmic deaths.

The Multicenter Automatic Defibrillator Implantation Trial (MADIT)[45] included patients with LVEF <35% and recent myocardial infarction who were screened with programmed ventricular stimulation. Patients with inducible VT or VF were enrolled in the study if inducibility of VT could not be suppressed by procainamide. There were 196 patients randomized to receive either an ICD or "conventional" therapy. The choice of conventional therapy was at the discretion of the investigator. Amiodarone and beta-blockers, the only drugs proven effective against VT and VF, were used predominantly but sporadically (in 45% and 5%, respectively, of "conventional" patients at last contact). The trial was terminated prematurely when about 75% of planned enrollment had occurred, because of marked benefit derived from ICD treatment (HR 0.46; 95% CI 0.26–0.82; $P = 0.009$). When the specific causes of death were examined, the ICD not only reduced arrhythmic death, but also appeared to reduce non-arrhythmic cardiac death, and deaths of unknown cause, which is unexplained and biologically implausible.

The Multicenter Unsustained Tachycardia Trial (MUSTT)[47] was a randomized trial of electrophysiologically guided antiarrhythmic therapy in patients with coronary artery disease, LVEF ≤0.40 and asymptomatic, non-sustained ventricular tachycardia. Seven hundred and four patients who satisfied these criteria, and in whom sustained VT was induced by programmed stimulation, were randomly assigned to receive either antiarrhythmic drug tailored by electrophysiologic testing, including drugs and ICDs (if drugs failed to suppress inducibility), or no antiarrhythmic therapy. The primary endpoint of cardiac arrest or death from arrhythmia was reached in 25% of those receiving electrophysiologically guided therapy, and in 32% of those assigned to no antiarrhythmic therapy (relative risk 0.73, 95% CI 0.53–0.99). Five-year total mortality was 42% in patients receiving EPS-guided therapy, versus 48% in controls (RR 0.80, 95% CI 0.64–1.01). In a non-randomized analysis the primary endpoint was less frequent among patients who received ICDs compared to patients discharged without an ICD (relative risk 0.24; 95% CI 0.13–0.45; $P < 0.001$). In contrast, the primary endpoint was similar among those receiving antiarrhythmic therapy compared to those on no therapy.

The second Multicenter Automatic Defibrillator Implantation Trial (MADIT II)[48] included patients with LVEF ≤30% but *without* evidence of sustained VT/VF and excluded those with recent (<1 month) myocardial infarction, coronary artery bypass graft (CABG) or percutaneous transluminal coronary angioplasty (PTCA) (<2 months). There were 1232 patients randomly assigned to receive an ICD (742 patients) or conventional medical therapy (490 patients). During an average follow-up of 20 months, the mortality rates were 19.8% in the conventional therapy group and 14.2% in the defibrillator group (HR 0.69, 95% CI 0.51–0.93). MADIT II was a landmark trial expanding ICD indications to patients with severe LVEF impairment due to ischemic cardiomyopathy but with no evidence of sustained ventricular arrhythmia.

Identifying those subjects with coronary artery disease (CAD) and severe LV dysfunction who will derive the greatest benefit from prophylactic ICD therapy remains a challenge. Several MADIT II subgroup studies have been reported including survival in elderly patients, QRS duration, and clinical risk factors, and time after MI.[53–57] An important question is whether ICD therapy maintains its efficacy in elderly subjects, addressed by Huang *et al* in a MADIT II substudy.[54] Among 1232 patients enrolled with prior infarct and LVEF ≤0.30, 204 were ≥75 years old and of those, 121 underwent ICD implant.

The hazard ratio for mortality in patients ≥75 years assigned to ICD compared with those in conventional therapy was 0.56 (95% CI 0.29–1.08; *P* = 0.08) after a mean follow-up of 17.2 months. Comparatively, the hazard ratio in patients <75 years assigned to ICD was 0.63 (0.45–0.88; *P* = 0.01) after 20.8 months. The ICD was associated with an equivalent reduction of mortality in elderly and younger patients. Dhar *et al* evaluated the prognostic significance of prolonged QRS relative to arrhythmic outcomes in medically and ICD-treated patients enrolled in MADIT II.[55] In the medically treated arm, prolonged QRS was a significant independent predictor of SCD (HR 2.12; 95% CI 1.20–3.76; *P* = 0.01). However, in the ICD-treated arm, prolonged QRS did not predict SCD or rapid VT/VF (HR 0.77; 95% CI 0.47–1.24; *P* = 0.28). The difference in the prognostic effect of prolonged QRS in these two groups was significant (*P* < 0.01). These results suggest that in MADIT II patients, prolonged QRS does not predict SCD/VT/VF in ICD-treated patients but does predict SCD in medically treated patients. This underscores the non-equivalence of VT/VF and SCD and the need for caution in inferring risk of SCD when using non-randomized databases that include only patients with ICDs.

Clinical risk factors may be useful to identify subjects who would benefit from a prophylactic ICD implant. Goldenberg *et al* developed a simple clinical risk score (NYHA class >II, age >70 years, BUN >26 mg/dl, QRS duration >0.12 s, and atrial fibrillation) using a proportional-hazards regression analysis for the end point of all-cause mortality in patients allocated to the conventional therapy arm of MADIT II.[56] A prespecified subgroup of very high-risk (VHR) patients (BUN ≥50 mg/dL and/or serum creatinine ≥2.5 mg/dL) was excluded. The benefit of the ICD was then assessed within risk score categories and separately in VHR patients. Crude mortality rates in the conventional group were 8% and 28% in patients with 0 and ≥1 risk factors, respectively, and 43% in VHR patients. ICD therapy was associated with a 49% reduction in the risk of death (*P* < 0.001) among patients with ≥1 risk factors (n = 786), whereas no ICD benefit was identified in patients with 0 risk factors (n = 345; HR 0.96; *P* = 0.91) and in VHR patients (n = 60; HR 1.00; *P* > 0.99). Patients that derive the greatest benefit from a prophylactic ICD are at intermediate risk, in contrast, low-risk and VHR patients have attenuated efficacy with an ICD.

One of the most important questions that clinicians pose when having to determine whether an asymptomatic patient with CAD and a LVEF ≤30% will benefit from ICD therapy is the time from most recent MI, evaluated by Wilber *et al* in a substudy of the MADIT II trial.[57] Mortality rates (deaths per 100 person-years of follow-up) in both treatment groups were analyzed by time from MI divided into quartiles (<18, 18–59, 60–119, and > = 120 months). In conventional care patients, these rates increased as time

from MI increased (7.8%, 8.4%, 11.6%, 14.0%; *P* = 0.03). Mortality rates in ICD patients were consistently lower in each quartile and showed minimal increases over time (7.2%, 4.9%, 8.2%, 9.0%; *P* = 0.19). Covariate-adjusted hazard ratios for risk of death associated with ICD therapy were 0.97 (95% CI 0.51–1.81; P = 0.92) for recent MI (<18 months) and 0.55 (95% CI 0.39–0.78; *P* = 0.001) for remote MI (> = 18 months). These investigators concluded that the survival benefit associated with ICDs appears to be greater for remote MI and remains substantial for up to 15 years after MI.

In summary, the efficacy of prophylactic ICD therapy based on the MADIT II criteria seems to be maintained in elderly patients, particularly in those without significant co-morbidities. QRS duration does not appear to be of use to further stratify patients that will benefit and some clinical risk factors such as impaired renal function, NYHA class, age >70 and atrial fibrillation may be helpful to identify patients at intermediate risk of dying, and who derive the greatest benefit from ICD therapy. Nonetheless none of these findings has been transferred into current guidelines and larger trials and prolonged follow-up are needed.

The most appropriate timing for the insertion of an ICD after an acute myocardial infarction (AMI) had not been specifically addressed in previous clinical trials. The Defibrillator in Acute Myocardial Infarction Trial (DINAMIT)[49] was a randomized trial that compared ICD versus no ICD in a group of patients recruited during the period immediately following an acute myocardial infarction (6–40 days). Inclusion criteria were LVEF <35% and depressed heart rate variability defined as standard deviation of the N–N interval (SDNN) ≤70 ms. There was no difference in the primary outcome of overall mortality between the two groups (95% CI 0.76–1.55; *P* = 0.66) (follow-up 30 ± 13 months). However, there was a reduction in arrhythmic deaths that was offset by an increase in non-arrhythmic deaths in the ICD group. The conclusion of the DINAMIT study reinforces the need to delay the decision to implant an ICD by at least six weeks in patients with a recent myocardial infarction. Reassessment of LVEF at the end of this waiting time is required in order to confirm the severity of LV dysfunction. This trial also highlights the presence of competing risks in the early post-AMI phase that may offset the benefits of the ICD.

Primary prevention of SCD in non-ischemic dilated cardiomyopathy (DCM)

Non-ischemic dilated cardiomyopathy is a term that encompasses a variety of etiologies that may lead to the final outcome of dilated cardiomyopathy. This should be noted when interpreting the various different clinical trials reported to date. In the Cardiomyopathy Trial (CAT)[50] patients with recent onset of DCM and LVEF ≤30% were

randomly assigned to ICD vs no ICD. The primary endpoint was all-cause mortality at one year of follow-up. The trial was terminated after the inclusion of 104 patients (50 ICD, 54 control) because the all-cause mortality rate at one year did not reach the expected 30% in the control group. Mean follow-up was 22.8 ± 4.3 months; no SCD occurred during the first or second year. Cumulative survival was not significantly different between the two groups (93% and 80% in the control group versus 92% and 86% in the ICD group after two and four years, respectively). The lack of benefit for the ICD group could be explained by the uncertain evolution of a recently diagnosed DCM with some patients having spontaneous recovery of LVEF to near normal values.

The Amiodarone Versus Implantable Cardioverter-defibrillator Randomized Trial (AMIOVIRT)[51] randomized 103 patients with DCM, LVEF <35% and asymptomatic non-sustained ventricular tachycardia to receive either amiodarone or an ICD. The primary endpoint was total mortality; secondary endpoints included arrhythmia-free survival, quality of life, and costs. The study was stopped when the prospective stopping rule for futility was reached. The percentages of patients surviving at one year (90% vs 96%) and three years (88% vs. 87%) in the amiodarone and ICD groups, respectively, were not statistically different ($P = 0.8$). Quality of life was also similar with each therapy (P = NS). Amiodarone showed a trend towards improved arrhythmia-free survival ($P = 0.1$) and lower costs during the first year of therapy ($8879 v. $22 039, $P = 0.1$).

In the Defibrillators in Non-Ischemic Cardiomyopathy Treatment Evaluation (DEFINITE)[52] study, 458 patients with DCM, LVEF <36% and premature ventricular complexes or non-sustained VT were randomized to receive standard medical therapy alone versus standard medical therapy plus a single-chamber ICD. Standard medical therapy included ACE inhibitors (86%) and beta-blockers (85%); mean LVEF was 21%. During a mean follow-up of 29 ± 14.4 months, there were 68 deaths: 28 in the ICD group and 40 in the standard therapy group (HR 0.65; 95% CI 0.40–1.06; $P = 0.08$). The mortality rate at two years was 14.1% in the standard therapy group and 7.9% in the ICD group. There were 17 sudden deaths from arrhythmia: three in the ICD group and 14 in the standard therapy group (HR 0.20; 95% CI 0.06–0.71; $P = 0.006$). The conclusion was that the addition of an ICD to standard treatment that should include an ACE inhibitor plus a beta-blocker significantly reduces SCD but has minimal impact in reducing overall mortality.

Primary prevention of SCD in patients with dilated cardiomyopathy

The Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT)[27] was the largest trial including DCM patients. It randomly assigned 2521 patients with NYHA class II or III heart failure and a LVEF ≤35% to conventional therapy for heart failure plus placebo conventional therapy plus amiodarone, or conventional therapy plus a conservatively programmed, shock-only, single-lead ICD. The primary endpoint was death from any cause. Median LVEF was 25%, 70% were in heart failure NYHA class II and 30% were in class III. The cause of heart failure was ischemic in 52% and non-ischemic in 48%. During a median follow-up of 45.5 months, there were 244 deaths (29%) in the placebo group, 240 (28%) in the amiodarone group, and 182 (22%) in the ICD group. The risk of death on amiodarone was similar to that on placebo (HR 1.06; 97.5% CI 0.86–1.30; $P = 0.53$) while ICD therapy was associated with a decreased risk of death (HR 0.77; 97.5% CI 0.62–0.96; P = 0.007) and an absolute decrease in mortality of 7.2 percentage points after five years in the overall population, independent of whether the cause of heart failure was ischemic or non-ischemic (Fig. 40.1). Of note, ICD therapy had a 46% relative risk reduction in mortality in patients with NYHA class II (HR 0.54; 97.5% CI 0.40–0.74) (Fig. 41.3). In contrast, patients with NYHA class III had no benefit from ICD therapy (HR 1.16; 97.5% CI 0.8–1.61). There is no obvious biologic reason for this unexpected result, but it is possible that patients with more advanced heart failure die from pump failure, and resynchronization therapy or heart transplant may be the therapies of choice. These findings should be interpreted with caution since other trials such as MADIT II have not reproduced these findings. Current guidelines recommend prophylactic ICD therapy in patients with both NYHA Class II and III.

ICD for secondary prevention of SCD

All the secondary prevention trials comparing amiodarone versus ICD in patients surviving VT/VF were extensively described in the previous edition of this book.[58] The three largest of these were the Canadian Implantable Defibrillator Study (CIDS),[59] the Antiarrhythmic versus Implantable Defibrillator (AVID)[60] and the Cardiac Arrest Study Hamburg (CASH).[61] CASH enrolled patients with prior VF, whereas CIDS and AVID study enrolled both patients with prior VF as well as patients with hemodynamically unstable VT. CIDS also enrolled patients with decreased LV function, syncope and inducible VT.

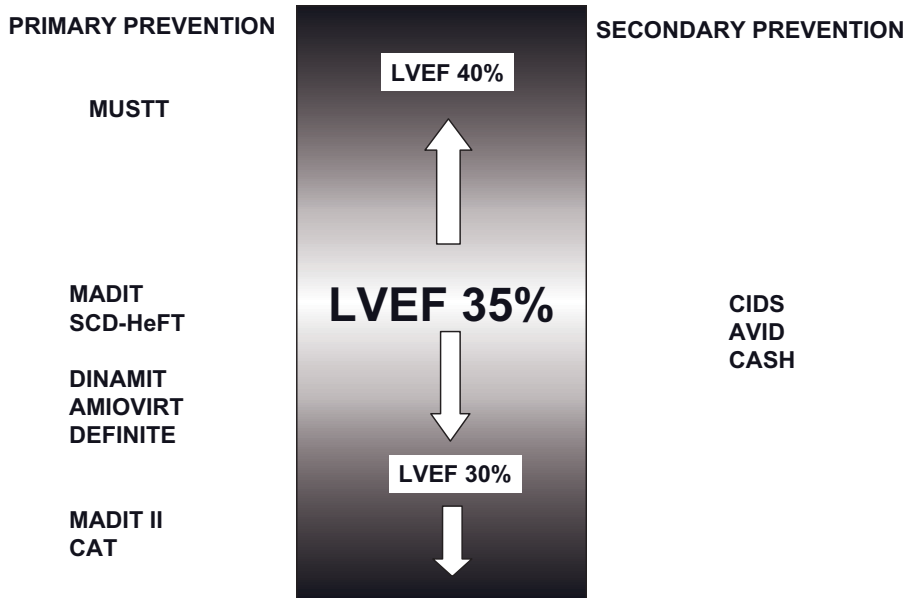
A meta-analysis including the three trials[62] showed a significant reduction in death from any cause with the ICD, with a summary HR (ICD vs amiodarone) of 0.72 (95% CI 0.60–0.87; $P = 0.0006$). For the outcome of arrhythmic death the HR was 0.50 (95% CI 0.37–0.67; $P < 0.0001$). Survival was extended by a mean of 4.4 months by the ICD over a follow-up period of six years. Patients with LVEF ≤35% derived significantly more benefit from ICD therapy than those with better LV function (HR 1.2, 95% CI 0.86–1.76 in


Figure 40.1 Clinical trials evaluating the role of ICD in both primary and secondary indications. LVEF <35% is the threshold suggested by most primary prevention trials. Graded color towards an LVEF of 40% suggests that the benefit of ICD is less marked than in patients with more severe deterioration of LVEF.

patients with LVEF >35% vs HR 0.66, 95% CI in patients with LVEF ≤35%, $P_{interaction}$ = 0.011). The point estimates of ICD benefit from the three studies were consistent with each other ($P_{heterogeneity}$ = 0.306).

Among patients presenting with life-threatening sustained VT or VF the balance of evidence now favors ICD therapy over amiodarone, particularly in those with impaired LV function (<35%). In light of the modest prolongation of life conferred by the ICD and its high cost, where resources are limited, efforts should be directed towards identifying patients in higher-risk groups and considering amiodarone as a reasonable alternative.

Antiarrhythmic drugs as adjunctive ICD therapy

ICDs and antiarrhythmic drugs should not be considered as exclusive alternatives.[63] In fact, a significant proportion of ICD patients receive concomitant antiarrhythmic therapy to help control supraventricular tachyarrhythmia, recurrent ventricular arrhythmia and frequent appropriate and inappropriate ICD shocks. Indeed, the ICD does not prevent VT/VF, only its fatal consequences.

In the OPTIC[16] study, 412 patients with an ICD were randomized to receive blinded amiodarone + beta-blocker vs sotalol alone vs beta-blocker alone for one year. The primary outcome was ICD shock for any reason; they occurred in 12 patients (10.3%) assigned to amiodarone plus beta-blocker, 26 (24.3%) assigned to sotalol, and 41 (38.5%) assigned to beta-blocker alone. A reduction in the risk of shock was observed with use of either amiodarone plus beta-blocker or sotalol versus beta-blocker alone (HR 0.44; 95% CI 0.28–0.68; P < 0.001). Amiodarone plus beta-

blocker significantly reduced the risk of shock compared with beta-blocker alone (HR 0.27; 95% CI 0.14–0.52; P < 0.001) and with sotalol (HR 0.43; 95% CI 0.22–0.85; P = 0.02). The rates of study drug discontinuation at one year were 18.2% for amiodarone, 23.5% for sotalol, and 5.3% for beta-blocker alone. Adverse pulmonary and thyroid events and symptomatic bradycardia were more common among patients randomized to amiodarone. Amiodarone should be initiated in ICD patients presenting with frequent shocks both appropriate and inappropriate; sotalol is not as effective but is an acceptable alternative. ICD therapy whether appropriate or inappropriate leads to serious discomfort and anxiety in patients with ICDs. The OPTIC trial provides strong evidence that both sotalol and amiodarone are highly effective in preventing shocks and should be initiated once either inappropriate or appropriate shocks are documented.

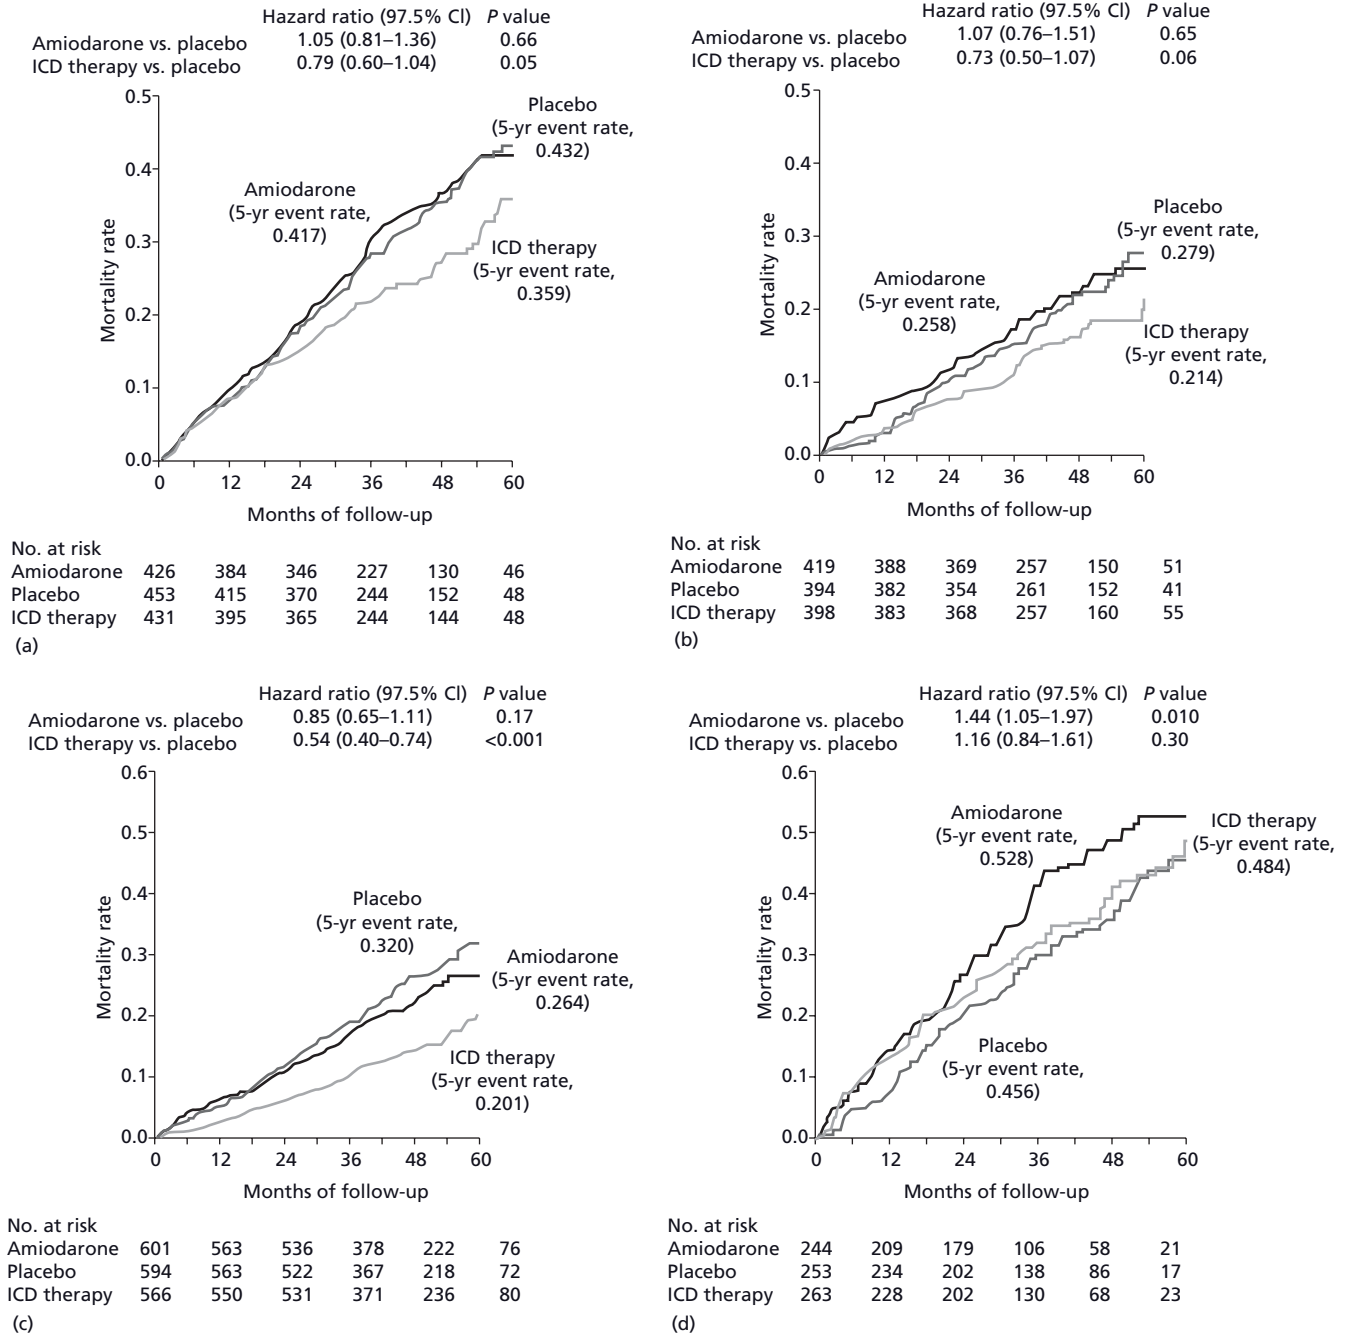
The Shock Inhibition Evaluation with Azimilide (SHIELD) trial randomized 633 ICD recipients in a double-blind, placebo-controlled study to evaluate the effect of daily doses of 75 or 125 mg of azimilide on recurrent symptomatic ventricular tachyarrhythmias and ICD therapies.[64] The total of all-cause shocks plus symptomatic ventricular tachycardia (VT) terminated by antitachycardia pacing (ATP) was significantly reduced by azimilide, with relative risk reductions of 57% (HR 0.43, 95% CI 0.26–0.69, P = 0.0006) at the 75 mg dose and 47% (HR 0.53, 95% CI 0.34–0.83, P = 0.0053) at the 125 mg dose. The reductions in all-cause shocks with both doses of azimilide did not achieve statistical significance. The incidence of all appropriate ICD therapies (shocks or ATP-terminated VT) was reduced significantly among patients taking 75 mg azimil-


Figure 40.2 Kaplan–Meier estimates of death from any cause for (a) ischemic and (b) non ischemic cardiomyopathy in the SCD-Heft trial (upper panel). Kaplan–Meier estimates of death from any cause in NYHA Class II (c) and III patients (d). (From Bardy et al[27]).

ide (HR 0.52, 95% CI 0.30–0.89, P = 0.017) and those taking 125 mg of azimilide (HR 0.38, 95% CI 0.22–0.65, P = 0.0004). Azimilide significantly reduced the recurrence of VT or ventricular fibrillation terminated by shocks or ATP in ICD patients, thereby reducing the burden of symptomatic ventricular tachyarrhythmias.

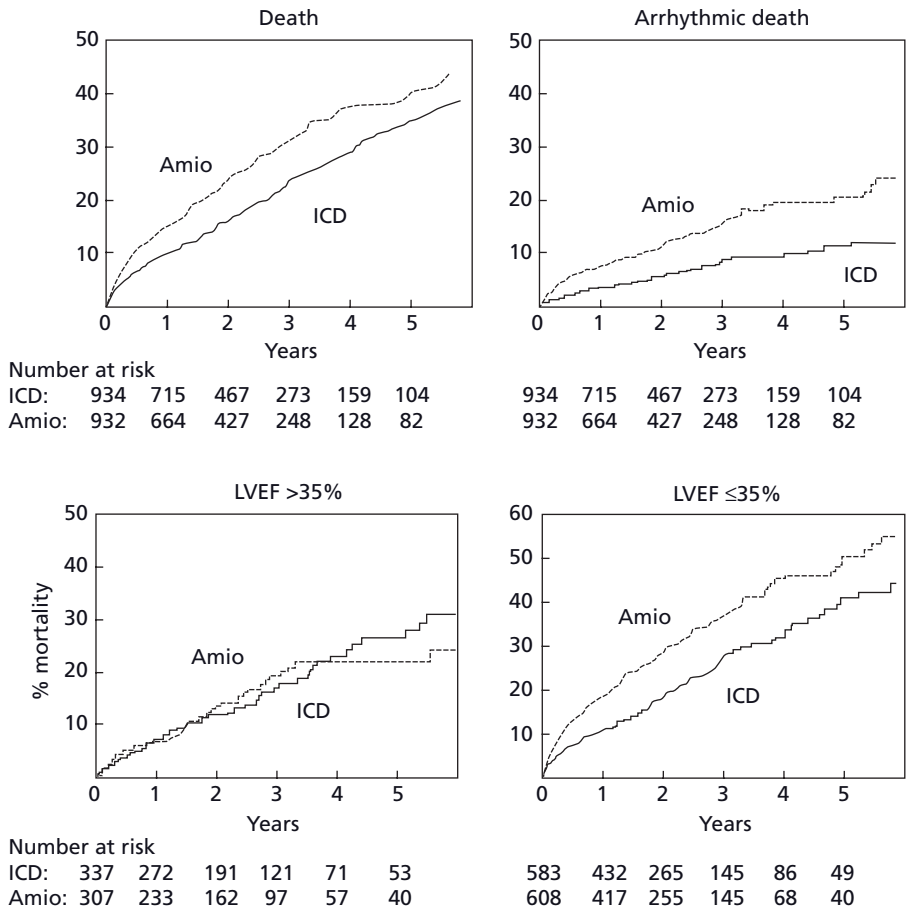
Three randomized clinical trials have assessed the effect of omega 3 fatty acids in patients with an ICD and previous VT/VF.[65–67] Raitt and collaborators randomized 200 patients with an ICD and a recent episode of sustained VT or VF, in a double-blind, placebo-controlled trial, to receive fish oil 1.8 g/d, 72% omega 3 PUFAs, or placebo; they were


Figure 40.3 Meta-analysis of clinical trials evaluating the role of ICD therapy for secondary prevention of SCD. The upper panel shows the cumulative risk of fatal events for the amiodarone and ICD treatment arms and the lower panel shows the cumulative risk for death according to LVEF ≤35% or ≥35%. (From Conolly *et al*[62]).

followed up for a median of 718 days (range 20–828 days).[65] Time to first episode of ICD treatment for VT/VF was the primary outcome. Patients randomized to receive fish oil had ICD therapy for VT/VF at six, 12, and 24 months, 46% (5%), 51% (5%), and 65% (5%) compared with 36% (5%), 41% (5%), and 59% (5%) for patients randomized to receive placebo (*P* = 0.19). Recurrent VT/VF events were more common in patients randomized to receive fish oil (*P* < 0.001). These investigators concluded that fish oil supplementation did not reduce the risk of VT/VF and may be proarrhythmic in some patients.

Leaf *et al* randomized 402 patients with ICDs to double-blind treatment with either fish oil or an olive oil daily supplement for 12 months.[66] The primary endpoint was a composite of time to first ICD event for VT/VF or death from any cause. Treatment with the fish oil supplement showed a trend toward a prolonged time to the first ICD event or death from any cause (risk reduction of 28%; *P* = 0.057). In patients "on treatment" for at least 11 months, the antiarrhythmic benefit of fish oil was improved for those with confirmed events (risk reduction of 38%; *P* = 0.034). The authors interpreted these findings as evidence that for individuals at high risk of fatal ventricular

arrhythmias, regular daily ingestion of fish oil fatty acids may significantly reduce potentially fatal ventricular arrhythmias.

The Study on Omega-3 Fatty acids and ventricular Arrhythmia (SOFA) was a randomized, parallel, placebo-controlled, double-blind trial that recruited 546 patients with ICDs and prior documented VT/VF.[67] Patients were randomly assigned to receive 2g/d of fish oil (n = 273) or placebo (n = 273) for a median period of 356 days. The primary outcome was a composite of appropriate ICD intervention for VT/VF or all-cause death. The primary endpoint occurred in 81 (30%) patients taking fish oil vs 90 (33%) patients taking placebo (HR 0.86; 95% CI 0.64–1.16; *P* = 0.33). This study did not indicate evidence of benefit or harm of omega 3 PUFAs in patients with an ICD and prior VT/VF. A recent meta-analysis pooled the data from the described trials that included a total of 573 patients who received fish oil and 575 patients who received a control; at one year there was no overall effect of fish oil on the relative risk of ICD discharge.[68] Significant heterogeneity was observed between trials and this meta-analysis was unable to show any significant effect on the relative risk of ICD therapy.

In summary, adjunctive therapy for the prevention of recurrent shocks has clinical relevance primarily by improving quality of life by preventing both appropriate and inappropriate shocks and potentially prolonging device longevity. Amiodarone and sotalol have both shown significant reductions in device therapy and are recommended for patients with recurrent shocks. Azimilide has shown some promising results but there has been no head-to-head comparison with amiodarone or sotalol. There is currently no strong evidence that supports the routine use of fish oils for the reduction of ICD therapies.

Prevention of less common cardiomyopathies and channelopathies

Several less common disorders may manifest with SCD as primary clinical presentation and include a heterogeneous group of cardiomyopathies such as hypertrophic cardiomyopathy (HCM), arrhythmogenic right ventricular dysplasia/cardiomyopathy (ARVD/C) and Chagas' disease. Channelopathies such as the Brugada syndrome, long QT syndrome and catecholaminergic polymorphic VT are among the most frequent genetic disorders. Some of these conditions have a very low prevalence and there are no data from randomized clinical trials. Nonetheless, SCD is a relatively frequent and devastating clinical presentation that affects young people and their siblings.[69,70] The level of evidence for all these disorders is C, and larger studies assessing the role of primary prevention are needed.[6,71]

Hypertrophic cardiomyopathy

HCM is a relatively common cardiac disorder (adult prevalence about 1:500) in which SCD is a devastating component, which may occur at any age but particularly in young, often asymptomatic patients. Risk factors for SCD have been derived from observational studies and international registries. Major risk factors include prior cardiac arrest; family history of SCD, syncope or spontaneous sustained or non-sustained VT, LV thickness >30 mm and an abnormal blood pressure response to exercise.[6,71] The implant of an ICD for secondary prevention of SCD is widely accepted based on small observational studies and expert opinion.[71]

The prophylactic use of an ICD is also appropriate in those individuals with any of the aforementioned risk factors. It remains unclear which risk factor has the highest predictive accuracy and *a single* risk factor may be a sufficient indication for an ICD for primary prophylaxis. Maron *et al*[72] recently reported data from a multicenter registry that included 506 patients with HCM with an ICD implanted for either primary or secondary prophylaxis. The mean follow-up was 3.7 ± 2.8 years. The primary outcome was appropriate shocks delivered by the ICD.

ICD therapy appropriately terminated ventricular tachycardia/fibrillation in 103 patients (20%). Intervention rates were 10.6% per year for secondary prevention after cardiac arrest (five-year cumulative probability, 39% (SD, 5%)), and 3.6% per year for primary prevention (five-year probability, 17% (SD, 2%)). Time to first appropriate discharge was up to 10 years, with a 27% probability of receiving therapy five years or more after implantation. For primary prevention, 35% of patients with appropriate ICD interventions had undergone implantation for only a single risk factor; likelihood of appropriate discharge was similar in patients with one, two, three or more risk markers (3.83, 2.65, and 4.82 per 100 person-years, respectively; $P = 0.77$). An important proportion of ICD discharges occurred in primary prevention patients who had undergone implantation for a single risk factor. In summary, patients with HCM and a secondary prevention indication have a 10.6% yearly rate of appropriate shocks in contrast to patients with a primary indication who have a 3.6% yearly rate of appropriate shocks independent of the risk factors previously mentioned.

Arrhythmogenic right ventricular cardiomyopathy (ARVC)

ARVC may manifest as SCD in younger patients and selected subjects may be at higher risk for SCD. There is some evidence identifying high-risk subgroups derived from observational studies and it is reasonable to recommend the use of an ICD in these patients.[73] Risk factors that identify patients that may be at risk of life-threatening arrhythmias include induction of VT during electrophysiologic testing, detection of non-sustained VT on ambulatory ECG monitoring, male gender, severe RV dilation and extensive RV involvement.[74] Presentation at an age <5 years, LV involvement, prior cardiac arrest and unexplained syncope may also serve as markers of increased risk for SCD.[6,75] However it is important to realize that these risk factors have not been validated in large prospective series. There is a wide variation in presentation and course of ARVC patients; however, patients presenting with syncope, sustained VT or SCD appear to be a higher-risk group.

The role of ICD therapy for primary prevention of SCD in patients with ARVC is unclear and no data from randomized clinical trials are available. The decision to implant an ICD for primary prophylaxis in patients with ARVC may be prompted by the presence of one or more of the following markers: family history of SCD or ARVC, syncope, extensive RV involvement, and LV involvement.[6]

Chagas' cardiomyopathy

Chagas' disease is an endemic parasitic disease that affects more than 100 million people in Latin America. Recent

migration patterns have made North America and Europe also vulnerable and several cases have been reported in the last years.[76–78] Dilated cardiomyopathy, progressive heart failure, conduction disorders and life-threatening arrhythmias are common clinical presentations.[78] SCD is the principal cause of death in Chagas' disease, accounting for about 55–65% of deaths affecting individuals during their most productive years, leading to an estimated SCD incidence of 24 per 1000 patient-years.[78] There is a lack of controlled trials in the prevention or treatment of SCD associated with Chagas' disease.

The Chagas Cardiomyopathy Bisoprolol Intervention Study (CHARITY)[79] is an ongoing randomized trial conducted in Colombia, testing bisoprolol vs placebo in a population with Chagas' disease and symptomatic heart failure. SCD is one of the secondary outcomes. The Benznidazole Evaluation For Interrupting Trypanosomiasis (BENEFIT) trial is a large randomized double-blind trial that is testing the hypothesis whether treatment with the anti-trypanosomal agent benznidazol reduces both PCR serology and clinical outcomes that include SCD, ventricular tachycardia, overall mortality and cardiac mortality.[80]

Current data from registries and small observational trials suggest that the ICD has a similar beneficial effect in patients with Chagas' cardiomyopathy compared to other non-ischemic dilated cardiomyopaties.[81,82] Of note, progression of LV dysfunction and heart failure is more aggressive in patients with Chagas' cardiomyopathy and may affect the overall benefit of ICD therapy in this population. Further studies will be needed to clarify the role of ICD therapy in the prevention of SCD.

Brugada syndrome

The diagnosis of Brugada syndrome is based on characteristic 12-lead ECG manifestations that include J point segment elevation in leads V1–V3 and right bundle branch block pattern that may be intermittent.[83] The disease is transmitted in an autosomal dominant pattern with more than 90% of cases being male. The genetic alteration has been localized to the cardiac sodium channel gene (SCN5A).[84]

Identifying asymptomatic subjects that are at increased risk of SCD is of clinical importance but remains a controversial topic. There are no data indicating that family history predicts SCD in patients with Brugada syndrome. Similarly there is no evidence that asymptomatic subjects with no family history are at low risk. Patients with a spontaneous characteristic ECG pattern compared to ECG changes elicited by pharmacologic challenge appear to have a worse prognosis.[85] Furthermore, patients with a spontaneous characteristic ECG pattern and syncope have a sixfold higher risk of SCD compared with patients without syncope and spontaneous ECG changes.[85]

Some investigators promote the use of EPS to identify patients with asymptomatic Brugada syndrome at high risk of SCD.[6,83] This practice remains highly controversial as other investigators have reported a low accuracy for EPS to predict SCD.[83–85] In summary, it appears reasonable to offer an ICD in patients who have survived a cardiac arrest and present with polymorphic VT or syncope together with spontaneous characteristic Brugada ECG pattern. Primary prevention with an ICD in asymptomatic patients with the Brugada syndrome is based on individual patient selection.[6,86]

Long QT syndrome

The long QT syndrome is frequently associated with SCD. Long-term therapy with beta-blockers, permanent pacing or left cervicothoracic ganglionic sympathectomy have been reported to reduce cardiac events.[6,87,88] A number of clinical markers have been suggested as risk stratifiers for SCD. History of syncope, family history of SCD, cardiac arrest, torsades de pointes and type of long QT (LQTS 2–3) have been suggested by some investigators as markers of SCD.[87] ICD is recommended for patients who have a recurrence of syncope or VF while receiving beta-blockers. Primary prevention with an ICD may be indicated in patients felt to be at very high risk and those unable to receive beta-blockers. Genetic analysis may in the future aid in identifying patients at higher risk of SCD and may justify implanting an ICD for primary prevention.[6,88]

Catecholaminergic polymorphic VT

Cathecholaminergic polymorphic VT (CPVT) is an inherited disease characterized by life-threatening arrhythmias (usually triggered by emotion or exercise). The mortality rate in untreated individuals is 30–50% by age 40.[89] Nonsustained or sustained bidirectional VT is a frequent clinical presentation, usually triggered by exercise. Irregular polymorphic VT or VF can also be seen in these patients. Beta-blockers are the therapy of choice. If syncope recurs on appropriate beta-blocker therapy an ICD is indicated.[6,89,90]

Application of current evidence in under-represented populations

Translating evidence derived from clinical trials may be challenging in specific under-represented populations. In most clinical trials testing the ICD, patients over 75 years of age have been under-represented and the benefits of ICD therapy in this subgroup remain debatable. A recent study combined individual data from the CIDS, AVID and CASH studies and divided the population into those aged ≥75 and

<75 years.[91] Overall, 1866 patients were included in this analysis; 252 patients were aged ≥75 years old (13.5%). LVEF was similar in both groups (32.6 ± 13.7 vs 33.8 ± 14.9%, *P* = 0.20) as was baseline NYHA class III or IV (12.3 vs 11.8%, *P* = 0.38). Older patients were less likely to have VF as their presenting arrhythmia (39 vs 53%, *P* = 0.0001). Over a mean follow-up of 2.3 years, older patients were more likely to die from both non-arrhythmic (8.74% per year vs 3.96% per year, *P* = 0.001) and arrhythmic death (6.73% per year vs 3.84% per year, *P* = 0.03). The ICD significantly reduced all-cause and arrhythmic death in patients aged <75 years (all-cause death HR 0.69, 95% CI 0.56–0.85, *P* < 0.0001; arrhythmic death HR 0.44, 95% CI 0.32–0.62, *P* < 0.0001), but not in patients aged ≥75 years old (all-cause death HR 1.06, 95% CI 0.69–1.64, *P* = 0.79; arrhythmic death HR 0.90, 95% CI 0.42–1.95, *P* = 0.79).

Evidence from observational studies suggests that elderly patients with multiple co-morbidities may derive less benefit from ICD therapy, possibly due to competing risks that dilute the effects of ICD therapy. End-stage renal failure has been identified as a potential co-morbidity that reduces the benefit of ICD.[92,93] ICD therapy should not be withheld based on age alone; however, careful consideration of the risk of non-arrhythmic death among elderly patients and patients with multiple co-morbidities, especially end-stage renal disease, should be taken into account when considering ICD implantation.

Cardiac resynchronization therapy and ICD for SCD prevention

Whether ICD therapy alone or combined with cardiac resynchronization therapy in appropriate heart failure candidates has an impact on SCD remains a matter of debate. The Comparison Of Medical therapy, Pacing, And defibrillatION in heart failure (COMPANION)[94] trial included 1520 patients with advanced heart failure (NYHA class III–IV) due to ischemic or non-ischemic cardiomyopathy

---

BOX 40.1 Recommendations for ICD therapy

Primary prevention

Class I
- Patients with ischemic heart disease with or without mild to moderate symptoms and LVEF <35%, due to prior MI who are at least 40 days post MI (measured at least one month post MI and three months post coronary revascularization procedure) and are in NYHA class II or III (**Level A**)
- Patients with LVEF <30%, due to prior MI who are at least 40 days post-MI (measured at least one month post MI and three months post coronary revascularization procedure) and are in NYHA class I (**Level A**)
- Patients with non-ischemic cardiomyopathy LVEF <35%, and NYHA functional class II–III (**Level B**)
- Patients with familial or inherited conditions such as, but not limited to, long QT syndrome, hypertrophic cardiomyopathy, Brugada syndrome or ARVD and at a high risk for life-threatening ventricular tachyarrhythmias (**Level C**)
- Patients with non-sustained VT due to prior MI who are at least 40 days post MI (measured at least one month post MI and three months post coronary revascularization procedure) LVEF <40% and inducible VF or sustained VT at electrophysiologic study (**Level B**)

Class IIa
- Patients with non-ischemic cardiomyopathy with unexplained syncope and, LVEF <30% (**Level C**)
- Patients with sustained VT with normal or near normal LVEF (**Level C**)
- Patients with HCM who have one or more risk factors for SCD (**Level C**)

- Patients with ARVD/C who have one or more risk factors for SCD (**Level C**)
- Patients with long QT syndrome with syncope and/or VT while receiving beta-blockers (**Level C**)
- Patients with Brugada syndrome with unexplained syncope or documented VT that has not resulted in cardiac arrest (**Level C**)
- Patients with catecholaminergic polymorphic VT who present with syncope/documented sustained VT while receiving beta-blockers (**Level C**)
- Patients with Chagas' cardiomyopathy and LVEF <35% and NYHA II or III (**Level C**)

Secondary prevention

Class I
- Patients with aborted cardiac arrest due to VF/VT not due to a transient or reversible cause (**Level A**)
- Spontaneous sustained VT in association with structural heart disease (**Level B**)
- Syncope of undetermined origin with clinically relevant, hemodynamically significant sustained VT or VF induced at electrophysiology study (**Level B**)
- Spontaneous sustained VT in patients who do not have structural heart disease that is not amenable to other treatments (**Level B**)

Class IIa
- Patients with unexplained syncope non-ischemic dilated cardiomyopathy and LVEF <35% (**Level C**)
- Patients in hospital with sustained VT awaiting for cardiac transplantation (**Level C**)

and a QRS interval of at least 120 msec who were randomly assigned to optimal pharmacologic therapy alone or in combination with cardiac resynchronization therapy (CRT) with either a pacemaker or a pacemaker/defibrillator. The primary composite endpoint was the time to death or hospitalization for any cause. Mean LVEF was 22% and all the patients had a QRS duration >150 ms. The total annual mortality in the control group was 19% and the addition of ICD to biventricular pacing reduced the relative risk by 36% (HR 0.64, 95% CI 0.48–0.86). This benefit was maintained independent of type of cardiomyopathy.

The CArdiac REsynchronization Heart Failure (CARE-HF)[95] study randomized 813 patients with advanced heart failure (NYHA class III–IV), QRS prolongation (>120 msec) and LVEF <35% who were followed for a mean of 29.4 months. The primary endpoint (time to death from any cause or an unplanned hospitalization for a major cardiovascular event) was significantly reduced in the CRT compared to medical therapy group (HR 0.63; 95% CI 0.51–0.77; $P < 0.001$). Death was also significantly reduced in the CRT compared to medical therapy group (HR 0.64; 95% CI 0.48–0.85; $P < 0.002$). The extended CARE-HF follow-up also observed a significant reduction in SCD (HR 0.54, 95% CI 0.35–0.84, $P = 0.005$).[96] Thus it is reasonable to recommend CRT + ICD when there is an overlapping indication (advanced heart failure, EF <35%, QRS duration >120 msec).

Pacemaker therapy, including cardiac resynchronization therapy

William D Toff[1] and A John Camm[2]
[1]Department of Cardiovascular Sciences, University of Leicester, Leicester, UK
[2]Cardiac and Vascular Sciences, St George's University of London, London, UK

Introduction and historical perspective

The development and implementation of the first fully implantable cardiac pacemaker in 1958 transformed the outlook for patients with symptomatic bradycardia and Stokes–Adams attacks.[1] Since then, technologic advances and innovation over five decades have enabled the development of increasingly sophisticated pacing systems, better able to simulate the normal cardiac activation sequence, and a wide variety of different pacing modes is now available.

Initially, pacemakers were only implanted for atrioventricular (AV) block, but their use was soon extended to the management of symptomatic bradycardia associated with sinus node disease. In recent years, improved understanding of pathophysiologic mechanisms has prompted the assessment of pacemaker therapy in other conditions such as neurocardiogenic syncope, hypertrophic cardiomyopathy and paroxysmal atrial fibrillation. Most recently, the development of cardiac resynchronization therapy using biventricular pacing has emerged as an important treatment for selected patients with heart failure. With the emergence of new indications for pacing and the availability of a vast array of different pacing modes and techniques, an evidence-based approach to the practice of cardiac pacing has become increasingly important.

Goals of cardiac pacing

The fundamental aims of cardiac pacing are to relieve symptoms, to improve the quality of life and, in some instances, to prolong survival. The achievement of these aims is mediated by improvements in hemodynamic function and functional capacity, reduction in cardiovascular morbidity, and prevention of sudden death. Any consideration of the utility and optimal mode of pacing must have regard to all of these factors. It is important to note that hemodynamic differences between alternative pacing modes do not always translate into significant differences in clinical outcomes and comprehensive assessment in randomized clinical trials is therefore essential. It is also important to bear in mind that inappropriate pacing or complications from pacing may result in new or worse symptoms and increased cardiovascular morbidity. This is perhaps best exemplified by the pacemaker syndrome.[2]

Current pacing practice

The most recent world survey of cardiac pacing reported that there were over 540 000 new pacemaker implants in the 43 contributing countries in 2005[3] and the number of new implants is continuing to rise.[3–5] There is considerable national and regional variation in the implant rate. In the USA in 2005, there were approximately 752 new implants per million population. In Europe, figures ranged from 101 per million (Russia) to 789 per million (Belgium).[3] These variations may partly reflect differences in the age distribution and morbidity of the relevant populations but availability of resources and variations in standards of medical care and attitudes to pacing may also be relevant. There has also been some suggestion, in the past, of inappropriate and excessive pacemaker implantation.[6]

In an effort to define appropriate pacing practice, a joint task force subcommittee of the American College of Cardiology (ACC) and the American Heart Association (AHA) has published guidelines for permanent pacemaker implantation, most recently in 2008 (Table 41.1).[7] Similar guidelines have also been published in Europe by a task force of the European Society of Cardiology (ESC), in collaboration with the European Heart Rhythm Association.[8]

Table 41.1 ACC/AHA/HRS guidelines: indications for permanent cardiac pacing[7]

Condition	Class I	Class IIa	Class IIb	Class III
Acquired AV block in adults				
First-degree		First- or second-degree AV block with symptoms similar to those of pacemaker syndrome or hemodynamic compromise (B)	First- or second-degree AV block, with or without symptoms, associated with neuromuscular diseases such as myotonic muscular dystrophy, Erb dystrophy or peroneal muscular atrophy (B)	Asymptomatic first-degree AV block (B)
Second-degree	Second-degree AV block with associated symptomatic bradycardia regardless of site or type of block (B)	See above	See above	Asymptomatic type I second-degree block at the supra-His (AV node) level or not known to be intra- or infra-Hisian (C)
	Asymptomatic type II second-degree AV block with a wide QRS, including isolated RBBB (B)	Asymptomatic type II second-degree AV block with a narrow QRS (B)		
	Second-degree AV block during exercise in the absence of myocardial ischemia (C)	Asymptomatic second-degree block at intra- or infra-His levels found at EPS (B)		
Third-degree (CHB)	CHB and advanced second-degree AV block at any anatomic level associated with any of the following: • Bradycardia with symptoms (including heart failure) or ventricular arrhythmia presumed due to AV block (C) • Arrhythmias and other conditions requiring drug therapy that results in symptomatic bradycardia (C) • Sinus rhythm, with documented asystole ≥3 s, an escape rate <40/min or an infranodal escape rhythm in awake, symptom-free patients (C) • AF and bradycardia with one or more pauses ≥5 s in awake, symptom-free patients (C) • Prior catheter ablation of the AV junction (C) • Postoperative AV block that is not expected to resolve after cardiac surgery (C)	Persistent third-degree AV block with an escape rate >40/min in asymptomatic adults without cardiomegaly (C)	AV block in the setting of drug use and/or toxicity when block is expected to recur even after the drug is withdrawn (B)	AV block that is expected to resolve and is unlikely to recur (for example, drug toxicity, Lyme disease, transient increased vagal tone or during hypoxia in sleep apnea syndrome without symptoms) (B)

Table 41.1 *Continued*

Condition	Class I	Class IIa	Class IIb	Class III
	• Neuromuscular diseases, such as myotonic muscular dystrophy, Kearns–Sayre syndrome, Erb dystrophy or peroneal muscular atrophy with or without symptoms (B) Asymptomatic persistent third-degree AV block at any anatomic site with mean awake ventricular rates ≥40/min if cardiomegaly or LV dysfunction is present or block is infranodal (B) Third-degree AV block during exercise in the absence of myocardial ischemia (C)			
Chronic bifascicular or trifascicular block	Associated with advanced second-degree AV block or intermittent CHB (B)	Syncope not demonstrated to be due to AV block when other likely causes have been excluded, specifically VT (B)	Neuromuscular diseases such as myotonic muscular dystrophy, Erb dystrophy or peroneal muscular atrophy with bifascicular or any fascicular block, with or without symptoms (C)	Fascicular block without AV block or symptoms (B)
	Associated with type II second-degree AV block (B)	Incidental finding at EPS of markedly prolonged HV interval (≥100 ms) in asymptomatic patients (B)		Fascicular block with first-degree AV block without symptoms (B)
	Alternating bundle branch block (C)	Incidental finding at EPS of pacing-induced infra-His block that is not physiological (B)		
AV block after the acute phase of myocardial infarction (MI)	Persistent second-degree AV block in the His–Purkinje system with alternating bundle branch block or third-degree AV block within or below the His–Purkinje system after ST elevation MI (B) Transient advanced second- or third-degree infranodal AV block and associated bundle branch block. If the site of block is uncertain, an EPS may be necessary (B) Persistent and symptomatic second- or third-degree AV block (C)	None	Persistent second- or third-degree AV block at the AV node level, even in the absence of symptoms (B)	Transient AV block in the absence of intraventricular conduction defects (B) Transient AV block in the presence of isolated left anterior fascicular block (B) New bundle branch block or fascicular block in the absence of AV block (B) Persistent asymptomatic first-degree AV block in the presence of bundle branch block or fascicular block (B)

Table 41.1 *Continued*

Condition	Class I	Class IIa	Class IIb	Class III
Sinus node dysfunction (SND)	SND with documented symptomatic bradycardia, including frequent sinus pauses that produce symptoms (C)	SND with heart rate <40/min when a clear association between significant symptoms consistent with bradycardia and the actual presence of bradycardia has not been documented (C)	Minimally symptomatic patients with chronic heart rates <40/min whilst awake (C)	SND in asymptomatic patients (C)
	Symptomatic chronotropic incompetence (C)	Syncope of unexplained origin when clinically significant abnormalities of sinus node function are discovered or provoked at EPS (C)		SND in patients in whom the symptoms suggestive of bradycardia have been clearly documented to occur in the absence of bradycardia (C)
	Symptomatic sinus bradycardia that results from required drug therapy for medical conditions (C)			SND with symptomatic bradycardia due to nonessential drug therapy (C)
Hypersensitive carotid sinus syndrome and neurocardiogenic syncope	Recurrent syncope caused by spontaneously occurring carotid sinus stimulation and carotid sinus pressure that induces ventricular asystole of >3 s (C)	Syncope without clear, provocative events and with a hypersensitive cardio-inhibitory response ≥3 s (C)	Significantly symptomatic neurocardiogenic syncope associated with bradycardia documented spontaneously or at the time of tilt-table testing (B)	Hypersensitive cardio-inhibitory response to carotid sinus stimulation without symptoms or with vague symptoms (C)
				Situational vasovagal syncope in which avoidance behavior is effective and preferred (C)
Pacing to prevent tachycardia	Sustained pause-dependent VT, with or without QT prolongation (C)	High-risk patients with congenital long-QT syndrome (C)	Prevention of symptomatic, drug-refractory, recurrent AF in patients with co-existing sinus node disease (B)	Frequent or complex ventricular ectopic activity without sustained VT in the absence of the long-QT syndrome (C)
				Torsades de pointes VT due to reversible causes (A)
				Prevention of AF in patients without any other indication for pacemaker implantation (B)
Pacing with devices that automatically detect and pace to terminate tachycardia	None	Symptomatic recurrent SVT that is reproducibly terminated by pacing when catheter ablation and/or drugs fail to control the arrhythmia or produce intolerable side effects (C)	None	Presence of an accessory pathway that has the capacity for rapid anterograde conduction (C)

Table 41.1 *Continued*

Condition	Class I	Class IIa	Class IIb	Class III
Hypertrophic cardiomyopathy (HCM)	SND or AV block in patients with hypertrophic cardiomyopathy as described above (C)	None	Medically refractory, symptomatic patients with HCM and significant resting or provoked LV outflow tract obstruction (A). (A dual-chamber ICD should be considered when risk factors for sudden death are present)	Asymptomatic or medically controlled patients (C)
				Symptomatic patients without evidence of LV outflow obstruction (C)
Cardiac resynchronization therapy (CRT) in patients with severe systolic heart failure	For patients who have LV EF ≤35%, QRS duration ≥120 ms and sinus rhythm, CRT with or without ICD is indicated for the treatment of NYHA class III or ambulatory class IV heart failure symptoms with optimal medical therapy (A)	For patients who have LV EF ≤35%, QRS duration ≥120 ms and atrial fibrillation, CRT with or without an ICD is reasonable for the treatment of NYHA class III or ambulatory class IV heart failure symptoms on optimal medical therapy (B)	For patients with LV EF ≤35% with NYHA class I or II symptoms who are receiving optimal medical therapy and who are undergoing implantation of a permanent pacemaker and/or ICD with anticipated frequent ventricular pacing, CRT may be considered (C)	CRT is not indicated for asymptomatic patients with reduced LV EF in the absence of other indications for pacing (B)
		For patients with LV EF ≤35% with NYHA class III or ambulatory class IV symptoms who are receiving optimal medical therapy and who have frequent dependence on ventricular pacing, CRT is reasonable (C)		CRT Is not indicated for patients whose functional status and life expectancy are limited predominantly by chronic non-cardiac conditions (C)
After cardiac transplantation	Persistent inappropriate or symptomatic bradycardia not expected to resolve and other Class I indications for permanent pacing (C)	None	Prolonged or recurrent relative bradycardia, which limits rehabilitation or discharge after postoperative recovery from cardiac transplantation (C)	None
			Syncope after cardiac transplantation even when bradyarrhythmia has not been documented (C)	

Table 41.1 *Continued*

Condition	Class I	Class IIa	Class IIb	Class III
Children, adolescents and patients with congenital heart disease	Advanced second- or third-degree AV block associated with symptomatic bradycardia, ventricular dysfunction or low cardiac output (C)	Congenital heart disease and sinus bradycardia for the prevention of recurrent episodes of intra-atrial re-entrant tachycardia; SND may be intrinsic or secondary to antiarrhythmic treatment (C)	Transient postoperative third-degree AV block that reverts to sinus rhythm with residual bifascicular block (C)	Transient postoperative AV block with return of normal AV conduction in the otherwise asymptomatic patient (B)
	Sinus node dysfunction with correlation of symptoms during age-inappropriate bradycardia (B)	Congenital third-degree AV block beyond the first year of life with an average heart rate <50/min, abrupt pauses in ventricular rate that are 2 or 3 times the basic cycle length, or associated with symptoms due to chronotropic incompetence (B)	Congenital third-degree AV block in asymptomatic children or adolescents with an acceptable rate, a narrow QRS complex, and normal ventricular function (B)	Asymptomatic bifascicular block with or without first-degree AV block after surgery for congenital heart disease in the absence of prior transient complete AV block (C)
	Postoperative advanced second- or third-degree AV block that is not expected to resolve or that persists at least 7 days after cardiac surgery (B)	Sinus bradycardia with complex congenital heart disease with a resting heart rate <40/min or pauses in ventricular rate >3 s (C)	Asymptomatic sinus bradycardia after biventricular repair of congenital heart disease with a resting heart rate <40/min or pauses in ventricular rate >3 s (C)	Asymptomatic type I second-degree AV block (C)
	Congenital third-degree AV block with a wide QRS escape rhythm, complex ventricular ectopy, or ventricular dysfunction (B)	Congenital heart disease an impaired hemodynamics due to sinus bradycardia or loss of AV synchrony (C)		Asymptomatic sinus bradycardia with the longest R–R interval <3 s and the minimum rate >40/min (C)
	Congenital third-degree AV block in the infant with a ventricular rate <55/min or with congenital heart disease and a ventricular rate <70/min (C)	Unexplained syncope in the patient with prior congenital heart surgery complicated by transient complete heart block with residual fascicular block after a careful evaluation to exclude other causes of syncope (B)		

CHB, complete heart block; CHF, congestive heart failure; EPS, electrophysiology study; VT, ventricular tachycardia; RBBB, right bundle branch block.

The grade of evidence supporting each recommendation is indicated in parentheses:

(A) data derived from multiple randomized clinical trials involving a large number of individuals

(B) data derived from a limited number of trials involving comparatively small numbers of patients or from well-designed data analyses of non-randomized studies or observational data registries

(C) recommendation based on consensus opinion of experts.

Class I – conditions for which there is evidence and/or general agreement that pacing is beneficial, useful and effective.

Class II – conditions for which there is conflicting evidence and/or a divergence of opinion about the usefulness/efficacy of pacing.

Class III – conditions for which there is evidence and/or general agreement that pacing is not useful/effective and in some cases may be harmful.

Class II is subdivided into Class IIa – weight of evidence/opinion is in favor of usefulness/efficacy and Class IIb – usefulness/efficacy is less well established by evidence/opinion.

Based on Epstein *et al.*[7]

Conventional indications for pacing

The principal indication for cardiac pacing is to relieve or prevent symptoms associated with bradycardia. In high-grade AV block, however, there is evidence that survival may also be improved by pacing, even in the absence of symptoms, and pacing should be considered on prognostic grounds alone.

Where significant symptoms are clearly associated with documented bradycardia, the requirement for pacing will rarely be in doubt. In other contexts, the cause of symptoms may be unclear and it is important to note that the most common symptoms are non-specific and prevalent in the elderly population, even in the absence of bradycardia.

The most common causes of bradycardia requiring pacing are impaired impulse formation, as in sinus node disease, or a disturbance of cardiac conduction, as in AV block. These conditions account for the vast majority of primary pacemaker implants.[3] The remainder includes patients paced for a variety of conditions, including carotid sinus syndrome, cardio-inhibitory forms of neurocardiogenic syncope and others.

Atrioventricular block

First-degree atrioventricular block
Isolated prolongation of the PR interval may be a normal variant in healthy young subjects.[9] In older subjects, it is more often associated with underlying pathology, such as conducting system fibrosis or coronary artery disease, but it does not usually give rise to symptoms and pacing is not generally indicated.

Occasionally, symptoms may arise if the PR interval is markedly prolonged. Atrial systole may then closely follow delayed ventricular systole from the previous cycle, resulting in a comparable hemodynamic disturbance to that seen in the pacemaker syndrome[10,11] and a favorable response to dual-chamber pacing has been reported.[12] Symptomatic first-degree AV block with a demonstrable improvement during temporary dual-chamber pacing may reasonably be considered at least a **Class IIa**[13] and perhaps even a Class I[14] indication for pacing (**Level B**).

Second-degree atrioventricular block
When second-degree AV block of any type is associated with clearly attributable symptoms, pacing is indicated. In the absence of symptoms, the situation is more complex. Prognosis is thought to relate to the site of block, proximal block at the level of the AV node being more benign than distal block in the His–Purkinje system.[15] The ECG classification into Mobitz type I (Wenckebach), Mobitz type II or

advanced (2:1, 3:1 or 4:1) second-degree AV block is purely descriptive and the site of block cannot always be inferred although electrophysiologic studies have shown that type I block is most commonly proximal whereas type II block is almost always distal.[16] In the past, type I second-degree AV block has often been regarded as benign but evidence from the Devon Heart Block and Bradycardia Survey (a non-randomized, observational study) suggests that in unpaced patients aged 45 years or over, even amongst those without attributable symptoms, there is an increased incidence of adverse outcomes (symptomatic bradycardia, higher degree AV block or impaired survival) compared to the general population and that pacing is associated with improved survival.[17,18] Guidelines differ in their conclusions but published opinion suggests that pacing should be considered in asymptomatic type I second-degree AV block, particularly in older patients with structural heart disease[19,20] (**Class IIa, Level C**). In young subjects, however, asymptomatic type I second-degree AV block occurring during sleep or associated with athletic training is more likely to reflect high resting vagal tone and pacing is unnecessary.[21,22] In type II second-degree AV block, progression to complete AV block is common, particularly when the QRS complex is wide,[15] and pacing is indicated even in the absence of symptoms (**Class I, Level C**).

Complete atrioventricular block
In symptomatic complete AV block, pacing usually, although not invariably, improves the symptoms and should always be considered. Irrespective of symptoms, however, untreated acquired complete heart block is associated with significantly impaired survival. Overall mortality may exceed 50% at 1 year, the outlook being worse in older patients (>80 years) and those with associated non-rheumatic structural heart disease.[23] Male sex and a history of syncope have also been associated with a worse outlook in some studies[24] but there is conflicting evidence regarding syncope.[25] Transient AV block carries a more favorable prognosis, with a 1-year mortality of 36%, compared with 70% in patients with permanent AV block,[23] but a significant proportion of patients (38–39% over median follow-up of 36–54 months) progress to permanent AV block and become pacemaker dependent when paced.[26]

Observational studies of outcome in paced patients during the early days of cardiac pacing suggested that pacing in complete AV block could improve survival to approach that of a similar age- and sex-matched group.[24] Mortality was higher in those with a history of myocardial infarction but not influenced by pre-pacing QRS duration or morphology, ventricular rate (dichotomized about 40/min) or whether AV block was intermittent or constant.[27] In a more recent study of patients aged ≥65 years, paced for symptomatic, high-grade AV block, overall survival

was less than expected for an age- and sex-matched cohort.[28] However, in patients aged <80 years without structural heart disease, survival was normal. Congestive heart failure, chronic obstructive pulmonary disease, age, syncope, insulin-dependent diabetes and male gender emerged as independent predictors of increased mortality. There have been no prospective randomized trials to assess the impact of pacing in high-grade AV block but the prevalence of symptoms, the high mortality without pacing, the strength of the data from observational studies, and the absence of any alternative therapy suggest that such a trial is neither ethical nor necessary. The vast majority of patients with complete AV block should be paced, whether or not they have symptoms (**Class I, Level C**)

Congenital complete atrioventricular block

In patients surviving to adulthood, the prognosis of congenital complete AV block has previously been regarded as benign, based largely on retrospective studies of a small series of patients.[29] More recent data concerning long-term follow-up (7–30 years) of 102 patients with isolated congenital complete AV block, who survived without symptoms to the age of 15 years, suggests a less favorable outlook.[30] Stokes–Adams attacks occurred in 27 patients, of whom eight died (six during the first attack) and six others required cardiac resuscitation. All survivors received pacemakers. A further eight patients had repeated fainting spells requiring pacing and 27 others were paced for other reasons (fatigue, effort dyspnea, dizziness, ectopics during exercise, mitral regurgitation or slow ventricular rates). Of 40 patients followed for 30 years, only four remained asymptomatic without pacing. The only significant predictor of risk was QTc prolongation, which was seen in seven patients, all of whom had Stokes–Adams attacks and three of whom died. In contrast to previous studies, low ventricular rates, widened QRS complexes, poor chronotropic response to exercise and ectopics were not predictive of future Stokes–Adams attacks or death. These data support the authors' recommendation of prophylactic pacing in adolescents and adults with congenital complete AV block, even without symptoms, notwithstanding the fact that a number of questions remain unanswered (**Class IIa, Level C**).[31]

Fascicular block

In asymptomatic subjects with unifascicular block (right bundle branch block, left anterior hemiblock or left posterior hemiblock), the risk of progression to high-grade AV block is remote[32] and pacing is not indicated (**Class III, Level C**). In asymptomatic bifascicular block (left bundle branch block or right bundle branch block with left anterior or posterior hemiblock), the risk of progression to high-grade AV block is in the region of 2% per annum. Prognosis

is principally determined by the presence or absence of underlying structural heart disease and prophylactic pacing is not routinely indicated (**Class III, Level B**).[33] Progression to high-grade AV block is more commonly seen in patients with a history of syncope but should not be presumed to be the cause without further assessment. If high-grade AV block is documented, pacing is mandatory (**Class I, Level B**). When the cause of syncope remains unclear, an electrophysiology study may help identify patients likely to benefit from pacemaker implantation. A prolonged HV interval >100 ms and His–Purkinje block during atrial pacing have high specificity for prediction of subsequent progression to high-grade AV block.[34,35] Less marked HV prolongation (>70 ms) is more common but its significance is uncertain.[36] Sensitivity for disclosure of latent high-grade AV block may be markedly enhanced by the use of intravenous disopyramide during the study but this is not advised in patients with impaired left ventricular (LV) function.[37] The electrophysiology study may also be of value to identify inducible ventricular tachycardia,[38] which argues against the empiric use of permanent pacing in this context. However, in patients with bifascicular block and a history of syncope for which no other cause is apparent despite thorough evaluation, including an electrophysiology study, empiric pacing may be the most expeditious course. This strategy is principally justified for relief of symptoms as pacing does not appear to influence mortality or the incidence of sudden death in this context (**Class IIa, Level B**).[33]

Atrioventricular and bundle branch block after myocardial infarction

Transient conduction disturbance is a relatively common complication of acute myocardial infarction. Long-term prognosis is principally determined by the extent of myocardial injury. When AV block complicates inferior myocardial infarction, it typically resolves within a few days and rarely persists beyond 2 or 3 weeks. In anterior infarction, however, AV block may reflect extensive septal necrosis and the prognosis is poor despite pacing.[39] Patients with high-grade AV block persisting for more than 3 weeks after myocardial infarction should be considered for permanent pacing (**Class I, Level C**).

The occurrence of an intraventricular conduction disturbance (apart from isolated left anterior hemiblock) in patients with acute myocardial infarction identifies a group with poor short-term and long-term prognosis and an increased risk of sudden death.[40] The poor prognosis in this group, however, is mainly attributable to a high incidence of malignant ventricular arrhythmia, pump failure, and electromechanical dissociation, rather than progressive conduction disturbance. A prospective study of 50 patients randomized to pacing or control groups and followed for 5 years showed no significant difference in survival.[41]

However, evidence from a retrospective multicenter study of patients with bundle branch block complicating myocardial infarction indicates that transient high-degree AV block during the acute phase is associated with a high incidence of recurrent AV block and sudden death that may be reduced by pacemaker implantation.[42,43] The risk appears to be particularly high in patients with block involving the right bundle and at least one fascicle of the left bundle (**Class I, Level B**).[43,44]

Sinoatrial disease

Sinoatrial disease encompasses a wide spectrum of arrhythmia including sinus bradycardia, sinus arrest, sino-atrial block, sick sinus syndrome, the tachycardia–bradycardia syndrome and chronotropic incompetence (failure to reach at least 80% of the maximum predicted heart rate at peak exertion).[45] The prognosis in sinoatrial disease is generally good unless myocardial ischemia, heart failure or systemic embolism is present.[46] Permanent pacing is indicated for the relief of symptoms that are due to bradycardia.

The efficacy of pacing in sick sinus syndrome has been assessed in a randomized trial.[47] One hundred and seven patients with symptomatic sick sinus syndrome were randomized to receive no treatment, oral theophylline or permanent dual chamber adaptive rate (DDDR) pacing. Patients were excluded in very severe cases, defined as symptomatic resting sinus rate <30/min, sinus pauses >3 s or heart failure refractory to treatment with angiotensin-converting enzyme (ACE) inhibitors and diuretics. During a mean follow-up period of 19 months, both pacing and theophylline were associated with a lower incidence of heart failure compared with no treatment (3%, 3% and 17% respectively) but only pacing was associated with a significantly lower incidence of syncope (6%, 17% and 23% respectively). Pacing remains the treatment of choice for patients with symptomatic sick sinus syndrome (**Class I, Level B/C**). In the absence of long-term follow-up data to confirm efficacy and safety, theophylline or other pharmacologic means of chronotropic support cannot be recommended.

Pacing does not appear to improve survival in sinoatrial disease[48] and it is not generally indicated in asymptomatic patients (**Class III, Level C**). Such patients, however, should be followed closely to assess progression. Athletically trained subjects may have sinus rates as low as 30/min during sleep with pauses of almost 3 s.[49] These findings usually reflect high vagal tone and do not require pacing in the absence of symptoms. If lower rates or longer pauses are observed during sleep or if similar findings occur during the day, particularly if there is evidence of progression with time, prophylactic pacing may be justified on empiric grounds although there are no supportive data (**Class IIb, Level C**).

Mode selection in AV block and sinus node disease

In AV block, the essential requirement is that the ventricle be paced. When sinus rhythm and chronotropic competence are preserved, dual-chamber pacing with atrial tracking will ensure the maintenance of AV synchrony and physiologic rate adaptation. When sinus rhythm is absent or when chronotropic incompetence is present, an extrinsic sensor may be used to provide rate adaptation with either ventricular or dual-chamber pacing, as appropriate. In isolated sinoatrial disease, rate support can be achieved by single-chamber pacing in the atrium or ventricle, or by dual-chamber pacing.

Both dual-chamber pacing and adaptive rate single-chamber pacing have been shown to offer benefits in terms of improved hemodynamics, increased treadmill exercise tolerance and reduced symptoms when compared with single rate ventricular pacing in small randomized crossover studies.[50–58] The mean patient age in most of these studies was younger than the typical paced population although similar benefits have also been reported in patients aged 75 years or over.[59] Nonetheless, the long-term clinical benefit of physiologic pacing in the elderly has been questioned.[60] Small-scale quality of life studies have yielded conflicting results although physiologic pacing, with preservation of AV synchrony and rate adaptation, does appear to offer advantages in terms of symptoms and there is considerable evidence of patient preference for physiologic modes.[61] Single-chamber ventricular pacing is associated with an increased risk of pacemaker syndrome, which has been estimated to occur in between 7% and 20% of patients.[2] It has, however, been suggested that a subclinical form may be present in many apparently asymptomatic patients.[62] Data from retrospective studies suggest that ventricular pacing is associated with an increased risk of atrial fibrillation (AF), heart failure, and thromboembolism.[46,63] and with increased mortality in some patient groups.[64–66]

The Danish trial reported by Anderson and colleagues, was the first prospective randomized trial of pacemaker mode selection.[67] In this study, 225 patients with sick sinus syndrome were randomized to either single-chamber atrial (AAI) or single-chamber ventricular (VVI) pacing and followed for a mean of 3.3 years. Neither the incidence of AF or stroke nor survival differed significantly between the two groups, although the incidence of a combined endpoint of stroke plus peripheral embolism was significantly lower in the atrial paced group. Extended follow-up of the same group of patients was reported after a mean of 5.5 years.[68] The previously identified benefits of atrial pacing were enhanced, with a significantly lower incidence of AF, thromboembolism and heart failure in the atrial paced

group. All-cause mortality and mortality due to cardiovascular causes were also significantly lower in the atrial paced group. Only four of 110 patients in the atrial paced group developed second- or third-degree AV block, requiring pacemaker upgrade (0.6% per annum).[69]

The Pacemaker Selection in the Elderly (PASE) study randomized 407 patients, aged 65 or older (mean age 76 years), to ventricular or dual-chamber pacing.[70] All patients received DDDR pacing systems and mode randomization was achieved by programming of the pacemaker. The group included 175 patients with sinus node disease, 201 patients with AV block and 31 patients with other diagnoses. The study was powered to assess differences in health-related quality of life. As would be expected, there was marked improvement in quality of life (SF-36) after pacemaker implantation but there were no significant differences between groups in relation to pacing mode. It is noteworthy that 26% of the patients randomized to ventricular pacing crossed over to dual-chamber pacing because of symptoms attributed to pacemaker syndrome. Whilst potentially significant in itself, the high crossover rate confounds interpretation of the data, particularly in respect of clinical outcomes. In a multivariate analysis, a decrease in systolic blood pressure to <110 mmHg during ventricular pacing at the time of pacemaker implantation ($P = 0.001$), use of beta-blockers at the time of randomization ($P = 0.01$) and non-ischemic cardiomyopathy ($P = 0.04$) were the only variables that predicted crossover.[71]

The Canadian Trial of Physiologic Pacing (CTOPP), the largest reported to date, included 2568 patients aged 18 years or older (mean age 73 years), with either AV block (60%) or sinus node disease (40%), who were randomized to receive either a ventricular (VVIR) or a physiologic pacemaker.[72–74] In the physiologic arm, investigators selected either an atrial (AAIR) or a dual-chamber (DDDR) system. Adaptive rate pacing was used in both groups if chronotropic incompetence was evident and in patients with complete AV block randomized to receive ventricular pacing. Over a mean follow-up of 3 years there was no significant difference in the primary outcome of cardiovascular death or stroke (VVIR 5.5% per annum vs physiologic 4.9% per annum; relative risk reduction 9.4%; 95% confidence interval (CI) −10.5 to 25.7; $P = 0.33$). Neither was there any significant difference in all-cause mortality or in hospital admission for heart failure. There was, however, a significant, albeit modest reduction in AF (defined as an episode lasting more than 15 minutes) associated with physiologic pacing (VVIR 6.6% per annum vs physiologic 5.3% per annum; relative risk reduction 18.0%; 95% CI −0.3 to 32.6; $P = 0.05$), which became evident after about 2 years. Perioperative complications were more common with physiologic pacing (VVIR 3.8% vs physiologic 9.0%; $P < 0.001$) mainly in relation to the pacing lead(s). There was a trend suggesting that younger patients (<74 years) might have a reduced risk of stroke or cardiovascular death with physiologic pacing.

Subgroup analysis of the CTOPP data suggests that the benefits of physiologic pacing may be influenced by pacemaker dependency.[75] This was assessed in 87% of the enrolled patients by recording the unpaced heart rate at the first follow-up visit (2–8 months post implant). In patients with unpaced heart rates ≤60/min, the incidence of cardiovascular death or stroke was lower with physiologic pacing (VVIR 6.4% per annum vs physiologic 4.1% per annum; relative risk reduction 35.5%; 95% CI 12 to 53). By contrast, the treatment effect of physiologic pacing was slightly negative in patients with unpaced heart rates >60/min (VVIR 4.1% per annum vs physiologic 4.3% per annum; relative risk reduction −1.9%; 95% CI −50 to 31). The difference in treatment effect between the two groups was of only borderline significance ($P = 0.058$).

Quality of life improved with pacing but there were no significant differences according to pacing mode irrespective of pacemaker dependency.[76] A limited economic analysis in a subset of 472 patients showed that physiologic pacing was not cost-effective according to generally accepted standards unless used selectively in patients likely to be pacemaker dependent.[77]

The CTOPP investigators subsequently reported the results of extended follow-up after a mean of 6.4 years. The previously observed difference in the rate of AF persisted, with a relative risk reduction in the physiologic group of 20.1% (95% CI 5.4 to 32.5; $P = 0.009$) but there was no significant difference in the rate of cardiovascular death or stroke.[78]

The Mode Selection Trial (MOST) assessed the benefits of adaptive rate, dual-chamber pacing compared with adaptive rate, single-chamber, ventricular pacing in 2110 patients aged ≥21 years, with sinus node dysfunction.[79] A DDDR pacing system was implanted in all patients and the pacing mode was randomized to VVIR or DDDR. After a median follow-up of 33.1 months, there was no difference in the incidence of the primary endpoint, death or non-fatal stroke, between the groups (VVIR 23.0% vs DDDR 21.5%; $P = 0.48$).[80] However, dual-chamber pacing was associated with a lower incidence of AF (hazard ratio (HR) 0.79; 95% CI 0.66 to 0.94; $P = 0.008$). Heart failure scores were also significantly improved but this did not result in a lower incidence of hospitalization for heart failure in the primary unadjusted analysis (VVIR 12.3%; DDDR 10.3%; HR 0.82; 95% CI 0.63 to 1.06; $P = 0.13$). Quality of life was substantially improved by pacing with a small but significant advantage for the dual-chamber mode in three of the eight subscales of the SF-36.[81] Crossover from VVIR to DDDR mode occurred in 374 patients but 61 patients subsequently switched back, resulting in a crossover rate at final follow-up of 31.4%. Almost half of the crossovers were attributed

to pacemaker syndrome. The high crossover rate in PASE and MOST, where a mode change only required reprogramming of the device, contrasts with the low rates in CTOPP (2.7% at 3 years) and UKPACE (3.1% at 3 years), in which replacement of the pacing system would have been required. Although the high crossover rate in MOST complicates interpretation of the data, an analysis based on treatment received showed that it had no impact on the primary endpoint or other key clinical outcomes.[82] An economic analysis suggested that dual-chamber pacing in this patient group is cost-effective at conventionally accepted levels both within the 4-year time horizon of the trial and projected over the lifetime of the patients.[83]

The United Kingdom Pacing and Cardiovascular Events (UKPACE) trial enrolled patients aged ≥70 years with high-grade AV block. Prior to the trial, national registry data showed evidence of ageism in clinical practice, with elderly patients being much less likely to receive dual-chamber pacemakers than those who were younger.[84] In the trial, 2021 patients were randomly assigned to receive either single-chamber or dual-chamber pacemakers and followed for a minimum of 3 years. In the single-chamber arm, assignment to VVI or VVIR was also randomized. After median follow-up of 4.6 years, there was no significant difference in the primary outcome of all-cause mortality (VVIR 7.2% per annum vs DDDR 7.4% per annum; HR 0.96; 95% CI 0.83 to 1.11; $P = 0.33$). Median follow-up for other events was 3 years and showed no significant difference in the rates of AF, heart failure or a composite of stroke, transient ischemic attack (TIA) or other thromboembolism.[85] When VVI and VVIR pacing were compared separately with dual-chamber pacing, there was a significantly higher rate of stroke, TIA or other thromboembolism with VVI pacing than with DDD (2.5% per annum vs 1.7%; $P = 0.04$) but there were no other significant differences. Complications related to the implantation procedure were more common in the dual-chamber group than in the single-chamber group (7.8% vs 3.5%; $P < 0.001$), as were complications before hospital discharge (10.4% vs 6.1%; $P < 0.001$). Preliminary analysis of quality of life showed improvement with pacing but no significant difference according to randomized pacing mode. Suspected pacemaker syndrome occurred in only 2.7% of those receiving single-chamber pacing[86] and crossover from single- to dual-chamber pacing in 3.1%.[85]

The Danish Multicenter Randomized Study on Atrial Inhibited versus Dual-Chamber Pacing in Sick Sinus Syndrome (DANPACE) aims to examine the relative merits of single-lead atrial pacing (AAIR) and dual-chamber pacing (DDDR) in patients aged ≥18 years with sick sinus syndrome (including tachycardia-bradycardia syndrome) and normal AV conduction.[87] The primary outcome measure is all-cause mortality. Secondary outcomes include cardiovascular mortality, AF, thromboembolism, quality of life and

cost–benefit. Recruitment of 1415 patients (reduced from an original target of 1900) was completed in June 2008 and follow-up will be concluded in 2009.

A prior pilot study randomized 177 patients with sick sinus syndrome and normal AV conduction to single-chamber atrial pacing (AAIR), or dual-chamber pacing (DDDR) with either a short AV delay or a fixed long AV delay. During a mean follow-up of 2.9 years, echocardiography showed no significant changes in left atrial or ventricular diameter or in LV fractional shortening in the atrial pacing group. However, left atrial diameter increased in both of the dual-chamber groups and LV fractional shortening decreased in the dual-chamber group with short AV delay.[88] The incidence of AF was significantly lower in the atrial pacing group (7.4%) than in the dual-chamber groups with short (12.3%) or long (17.5%) AV delay, the benefit being most evident in patients with brady-tachy syndrome.[89]

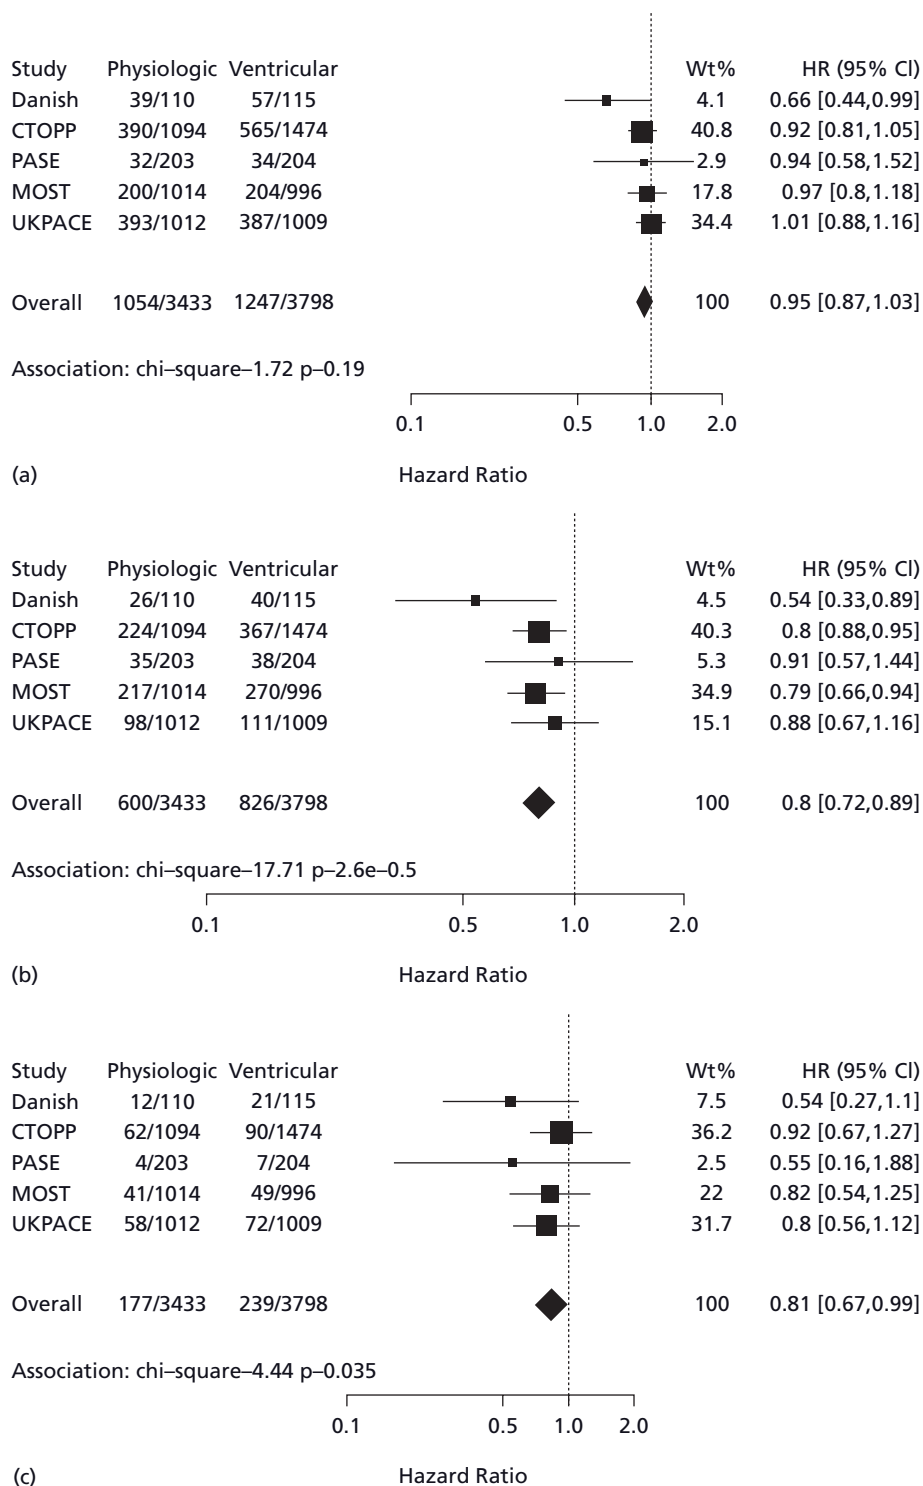
The benefits of physiologic pacing have been addressed in four other trials for which only limited data are available. An Italian study reported on 210 patients with high-grade AV block (100 patients) or sick sinus syndrome (110 patients) with no prior AF, randomly assigned to ventricular (VVI or VVIR) or atrial-based (AAI, DDD, DDDR or VDD) pacing.[90] The incidence of chronic AF was lower with atrial-based than with ventricular pacing, particularly in those with sick sinus syndrome. The Pacemaker Atrial Tachycardia (PAC-A-TACH) trial assessed the effect of pacing mode on atrial tachyarrhythmia recurrence in 198 patients with the tachycardia-bradycardia syndrome.[91] All patients received dual-chamber, adaptive rate pacemakers programmed to either VVIR or DDDR pacing. After a median of 23.7 months follow-up, 44% of patients crossed over from VVIR to DDD (due to pacemaker syndrome in 28% and atrial tachyarrhythmia in 13%) and 9% crossed over from DDDR to VVIR (due to recurrent atrial tachyarrhythmia in 7% and atrial lead problems in 2%). Intention-to-treat analysis showed no significant difference in atrial tachyarrhythmia recurrence rates at 1 year (VVIR 43%; DDDR 48%; $P = 0.09$). Mortality, a secondary outcome, was significantly higher in the VVIR group and the trial was stopped after follow-up of approximately 2 years in all patients. Cumulative mortality was 21% in the VVIR group and 5% in the DDDR group ($P < 0.001$). Pacing mode (risk ratio 4.3; 95% CI 1.6 to 11.4; $P = 0.004$) and prior history of myocardial infarction (risk ratio 3.1; 95% CI 1.4 to 6.7; $P = 0.006$) were identified as independent predictors of mortality.[92] The Systematic Trial of Pacing to Prevent Atrial Fibrillation (STOP-AF) randomly assigned 227 patients with sick sinus syndrome, all implanted with a DDDR pacing system, to either atrial-based (AAI or DDD) or ventricular pacing.[93,94] The results have not yet been presented or published. Finally, the ongoing Pacing the Octagenarian Plus (POPP) trial is comparing the effect of single-chamber


Figure 41.1 Effect of pacing mode, expressed as the HR and 95% CI. An HR <1.0 is shown to the left of the center line and favors atrial-based pacing. CIs that cross 1.0 signify a statistically non-significant effect. (a) All-cause mortality. (b) Incidence of atrial fibrillation. (c) Incidence of stroke (Reproduced with permission from Healey et al.[96])

(VVIR) and dual-chamber (DDDR) pacing on hospitalization for cardiovascular causes, functional capacity and quality of life in the very elderly.[95]

A prospectively planned meta-analysis of patient-level data from five of the trials (the Danish Trial, PASE, CTOPP, MOST and UKPACE) demonstrated a reduction in AF with atrial-based pacing (HR 0.80; 95% CI 0.72 to 0.89; $P = 0.00003$) and in stroke (HR 0.81; 95% CI 0.67 to 0.99; $P = 0.035$).[96] There was no significant reduction in mortality or heart failure and no convincing evidence that any patient subgroup derived special benefit from atrial-based pacing. The key findings are shown in Figure 41.1.

Two systematic reviews have comprehensively assessed the various parallel group and crossover randomized controlled trials comparing single-chamber ventricular pacing and dual-chamber pacing.[97,98] The aggregated data indicate an overall advantage for dual-chamber pacing, related to the lower incidence of AF and the reduction in pacemaker syndrome. These benefits must be weighed against the increased implant complications and cost. The overall estimate of cost-effectiveness of dual-chamber pacing varied between around UK £9000 and around UK £30 000 per quality-adjusted life-year, according to the assumptions made about the incidence and severity of pacemaker syndrome.[98]

A new paradigm for physiologic pacing

The results of the various prospective randomized trials suggest that the clinical benefits of physiologic or dual-chamber pacing may previously have been overestimated. Pacemaker recipients are often elderly with multiple co-morbidities and a high mortality from non-cardiovascular causes. Against this background, it may be unrealistic to expect a marked effect of pacing mode on quality of life, clinical events and mortality, all of which may be more influenced by other factors. A further explanation for the limited clinical benefits of physiologic pacing might be that the conventional placement of the ventricular lead at the right ventricular apex causes interventricular and intraventricular dyssynchrony that could offset the hemodynamic advantage of preserved AV synchrony. It has long been recognized that eccentric ventricular stimulation results in impaired LV performance.[99] Pacing at the right ventricular apex produces an activation sequence similar to that of left bundle branch block, the acquired form of which is associated with an adverse prognosis particularly in patients with heart failure.[32,100,101] Whilst this may partly reflect advanced underlying disease, there is some evidence that the conduction disturbance is an independent marker of adverse outcomes.[101] Paradoxically, the problem may be accentuated by dual-chamber pacing. In an analysis of patients in the MOST study with normal baseline QRS duration, the cumulative percentage of ventricular beats that were paced was greater with dual-chamber than with single-chamber pacing and a higher cumulative percentage of ventricular pacing was associated with an increased risk of heart failure hospitalization and AF with either pacing mode.[102] Further data suggesting a deleterious effect of right ventricular apical pacing have emerged from studies of pacing strategies in implantable cardioverter defibrillator (ICD) recipients. In the Dual-chamber and VVI Implantable Defibrillator (DAVID) trial, 506 patients with an ICD capable of dual-chamber adaptive rate pacing were randomly assigned to back-up ventricular pacing at 40/min or dual-chamber adaptive rate pacing at 70/min. All patients had ejection fraction ≤40% but no indication for cardiac pacing. Over 1 year, the incidence of the composite endpoint of death or hospitalization for heart failure was significantly increased in the dual-chamber paced group (HR 1.61; 95% CI 1.06 to 2.44).[103] Similarly, in a subgroup analysis of the Multicenter Automatic Defibrillator Implantation Trial (MADIT) II, which tested the benefit of a prophylactic ICD (single- or dual-chamber with back-up pacing) in patients with prior myocardial infarction and LV ejection fraction ≤30%, patients who were predominantly paced had an increased incidence of new or worsening heart failure.[104]

Recognition of the potential importance of dyssynchrony from right ventricular pacing has prompted a re-evaluation of what constitutes "physiologic" pacing and a new paradigm is emerging.[105,106] The key considerations are that, in addition to preserving AV synchrony, the selected therapy should minimize unnecessary ventricular pacing and minimize intraventricular and interventricular dyssynchrony when ventricular pacing is required.

Minimizing ventricular pacing

In patients with sinus node disease and normal AV conduction, single-chamber atrial pacing permits ventricular activation via the intrinsic conduction system, with complete avoidance of ventricular pacing. Although the subsequent development of AV conduction disturbance is infrequent (circa 1.7% per annum),[107] many physicians prefer to implant a dual-chamber system to insure against the risk. It is, however, noteworthy that the Danish study was the only randomized trial to use single-lead atrial pacing as the sole physiologic comparator and showed the greatest clinical benefits from physiologic pacing, including a reduction in mortality. The DANPACE trial will provide further information about the relative merits of the two approaches in due course.

If a ventricular lead is placed prophylactically or due to the presence of intermittent AV conduction disturbance, there are several programming options to minimize ventricular pacing although none will truly emulate normal physiology. Fixed, long AV delays are only partially effective in reducing ventricular pacing and may compromise upper-rate behavior and predispose to pacemaker-mediated tachycardia.[108] Other options include the use of the DDIR mode, which provides back-up pacing in the ventricle without tracking the atrial rhythm, and algorithms that permit automatic extension of the AV interval (AV search hysteresis) to favor intrinsic ventricular activation.[109,110] A number of manufacturers have recently introduced dual-chamber devices with new algorithms that combine functional AAIR pacing with ventricular monitoring and back-up DDDR pacing, when required.

These algorithms have been shown to be effective in reducing the cumulative percentage of ventricular pacing.[111,112] The recently reported Search AV Extension and Managed Ventricular Pacing for Promoting Atrioventricular Conduction (SAVE PACe) trial showed a lower incidence of AF with the use of AV search hysteresis and minimal ventricular pacing algorithms than with conventional dual-chamber pacing in patients with sinus node disease and normal AV conduction after a mean follow-up of 1.7 years (HR 0.6; 95% CI 0.41 to 0.88; $P = 0.009$).[113] The programming in the conventional dual-chamber arm of the study resulted in a particularly high frequency of ventricular pacing (median 99%), which may have amplified the apparent benefit of the new algorithms but the study nonetheless added to the evidence suggesting benefit from the avoidance of unnecessary ventricular pacing. Attention has been drawn to a potential disadvantage of the algorithms, which may permit or induce very long PR intervals, resulting in potentially significant AV desynchronization in some patients.[114] Further trials are in progress to assess the clinical utility of these new approaches.[115–117]

An additional consideration when programming devices to minimize ventricular pacing is the use of adaptive rate pacing using extrinsic sensors to determine the pacing rate. The Advanced Elements of Pacing Trial (ADEPT) demonstrated, perhaps surprisingly, that rate modulation using current dual-chamber pacemaker technology does not provide measurable improvements in either quality of life or exercise capacity in patients with a blunted heart rate response to exercise.[118] Although there was no difference in the prespecified composite clinical endpoint, rate modulation was associated with a higher frequency of hospitalization for heart failure. It may be that the advantages of restoring chronotropic competence are attenuated by the deleterious effects of increased ventricular pacing. The findings suggest that sensor-driven adaptive rate pacing should be avoided in the absence of chronotropic incompetence and that cautious programming is advisable when it is used.

Minimizing ventricular dyssynchrony

In patients who have permanent AV block and in those who are likely to require more than occasional ventricular pacing, the intraventricular and interventricular dyssynchrony associated with pacing at the right ventricular apex may be attenuated by the use of alternative or multiple pacing sites in the right ventricle, or biventricular pacing.

Alternative and multisite pacing
Numerous small and relatively short-term studies have shown improved hemodynamic function using pacing sites in the right ventricular outflow tract but results have been inconsistent, probably reflecting differences in patient selection, lead positioning and duration of follow-up.[119–121] The septal aspect of the outflow tract appears to be the optimal site[122] but the precise location for maximum hemodynamic advantage may vary between patients. The attainment of a suitable lead position requires sound knowledge of the anatomy, aided by radiologic and electrocardiographic confirmation of optimal lead placement.[123] Another approach that has been investigated is the use of direct His bundle or para-Hisian pacing, which would be expected to achieve the most physiologic ventricular activation pattern in patients with intact distal conduction.[124–126] The technique has been shown to be feasible and to improve hemodynamic and functional outcomes compared with pacing at the right ventricular apex but accurate lead placement is technically challenging and its role remains uncertain. Bifocal right ventricular pacing, with leads at the apex and in the outflow tract, has also been assessed, predominantly in patients with heart failure and conventional indications for cardiac resynchronization therapy.[127–129] Improved hemodynamic and functional outcomes have been demonstrated in the short and medium term and the technique may have a role in this setting for patients in whom transvenous placement of the LV lead is unsuccessful and surgical placement of an epicardial lead is not an option.[129]

Biventricular pacing
Recognition that the dyssynchrony associated with pacing at the right ventricular apex is analogous to that induced by left bundle brunch block has prompted consideration of biventricular pacing in patients with a bradycardic indication for pacing, NYHA class III or IV heart failure and impaired LV function. Patients requiring pacing for bradycardia were generally excluded from the trials of biventricular pacing in heart failure but extrapolation of their results suggests that it may be an attractive therapeutic option in this setting. It might also be of prophylactic benefit, even in those without heart failure or impaired LV function at the time of implant. The utility of biventricular pacing in patients paced for bradycardia was first demonstrated in observational studies in which patients with class III and IV heart failure, previously implanted with a right ventricular pacing system, were upgraded to a biventricular pacing system. The procedure was shown to be feasible and to result in improved NYHA class, ejection fraction and symptoms or quality of life after 3–6 months' follow-up.[130,131] In a pilot, randomized, crossover trial in patients with advanced heart failure, requiring replacement of conventional pacing systems, biventricular pacing was associated with improved hemodynamics, NYHA functional class, 6-minute walk distance and quality of life.[132]

The first randomized trial to assess biventricular pacing as a primary strategy in patients requiring anti-bradycardia pacing was the Post AV Nodal Ablation Evaluation (PAVE) trial, which compared right ventricular apical pacing and biventricular pacing in 184 patients, with or without heart failure or LV impairment, who were undergoing AV node ablation for AF.[133] After 6 months follow-up, biventricular pacing was associated with a greater improvement in 6-minute walk distance and ejection fraction was preserved, contrasting with a small fall with right ventricular apical pacing. A subsequent smaller 3-month crossover study in severely symptomatic patients with permanent AF, uncontrolled heart rate or heart failure undergoing AV node ablation showed only modest or no benefit from biventricular or LV pacing compared with right ventricular apical pacing, possibly due to the short follow-up.[134] More recently, the Homburg Biventricular Pacing Evaluation (HOBIPACE) compared biventricular pacing with conventional right ventricular pacing in 30 patients with AV block requiring pacing, LV dilation (≥60 mm) and reduced ejection fraction (≤45%) in a 3-month crossover design.[135] Biventricular pacing was superior with regard to LV function, quality of life and exercise capacity, the benefit being similar for patients in sinus rhythm and in AF.

Biventricular pacing has subsequently been compared with conventional dual-chamber pacing in a randomized parallel group study of 50 patients, unselected with regard to baseline ejection fraction, being paced for high-grade AV block.[136] After 12 months follow-up, ejection fraction was preserved, N-terminal pro-BNP fell and NYHA class improved in the biventricular paced group, whereas ejection fraction decreased and N-terminal pro-BNP and NYHA class were unchanged in the dual-chamber paced group.

Further trials are ongoing to assess the benefits of biventricular pacing as an alternative to conventional pacing in patients with impaired LV function and mild to moderate heart failure (the Biventricular versus Right Ventricular Pacing in Patients with AV Block (BLOCK-HF) trial),[137] without advanced heart failure (the Preventing Ventricular Dysfunction in Pacemaker Patients Without Advanced Heart Failure (PREVENT-HF) study),[138] with preserved LV function (the Pacing to Avoid Cardiac Enlargement (PACE) trial),[139] and unselected with regard to ejection fraction or heart failure at enrolment (the Biventricular Pacing for Atrioventricular Block to Prevent Cardiac Desynchronization (BioPace) study).[140]

Comment and recommendations

The available data suggest that dual-chamber pacing confers a modest advantage over single-chamber ventricular pacing due to the reduced risk of AF, the avoidance of pacemaker syndrome and a possible small benefit in quality of life. Interpretation of the data regarding pacemaker syndrome is complicated by the divergent estimates of mode intolerance between trials in which the mode randomization was achieved by software programming (PASE, PAC-A-TACH and MOST) and those in which it was achieved by hardware selection (the Danish study, CTOPP and UKPACE). Each design has strengths and weaknesses but software randomization trials are more vulnerable to the effect of investigator bias.[141] In the software randomization trials, crossover rates ranged from 26% to 44%, whereas in the hardware randomization trials, they did not exceed 5%. The true incidence of mode intolerance is most likely between the two extremes. Notwithstanding these uncertainties, dual-chamber pacing is the recommended mode for the majority of patients with sinus node disease or AV block, except in the presence of permanent AF (**Class I/IIa, Level A**). In patients with isolated sinus node disease and no evident abnormality of AV conduction on ECG or at implant, single-chamber atrial pacing remains an attractive option and provides the most physiologic pattern of ventricular activation.[142] Retrospective analysis of pooled data from 28 studies suggests that the risk of subsequent AV block, is low (0.6% per annum)[143] and this is supported by data from the Danish study.[69] Many physicians will nevertheless prefer to implant a dual-chamber system with features and programming tailored to provide functional AAIR pacing with minimal unnecessary ventricular activation.[144] The choice of pacing mode should take account of individual patient factors and in elderly patients with high-degree AV block, single-chamber ventricular pacing (VVIR) is a reasonable option. Adaptive rate pacing should be provided if there is evidence of chronotropic incompetence but unnecessarily aggressive programming of rate response should be avoided. In patients who are likely to require frequent ventricular pacing, alternative pacing sites, such as the septal aspect of the right ventricular outflow tract, may confer an advantage by minimizing dyssynchrony but further data are required before this approach can be recommended for routine practice. Ongoing trials will clarify the role of biventricular pacing in patients requiring pacing for bradycardia. It is, however, a reasonable option to consider, on an individual basis, in patients with NYHA class III or IV heart failure, a low ejection fraction (≤35%) and a high anticipated requirement for ventricular pacing (**Class IIa, Level B**). Consideration should also be given to implanting a combined device in patients with a conventional indication for an ICD.

New indications for pacing

Neurocardiogenic syncope

Neurocardiogenic syncope describes the clinical syndromes of syncope resulting from inappropriate autonomic

responses, manifested as abnormalities in the control of peripheral vascular resistance and heart rate.[145] It is thought to account for the largest proportion of faints in clinical practice. The most common forms are carotid sinus syndrome and vasovagal syncope but other related syndromes include cough, deglutition, and micturition syncope. A systematic approach to evaluate patients with syncope is essential and comprehensive guidelines have recently been published.[146,147] Carotid sinus massage[148,149] and tilt-table testing[150] are useful diagnostic tools in carotid sinus syndrome and vasovagal syncope respectively, enabling abnormal reflex responses to be categorized as cardio-inhibitory (asystole >3s, bradycardia or AV block), vasodepressor (fall in systolic blood pressure >50mmHg) or mixed. This has invited assessment of the utility of cardiac pacing which might be expected to benefit patients with predominantly cardio-inhibitory or mixed responses.

Carotid sinus syndrome

Early reports of pacing in carotid sinus syndrome confirmed its efficacy in some patients but persistent symptoms were seen in those with a significant vasodepressor response or hypotension during ventricular pacing.[151] The latter was improved by AV sequential pacing and it was suggested that this was the appropriate mode in patients with mixed responses. Attention has been drawn to the variable natural history of the condition, which may remit spontaneously, and the importance of a control group when evaluating therapy has been emphasized.[152] A prospective randomized trial of pacing in patients with severe carotid sinus syndrome randomized 60 patients to pacing (VVI in 18 and DDD in 14 patients) or no therapy (28 patients).[153] During a mean follow-up of 36 months, syncope recurred in 16 (57%) of the non-paced group and only three (9%) of the paced group; 19 patients (68%) in the non-paced group were eventually paced because of the severity of symptoms. Pacing is now the treatment of choice in all but the mildest forms of carotid sinus syndrome. Recent evidence suggests that carotid sinus syndrome is underdiagnosed and that comprehensive assessment of patients presenting with syncope, dizziness or falls may identify a significant number of otherwise unrecognized patients who may benefit from pacing.[154]

In the Syncope And Falls in the Elderly – Pacing And Carotid sinus Evaluation (SAFE PACE) trial, 24264 patients with falls or syncope were identified from a total of 71299 emergency room attendees aged ≥50 years during a 29-month period.[155] Patients with evident extrinsic or medical explanations for falling and those with cognitive impairment were excluded, leaving a residuum of 3384 non-accidental fallers. Of these, 1624 consented to and underwent carotid sinus massage, yielding 257 patients with cardio-inhibitory or mixed carotid sinus hypersensitivity, of whom 175 (mean age 73 years) were randomized to pacing or no

pacing and followed for 1 year, to test the hypothesis that dual-chamber pacing, with a rate drop response algorithm, might reduce the frequency of further falls. Paced patients were significantly less likely to fall (odds ratio 0.42; 95% CI 0.23 to 0.75) and syncope and injurious events were less frequent. A larger, multicenter, randomized controlled trial, SAFE PACE 2,[156] was subsequently undertaken to further evaluate these findings in a wider cultural setting and to clarify the relationship between symptoms and arrhythmia by the use of an implantable loop recorder in the non-paced patients. No data from this trial are currently available. However, a small crossover trial, comparing pacing (DDD with rate drop response) and no pacing (ODO mode) for 6 months each in 34 patients with recurrent unexplained falls and carotid sinus hypersensitivity has recently been reported.[156a] This failed to confirm the benefit from pacing that was observed in SAFE PACE but there was a high attrition rate, with only 25 patients completing both phases, and the study was consequently underpowered and inconclusive.

Comment and recommendations

Recurrent syncope caused by spontaneously occurring carotid sinus stimulation with a cardio-inhibitory response to carotid sinus massage (asystole >3s) is a **Class I, Level C** indication for pacing. Recurrent syncope without clear provocative events and with a cardio-inhibitory response to carotid sinus massage is a **Class IIa, Level C** indication for pacing. European guidelines also require that the asystolic response to carotid sinus massage be accompanied by syncope or presyncope. The role of pacing in patients with a history of recurrent falls (without clear evidence of syncope) and cardio-inhibitory carotid sinus hypersensitivity is uncertain and should be considered on an individualized basis (**Class IIb, Level B**).

Vasovagal syndrome

Pacing has also been evaluated in the so-called "malignant" form of vasovagal syndrome, characterized by recurrent syncope with only brief or absent prodromal symptoms. Evidence from several studies using temporary pacing during tilt testing indicates that pacing rarely prevents vasovagal syncope, reflecting the fact that hypotension precedes the onset of bradycardia in most patients. However, dual-chamber pacing does attenuate the evolution of the final and most extreme degrees of hypotension and may thereby prolong the symptomatic presyncopal period in selected patients with a documented cardio-inhibitory component.[157] A retrospective review of 37 patients receiving predominantly dual-chamber implanted pacemakers, followed for a mean of 50.2 months, reported symptomatic improvement in 89% with 62% remaining free of syncope and 27% completely asymptomatic. The collective syncopal burden was reduced from 136 to 11 episodes per year.[158]

The North American Vasovagal Pacemaker Study (VPS)[159] randomized patients with a history of frequent syncope (≥6 lifetime episodes) and a cardio-inhibitory response on tilt testing to receive either no pacing or DDI pacing with a pacemaker incorporating a specialized rate drop-sensing algorithm designed to detect the characteristic pattern of onset of bradycardia that is seen in vasovagal syndrome. The fall in heart rate is typically more marked than occurs with natural diurnal fluctuation yet less precipitous than that seen at the onset of complete AV block or asystole. On detection of a characteristic rate drop, pacing commences with a high initial intervention rate that gradually decreases.[160] It had been intended to enroll 284 patients, but the study was stopped after enrolment of only 54 patients due to substantial benefit in the paced group. During follow-up, syncope recurred in 22% of patients who were paced compared with 70% of those who were not (relative risk reduction 85.4%; 95% CI 59.7 to 94.7; P = 0.000022). There was no significant effect on presyncope (reported by 63% of paced patients and 74% of non-paced patients).

The Vasovagal International Study (VASIS) Group subsequently reported a multicenter European trial of similar design.[161] Forty-two patients with at least three syncopal episodes in the preceding 2 years and a cardio-inhibitory response to tilt testing were randomized to DDI pacing with rate hysteresis (n = 19) or no pacing (n = 23). Syncope recurred in only one (5%) of the paced patients but in 14 (61%) of the unpaced patients (P = 0.0006). The median time to first syncope in the unpaced group was 5 months.

The Syncope Diagnosis and Treatment (SYDIT) study compared the relative efficacy of dual-chamber pacing with a rate drop-sensing algorithm and pharmacologic therapy with atenolol.[162] Patients were eligible if they had at least three syncopal episodes in the preceding 2 years and a positive response to tilt testing (syncope with relative bradycardia). The study was terminated after 93 patients had been enrolled, as an interim analysis showed a significant effect in favor of pacing. Syncope recurred in only 4.3% of the paced group (after a median of 390 days) compared with 25.5% of the pharmacologically treated group (after a median of 135 days) (odds ratio 0.133; 95% CI 0.028 to 0.632; P = 0.004).

Less encouraging results have since been reported from two double-blind, placebo-controlled trials. In the second Vasovagal Pacemaker Study (VPS II),[163] the inclusion criteria were similar to those of the first VPS but in contrast to that study, VASIS and SYDIT, all patients received a pacemaker and were randomized to DDD pacing with a rate drop response algorithm (n = 48) or no pacing (ODO mode; n = 52). Over 6 months follow-up, syncope recurred in 33% of the paced group, compared with 42% of the non-paced group. The relative risk reduction in time to syncope with DDD pacing was 30% but this was not significant (95% CI −33% to 63%; P = 0.14).

In the Vasovagal Syncope and Pacing (SYNPACE) trial,[164] 29 patients with severe recurrent vasovagal syncope, reproduced on tilt-testing, all received a pacemaker which was randomly assigned to be programmed on (DDD pacing with rate drop response; n = 16) or off (inactive OOO mode; n = 13). During a median follow-up of 715 days, there was no significant improvement in syncope recurrence (50% of the paced group and 38% of the non-paced group) or in time to first syncope.

The difference in outcomes between the blinded and unblinded trials suggests a significant placebo or "expectation of benefit" effect from pacemaker implantation. This is supported by the results of a meta-analysis including data from nine randomized trials of pacing for vasovagal syncope.[165] The analysis showed that permanent pacing reduced the risk of recurrent syncope in the unblinded trials (odds ratio 0.09; 95% CI 0.04 to 0.22) but not in the double-blind trials (odds ratio 0.83; 95% CI 0.41 to 1.70). The accumulated data do not support the use of pacing as first-line therapy for vasovagal syncope. However, attention has been drawn to the limitations of the trials, all of which were relatively small, with even the largest (VPS II) being limited in power to rule out a modest benefit from pacing.[166,167] There was also variation in the enrolment criteria, including the requirement for a positive (cardio-inhibitory) tilt test. Pacing would only be expected to benefit patients in whom syncopal episodes were wholly or predominantly mediated by bradycardia or asystole. The utility of tilt testing to identify such patients is limited by poor reproducibility and a lack of correlation between the responses to tilt testing and the mechanism of spontaneous syncope.[146,168] The use of an implantable loop recorder to document the cardiac rhythm during spontaneous syncope and guide further therapy has shown promise and is being further evaluated in a randomized trial.[169,170]

Comment and recommendations

Pacing should not be considered as first-line therapy for the majority of patients with vasovagal syncope. The initial focus should be on conservative measures, such as education, reassurance and physical maneuvers, which may be particularly useful when there are prodromal symptoms.[146] Pacing may, however, be considered in patients with severe recurrent syncope refractory to other measures, in whom profound bradycardia or asystole is documented during tilt testing or spontaneous episodes. The uncertain benefits and the associated risks of pacing should be discussed with the patient (**Class IIa, Level B**).

Hypertrophic cardiomyopathy

The ability of pacing at the right ventricular apex to reduce the LV outflow tract (LVOT) gradient in patients with hypertrophic cardiomyopathy has been recognized for

over 30 years.[171] The benefits are thought to be due to eccentric activation of the septum, which may increase the LVOT diameter and decrease systolic anterior movement of the mitral valve during systole. Initial clinical studies showed encouraging short- and medium-term results, with decreased symptoms and improved exercise capacity associated with reductions of LVOT gradient in the region of 60%.[172–175] Favorable LV remodeling has also been observed after prolonged pacing.[176–178] Three prospective randomized crossover trials subsequently confirmed the ability of pacing to reduce the LVOT gradient. There was variable improvement in symptoms with evidence of a significant placebo effect but no significant change in exercise tolerance.[179–184] One study suggested an increased benefit from pacing in patients aged 65 years or over.[184]

Comment and recommendations

The role of dual-chamber pacing in the management of patients with hypertrophic obstructive cardiomyopathy remains controversial. The accumulated data suggest that pacing cannot be considered as primary or routine treatment but it may benefit some patients with symptoms refractory to drug therapy, significant outflow obstruction and contraindications for septal ablation or surgery (**Class IIb, Level A**). The acute hemodynamic response to pacing is not a reliable predictor of symptomatic or functional improvement and temporary pacing studies are thus of little value in patient selection.[175,176,184] Complete heart block is a recognized complication of both transcoronary alcohol septal ablation and surgical septal myectomy, for which permanent pacing may be required (**Class I, Level C**).[185,186] In patients at high risk of sudden death, an ICD may also be indicated.

Atrial fibrillation

The limited success of drug therapy in suppressing paroxysmal AF has prompted the assessment of various pacing strategies, even in patients with no other indication for pacemaker implantation. Possible mechanisms by which pacing might suppress AF in this context include reduction of bradycardia, overdrive suppression of atrial premature beats, elimination of compensatory pauses and reduction in inter- or intra-atrial conduction delay and dispersion of refractoriness that might otherwise favor re-entry. Atrial rate support has been shown to be of benefit in a small series of selected patients with the vagally mediated, pause-dependent form of AF, although concomitant drug therapy may still be required.[187] In a broader context, the use of atrial-based pacing,[188,189] atrial overdrive[190–193] and a variety of AF suppression algorithms[194–199] has been assessed in patients with and without conventional indications for pacing. Results have been inconsistent but generally disappointing. A possible confounder in some of the

studies is the potentially deleterious effect of inappropriate ventricular pacing, which may be increased by the use of atrial overdrive pacing algorithms and predispose to both tachycardia-related cardiomyopathy and the development of AF. The combination of atrial overdrive suppression algorithms with techniques to minimize ventricular pacing might attenuate these effects and this is currently being assessed.[115] Other techniques that have been assessed include biatrial pacing in patients with inter- or intra-atrial conduction delay,[200–204] and dual-site[205–209] or alternative site pacing (on the interatrial septum or at the coronary sinus os)[210–215]. Once again, results have been inconsistent with no clear evidence of clinical benefit.

Comment and recommendations

The use of pacing as a primary antiarrhythmic strategy in the management of AF is not justified by the available data. Interpretation of the data is confounded by variability in the pattern and frequency of arrhythmia, the clinical characteristics of the patients, and the endpoints and outcome measures between the studies, many of which have been small and underpowered. In patients with conventional indications for pacing, the use of a device with preventive algorithms may be justified in selected cases. These pacing modalities may be most effective when used as hybrid therapy with antiarrhythmic drugs. Indeed, it may be that much of the benefit in some of the studies is attributable to the facilitation of increased antiarrhythmic drug therapy by pacing. Pacing is not indicated for the prevention of AF in patients without other indications for pacemaker implantation (**Class III, Level B**).

Long QT syndrome

Patients with the long QT syndrome are at high risk of syncope and sudden death, usually due to polymorphic ventricular tachycardia. There are compelling data from observational studies[216–218] and from the International Long QT Syndrome Registry[219,220] indicating that cardiac pacing, with concomitant beta-blockade, may reduce the rate of recurrent syncope and sudden death. The benefit of pacing is thought to be due to the prevention of bradycardia and pauses, together with rate-related shortening of the QT interval. Unfortunately, for pacing to be effective, relatively high rates (>80/min) may be required[221] with the attendant disadvantage of reduced battery life and the potential risk of tachycardia-induced cardiomyopathy.[222]

Careful attention to pacemaker programming is essential.[223] Features that allow slowing of the heart rate below the programmed lower rate limit, such as hysteresis and sleep functions, and algorithms that may favor the occurrence of pauses should be disabled. Specific rate-smoothing algorithms that are capable of preventing postextrasystolic pauses may be useful.[224] There is indirect experimental and clinical evidence to suggest that pacing might be of particu-

lar value in patients with the LQT3 genotype,[225–227] which is particularly associated with increased dispersion of repolarization during bradycardia and with arrhythmia occurring during sleep,[228] but it should not be inferred that other genotypes will not benefit from pacing. Further data are required to clarify the extent to which therapy in the long QT syndrome can be guided by genotype. Pacing should be considered as an adjuvant to beta-blockade in all patients with long QT syndrome and symptomatic brady-cardia or high-grade AV block, and whenever there is evidence of pause-dependent malignant arrhythmias (**Class I, Level C**). In high-risk patients, an ICD may also be indicated.

Postcardiac transplantation

Bradycardia, usually due to transient sinus node dysfunction or AV block, may occur in almost two-thirds of patients in the first few weeks following orthotopic cardiac transplantation.[229] Recovery from transient AV block usually occurs within 16 days but transient sinus node dysfunction may persist for several weeks and the optimum time for consideration of permanent pacemaker implantation is uncertain.[230] In some cases, temporary treatment with oral theophylline may avert the need for permanent pacing.[231] The proportion of transplant recipients receiving permanent pacing for persistent bradycardia ranges from 2.8% to 29% in different centers.[232] The variation may reflect differences in the incidence of bradycardia and the criteria for permanent pacing although differences in surgical technique may also be relevant.[233] In paced transplant recipients, bradycardia often resolves and pacemaker usage decreases during the first few months.[234] Deferring consideration of permanent pacing until 3 weeks after transplantation may mean that some patients with transient sinus node dysfunction are spared unnecessary pacemaker implantation. Deferral is also associated with a commensurate increase in pacemaker usage in those paced. However, even with this strategy, less than half of those using their pacemakers at 3 months continue to do so at 6 months and there are no clear predictive factors to guide patient selection.[235]

Following heterotopic cardiac transplantation, the donor and recipient hearts beat independently of one another, the denervated donor heart typically beating at a faster rate. Competitive contraction of the two hearts may be deleterious and LV function in the recipient heart is improved when the two hearts beat out of phase. Acute studies have shown that paced linkage of the two hearts to produce consistent counterpulsation may result in significant functional improvement.[236] This technique has been evaluated in a chronic study using permanent dual-chamber pacemakers with the atrial channel connected to the donor atrium and the "ventricular" channel connected to the recipient atrium.[237] Paced linkage was associated with significant improvements in symptoms, general health, energy, levels of activity and maximum cardiac output in the donor heart.

Sleep apnea

Sleep apnea with hypersomnolence is estimated to affect 2–4% of middle-aged adults, although asymptomatic forms may be more frequent.[238] The condition is associated with an increased risk of hypertension and cardiovascular disease, including bradyarrhythmia.[239] It has been noted that treatment of the condition in patients with asymptomatic bradycardia occurring only during sleep may reduce the need for pacemaker implantation, provided that advanced disease of the sinus node or AV conducting system has been excluded.[240] Conversely, there have been reports of improvements in sleep-disordered breathing following pacemaker implantation in patients with sinus node dysfunction and AV block.[241]

Following similar observations in patients receiving atrial overdrive pacing for the suppression of atrial tachyarrhythmia, the efficacy of atrial overdrive was assessed in a randomized crossover trial.[242] A group of 15 patients with sinus node disease and sleep apnea, identified on screening, showed improved apnea and hypopnea indices during atrial overdrive pacing, compared with intrinsic rhythm. The mechanism of benefit is unclear but might relate to increased sympathetic activity during pacing. Surprisingly, both obstructive and central forms of sleep apnea were improved, suggesting a central mechanism affecting both respiratory rhythm and pharyngeal motor neurone activity.[243] However, subsequent studies failed to show significant benefit from atrial overdrive pacing in patients with obstructive sleep apnea with[244–247] or without[248–250] a bradycardia-related indication for pacing. A distinguishing feature of the earlier positive study, which might account for the discrepant findings, was that more than half of the patients had central sleep apnea and all had a significant number of central events. Improvements in apnea-hypopnea index and sleep quality have also been demonstrated after cardiac resynchronization therapy but only in those who responded to resynchronization, suggesting that the benefits are mediated by improved heart failure status rather than a specific effect of pacing.[251]

Neither pacing nor cardiac resynchronization therapy is currently indicated in patients without conventional indications for device therapy (**Class III, Level A**). In patients with sleep apnea who have an implanted device, atrial overdrive pacing and cardiac resynchronization therapy may improve symptoms but other specific therapies such as continuous positive airway pressure are more effective and may also be required (**Class IIb, Level A**).

Cardiac resynchronization therapy

Background

In the early 1990s, the use of dual-chamber pacing in patients with heart failure but no bradyarrhythmic indication for pacing was extensively explored. This was initially prompted by the suggestion that dual-chamber pacing with a short AV delay might improve cardiac function in dilated cardiomyopathy by improving the relationship between atrial and ventricular systole, thereby decreasing presystolic, mitral and tricuspid regurgitation and increasing ventricular filling time.[252] Initial hemodynamic and clinical studies yielded encouraging results[253,254] but others failed to show any significant benefit.[255,256] It might have been anticipated that patients with a prolonged PR interval and increased QRS duration would be most likely to benefit and this was confirmed in hemodynamic and short-term clinical studies.[257–259] Intraventricular conduction delay may be present in up to 40% of patients with severe heart failure.[260] This results in asynchronous contraction of the left and right ventricles, which may adversely affect hemodynamic function. Cardiac resynchronization therapy (CRT) aims to reverse these changes by using biventricular pacing to resynchronize left and right ventricular activation and by ensuring AV synchrony with an optimal AV delay if sinus rhythm is preserved. Biatrial synchronization may also be used in the presence of interatrial conduction delay.

The potential hemodynamic benefit of biventricular pacing was first demonstrated in an acute study in humans in 1983[261] but it was not until 1994 that the clinical application of the technique was reported in a patient with severe drug-refractory congestive heart failure.[262] Early case reports documented short-term clinical and hemodynamic improvement in patients with class III and IV heart failure using three- or four-chamber atrio-biventricular pacing.[262–264] Acute hemodynamic studies demonstrated decreased pulmonary capillary wedge pressure and increased peak LV dP/dt, systolic blood pressure and cardiac index during biventricular pacing.[264–268] Similar or greater improvements in some parameters were also reported with LV pacing alone.[265–268] The early studies of biventricular pacing used an epicardial pacing lead, implanted by limited thoracotomy or thoracoscopy, to pace the left ventricle, with a standard endocardial lead in the right ventricle. This approach has been superseded by the development of a technique for pacing the left ventricle by means of a lead introduced transvenously via the coronary sinus, with the tip located in one of the posterior or lateral cardiac veins overlying the LV free wall.[269] A coronary sinus angiogram is often used to create an anatomic map to guide placement of the specialized leads that have been developed for this type of pacing.[270]

Encouraging preliminary data regarding the clinical utility of CRT were reported from two non-randomized studies: InSync[271,272] and the French pilot study.[273] Several randomized trials have subsequently been completed in Europe and the USA to further assess the efficacy of CRT in ischemic and non-ischemic dilated cardiomyopathy. These include a number of short-term crossover and parallel group studies assessing the impact of CRT on symptoms, functional capacity and ventricular remodeling, and two larger studies designed to assess the impact on morbidity and mortality.

Randomized trials

The first Pacing Therapy in Congestive Heart Failure (PATH-CHF) trial was a single-blind randomized crossover trial, designed to evaluate the short- and long-term effects of univentricular and biventricular pacing in patients with NYHA class III or IV heart failure despite optimal medical therapy.[274,275] Patients were required to have a QRS duration ≥120 ms and a PR interval ≥150 ms. Two dual-chamber pacemakers were implanted, one with endocardial leads in the right atrium and ventricle, the other with an endocardial lead in the right atrium and a lead attached to the epicardial surface of the left ventricle via a limited thoracotomy. During the acute phase of the study, right and left univentricular pacing were compared with biventricular pacing, at preselected AV delays, using a randomized crossover design. Overall, biventricular and LV pacing had similar hemodynamic effects and increased LV dP/dt and pulse pressure more than right ventricular pacing. Pacing site had a greater influence on hemodynamics than the AV delay. During the chronic phase of the study, 41 patients were randomized to either atrio-biventricular pacing or the best atrio-univentricular mode (determined during the acute phase) for a 4-week period. This was followed by a 4-week wash-out phase without pacing and a further 4 weeks in the alternative mode. Compared with baseline, active pacing showed significant benefits in terms of peak oxygen consumption and 6-minute walk distance, with similar benefits in the univentricular and biventricular modes. Quality of life and NYHA functional class improved during the first pacing period but there was evidence of a placebo or carry-over effect, in that improvements were not eliminated during the subsequent wash-out period. There was, however, a further significant improvement during the second active pacing period, suggesting a genuine treatment effect. On completion of the crossover phase, patients were assigned to their best pacing mode and followed for 1 year. During that time, the number of days spent in hospital for heart failure was significantly lower than in the year before implantation.

The PATH-CHF II trial assessed the effects of atrial-synchronized left univentricular pacing. This was a

randomized crossover study, in which 86 patients with NYHA class II–IV heart failure were stratified according to QRS duration (120 ms to 150 ms v >150 ms) and outcomes were compared after 3-month periods of either LV or inactive pacing.[276] The long QRS group showed increased exercise tolerance and improved quality of life with active pacing, whereas the short QRS group showed no improvement in either outcome.

The Multi-Site Stimulation in Cardiomyopathy (MUSTIC) trial assessed the efficacy of transvenous biventricular pacing using a randomized blinded crossover design to compare outcomes after 12 weeks each of active and inactive pacing.[277] Patients had severe but stable heart failure due to idiopathic or ischemic LV systolic dysfunction (NYHA class III) despite optimal medical therapy, ejection fraction <35%, LV end-diastolic diameter (EDD) >60 mm, QRS duration >150 ms and no conventional indication for pacing. Sixty-seven patients in sinus rhythm were enrolled, of whom nine were withdrawn before randomization and 10 failed to complete the two crossover periods. In the 48 patients who completed the study, the 6-minute walk distance improved by 23% ($P < 0.001$) after 3 months of biventricular pacing. Quality of life scores improved by 32% ($P < 0.001$) and peak oxygen uptake by 8% ($P < 0.03$). Hospitalizations were decreased by two-thirds ($P < 0.05$). Active pacing was preferred by 85% of the patients ($P < 0.001$). At the end of the crossover phase, patients were programmed to their preferred mode; the clinical benefits were maintained at 1-year reassessment.[278,279]

The MUSTIC study had a separate limb for patients in AF, which enrolled 64 patients in NYHA class III with LV systolic dysfunction, chronic AF, a slow ventricular rate requiring pacing, and a broad paced QRS (≥200 ms).[280] There was a high drop-out rate and only 37 patients were successfully implanted and completed both crossover phases. An intention-to-treat analysis showed no benefit from CRT on exercise capacity or quality of life compared with right univentricular pacing. However, an analysis excluding patients in whom delivery of effective therapy was unsuccessful due to a low percentage of ventricular pacing, showed modest but statistically significant improvements. Eighty-five percent of patients preferred biventricular pacing and hospitalizations were less frequent during the CRT phase.

The Multicenter InSync Randomized Clinical Evaluation (MIRACLE) was a double-blind, parallel-group, randomized trial to assess the benefit of CRT in patients with NYHA class III or IV heart failure, on optimal and stable medical therapy, with ejection fraction ≤35%, LV EDD ≥55 mm and QRS duration ≥130 ms.[281] After baseline evaluation and successful implantation of a transvenous CRT pacing system, 453 patients were randomly assigned to receive active CRT or a control group with no pacing and followed for 6 months. In the CRT group, there were 12 deaths. In the control group, 16 patients died, two received a transplant and five missed the 6-month visit. One patient in each group withdrew due to device-related complications. Amongst those who completed the study, patients assigned to CRT had significant improvements in 6-minute walk distance, quality of life, NYHA class, peak oxygen consumption, and a composite heart failure score and there were fewer hospitalizations for heart failure. Echocardiography showed evidence of reverse LV remodeling, improved systolic and diastolic function, and decreased mitral regurgitation in the CRT group.[282]

MIRACLE ICD was a study of similar design in which 369 patients with an indication for an ICD received an ICD with CRT capability (CRT-D) and were randomly assigned to CRT on or CRT off.[283] After 6 months follow-up, CRT was associated with improved quality of life, functional status, treadmill time and peak oxygen uptake, although there was no difference in the change in 6-minute walk distance (a co-primary endpoint). In contrast to the earlier study in patients without an ICD indication, there were no significant differences in changes in LV size or function, overall heart failure status or rates of hospitalization. The MIRACLE ICD investigators also enrolled 222 patients with NYHA class II heart failure into a parallel study reported separately as MIRACLE ICD II.[284] Of the 191 successfully implanted patients, 186 were randomly assigned to CRT on or off. After 6 months follow-up, there was no significant improvement in exercise capacity but there were significant improvements in LV size and function, and a composite assessment of clinical status.

The CONTAK CD study assessed the safety and efficacy of CRT combined with an ICD in patients with NYHA class II–IV heart failure, ejection fraction ≤35%, QRS duration ≥120 ms and a conventional indication for an ICD.[285] The study began with a 3-month crossover design (n = 248) but later changed to a 6-month parallel group study (n = 333). The primary endpoint was also changed from peak oxygen consumption to a heart failure composite. The initial implants had an epicardial LV lead (11% of cases) but a transvenous lead was used subsequently (89% of cases). Of 581 enrolled patients, 501 were successfully implanted and 490 were randomly assigned to CRT on or CRT off. Three-month follow-up data from the crossover study were combined with 6-month data from the parallel study. CRT was associated with a non-significant 15% reduction in heart failure progression. There was a significant increase in peak oxygen consumption but only non-significant changes in NYHA class and quality of life, except for the subgroup in NYHA class III or IV, in which all functional status outcomes improved. CRT was associated with decreased LV dimensions and increased ejection fraction. Interpretation of the data is complicated by the change in study design and the power of the study was diminished by a lower than anticipated event rate, possibly due to improved medical

therapy during the course of the study, and the short follow-up in the crossover phase.

The Comparison of Medical Therapy, Pacing and Defibrillation in Heart Failure (COMPANION) trial included 1520 patients with class III or IV heart failure due to ischemic or non-ischemic cardiomyopathy, ejection fraction ≤35%, QRS width ≥120ms and sinus rhythm, who were randomly assigned in a 1:2:2 ratio to optimal pharmacologic therapy alone or with the addition of a CRT pacing system (CRT-P) or a CRT pacing system with defibrillation capability (CRT-D).[286] The primary endpoint was death or hospitalization from any cause. As compared with optimal pharmacologic therapy, CRT-P reduced the primary endpoint (HR 0.81; 95% CI 0.69 to 0.96; *P* = 0.014) and all-cause mortality (HR 0.76; 95% CI 0.58 to 1.01; *P* = 0.06). CRT-D (HR 0.64; 95% CI 0.48 to 0.86; *P* = 0.003). CRT was associated with early and sustained improvements in NYHA class, 6-minute walk distance, and quality of life.[286,287]

The Cardiac Resynchronization-Heart Failure (CARE-HF) trial enrolled 813 patients with class III or IV heart failure due to LV systolic dysfunction, ejection fraction ≤35% and QRS >120ms, who were randomly assigned to receive optimal medical therapy with or without CRT.[288] Echocardiographic evidence of dyssynchrony was also required in patients with QRS between 120ms and 149ms. Patients with atrial arrhythmias were excluded. The primary endpoint was a composite of death from any cause or unplanned hospitalization for a major cardiovascular event. After mean follow-up of 29.4 months, the incidence of the primary endpoint was significantly lower in the group receiving CRT (HR 0.63; 95% CI 0.51 to 0.77; *P* < 0.001). There was also a significant reduction in all-cause mortality (HR 0.64; 95% CI 0.48 to 0.85; *P* < 0.002) accompanied by significant improvements in symptoms, ejection fraction, NYHA class and quality of life. Echocardiography at 3 months and 18 months showed evidence of reverse remodeling with a lower end-systolic volume index and decreased mitral regurgitation. N-terminal pro-brain natriuretic peptide was also reduced. Extended follow-up for a further 8 months showed reduced mortality (HR 0.60; 95% CI 0.47 to 0.77; *P* < 0.0001), sudden death (HR 0.54; 95% CI 0.35 to 0.84; *P* = 0.005) and death due to heart failure (HR 0.55; 95% CI 0.37 to 0.82; *P* = 0.003).[289] In secondary analyses, no baseline characteristics or markers of response at 3 months emerged as useful predictors of the effect of CRT on mortality.[290,291]

The accumulated data from the various trials of CRT have been summarized in several systematic reviews and meta-analyses.[292–297] The aggregated data suggest that in patients with class III or IV heart failure due to LV systolic dysfunction with prolonged QRS duration, CRT reduces all-cause mortality and major cardiovascular morbidity, and improves quality of life (Fig. 41.2). Overall implant success rates are estimated at 93% (95% CI 92.2 to 93.7%) with a periprocedural complication rate of 4.3% (95% CI

3.6 to 5.1%), peri-implant mortality of 0.3% (95% CI 0.1 to 0.6%) and no other significant safety concerns.[295] Using currently accepted implant criteria, it is estimated that 1–3% of patients discharged alive after hospital admission for heart failure and 15–20% of patients attending specialized heart failure clinics may be candidates for CRT.[298] Economic analyses based on outcome data from the randomized trials suggest that CRT is a cost-effective therapeutic option using currently accepted thresholds in Europe and the USA.[294,299–301]

Unresolved issues in CRT

Notwithstanding the strong evidence base for CRT in patients meeting the enrolment criteria for the various randomized trials, there are several areas of clinical practice in which the available data are inconclusive.

Atrial fibrillation

The benefits of CRT depend on the effective delivery of biventricular pacing. In the presence of AF, which is a common occurrence in advanced heart failure, spontaneous ventricular activation by intrinsic conduction through an intact AV node may result in a marked reduction in the percentage of biventricular paced beats. Long-term clinical outcome data on the effectiveness of CRT in AF are limited, as both the COMPANION and CARE-HF trials included only patients with sinus rhythm. Some data are available from the MUSTIC-AF study[280] and several observational studies[302–308] which suggest that CRT may be beneficial, provided adequate biventricular pacing is achieved. Data from a European registry including 162 patients with permanent AF and 511 in sinus rhythm suggest that CRT in patients with AF results in similar improvements in ventricular function and functional capacity to those observed in patients with sinus rhythm but only after AV node ablation, which was performed when biventricular pacing occurred ≤85% of the time.[304] Comparable benefits were not seen in the group of patients who continued with pharmacologic rate control, even though biventricular pacing was achieved for over 85% of the time. Further data from an extension of the same registry, including 243 patients with permanent AF and 1042 in sinus rhythm, showed similar mortality in both groups after a median follow-up of 34 months.[307] In the patients with AF, survival was significantly improved in those who underwent ablation and CRT compared with those who received CRT alone. There were imbalances in some important baseline characteristics between the groups and these findings require verification in a prospective randomized trial. It might be supposed that reversal of structural changes in the atria and ventricles following CRT might favor spontaneous cardioversion and retention of sinus rhythm but observational data do not support that hypothesis.[303] Similarly, in patients in
Figure 41.2 Effect of CRT on (a) mortality, (b) hospitalization for heart failure, (c) quality of life assessed by Minnesota Living with Heart Failure Questionnaire. All data from randomized trials. (Reproduced with permission from Freemantle et al.[292])

sinus rhythm, CRT does not appear to influence the incidence of AF.[309]

Non-responders to CRT

A significant minority of patients fulfilling the criteria for CRT fail to benefit fully or at all from the therapy. The response to CRT may be characterized in terms of symptomatic or functional benefit, morbidity, mortality or cardiac remodeling and hemodynamic improvement but there is no universally agreed definition of what constitutes therapeutic success. Rates of non-response of 20–30% are often quoted but even higher rates have been reported, particularly in studies using objective parameters of LV remodeling.[310] The difference may partly reflect the well-recognized placebo effect of device implantation. Reasons for non-response include variability in the pattern and reversibility of intraventricular dyssynchrony,[311] suboptimal position of the LV lead[312] and factors related to the myocardial substrate, such as extensive scar tissue or transmural scar tissue at the LV pacing site in ischemic patients.[313] A wide variety of echocardiographic markers of dyssynchrony have been assessed for their ability to predict the response to CRT but no ideal approach has been found.[314,315] In the recently published Predictors of Response to CRT (PROSPECT) study, a wide range of conventional echocardiographic and tissue Doppler-based methods was evaluated but no single measure was found to improve patient selection for CRT beyond current guidelines.[316] It remains to be seen whether newer echocardiographic techniques that have shown some promise, such as speckle tracking[317] and three-dimensional imaging,[318] or cardiac magnetic resonance[319] will prove more successful.

Optimal positioning of the LV lead may be limited by the coronary venous anatomy. This is most often characterized by performing a coronary sinus venogram at the time of the CRT implant but non-invasive imaging by computed tomography has been shown to be feasible and may in the future enable anatomic limitations to be identified in advance.[320] The use of targeted lead placement using echocardiographic guidance has been evaluated in a randomized trial (the Investigating Non-Response to Cardiac Resynchronization: Evaluation of Methods to Eliminate Non-Response & Target Appropriate Lead Location (INCREMENTAL) study). Preliminary results have been presented and suggest that this approach may increase the responder rate in patients with ischemic cardiomyopathy.[321] In non-responders, repositioning of a suboptimally located LV lead should be considered. Surgical placement of an epicardial lead may facilitate targeted therapy when a satisfactory lead position cannot be achieved transvenously.[322] The available surgical options include direct lead placement via a small left thoracotomy, video-assisted thoracoscopy or robotic surgery.[323] A recent innovation that may improve the response to CRT is the addition of a third ventricular lead in either the right or left ventricle to achieve multisite pacing.[324–326] Encouraging initial results have been reported from small studies but further evaluation is required to determine the utility of this approach in non-responders and as primary therapy.

After implantation of a CRT device, individualized adjustment of the programmed AV and interventricular delay may improve the effectiveness of cardiac resynchronization.[327,328] Further complexity is added by the observation that the optimal settings may vary during exercise and over time during follow-up.[329,330] Techniques used to determine the optimal response include echocardiography, impedance cardiography, acoustic cardiography, surface or intracardiac electrocardiography and non-invasive hemodynamic monitoring.[331–333] The optimal method and the long-term impact of optimization on clinical outcomes have not yet been determined. Clinical trials are ongoing to assess the utility of the various approaches both at the time of the initial implant and during follow-up.

CRT in patients with narrow QRS complexes

The finding that LV dyssynchrony is present in up to 43% of heart failure patients with narrow QRS complexes (<120 ms)[334] has prompted the evaluation of CRT in this setting. Small observational studies showed improvements in symptoms, NYHA class, 6-minute walk distance and ejection fraction, with echocardiographic evidence of reverse remodeling after 3–6 months follow-up. The changes were similar to those observed in CRT recipients with broad QRS complexes.[335–337] The results of two randomized studies, however, were disappointing.

In the Resynchronization Therapy in Normal QRS (RethinQ) trial, 172 patients with standard indications for an ICD, NYHA class III heart failure, ejection fraction ≤35%, QRS duration <130 ms and echocardiographic evidence of mechanical dyssynchrony were implanted with an ICD with CRT capability and randomly assigned to CRT on or off.[338] After 6 months follow-up, there were no significant differences between the groups in a primary endpoint based on peak oxygen uptake during cardiopulmonary exercise testing, except in a prespecified subgroup with QRS duration ≥120 ms. NYHA class was improved in the CRT group compared with the controls but there were no significant differences in quality of life, 6-minute walk distance, echocardiographic measures or heart failure events requiring intravenous therapy. The Evaluation of Screening Techniques in Electrically-Normal, Mechanically-Dyssynchronous Heart Failure Patients Receiving Cardiac Resynchronization Therapy (ESTEEM-CRT) trial was an unblinded single-arm feasibility study, in which 68 patients with NYHA class III heart failure, ejection fraction ≤35%, QRS duration <120 ms and echocardiographic evidence of mechanical dyssynchrony were implanted with an ICD with CRT capability and assessed 1 month post-implant

and again after 6 months.[339] Patients' symptoms improved but there were no changes in exercise performance or echocardiographic measures. The symptomatic improvement was attributed to bias from the unblinded assessment or a placebo effect.

It is unclear whether these negative findings reflect ineffectiveness of CRT in patients with a narrow QRS complex, the influence of confounding factors compromising the response in relatively small short-term studies or the limitations of our current understanding and the available tools for assessing dyssynchrony, as demonstrated in the PROSPECT study. Some limited encouragement may be offered by the DESIRE study, which attempted to identify CRT responders on the basis of simple echocardiographic indices of dyssynchrony, regardless of QRS width, in a group of 64 patients with class III or IV heart failure, ejection fraction ≤40%, LV EDD ≥27 mm/m² and QRS <150 ms.[340] Patients were assigned to one of two groups after enrolment according to the presence or absence of dyssynchrony on a baseline echocardiogram. After 6 months follow-up, 55% of the patients showed clinical improvement, including 70% of those with dyssynchrony and 42% of those without ($P < 0.04$). Baseline QRS did not predict response to CRT. Unfortunately, the design of the study rendered it susceptible to a possible placebo effect and assessment bias, and the modest sensitivity and specificity of the echocardiographic measures of dyssynchrony inevitably limit their clinical utility. Further insights may come from the ongoing Echocardiography Guided Cardiac Resynchronization Therapy (Echo-CRT) trial, which is examining the effect of CRT on mortality and hospitalization for heart failure in ICD recipients with advanced heart failure, ejection fraction ≤35%, ventricular dyssynchrony on echocardiography and QRS duration <130 ms.[341] At present, CRT is not recommended in patients with a narrow QRS.

CRT in patients with class I or II heart failure

The favorable effects of CRT in patients with advanced heart failure invite speculation that patients with less severe symptoms might also benefit and that earlier intervention might prevent disease progression. Some support for this hypothesis comes from the MIRACLE ICD II trial,[284] which assessed the efficacy of CRT in 186 ICD recipients with NYHA class II heart failure, and similarly from the findings in the subset of 263 patients with class I or II heart failure in the CONTAK CD study.[285] Both studies showed evidence of reverse remodeling after CRT although there was no improvement in exercise capacity or quality of life. Reverse remodeling and improved ejection fraction after CRT were also demonstrated in an observational study of 50 patients with NYHA class II heart failure, the changes being similar to those observed in a parallel group in NYHA class III or IV.[342] Further evidence was provided by a subgroup analysis of data from the CARE-HF trial, which

showed beneficial effects on morbidity and mortality even in a group of 175 patients whose symptoms improved to NYHA class I or II after enrolment but prior to randomization and delivery of CRT.[343]

More recently, the REsynchronization reVErses Remodeling in Systolic Left vEntricular Dysfunction (REVERSE) trial assessed whether CRT could attenuate progression of heart failure and reverse LV remodeling in patients with mild or resolved symptoms (NYHA class I or II) and LV dysfunction.[344] Patients were enrolled in Europe and North America with QRS duration ≥120 ms, ejection fraction ≤40% and LV EDD ≥55 mm. A total of 610 patients were successfully implanted with a CRT device, with ICD capability if indicated, and randomly assigned to CRT on or off. After 1 year, CRT had no significant impact on the primary endpoint, a composite reflecting clinical status.[345] There was, however, evidence of reverse remodeling, with decreased LV end-systolic and end-diastolic volumes and increased ejection fraction. Time to first hospitalization for heart failure was increased in the CRT group but there was no difference in quality of life or 6-minute walk distance. Two-year follow-up of the 262 European patients has recently been reported.[346] Worsening of the clinical composite score was less frequent with CRT active than in the control group (19% vs 34%; $P = 0.01$). Echocardiographic improvements were sustained but again there was no difference in quality of life or functional status, possibly due to the mild initial symptoms. The study suggests that CRT may modify disease progression in patients with mild symptoms but firm conclusions must await the results of two larger ongoing trials comparing CRT-D with ICD alone in patients in NYHA class I and II (MADIT-CRT)[347] or class II (The Resynchronization/ Defibrillation for Ambulatory Heart Failure Trial – RAFT).[348] These trials are powered for composite primary endpoints including mortality and heart failure events or hospitalization.

Incremental benefit of combined CRT and ICD therapy

There is substantial overlap between the current indications for CRT and those for a primary prevention ICD, as defined by MADIT II[349] and the Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT).[350] In patients with indications for both devices, the implantation of a combined CRT-D system is a logical option although it cannot be assumed that the mortality benefit of combined therapy will be greater than that of either device alone. The only trial to have randomly assigned patients to receive CRT-P or CRT-D was COMPANION,[286] which was not designed to make a direct comparison of the two options. The finding that the reduction in all-cause mortality with CRT-D was significant whereas that with CRT-P was not must be interpreted with caution, as the follow-up was relatively short with a median of only 14 months. It is important also to

note that both COMPANION and CARE-HF[288] excluded patients with a conventional indication (at that time) for an ICD. A degree of complexity is added by the fact that improvement in NYHA class after initiation of CRT may move the patient into or out of a category for which ICD efficacy has been demonstrated. The incremental benefit of CRT-D is further called into question by the finding in the CARE-HF trial that CRT-P reduced not only death due to heart failure but also sudden death, and by observational data suggesting a reduction in susceptibility to ventricular arrhythmia after upgrading from ICD therapy to CRT-D.[351] A provocative and concerning finding in COMPANION was that the need for ICD therapy in CRT-treated patients was associated with more advanced disease and predicted a number of major adverse outcomes, including risk of subsequent sudden death.[352] It is also noteworthy that a subgroup analysis in SCD-HeFT showed the benefits of ICD therapy to be limited to patients in NYHA class II, with no clear advantage to those in class III who comprise the main group for which CRT is currently indicated.[350] The incremental benefit of CRT-D over CRT-P is currently uncertain[297,353] and a matter of ongoing debate.[354,355] Economic analysis suggests that CRT-D is unlikely to be a cost-effective option compared with CRT-P in the treatment of patients with class III and IV heart failure due to LV dysfunction but it is more likely to be so in younger patients (<60 years) or those with a high risk of sudden death (>7% per annum).[356] A trial directly comparing CRT-P and CRT-D would be of considerable value. Meanwhile, the decision as to whether or not to offer CRT-D rather than CRT-P to individual patients with indications for both CRT and an ICD must be made on an individual basis.

Comment and recommendations

There is considerable evidence that CRT, with or without an ICD, can improve a wide range of hemodynamic and clinical outcomes, including mortality, in patients who have NYHA class III or IV heart failure despite optimal medical therapy, with LV ejection fraction ≤35%, increased QRS duration (≥120 ms) and sinus rhythm (**Class I, Level A**). Patients in atrial fibrillation may also benefit, provided a sufficiently high proportion of biventricular paced beats can be achieved by AV node ablation or otherwise, although further studies are required in this area (**Class IIa, Level B**). Further data are also required to clarify the role of CRT in patients with mild or moderate symptoms. CRT cannot be recommended for patients with narrow QRS complexes (**Class III, Level A**).

Future perspectives

The role of pacemaker therapy in the treatment of symptomatic bradycardia is now firmly established. Some questions remain regarding mode selection, particularly regarding the role of single-chamber atrial pacing in patients with isolated sinus node disease, and the optimal location of the atrial and ventricular leads. Further technologic developments will bring new device algorithms to minimize ventricular pacing, new tools to facilitate selective site pacing, and pacing systems that are compatible with magnetic resonance imaging.[357] Future clinical trials are likely to enhance our understanding of the role of pacing in indications other than sinus node disease and AV block and to clarify the potential role of CRT in patients with conventional indications for pacing and in those with less advanced disease. Techniques for achieving cardiac resynchronization are likely to improve, as are methods to predict those who will respond. In the longer term, there is the promise of exciting new developments that may transform the way in which pacemaker therapy is delivered. The use of cardiac stimulation mediated by ultrasound energy, as an alternative to implanted leads, has recently been reported.[358] Biologic therapies are evolving and there is hope that a biologic pacemaker, achieved using gene therapy or stem cell technology, might ultimately become a clinical reality.[359] A key message from the first 50 years of cardiac pacing is that new technologies and innovations in pacemaker therapy must be critically evaluated in well-designed clinical trials to achieve a proper understanding of their clinical utility and to facilitate their further evolution.

42 Syncope

David G Benditt, Fei Lu and Scott Sakaguchi
Cardiac Arrhythmia Center, University of Minnesota Medical School, Minneapolis, MN, USA

Introduction

Syncope is a symptom in which transient loss of consciousness (TLOC) occurs as a consequence of a spontaneously self-limited period of cerebral hypoperfusion.[1–3] A wide range of conditions may be responsible for triggering syncope; in many instances the faint is relatively benign (e.g. vasovagal faint) but others (e.g. certain cardiac arrhythmias) may have more serious implications. In any case, whether the underlying problem is "innocent" or potentially life-threatening, syncope may lead to physical injury, accidents that put others at risk, and economic loss. Consequently, the management goals are to identify the specific causes(s) of the symptoms, and thereafter develop a treatment plan designed to prevent recurrences.[1]

This chapter provides a brief summary of the major causes of syncope, including nomenclature concerns, but focuses principally on clinical management (diagnosis and treatment), particularly changing treatment concepts for neurally mediated reflex syncope and orthostatic syncope. Whenever possible, the recommendations provided here are adapted from the European Society of Cardiology Syncope Task Force guidelines.[1] However, that was not always possible. In such cases, we have either elected not to provide a "level" of recommendation or, when it seemed reasonable, to indicate by means of an asterisk (*) that the recommendation is based on the authors' opinion.

Nomenclature

"Syncope" must be distinguished from the many other forms of transient loss of consciousness (TLOC) or "TLOC/syncope mimics" (Fig. 42.1). Unfortunately, physicians

remain uncertain regarding this distinction. Despite the efforts of some,[1–4] the confusion continues to be exacerbated by imprecise writing in the medical literature.[5–7] For example, the recent scientific statement from the American College of Cardiology Foundation (ACCF) and the American Heart Association (AHA) confuses the definition of "true syncope" with the broader concept of TLOC.[5] Similar imprecise characterization of syncope may be found in a widely cited report from the Framingham Study[6] and in a relatively recent clinical review article in the *British Medical Journal*.[7] Inaccurate advice from seemingly authoritative sources unnecessarily confounds the "syncope" evaluation and results in the undertaking of expensive but low-yield tests such as electroencephalograms (EEGs) and imaging studies of the head. In an effort to clarify matters, several groups have attempted to both address the vagaries of terminology[1–4] and develop more cost-effective ways to evaluate syncope patients.[1,8–14]

Incidence, natural history, and prognosis

Frequency in the population

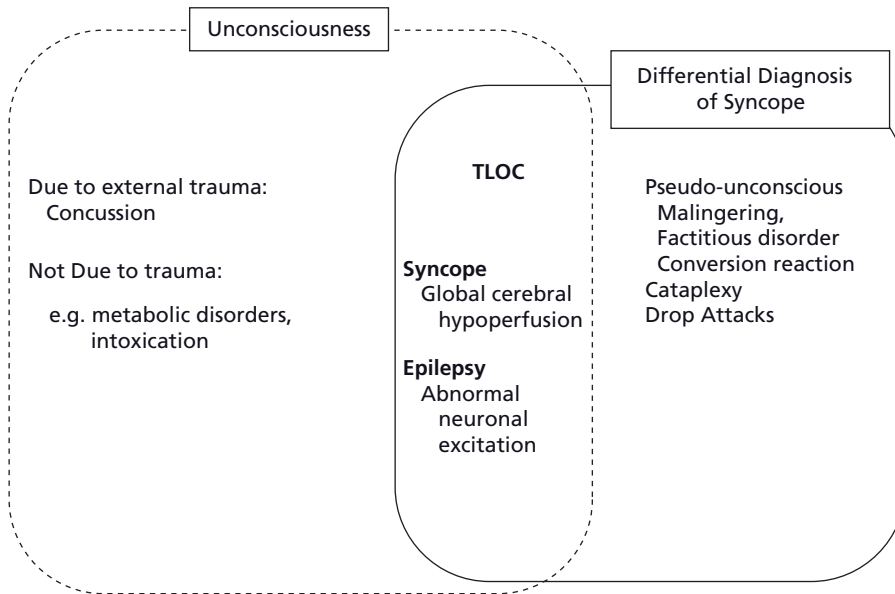
Syncope has been variably reported to account for approximately 1–3 % of emergency department (ED) visits (the 1% is the more recent estimate) and 1–6% of general hospital admissions in the United States.[15–17] In numerical terms, the National Hospital Ambulatory Medical Care Survey of 2006 in the United States noted that primary diagnoses of "syncope and collapse" (ICD-9; 780.2) had increased from approximately 887 000 ED visits in 2001 to greater than 1 125 000 ED visits in 2006. On the other hand, "syncope and collapse" listed among all US hospital discharge diagnoses in the 2006 National Hospital Discharge Survey remained relatively constant over this same time period: 405 000 in 2001 and 411 000 in 2006. This suggests, perhaps, that ED physicians are becoming less hesitant to have such patients evaluated on an outpatient basis.


Figure 42.1 Schematic illustrating the relationship of "syncope" to other conditions that cause real or apparent transient loss of consciousness (TLOC). Syncope is characterized by causing TLOC as a result of a self-limited inadequacy of cerebral perfusion.

In part, variations among published reports examining epidemiologic aspects of "syncope" may relate to the terminology issues alluded to above. In any event, as pointed out by Sheldon and Serletis,[18] conventional clinical epidemiologic terms such as "prevalence" (the proportion of people with the disease) and "incidence" (the proportion of people acquiring the disease in a sampling interval) are not readily applicable to the problem of understanding the epidemiology of "syncope". For instance, these authors argue quite insightfully that syncope prevalence must approach zero since at any point in time very few people are unconscious. Similarly, since syncope is a transient symptom that vanishes, its true "incidence" is difficult to assess. Sheldon and Serletis[18] suggest more meaningful indices such as cumulative proportion, cumulative event rate or cumulative incidence.

Given the limitations noted above, it is possible to obtain from the literature a rough sense of the "burden" of syncope in various population subsets. Thus, the Framingham Study (in which biennial examinations were carried out over a 26-year period in 5209 free-living individuals) reported occurrence of at least one syncope event in approximately 3% of men and 3.5% of women in a relatively broad-based free-living population sample.[19] The first syncope occurred at an average age of 52 years (range 17–78 years) for men and 50 years (range 13–87 years) for women. Further, while syncope occurred at virtually all ages, syncope burden tended to increase with advancing age from 8/1000 person-exams in the 35–44 year old age group to approximately 40/1000 person-exams in the ≥75 year age group.

In more selected populations, syncope has been estimated to occur in 15% of children <18 years of age, 25% of the young military population, and in up to 23% of a nursing home population >70 years of age.[15,16,18–24] However, with respect to the elderly patient, the reported frequency may well be an underestimate since up to 20% of these individuals are believed to be forgetful for such episodes (i.e. retrograde amnesia).

Two reports provide the most up-to-date assessment of syncope burden among free-living persons. Ganzeboom et al[22] surveyed medical students in The Netherlands and found that 39% had fainted at least once by about age 25 (women 47% versus men 24%). A Canadian report indicated that the likelihood of at least one faint was 37% by age 60, and almost all first spells occurred by age 40.[24] Combined, these studies suggest that 40% of people faint at least once in their lives.

Recurrence rates

Among patients who have experienced syncope, it has been estimated that syncope recurrences occur in about 30%.[19,22,24] About one-third of patients have recurrences of syncope by 3 years of follow-up, with most recurrences occurring within the first 2 years. Predictors of recurrence of syncope include:
- age <45 years
- a psychiatric diagnosis, and
- a long history of prior syncope recurrences; in particular, patients with more than six syncope spells and a positive tilt-table test (i.e. suggestive that syncope is of neurally mediated reflex origin) have a high risk of syncope recurrence (>50% over 2 years).

Mortality

The presence and severity of co-existing structural heart disease are the most important predictors of mortality risk

in syncope patients. Thus, among individuals with cardiac syncope (i.e. primary cardiac arrhythmia, an ischemic episode or severe valvular heart disease), the 1-year mortality is high (ranging between 18% and 33%) compared to that for patients with either non-cardiac (including "vasovagal") causes of syncope (0–12%) or unexplained syncope. The risk of death differences are even more striking when considering "sudden cardiac death" events: the 1-year incidence of sudden death is approximately 24% in patients with a cardiac cause versus about 3% in the other two groups.[6,19]

Although patients with cardiac syncope have higher mortality rates compared with those of non-cardiac or unknown causes, cardiac syncope patients do not as a rule appear to exhibit a higher mortality when compared with matched controls having similar degrees of heart disease.[25–29] There are, however, some important exceptions to this rule. These include severe aortic stenosis (average survival without valve replacement of 2 years), hypertrophic cardiomyopathy in which syncope at diagnosis is a predictor of increased sudden death risk, and possibly patients with heart failure and severe left ventricular dysfunction.[29] The mortality risk associated with syncope in the setting of one of the channelopathies (e.g. Brugada syndrome, long QT syndrome (LQTS)) or in the presence of arrhythmogenic right ventricular dysplasia (ARVD) may reasonably be considered to fall into this exception as well, if the syncope is known to be due to ventricular tachyarrhythmias.

A number of subgroups of syncope patients can be identified who have an excellent prognosis. These include young healthy individuals without heart disease and normal electrocardiogram (ECG), individuals with the most common forms of neurally mediated reflex syndromes (i.e. vasovagal faint, most situational faints) and syncope of unknown cause (5% first-year mortality). Patients with carotid sinus syndrome (CSS) may be expected to have a more worrisome prognosis given the close association of CSS with underlying atherosclerotic cardiovascular disease. However, syncope may result in injury. Major morbidity such as fractures and motor vehicle accidents are reported in 6% of patients, and minor injury such as laceration and bruises in 29%. Recurrent syncope is associated with fractures and soft tissue injury in approximately 12% of patients.

Prognostic issues remaining to be resolved

Failing to distinguish the additional risks associated with recurrent syncope from the risks accompanying any underlying co-morbidity (especially heart disease) is a common error. The result is that physicians may overlook the need to address syncope risk directly as they focus on the treatment of the underlying heart disease (or occasionally vice versa).

For instance, implantable cardioverter-defibrillator (ICD) therapy is often recommended in patients with syncope and left ventricular ejection fraction (LVEF) <30%. Clearly, an ICD may well be indicated, but it would be indicated even in the absence of syncope. On the other hand, while the ICD may prevent sudden death, it takes time to detect an arrhythmia and initiate treatment; consequently, it may not protect the patient from injury due to recurrent syncope (even if the syncope is due to ventricular tachyarrhythmias). Further assessment of the patient is needed.

The impact of syncope has been a particular concern in "channelopathy" patients, specifically in LQTS or Brugada pattern.[30–33] With regard to LQTS, in one large prospective observational trial in >800 patients,[30] cardiovascular endpoints including apparent syncope, cardiac arrest and sudden death occurred in 23% of patients. Syncope was associated with a fivefold increased risk of cardiac arrest or sudden death, but it was not a sensitive predictor of death risk. Similarly, in patients with the so-called Brugada pattern on ECG who have a history of syncope, the observation has been made that syncope is not a sensitive predictor of or risk factor for sudden death. In a multicenter study, 40% of 220 Brugada patients implanted with an ICD had a history of syncope, but the patients with syncope were not at a higher risk of appropriate ICD discharge than those who had been asymptomatic.[31] Similarly, in a large meta-analysis encompassing 1140 patients (262 of them (23%) with a history of syncope), the patients with syncope had the same risk of ventricular tachyarrhythmias as those who had been without syncope, and a significantly lower risk than those presenting with documented cardiac arrest.[33]

Pathophysiology

The syncope victim is usually in the upright position at the onset of the attack. Syncope in the supine position should raise the possibility of marked bradycardia or very rapid tachyarrhythmias. Supine syncope due to neural reflex hypotension has also been reported, but is believed to be uncommon.

The relationship of upright posture to increased susceptibility to transient cerebral hypoperfusion is readily understandable since in humans, upright posture substantially reduces the safety factor for cerebral perfusion. Upon arising from being seated or supine, approximately 500–1000 mL of blood moves relatively rapidly from the central circulation to the venous system below the diaphragm. Physiologic adaptive countermeasures, including peripheral vaso- and venoconstriction, enhanced muscle pump activity, thoracic respiratory pump action, and moderate tachycardia, automatically come into play to prevent an otherwise inevitable drop in cerebral blood flow. Addition-

ally, the "autoregulatory" nature of the cerebrovascular circulation helps to maintain flow despite fluctuation of perfusion pressure. Thus, the healthy well-hydrated human is usually able to cope quite effectively with even very abrupt positional change. On the other hand, despite built-in compensatory mechanisms, many individuals (even those in good health) may experience transient symptomatic hypotension when moving quickly from the supine or seated to upright posture. In the vast majority, this scenario is typically abrupt in onset, occurs promptly after posture change (i.e. "immediate" hypotension), is brief in duration, and is manifest only as a temporary loss of vision (so-called "gray-out").[34] The immediate hypotensive event is rarely a cause for concern. However, of a more serious nature, in some patients frank syncope may occur after movement to upright posture (so-called postural or "orthostatic" faints). In these cases, the faint is usually somewhat delayed after the postural change, suggesting that the mechanism is more than just the "immediate" hypotensive response.[35] In some of these patients there appears to be a more complete failure of physiologic adaptation mechanisms, due to diseases of the autonomic nervous system. In the majority of cases, however, more commonly encountered conditions are the cause, including:

• drug therapy (e.g. diuretics, vasodilators)
• generalized frailty in a chronically ill individual
• dehydration
• recent exposure to extended periods of bedrest or gravitation-reduced environment.

Quite often, hypotension leading to syncope is the result of neurally mediated reflex disturbances of blood pressure control (e.g. vasovagal faint, situational faints, carotid sinus syndrome, etc.). Vasovagal and situational faints (e.g. post-micturition syncope) are among the most frequent causes of syncope in all age groups, and are the most common of the so-called neurally mediated reflex syncope syndrome (Box 42.1). In some of these cases the predominant outcome of inappropriate neural reflex activity is parasympathetic-induced bradycardia or asystole (so-called cardio-inhibitory syncope). In others, symptomatic hypotension is due primarily to inappropriate vasodilation (i.e. vasodepressor syncope). In most cases, however, both phenomena contribute.[1,36,37]

Primary cardiac arrhythmias are a less frequent cause of syncope in the general population than are the conditions noted above. Nonetheless, when at fault (usually in individuals with structural heart disease) they are important to identify since they may have a worrisome prognosis, and they can usually be treated effectively whether by drugs, ablation or implantable devices.

Paroxysmal supraventricular and ventricular tachycardias (SVT, VT), intermittent atrioventricular (AV) block or sinus node pauses are among the most common primary cardiac arrhythmias associated with syncope. However, the basis for syncope in the setting of these arrhythmias may be complex. By way of example, an abrupt blood pressure decrease starting immediately after tachyarrhythmia onset occurs even in patients with normal hearts. Certainly, the rapid heart rate plays an important role in this phenomenon. However, other factors may contribute. Sudden atrial distension and vigorous atrial contraction against closed AV valves (in tachycardias with AV dissociation) may cause not only a reduced forward flow but also a neurally mediated reflex vasodilation that may undermine the effectiveness of adaptive vaso- and venoconstrictive mechanisms. Further, in elderly or infirm patients, muscle pump and respiratory pump activity may be compromised, thereby increasing the chance that perfusion pressure may fall below the autoregulation capability of the cerebrovascular bed.

In patients with cardiac disease such as hypertrophic cardiomyopathy (HCM) or aortic stenosis, both SVT and VT may cause cardiac syncope. However, neurally mediated reflex hypotension may also contribute; the triggers are believed to come from the heart itself, presumably via excessive stretch on ventricular and atrial mechanoreceptors.

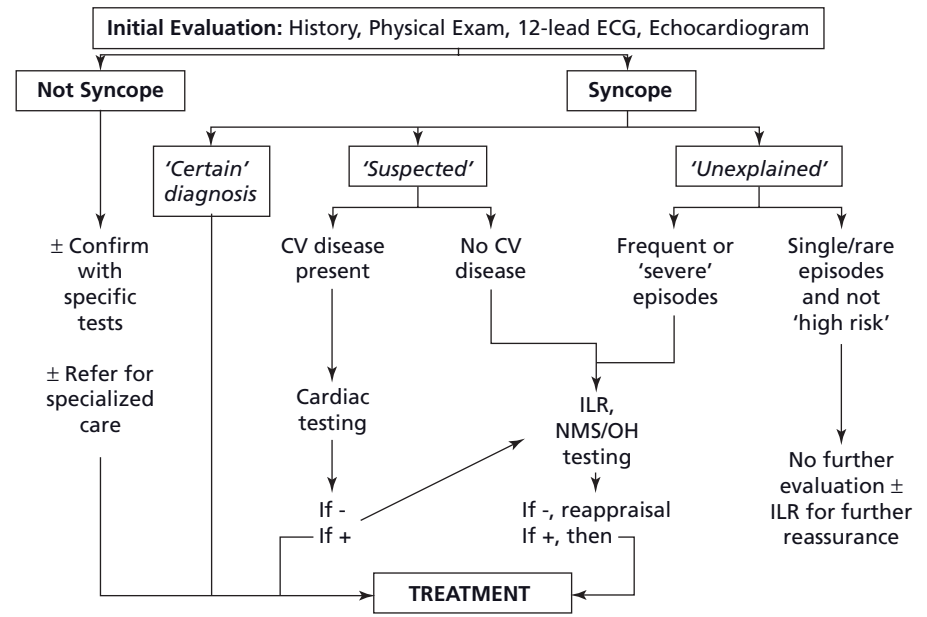
Diagnosis

The European Society Task Force on Syncope guidelines,[1] the American College of Cardiology Task Force report on tilt-table testing,[38] the American Academy of Emergency Medicine practice guidelines[39] and the ACC/AHA Scientific Statement on Syncope[5] provide recommendations regarding the appropriate strategy for diagnosis and treatment of syncope (Fig. 42.2), including risk-stratification advice regarding the need for hospitalization. For the most part these recommendations have been primarily "expert" consensus-based documents. However, recently several observational studies and randomized clinical trials have begun to contribute to our better understanding of how syncope management practices might be improved.

Classification of the causes of syncope

Box 42.1 provides a classification of the principal causes of syncope likely to be encountered in general internal medicine or family practice. However, it should be borne in mind that a single diagnosis may not be sufficient; more than one cause may contribute to the clinical picture (especially in the older patient).

Neurally mediated reflex syncope
The vasovagal (or "common") and situational faints occur in virtually all age groups, and may be triggered by any of a variety of factors, including prolonged standing (particu-

Figure 42.2 Algorithm, modified from that proposed by the European Society of Cardiology Syncope Task Force guidelines,[1] depicting an approach to the clinical evaluation of syncope. As discussed in the text, a careful initial evaluation by an experienced clinician can often provide a "certain" diagnosis of the cause of syncope. In such cases, no further evaluation is needed, and treatment as needed may begin. However, in many instances the outcome of the initial assessment is only a "suspected" diagnosis or even an "unexplained" cause. In such cases, further selective testing is needed. An appropriate pathway is indicated here. See text for details. ILR, implantable or insertable loop recorder; NMS, neurally mediated reflex syncope; OH, orthostatic hypotension; TLOC, transient loss of consciousness.


BOX 42.1 Syncope and syncope mimics: a classification

Syncope
- Neurally mediated reflex syncope
  - Vasovagal faint
  - Carotid sinus syncope
  - Situational faints (e.g. cough syncope, post micturition, defecation, etc.)
  - Pain triggered
- Orthostatic syncope
  - Chronic blood/plasma loss (e.g. hemorrhage, diarrhea)
  - Primary autonomic failure syndromes (e.g. pure autonomic failure, multiple system atrophy, Parkinson's disease with autonomic failure)
  - Secondary autonomic failure syndromes (neuropathies: diabetic, alcohol, amyloid)
  - Drugs (vasodilators, diuretics)
- Primary cardiac arrhythmias
  - Sinus node dysfunction (including bradycardia/tachycardia syndrome)
  - AV conduction system disease
  - Paroxysmal supraventricular and ventricular tachycardias
  - Channelopathies (LQTS, Brugada, etc.)
  - Implanted device (pacemaker, ICD) malfunction

- Structural cardiovascular or cardiopulmonary disease
  - Severe aortic stenosis
  - Acute myocardial infarction/ischemia
  - Cardiac valvular disease/ischemia infarction
  - Atrial myxoma, ball-valve thrombus
  - Obstructive cardiomyopathy
  - Pericardial disease/tamponade
  - Prosthetic valve malfunction
  - Pulmonary embolus
  - Pulmonary hypertension
  - Subclavian steal syndrome
- Cerebrovascular
  - Vascular steal syndromes
  - Acute hypoxemia
  - Migraine

Syncope mimics – disorders resembling syncope
- Seizures
- Psychogenic "syncope" (conversion reaction)
- Hyperventilation (hypocapnia)
- Intoxications
- Accidental falls (usually in elderly/infirm persons)

larly in warm, emotionally charged environments), unpleasant sights, and pain. The diagnosis is most often suspected from the medical history; however, the history is not always definitive, especially in the elderly.[40] In such cases, the accounts of eye-witnesses become crucial and tilt-table testing (**Class IIa, Level C**) and use of implantable loop recorders (**Class I, Level B**) become important diagnostic tests.[1,41–45] The ATP test, although controversial

(**Class IIb*, Level C**), may also prove helpful to the clinician, especially in the older patient in whom pacemaker therapy is a consideration.[46–49]

Carotid sinus syndrome is one form of neurally mediated reflex syncope that tends to occur in older male patients, probably related to higher predilection to atherosclerotic cardiovascular disease in that population. Published experience suggests that CSS may be a more

important cause of non-accidental "falls" or "spells" in older individuals than had previously been appreciated.[50] The condition is suspected by careful history taking, but its presence is confirmed when symptoms are reproduced during carotid sinus massage (best undertaken with the patient in the upright position secured on a tilt-table), particularly if there is concomitant induction of an asystolic pause, paroxysmal AV block, and/or a marked drop in systemic arterial pressure (**Class I, Level B**). In the absence of symptom reproduction, a pause of ≥5 seconds is often considered sufficient to support the diagnosis (assuming other etiologies of syncope have been excluded). An implantable loop recorder (ILR) may also prove helpful in suggesting the diagnosis of CSS, but limitations include absence of direct correlation of syncope with carotid stimulation, and the possibility of "missing" a major vasodepressor hypotension episode since it is not yet possible to monitor systemic pressure with these devices.

Orthostatic (postural) syncope

Frank syncope induced by moving from supine or seated to upright posture is an important problem in elderly or less physically fit individuals, or patients who are volume depleted. Iatrogenic factors such as excessive diuresis or aggressive prescription of antihypertensive drugs may be important contributors. Inadequate fluid intake, especially by older persons who have diminished thirst drive or who purposely avoid fluids due to genitourinary system issues, is another important contributor. Less often, primary forms of autonomic nervous system dysfunction are the underlying predisposing cause, including pure autonomic failure, multiple system atrophy, and Parkinson's disease.[51–53]

In most clinical practices overt primary autonomic dysfunction is relatively rare. Nevertheless, becoming familiar with its presentations may be of value in determining the cause of orthostatic symptoms in some patients, and perhaps better understanding symptoms in a much larger group of patients who have less well-defined disorders, such as postural orthostatic tachycardia syndrome (POTS). Furthermore, as the features of autonomic dysfunction become more widely appreciated, subtly affected patients will be identified more often. For instance, Low *et al*[54] reviewed an experience in 155 patients referred for assessment of suspected orthostatic hypotension. Findings in this referral population revealed that among the most severely affected symptomatic patients (n = 90, mean age 64 years), pure autonomic failure accounted for 33%, multisystem atrophy for 26%, and autonomic/diabetic neuropathy for 31%. Finally, secondary autonomic dysfunction due to neuropathies associated with chronic diseases (e.g. diabetes mellitus), toxic agents (e.g. alcohol) or infections (e.g. Guillain–Barré syndrome) are relatively common in medical practice, and may also cause syncope in association with orthostatic hypotension.

Primary cardiac arrhythmias

Primary cardiac arrhythmias (i.e. those rhythm disturbances arising as a result of cardiac conduction system disturbances, anomalous electrical connections, myocardial disease or "channelopathies") are less frequent causes of syncope than either the neurally mediated or orthostatic triggers, but they are of importance due to their more worrying prognostic implications. In general terms, the arrhythmias most often associated with syncope or near-syncope are the bradyarrhythmias accompanying sinus node dysfunction or AV block, and the tachyarrhythmias of ventricular origin. Only a very brief overview is provided here as these conditions are discussed in detail elsewhere in this volume.

Sinus node dysfunction Sinus node dysfunction (SND) comprises various sinus node and/or atrial arrhythmias that may result in persistent or intermittent periods of inappropriate slow (sinus bradycardia, sinus pauses, sinoatrial exit block) or, on the other hand, excessively fast heart beating (most often atrial fibrillation or atrial flutter), or both manifestations at different times in the same individual.[55,56] SND may be considered to be "intrinsic" or "extrinsic". Intrinsic SND is closely associated with structural disturbances in the atria (e.g. fibrosis, chamber enlargement) resulting from aging, disease or prior cardiac surgery. Extrinsic SND may be due to autonomic nervous system influences, cardioactive drugs, and/or metabolic disturbances.[57–59] In terms of syncope, bradyarrhythmias associated with SND appear to be the more important culprits than tachyarrhythmias.[56]

Disturbances of atrioventricular conduction Disturbances of AV conduction range from relatively innocent abnormalities (e.g. first-degree AV block) to complete conduction failure (third-degree AV block).[60–62] As a rule, however, it is the more severe forms of acquired AV block (that is, Mobitz type II block, "high-grade" and complete AV block) that are most closely associated with syncope. In contrast to acquired forms of AV block, congenital complete AV block was for a long time considered to be relatively benign. However, it is now known that syncope is more common and mortality greater in congenital AV block patients than had previously been suspected.[60]

Whether syncope occurs in patients with various forms of bundle branch block or fascicular conduction system disease depends both on the risk of developing high-grade or complete AV block and on the risk of occurrence of ventricular tachyarrhythmias.[62] Diagnostic electrophysiologic testing may be useful in such cases.

Ventricular tachyarrhythmias Ventricular tachyarrhythmias (VT) have been reported to be responsible for syncope in up to 20% of patients referred for electrophysiologic assess-

ment. Risk factors favoring VT as a cause of syncope include underlying structural heart disease, underlying conduction system disease, congenital or drug-induced LQTS or other so-called "channelopathies". The latter conditions present special risks of both syncope and sudden death.[63–68] Syncope in channelopathy patients may be due to any cause (including vasovagal faints), but the specific and most critical risk is syncope due to polymorphic VT, including torsades de pointes. The mere presence of a "history of syncope" is not sufficient reason to implicate a VT as the cause and consequently, while ICD therapy in such a situation (i.e. no evidence of a VT) is recommended by guidelines (**Class IIb, Level B**), there continues to be room for debate.[68] In any case, the assumption that VT is the cause of syncope should not be taken lightly even if an ICD has been placed. An ICD may prevent premature death, but may act too late to prevent syncope (or, as alluded to already, may not even be relevant to the cause of syncope in a particular individual).[25,28,29]

Supraventricular tachyarrhythmias Supraventricular tachycardias are relatively infrequent causes of syncope.[1,69,70] Tachycardia rate, the volume status and posture of the patient at time of onset of the arrhythmia, the presence of associated structural cardiopulmonary disease, the integrity of reflex peripheral vascular compensation, and the promptness with which normal cardiac activity resumes after termination of the tachycardia are key factors determining whether hypotension of sufficient severity to cause syncope occurs.[70]

Structural cardiovascular or cardiopulmonary disease

Structural cardiac or cardiopulmonary disease is often present in syncope patients, particularly those in older age groups. However, in these cases it is usually arrhythmias associated with structural disease, rather than the abnormal structure itself, that are more often the cause of symptoms. In terms of syncope directly attributable to structural disease, the most common is that which occurs in conjunction with acute myocardial ischemia or infarction, pulmonary embolism and pulmonary hypertension. The basis of syncope in these conditions is multifactorial, including both the hemodynamic impact of the specific lesion as well as neurally mediated reflex effects.

Syncope may also occur and be a presenting feature in conditions in which there is fixed or dynamic obstruction to left ventricular outflow (e.g. aortic stenosis, hypertrophic obstructive cardiomyopathy (HOCM)). In such cases symptoms are often provoked by physical exertion, but may also develop if an otherwise benign arrhythmia should occur (e.g. atrial fibrillation). The basis for the faint is in part inadequate blood flow due to the mechanical obstruction. However, especially in the case of valvular aortic ste-

nosis, ventricular mechanoreceptor-mediated bradycardia and vasodilation is thought to be an important contributor. In obstructive cardiomyopathy, neural reflex mechanisms may also play a role in causing syncope, but atrial tachyarrhythmias (particularly atrial fibrillation) or ventricular tachycardia (even at relatively modest rates) can also trigger hypotension.[71–74]

Cerebrovascular, neurologic, and psychiatric disturbances

Cerebrovascular disease and neurologic disturbances are rarely the cause of true syncope.[1] However, these conditions may result in a clinical picture that can be mistaken for syncope even by experienced practitioners. For example, temporal lobe epilepsy may closely mimic (or induce) neurally mediated reflex bradycardia and hypotension. In such cases, neurologic consultation becomes essential.

Fixed cerebrovascular disease is almost never responsible for syncope due to the redundancy of the cerebral circulation (multiple vessels accessing the circle of Willis).[75] Consequently, searching for carotid artery disease in syncope patients by Doppler studies or angiography is rarely useful. On the other hand, global cerebrovascular spasm (possibly as part of a migraine syndrome) could trigger syncope. However, as well as can be determined, the frequency with which this mechanism occurs is vanishingly small; most faints in "migraineurs" are of vasovagal origin.[75]

Psychiatric conditions do not cause syncope, but may result in syncope mimics. Thus, conversion reactions may be responsible for symptoms that are difficult to distinguish from loss of consciousness events. Similarly, anxiety attacks may be associated with severe hyperventilation resulting in hypocapnia and transient alkalosis that cause "syncope-like" symptoms. Considerable effort (including multiple consultations to various specialists) is often expended before a pseudo-syncope diagnosis is comfortably established. When these conditions are suspected, psychiatric consultation is needed.

Strategy for the diagnostic evaluation

Structure of the syncope evaluation

The ultimate goal of the diagnostic evaluation is to establish a sufficiently strong correlation between symptoms and detected abnormalities to permit both an assessment of prognosis and initiation of an appropriate treatment plan. Care must be taken to avoid assuming that the mere presence of an abnormality provides a basis for the patient's symptoms.

A careful history and physical examination form the basis for the initial assessment of the syncope patient (see Fig. 42.2). Alone, these first steps provide a diagnosis in a substantial proportion of patients, especially in younger

individuals in whom vasovagal faints predominate and the history is clear-cut. However, in many other cases even an experienced history-taker cannot be certain of the diagnosis, and further testing is needed. In this regard, the front-line physician must determine whether such testing requires hospitalization or if outpatient evaluation is safe (i.e. minimal chance of mortality or syncope recurrence with either injury or necessitating hospitalization within the next few weeks to months). Thus, patients who may be safely evaluated outside hospital include those "low-risk" individuals who exhibit any of the following features: absence of evident structural heart disease and a normal ECG, history of recurrent syncope over many years or suspicion that the presentation is that of a "syncope mimic" (e.g. psychogenic pseudo-syncope). Unfortunately, however, apart from these very low-risk patients, it is difficult to "risk stratify" moderate- to high-risk TLOC/syncope patients.[76,77]

Although, as noted earlier, ED practice patterns in the US may be changing, hospital admission for syncope management remains very frequent despite the fact that in many instances outpatient assessment would be just as safe and far less expensive. Potentially, greater availability of "syncope management units" (SMU), "rapid access blackout clinics" (best illustrated by that in Manchester, UK) or "TLOC/syncope clinics" may reduce inappropriate hospital admissions.

Medical history taking The first step in the assessment of the patient with presumed syncope is to obtain a detailed medical history of the events, including interviewing bystanders and relatives.[1,40,78–82] Throughout the history taking, it is important to bear in mind that co-morbidities may contribute to syncope susceptibility. Consequently, it is essential to pay attention to other disease conditions that may be present.

Unfortunately, the utility of history taking is limited by the practitioner's clinical experience. Consequently, the availability of a more structured history-taking instrument may prove helpful. Several reports have provided insight into this aspect of the clinical care pathway.[40,80]

In the most recent of the structured history-taking approaches, a quantitative method was applied by the Calgary Syncope Symptom Study in assessing whether vasovagal syncope could be distinguished from epilepsy and if vasovagal syncope could be distinguished from other causes of syncope.[80] With regard to the syncope versus seizures question, the findings in 539 patients in whom the cause of loss of consciousness was known (various types of epilepsy, vasovagal syncope, and cardiac arrhythmias) were assessed. A point score to differentiate syncope from seizures was derived, and proved to have a sensitivity of 94% and a specificity of 94%. Historical aspects suggestive of seizure activity included preceding

emotional stress, "déjà vu" sensation, unusual posturing or motor activity during an event, confusion upon awakening or tongue injury. Conversely, syncope was favored by separate episodes of pre-syncope, diaphoresis or an event precipitated by prolonged standing or sitting.

In terms of the second issue, the causes of syncope were known in 323 patients. The point score correctly classified 90% of patients, diagnosing vasovagal syncope with 89% sensitivity and 91% specificity.[80] Factors favoring vasovagal syncope included pre-syncope or syncope with orthostatic stress, pain or medical settings, and a prodrome of warmth or diaphoresis. Elements suggesting causes other than vasovagal syncope included a history of cardiac conduction system disease, supraventricular tachycardia, diabetes or findings such as cyanosis during syncope or having a first syncope at age >35 years.

The medical history is not equally valuable in all age groups. Del Rosso *et al*[81] found that the medical history was only one-fifth (5% v 25%) as effective for defining a cause of syncope in individuals >65 years compared to younger patients. Further, recollection of prodromal symptoms was also less in older versus younger individuals. Consequently, the evaluation of the elderly "fainter" inevitably will require greater reliance on ancillary tests.

Physical examination Physical findings that suggest a basis for syncope include:
• orthostatic hypotension: the frequency of orthostatic fainting is low in young patients; it has been reported to account for 30% of faints in patients >75 years of age[82]
• abnormal response to carotid sinus massage (CSM): this is unusual in younger fainters, but becomes an important condition as individuals age. CSM is usually recommended as part of the syncope evaluation in all syncope patients >55 years of age. A CSM-induced pause >3 seconds duration is considered abnormal and, while not definitive, raises the possibility of carotid sinus syndrome as a cause of symptoms
• upper extremity differences in blood pressure/pulse suggesting subclavian steal or aortic dissection
• pathologic cardiac murmurs (e.g. aortic stenosis, HCM) or vascular bruits
• evidence of pulmonary hypertension (often supported by echocardiographic findings).
The 12-lead ECG is part of the initial evaluation, although it only infrequently (<5% of cases) identifies a specific cause of syncope. However, 12-lead ECG findings such as a Q-wave, left ventricular hypertrophy, a prolonged QT interval, Brugada syndrome pattern or ventricular pre-excitation pattern may suggest the presence of organic heart disease or electrophysiologic abnormality, that helps to direct further testing. Similarly, echocardiography is increasingly considered to be an element of the initial evaluation (especially in North America), although its use may

be best reserved for instances when the status of underlying cardiac disease is unclear based on history or prior studies. For the most part, the value of the echocardiogram is in assessing left ventricular function and occasionally evaluating the severity of suspected structural abnormalities such as aortic or mitral valvular stenosis, or pulmonary hypertension.

If the initial evaluation (history, physical examination, 12-lead ECG, and echocardiogram) provides a "definite" diagnosis, no further testing is needed and if warranted, treatment may be started. However, the initial evaluation is often only suggestive of a basis for loss of consciousness or is non-diagnostic. In such cases the investigation must be continued, but can be directed more effectively based on the "initial evaluation" findings (see Fig. 42.2).

Additional testing As a rule, if structural heart disease is deemed absent by initial evaluation and there is no history of "palpitations", then neurally mediated reflex syncope or orthostatic hypotension is by far the most likely cause of syncope. In this setting, tilt-table testing in conjunction with related assessment of autonomic nervous system function (e.g. carotid sinus massage, response to cough, etc.) is the most useful diagnostic approach. However, it may be reasonably argued that an ILR might be an even more cost-effective strategy at this stage.[41–44]

If abnormal cardiac findings were identified on the initial evaluation, then the next step should be determining their functional significance by hemodynamic and/or angiographic assessment. In addition, since cardiac arrhythmias are a common cause of syncope in patients with structural cardiac disease, assessing the patient's susceptibility to tachy- and bradyarrhythmias becomes a priority. The strategy for this latter step will depend on an estimate of the immediate mortality risk. In low-risk settings, non-invasive techniques (for example, ambulatory ECG) or ILRs may be reasonable (see below). On the other hand, if the risk is assessed to be higher (e.g. low LVEF, clinically relevant valvular heart disease), then invasive electrophysiologic testing is warranted. Such testing may be helpful even in patients with low LVEF and criteria for ICD therapy, for reasons explained earlier. Tilt-table testing would follow if the diagnosis remains in doubt.[1] Only infrequently should specialized neurologic studies be ordered early in the evaluation (for example, if the history was suggestive of a seizure disorder rather than syncope).[1,83,84]

Electrocardiographic (ECG) recordings Documenting the cardiac rhythm (and, if possible, the corresponding arterial blood pressure) during a spontaneous episode is perhaps the single most valuable observation in the evaluation of syncope. However, most syncope patients have a symptom frequency (i.e. interval between events) measured in weeks or months, but not days. Consequently, syncope–ECG correlation is rarely achieved with 24-hour or 48-hour Holter monitoring (yield is variably reported as 6% and 20%, but may in fact be much less). Longer term ambulatory ECG recording is usually needed.

Both wearable and implantable long-term (weeks to months) ECG monitor systems are available. Unfortunately, conventional event recorders often have limited diagnostic utility in syncope if the patient has to apply the recorder to the chest just prior to or immediately following the period of unconsciousness. In the absence of a very prolonged premonitory warning period or the presence of a very astute bystander, such use is often impossible. To circumvent these latter limitations, a continuously attached event recorder system using wireless telemetry (so-called mobile cardiac outpatient telemetry, MCOT) has recently been introduced. These devices not only permit the recording of transient events, but also offer the ability for critical data to be transmitted without need for patient interaction. In a recent report, MCOT (Cardionet Inc, San Diego, CA) provided a significantly higher diagnostic yield when compared with a conventional patient-activated external looping event monitor (LOOP) in a 17-center prospective clinical trial with patients randomized to either LOOP or MCOT for up to 30 days.[85] A total of 266 patients who completed the monitoring period were analyzed. A diagnosis was made in 88% of MCOT subjects compared with 75% of LOOP subjects ($P = 0.008$). Currently, MCOT is only available in the USA.[85,86]

Implantable loop recorders (ILRs) such as the Reveal® family (Medtronic Inc, Minneapolis, MN) and Confirm® (St Jude Medical Inc, St Paul, MN) have become important tools for capturing transient arrhythmias.[41–45,87,88] On the downside, although remote downloading of stored data is now available (e.g. Carelink®, Medtronic Inc), these ILRs still require manual interaction by the patient or other individual in order to initiate transmission. A newer generation ILR (Sleuth®, Transoma Inc, St Paul, MN) overcomes this latter limitation by providing wireless download capability that operates without need for human interaction.

ILRs have been the subject of several important studies that illustrate their value in the diagnosis of the causes of syncope. In the ISSUE 2 diagnosis study,[45] 343 patients with suspected reflex syncope underwent tilt-table testing (positive in 164, 48%). In addition, 180 patients underwent an adenosine triphosphate (ATP) test (positive in 53, 29%). All patients also had an ILR placed. Syncope was documented by the ILR in 106 (26%) patients at a median of 3 months follow-up. An asystolic pause was more frequently found during spontaneous syncope than during tilt-testing (45% v 21%, $P = 0.02$), although there was a trend for those with an asystolic response on tilt-test also to have an asystolic response during spontaneous syncope (75% v 37%, $P = 0.1$). Patients with positive ATP test responses showed syncope

recurrence rates and apparent mechanism of syncope similar to those with negative ATP tests.

In the Eastbourne Syncope Assessment (EaSyAS) trial,[88] 201 patients (median age 74) with recurrent unexplained syncope were randomized to receive an ILR or conventional diagnostic strategy. During follow-up (median duration, 17 months), an ECG diagnosis was obtained in 42 (43%) ILR patients compared to eight (6%) patients in the conventional diagnosis group (hazard ratio (HR) 6.53, 95% confidence interval (CI) 3.73–11.4, $P < 0.001$).

Exercise testing is usually of limited utility in assessing the basis of syncope unless the medical history indicates that the events are clearly related to physical exertion. Thus, when selectively employed, exercise testing may permit detection of rate-dependent AV block, exercise-induced tachyarrhythmias or the exercise-associated variant of neurally mediated syncope.[89,90] Finally, although the signal-averaged ECG (SAECG) cannot provide direct evidence for the cause of syncope, such testing may be helpful in patients with ischemic heart disease if "normal"; a normal SAECG tends to exclude susceptibility to ventricular tachyarrhythmias.[91–94] Similarly, a negative T-wave alternans (TWA) test tends to reduce the likelihood of a life-threatening tachyarrhythmia being the cause of the patients' symptoms.[95,96]

In summary, the basis of infrequent but recurring syncope episodes is unlikely to be established by either conventional 24- or 48-hour ambulatory ECG recording, or by conventional external "event" recorders. The longer monitoring capabilities of MCOT systems provide some distinct advantages. Nevertheless, even MCOT may be difficult for patients to tolerate for more than 2–3 weeks. Consequently, in such a setting, consideration should be given to utilizing an ILR. ILRs have proved to be cost-effective, with the majority of ILR patients providing symptom–ECG correlation within a year of device placement.

Imaging techniques Echocardiography is the most widely employed imaging technique in the syncope evaluation, but it rarely provides a definitive basis for symptoms. Nonetheless, the echocardiogram is invaluable in many syncope evaluations given the importance of identifying underlying structural heart disease in these patients. Further, in some cases the echocardiogram may provide direct clues to the cause if, for example, HOCM, severe valvular aortic stenosis, intracardiac tumor (e.g. myxoma) or anomalous origin of one of the coronary arteries is detected.

Head-up tilt-table testing and electrophysiologic testing To date, the head-up tilt-table test is the only diagnostic tool to have been subjected to sufficient clinical scrutiny to assess its effectiveness in the diagnostic evaluation of vasovagal syncope. The evidence supporting its utility in this setting is sufficiently convincing, and both the ESC Syncope Task Force and an ACC "expert" task force have provided recommendations regarding indications for and methodology of appropriate use of the tilt-table laboratory[1,38] (**Class II, Level B**). Such testing, especially when undertaken in the absence of drugs, appears to discriminate well between symptomatic patients and asymptomatic control subjects; this remains true even when nitroglycerin (so-called "Italian protocol") or isoproterenol is used. Tilt-table testing at 60, 70, and 80 degrees exhibited specificities of 92%, 92%, and 80% respectively with low-dose isoproterenol provocation.[97] On the other hand, equally strong evidence indicates that head-up tilt is not useful to predict treatment effectiveness (**Class III, Level B**). The ISSUE study clearly demonstrated that the physiologic observations on the tilt-table do not reliably correspond to those obtained when spontaneous faints are recorded.[44,45,98] Thus, tilt-table tests may demonstrate susceptibility to vasovagal faints, but do not provide insight into whether the spontaneous events are cardio-inhibitory, vasodepressor or "mixed" in nature. On the other hand, recordings made by ILRs during spontaneous faints are highly reproducible and therefore predictive of mechanism of subsequent events.[99]

Although there are no large randomized studies, there is reasonably strong evidence to indicate that electrophysiologic testing (EPS) is most likely to be diagnostic in individuals with underlying structural heart disease[100–104] (**Class II, Level B**). For example, in a review by Camm and Lau,[69] testing was clearly more successful in patients with structural cardiac disease (71%) than in patients without (36%). However, care must be taken in interpreting EPS findings in syncope patients. Fujimura et al[105] found that among 21 syncope patients with known symptomatic sinus pauses or AV block, EPS only correctly identified 3/8 of the former (sensitivity 37.5%) and 2/13 of the latter patients (sensitivity 15.4%). On the other hand, although firm evidence is lacking, the induction of sustained re-entry supraventricular or ventricular tachycardia in a syncope patient is highly likely to be significant. These arrhythmias are rarely inconsequential bystanders.

The combination of tilt-table testing and invasive EPS has been evaluated in syncope patients, but the reports are few, date from the pre-ILR era (i.e. a true "gold standard" was not available to confirm findings), and were not controlled. By way of example, Sra et al[104] reported EPS results in conjunction with head-up tilt testing in 86 consecutive patients referred for evaluation of unexplained syncope. EPS was abnormal in 29 (34%) of patients, with the majority of these (21 patients) exhibiting inducible sustained monomorphic VT. Among the remaining patients, head-up tilt testing proved positive in 34 (40%) cases, while 23 patients (26%) remained undiagnosed. In general, patients exhibiting positive electrophysiologic findings were older, more frequently male, and had lower LVEFs and more structural

heart disease than patients with positive head-up tilt tests or patients in whom no diagnosis was determined. Using a similar approach, Fitzpatrick *et al*[106] analyzed findings in 322 syncope patients. Conventional EPS provided a basis for syncope in 229 of 322 cases (71%), with 93 patients having a normal study. Among the patients with abnormal EPS findings, AV conduction disease was diagnosed in 34%, sinus node dysfunction in 21%, CSS in 10%, and an inducible sustained tachyarrhythmia in 6%. In the 93 patients with normal EPS, tilt-table testing was undertaken in 71 cases, and resulted in syncope consistent with a vaso-vagal faint, in 53/71 (75%) of this subset.

Neurologic studies Conventional neurologic laboratory studies (EEG, head CT and MRI) have a low diagnostic yield in unselected syncope patients. For instance, among the 433 syncope evaluations reviewed by Kapoor,[107] the EEG proved helpful in only three cases. Consequently, these studies should be restricted to those situations in which other clinical observations suggest nervous system disease (see discussion earlier). On the other hand, given the importance of dysautonomic causes of syncope and related syndromes (i.e. orthostatic syncope, POTS, inappropriate sinus tachycarda),[108–111] tilt-table testing and other tests of autonomic function have an increasingly important role to play (see earlier discussion).

Syncope management units

The ineffectiveness of conventional approaches to evaluation of the suspected syncope patient is widely recognized, and has been highlighted by two major studies from Italy, OESIL and EGSYS.[9,112,113] Both illustrated the inefficiency of the standard approach. Further, in each case a follow-up study (OESIL-2, EGSYS-2) demonstrated that a more standardized guideline-based care pathway (such as could be provided in a structured multidisciplinary syncope management unit (SMU), as recommended by the ESC Syncope Task Force) significantly improved diagnostic yield and reduced hospital admissions, resource consumption, and overall costs.[114–116] Two different models of syncope facilities have been developed, one primarily centered within emergency departments (ED)[117] and the other within the cardiology or medicine department.[116]

The SMU operating primarily within an ED usually has risk stratification (i.e. identifying those individuals who can be sent for outpatient assessment versus those needing hospital admission) as its principal goal. In this regard, the prospective single-center SEEDS study[115] evaluated the hypothesis that a designated syncope unit in the ED improves diagnostic yield and reduces hospital admission for patients with syncope who were considered to be at intermediate risk for an adverse cardiovascular outcome. Patients were randomly allocated to one or other of two treatment arms: syncope unit evaluation or standard care.

The study enrolled 103 individuals, with 51 patients randomized to SMU care. Comparing SMU versus standard care patients, a presumptive diagnosis was established in 34 (67%) and five (10%) patients respectively, and hospital admission was required for 22 (43%) and 51 (98%) patients, respectively. The SMU care pathway reduced total patient-hospital days from 140 to 64. Thus, the SMU appeared to improve diagnostic yield and cost-effectiveness of care significantly.

In another ED-based study, a previously developed rule set (the so-called "San Francisco Syncope Rule") was applied.[116] This strategy combined the presence of any of the following observations to risk stratify patients: an abnormal ECG, symptoms of shortness of breath, a hematocrit <30%, systolic blood pressure <90 mmHg or a history of congestive heart failure. The rule was 98% sensitive and 56% specific to predict serious outcomes (defined as death, myocardial infarction, arrhythmia, pulmonary embolism, stroke, subarachnoid bleed, significant hemorrhage or any condition resulting in a return ED visit and hospitalization) in 791 patients referred to a teaching hospital. However, in one external validation cohort,[117] the San Francisco Syncope Rule had a lower sensitivity and specificity (89% and 42%).

The SMU model adopted in some Italian hospitals is a functional or "virtual" unit managed inside the department of cardiology. Where appropriate, patients are jointly managed with other specialists. The patients may be referred to the unit from any of several sites, including the ED, inpatient services or outpatient clinics.

In the context of the more structured approach to the syncope evaluation, EGSYS-2[9–11] provided a prospective, controlled, multicenter study designed to determine if a "standardized" method of care is superior to the usual care.[10] There were 929 patients in the usual care pathway and 745 patients in the standardized care group. At the end of the evaluation, the standardized care group had a 17% lower hospitalization rate (39% v 47%), 11% shorter in-hospital stay (7.2 ± 5.7 v 8.1 ± 5.9 days) and 26% fewer tests performed per patient (median 2.5 v 3.4). Additionally, standardized care patients had 75% fewer discharges with "unexplained syncope" (standardized 5% v usual care 20%). The mean cost per patient was 19% lower (€1127 v 1394), and the mean cost per diagnosis was 29% lower (€1240 v 1753) in the standardized care group.

SMUs of the type discussed here, while strongly advocated by the ESC Syncope Task Force,[1] are only infrequently found in either North America or Europe. In 2005, a survey of United States and Canadian medical centers revealed that only four of 28 reporting centers (4/28, 14%) had organized an SMU.[118] Of the centers with an SMU, the unit was described as a "physical space" in one case and as a "virtual unit" (i.e. not a defined physical entity) in the others.

Treatment

The effectiveness of syncope prevention varies, depending upon the specific diagnosis. Thus, susceptibility to syncope due to a well-documented, inducible, and ablatable SVT should be entirely eliminated (**Class I, Level B**). Similarly, although effectiveness of treatment is not likely to be as outstanding as the ablation example, the evidence supporting the utility of cardiac pacing in CSS and acquired AV block is substantial (**Class IIa, Level B**). On the other hand, evidence favoring the effectiveness of pharmacologic management in vasovagal syncope is much weaker (**Level C**, with the possible exception of midodrine – **Level B**).

Neurally mediated reflex syncope

The initial treatment of most patients with neurally mediated syncopal syndromes comprises reassurance and education. The education component must focus on avoidance of triggering events (e.g. hot crowded environments, dehydration, effects of cough, etc.), recognition of premonitory symptoms, and maneuvers to abort the episode (e.g. leg crossing, muscle tensing, supine posture).

Acute intervention by medical personnel is rarely possible in the case of the vasovagal fainter. However, affected individuals can be taught physical counter-maneuver techniques that may prove useful for aborting evolving episodes if there is enough warning. For instance, leg crossing with leg and thigh muscle tensing can abruptly increase blood pressure and potentially avert an imminent faint (**Class IIa, Level B**).[119] Arm tensing (tugging), squatting or lowering the head to a more dependent position are other useful maneuvers.

The multicenter, prospective, randomized Physical Counter-pressure Maneuver (PCM) trial[119] assessed the effectiveness of physical counter-pressure maneuvers (PCM) in 223 patients (38 ±15 years) with recurrent vasovagal syncope and recognizable warning symptoms: 117 patients were randomized to standardized conventional therapy alone and 106 patients received conventional therapy plus training in counter-pressure maneuvers (i.e. leg crossing, arm tensing). The median yearly syncope burden during follow-up was significantly lower in the group trained in PCM than in the control group ($P < 0.004$); overall, 51% of the patients with conventional treatment and 32% of the patients trained in PCM experienced a syncope recurrence ($P < 0.005$).

In the case of vasovagal syncope, when symptoms are recurrent or severe or threaten lifestyle or occupation, a prevention strategy is needed. In this context, and given a highly motivated patient with recurrent vasovagal symptoms, the prescription of progressively prolonged periods of enforced upright posture (so-called "tilt-training" or "standing training") or other physical maneuvers may be useful for reducing syncope susceptibility (**Class IIb*, Level B**).[120,121] The goal of tilt-training (more accurately termed standing training) is to normalize neurovascular response to orthostatic stress[32]. Initially the "tilt-training" concept used repeated in-hospital exposure to postural stress by tilt-table tests until syncope was no longer inducible. However, this approach is impracticable. Currently, the method entails home "standingtraining" for progressively longer periods of time over 10–12 weeks. At the beginning, the recommended standing duration is 3–5 minutes twice daily; standing duration is then gradually lengthened every 3–4 days to as much as 30–40 minutes twice daily.

The value of tilt-training remains controversial. Non-randomized studies suggest that it reduces susceptibility to recurrent vasovagal syncope if undertaken consistently.[120,121] However, compliance is a limitation and randomized observations have been less encouraging.[122,123] A randomized study using a hard clinical endpoint (i.e. syncope recurrence or syncope burden) is needed before we can derive any solid conclusion regarding efficacy of the tilt-training approach.

Despite the safety, portability, and inexpensive nature of most physical treatments for reducing susceptibility to vasovagal faints, their inconvenience is a problem. Consequently, many vasovagal fainters (and their doctors) still search for a pharmacologic approach. In this regard, so-called "volume expanders" (e.g. electrolyte-containing drinks, fludrocortisone, salt tablets) are safest. However, with rare exceptions,[124] their effectiveness is largely anecdotal (**Class IIb*, Level B**). A controlled trial with fludrocortisone in adults is currently ongoing (the POST2 study).

Beta-adrenergic blocking drugs were among the first agents proposed for use in preventing vasovagal syncope. Early small studies suggested benefit but more recent observations, including the placebo-controlled, double-blind POST trial,[125] raise doubts (**Class IIb*, Level B+**).

Other agents that have been used in difficult-to-treat vasoavgal fainters include midodrine (a vasoconstrictor), disopyramide, and serotonin reuptake inhibitors. However, for any of these only a small experience currently exists.[126–134] Midodrine may be an exception in that several single-center studies, including a controlled trial in which instruction regarding maintenance of hydration served as a control, tend to support its effectiveness[132–134] (**Class IIa, Level B**).

Cardiac pacing is highly successful in CSS (**Class IIa, Level B**) when bradycardia has been documented[135] but is less effective in other forms of neurally mediated faints. In this regard, early trials provided strong supportive evidence of efficacy of cardiac pacing in vasovagal

syncope.[136–138] However, in these studies the control group did not receive a pacemaker. More recent reports, in which pacemakers were placed in both the treatment and control groups, have tended to downplay the value of cardiac pacing in this setting.[139,140]

The value of establishing the specific characteristic of the neurally mediated faint for determining treatment strategy has recently been addressed in the ISSUE-2 study.[45] This trial used a strategy of early ILR use, with therapy delayed until documentation of syncope was obtained. In ISSUE-2, 53 patients received ILR-based specific therapy, mostly pacemaker therapy (n = 47), and 50 patients received counseling (education and reassurance). The 1-year recurrence rate in patients assigned to a specific therapy was 10% compared with 41% in the patients without specific therapy (80% relative risk reduction for patients, and 92% for burden). The 1-year recurrence rate in patients with pacemakers was 5%.

Orthostatic syncope

Reducing susceptibility to symptomatic orthostatic hypotension necessitates multiple strategies. Education focusing on predisposing factors such as abrupt posture change, dehydration or concomitant illness is important. Thereafter, whenever possible, non-essential offending medications (e.g. diuretics, vasodilators) should be eliminated.

Patients should also be taught about physical countermaneuvers (see earlier) designed to ameliorate problems associated with upright posture. However, care must be taken to alert older or infirm patients to risks of falling when applying maneuvers such as leg crossing.[141] Thereafter, longer-term prevention may include "tilt-training".[120,121]

Other physical maneuvers designed to diminish displacement of central volume to the lower extremities during upright posture include use of anti-gravitational hose and/or abdominal binders, elevation of the head of the bed at night, and (currently in investigation) a portable breathing device that increases impedance during inspiration (ITD).[142,143] With regard to the latter, Melby *et al*[143] utilized the ITD in a short-term acute intervention study in normal controls and patients with a history of orthostatic hypotension. Both groups were studied after abrupt movement from a gravitationally neutral position to upright standing. Findings indicated that the reduced intrathoracic pressure associated with breathing through the ITD was accompanied by a lesser fall of systemic pressure upon assuming the upright posture. More recently, van Thijs *et al*[144] employed a similar approach and observed essentially the same potential benefit. A longer term controlled trial is needed.

In terms of pharmacologic treatment, increased dietary salt and/or use of salt-retaining steroids (i.e. principally fludrocortisone) is usually the first step (**Class IIb, Level C**), followed if needed by judicious dosing with the arterial and venous constrictor midodrine. Additional benefit has been reported with the use of agents such as erythropoietin in order to increase circulating blood volume. Unfortunately, however, often the older orthostatic hypotension patient is also susceptible to supine hypertension. This combination results in an obvious therapeutic dilemma requiring very careful individualized manipulation of the various treatment options.

Cardiac arrhythmias

Evidence supports cardiac pacemaker therapy in patients with syncope due to bradyarrhythmias (**Class I, Level B**).[145,146] In the case of paroxysmal supraventricular tachyarrhythmias (PSVT) with syncope, there is little in the way of long-term follow-up studies examining the efficacy of conventional antiarrhythmic drug treatment. However, transcatheter ablation has become a very safe and cost-effective treatment option.

In the case of syncope due to VT, the almost ubiquitous presence of underlying left ventricular dysfunction increases proarrhythmic risk associated with most antiarrhythmic drug therapy. In these cases, despite early consideration of class 3 agents (particularly amiodarone), there remains the difficulty of assuring effective prophylaxis; consequently, transcatheter ablation and ICDs are increasingly important considerations. Currently, ablation techniques are appropriate first choices in only a few forms of VT, specifically symptomatic patients with right ventricular outflow tract tachycardia and bundle branch re-entry tachycardia (**Class IIb, Level B**).

With regard to implantable devices for symptomatic VT, several prospective treatment trials provide evidence favoring ICD efficacy (**Class I, Level A**) compared to pharmacologic approaches, especially in the setting of diminished left ventricular function.[63,147–151] Although these studies did not directly target syncope patients, it is reasonable to extend the observations to those syncope patients in whom ventricular tachyarrhythmias and poor left ventricular function are identified.[152]

In the subset of patients in whom structural cardiovascular or cardiopulmonary disease is the cause of syncope, treatment is best directed at amelioration of the specific structural lesion. However, it may be impossible to eliminate the underlying problem adequately. For instance, modifying outflow gradients in HOCM is not readily achieved by pharmacologic or surgical therapies. Therefore, although controversial, cardiac pacing continues to be employed (often as an ICD) in individuals who have experienced syncope or who have a worrisome family history (**Class IIb, Level B**).[153–156]

Cost-effectiveness issues

Syncope occurs in all age groups and can be responsible for considerable morbidity and lifestyle disturbance.[1,9,12–14,157–159] Consequently, lost productivity, economic derangement, and loss of vocation are important considerations when assessing the manner in which syncope is to be evaluated and treated.[43,160–163] Currently, in contrast to earlier reports,[162,163] given availability of ILRs, better understanding of the limitations of previously used testing strategies, and evidence favoring the structured SMU approach to syncope management, there is the potential to markedly improve the frequency with which a specific diagnosis is obtained, thereby reducing the cost per specific diagnosis.

Conclusion

Syncope is a common medical problem with many potential causes and a tendency to recur. Assessment of each patient must be thorough, with particular attention paid to recognition and evaluation of structural cardiac and/or vascular disease. Box 42.2 summarizes the key steps that need to be addressed.

When structural cardiovascular disease is thought likely, hemodynamic and angiographic studies are often needed to address severity and direct appropriate treatment strategy. On the other hand, syncope in the absence of structural cardiovascular disease is more often either neurally medi-ated reflex in origin or the result of orthostatic hypotension (often drug induced). In such cases, without the diagnosis being clear from the medical history and physical examination alone, autonomic function testing (particularly tilt-table testing) is warranted to confirm the diagnostic suspicion.

The treatment of syncope has been the subject of relatively few clinical trials and consequently treatment recommendations are based principally on "expert consensus". Given this important limitation, when structural cardiovascular disturbances or primary cardiac arrhythmias are the cause, appropriately directed therapy is likely to be highly effective. On the other hand, in neurally mediated reflex faints and orthostatic hypotension leading to syncope, documentation of pharmacologic treatment efficacy (with the possible exception of midodrine) is less convincing, and physical counter-maneuvers have become increasingly important; this is the case for both acute intervention (e.g. leg crossing and muscle tensing) and long-term benefits (i.e. tilt-training).

A small but increasing number of clinical observational reports and randomized placebo-controlled trials have recently improved our understanding of the TLOC/syncope complex. However, not every element of syncope/TLOC management can be subjected to such intense evaluation. The role of expert consensus opinion, both in day-to-day care as well as in practice guideline development, remains essential.

Acknowledgment

BOX 42.2 Key messages: the evaluation of the syncope patient

The goals
- establish a correlation between symptoms and detected abnormalities
- assess prognosis
- ascertain if evaluation requires hospitalization
- initiate appropriate treatment plan.

Key steps
- obtain detailed medical history (including bystanders/relatives)
- determine presence of underlying structural heart disease
- consider need for obtaining ECG/symptom correlation

Factors determining need for further tests
- evidence for structural cardiovascular disease
- certainty of the initial clinical impression,
- number and frequency of syncopal events
- occurrence of injury or accident
- family history of syncope or sudden death
- occupation, avocation

43 Cardiopulmonary resuscitation

Michael Colquhoun
School of Medicine, Cardiff University, Cardiff, Wales, UK

Introduction

Cardiac arrest may complicate any type of heart disease, but is particularly common in coronary heart disease; one half of all deaths caused by the condition present as sudden cardiac death.[1] Approximately 400 000–460 000 individuals in the USA[2] and 700 000 in Europe[3] experience sudden cardiac arrest each year, making the condition a major health problem (**Level C**).[2,3] Unexpected cardiac arrest also remains an important problem in hospital with an incidence of 0.174 ± 0.087 per bed per year reported in one recent large American multicenter cohort study.[4]

The modern era of resuscitation began with the development of defibrillators suitable for clinical use[5,6] and the demonstration of the effectiveness of expired air ventilation and closed chest compression that extended the time available for successful defibrillation.[7,8] The development of the portable defibrillator made resuscitation outside hospital a practical proposition. Particular credit goes to Pantridge in Belfast who recognized that hospital-based coronary care units would have limited impact on mortality in a condition where 60% of deaths occurred within one hour of the onset of symptoms.[9] He developed the first mobile coronary care unit in the world and the report of 10 patients admitted alive to hospital following defibrillation[10] acted as a stimulus to the development of similar strategies for managing cardiac arrest worldwide.

Establishing an evidence base for resuscitation practice

The development of effective resuscitation strategies led to a demand for standardized guidelines for clinical practice.

A commitment to foster an international evidence base for resuscitation practice and publish consistent guidelines for practice led to the foundation of the International Liaison Committee on Resuscitation (ILCOR). A regular five-year cycle of evidence review and publication of guidelines is now well established.[11–14]

The ILCOR methodology is based on a rigorous evaluation of *all* the available evidence relating to a specific topic using standardized worksheets,[15,16] which remain accessible at www.c2005.org.[17] In 2005, guidelines for practice were published with only minor differences between those of the European Resuscitation Council[18,20] and the American Heart Association.[19,21]

In this chapter, the basis for the practice of resuscitation of adult subjects is reviewed in the light of the evidence evaluation process described above. Common to nearly all resuscitation attempts is the application of basic life support to maintain breathing and a circulation until definitive treatment with defibrillation or other advanced techniques can be implemented. It is one of the few strategies proved to improve outcome from cardiac arrest and is the subject of the first section.

The remainder of the chapter is concerned with advanced life support topics. Defibrillation is considered in detail in the second section; it is the only definitive treatment for the majority of patients with cardiac arrest, and one of the few techniques with an unequivocal evidence base for its effectiveness. The third section is concerned with other advanced life support techniques that aim to maintain breathing and the circulation while treatment to restore the circulation is given.

Adult basic life support

Recognition of cardiac arrest

The prompt recognition of cardiac arrest is the key to starting resuscitation with the minimum of delay; recent studies

have helped clarify the most accurate methods for diagnosing cardiac arrest. The traditional method of palpating the carotid pulse has now been shown to be unreliable[22,23] (**Level B**) although there is no convincing evidence that checking for movement, breathing or coughing is superior[24] (**Level C**). Agonal gasps are common after the onset of cardiac arrest and bystanders often report that such subjects are breathing when interrogated by ambulance call takers. This can result in CPR being withheld or delayed[25] (**Level C**). It is recommended therefore that rescuers should start CPR in an unresponsive (unconscious) victim who is not moving or breathing. Even if the victim is taking occasional gasps, cardiac arrest should be suspected and CPR started (**Class IIa**).

Airway and ventilation

Opening the airway

Several prospective studies using clinical or radiologic indicators of airway patency have shown that the head tilt–chin lift method is practicable, safe and effective[26–28] (**Level C**). This was confirmed in a case series[29] (**Level C**). It is recommended that rescuers should use this method to open the airway (**Class IIa**). No study has evaluated the use of routine finger sweeps to clear the airway in the absence of an obvious obstruction; finger sweeps should only be employed if a visible obstruction is present in the oropharnyx (**Class IIb**).

Ventilation

Manikin studies[30] and one human study[31] showed that when no advanced airway (e.g. a tracheal tube) was present a tidal volume of 1 L produced significantly more gastric distension than 500 mL (**Level C**). In anethetized patients with no advanced airway in place, ventilation with 455 mL of room air was associated with acceptable although reduced oxygen saturation when compared with 719 mL. There was no difference in oxygen saturation between volumes of 624 mL and 719 mL[32] (**Level C**). Another study compared patients in cardiac arrest mechanically ventilated with oxygen at 12 L per minute. Smaller volumes of 500 mL were associated with a higher arterial PCO_2 and worse acidosis but no differences in PaO_2 than with volumes of 1 L[33] (**Level B**).

Small case series[34] and an animal study[35] showed that hyperventilation is associated with increased intrathoracic pressure, decreased coronary and cerebral perfusion and (in the animal study) decreased return of spontaneous circulation (ROSC). A case series of patients showed that ventilation rates of >10 min^{-1} and inspiratory times of >1 s were associated with poor survival[37] (**Level C**). In summary, larger tidal volumes and higher ventilation rates may be detrimental while the adverse consequences of smaller volumes appear acceptable.

The recommended technique for mouth-to-mouth ventilation using exhaled air or bag-valve-mask ventilation using room air or oxygen is to give one breath within an inspiratory time of 1 s (**Class IIa**) sufficient to make the chest rise (**Class IIa**). After an advanced airway is in place (e.g. tracheal tube, Combitube™, laryngeal mask airway, etc.), the patient should be ventilated with supplementary oxygen sufficient to make the chest rise. In such patients the lungs should be ventilated at a rate of 8–10 ventilations min^{-1} without pausing during chest compressions to deliver ventilations (**Class IIa**). There were insufficient data to recommend for or against the use of mechanical ventilators.

Chest compressions

The crucial importance of chest compressions has been increasingly recognized in recent years (for review of the subject see Chamberlain, Handley and Colquhoun).[36] Unfortunately there is increasing evidence that compressions are performed particularly badly in practice. In recent treatment recommendations, particular emphasis is placed on ways of increasing the number and quality of chest compressions during resuscitation attempts.

Hand position

There is insufficient evidence to recommend any one specific hand position when performing chest compressions in adults. Based on manikin studies in healthcare professionals demonstrating shorter pauses between ventilations and compressions[37] and improved performance[38] it is recommended that the hands should be placed 'in the centre of the chest' with the dominant hand in contact with the sternum (**Class IIa, Level C**).

Rate and depth

Studies in humans have given conflicting results; in one study a rate of 120 min^{-1} provided improved hemodynamics over standard cardiopulmonary resuscitation (CPR)[39] (**Level C**). Studies that employed mechanical compression, however, have showed no improvement with rates of up to 140 min^{-1} compared to 60 min^{-1}[40,41] (**Level C**). Observational studies show that hospital healthcare providers[42,43] and emergency medical services (EMS) personnel[44,45] give fewer compressions than currently recommended (**Level C**). These studies[43,44] also showed that compression depth is often inadequate.

In animal models of cardiac arrest, deeper compressions correlated with increased ROSC and 24-hour survival than standard compression depths[46–48] (**Level C**).

Decompression of the chest

In one animal study incomplete chest recoil was associated with increased intrathoracic pressure, decreased venous

return and decreased coronary and cerebral perfusion.[49] There are no comparable human data. Lifting the hands slightly but completely off the chest between compressions allowed full recoil of the chest in a manikin study[50] (**Level C**). Observational studies in human CPR[35] and manikin studies[50] have shown that incomplete chest recoil is common during CPR (**Level C**).

Duty cycle

This term describes the time spent in compression as a proportion of the time between the start of one compression and the next. Coronary blood flow is determined in part by duty cycle (reduced when >50%) and the extent of chest relaxation at the end of each compression[51] (**Level C**). There is a lack of clinical evidence from human studies, but data from animal or mathematical models suggest a cycle of 20–50% is optimal[46,52–55] (**Level C**).

A duty cycle of 50% is much easier to achieve than cycles where compressions constitute a smaller percentage of the time,[56] an important practical issue for both performance and training (**Level C**).

Following analysis of this evidence, it is recommended that chest compressions should be performed with the hands placed in the center of the chest (**Class IIa**) at a rate of at least 100 min^{-1} (**Class IIa**), compressing the sternum to a depth of at least 4–5 cm. Rescuers should allow complete recoil of the chest between compressions (**Class IIb**). It is reasonable to use a duty cycle of 50% (**Class IIb**). Rescuers should minimize interruption of chest compressions for checking the pulse, analyzing rhythm or performing other activities (**Class IIa**).

A manikin study showed that compression depth deteriorated within one minute, but rescuers only became aware of fatigue after five minutes[57] (**Level C**). In consequence, it is recommended that where feasible, rescuers should rotate the duties of compression regardless of whether they feel fatigued (**Class IIb**).

Compression ventilation sequence

Interrupting compressions Observational studies and secondary analysis of randomized trials have shown that interruption of chest compressions is commonplace[42,44,58] (**Level C**). Animal studies consistently show that interruptions in chest compression are associated with reduced ROSC, survival and postresuscitation myocardial dysfunction[59–61] (**Level C**). One retrospective study that employed ventricular fibrillation (VF) waveform analysis to predict the probability of defibrillation showed that interruptions in chest compression were associated with a reduced chance of conversion to another rhythm[62] (**Level C**).

On the basis of this evidence it is recommended that rescuers should minimize interruptions to chest compression (**Class IIa**).

Compression/ventilation ratio during CPR The number of compressions delivered per minute is determined by the compression rate, the compression/ventilation ratio and the time required to provide ventilation. Evidence from clinical studies shows that rescuers tend to ventilate too quickly and perform too few chest compressions when observed in actual resuscitation attempts. One observational study showed that paramedics perform ventilation at excessive rates in intubated patients and the same was found in a study of hospital responders both with and without an advanced airway in place[35,42,44] (**Level C**). A study of downloads from automated external defibrillators (AEDs) used by EMS personnel showed that chest compressions are frequently delivered at rates other than those recommended in guidelines. Adherence to recommended rates appeared to be associated with improved outcome[45] (**Level C**). A comparable study in trained lay responders in public access defibrillation (PAD) schemes showed widely differing rates of compression, often given too quickly, but pauses were also commonplace.[63] The compression/ventilation ratios employed also varied considerably. The AED algorithms (that require a "hands-off" period during rhythm analysis) were responsible for some of the pauses, but many were prolonged and unexplained. The outcome was that the number of compressions given was very much lower than recommended in guidelines (**Level C**).

Animal studies consistently show that hyperventilation is associated with lower coronary and cerebral perfusion and poorer survival while chest compressions given continuously or with minimal interruptions are associated with improved hemodynamics and improved survival[59,60,64–66] (**Level C**).

Various compression/ventilation ratios have been applied in animal models of cardiac arrest but without a consistent outcome on which to recommend any one particular ratio.[67–69] There are no adequate data from human studies. A mathematical analysis suggested that a ratio of 30/2 would provide the best blood flow and oxygen delivery[70] (**Level C**).

To optimize the number of compressions delivered, to reduce interruptions and simplify instruction (and skill retention), it is recommended that a single compression/ventilation ratio of 30/2 be used by the lone rescuer of infants, children and adults (**Class IIa**). Compressions should be delivered at a rate of at least 100 per minute (**Class IIa**).

Initial steps in the resuscitation sequence may include:
- opening the airway while assessing the patient
- giving 2–5 breaths while initiating resuscitation
- continuing resuscitation with a compression/ventilation ratio of 30/2.

Chest compression-only CPR

There have been no prospective human studies of compression-only CPR. A randomized prospective trial of

compression-only CPR prior to EMS arrival in Seattle (a city with a very rapid EMS response time) showed a trend towards improved survival in those receiving compressions only, but the difference was not statistically significant[71] (**Level B**). Animal studies have shown compression-only CPR to be as effective as conventional CPR with ventilation in the first few minutes after the onset of cardiac arrest.[64–66] A compression/ventilation ratio of 30/2 maintained arterial oxygen saturation at two-thirds of normal whereas compressions only resulted in oxygen desaturation within two minutes.[69]

In observational studies of adult cardiac arrest treated by lay persons trained in standard CPR, survival with compression-only CPR was better than when victims received no CPR, but not as good as when victims received both compressions and ventilations[72,73] (**Level C**).

On the basis of this evidence, the recommendation is that rescuers should provide compression-only CPR if they are unwilling to perform airway and breathing maneuvers or if they are untrained and uncertain how to undertake CPR (**Class IIa**).

Advanced life support: defibrillation

Procedures before defibrillation

The precordial thump

There are no prospective studies of the precordial thump. Case series have reported VF or pulseless ventricular tachycardia (VT) converted to a perfusing rhythm following a precordial thump.[74–76] The likelihood of success was higher in VT[74–78] but decreased rapidly with time.[76] Observational studies also report that other arrhythmias including unstable supraventricular tachycardia (SVT) were terminated by a precordial thump[79,80] (**Level C**).

Observational studies show that an effective precordial thump is delivered by a closed fist from a height of 5–40 cm.[75,76,78] Adverse events include acceleration of the rate of VT, conversion of VT into VF, the production of complete heart block and asystole.[75,77,78,81–84] Current data do not allow these events to be reliably predicted (**Level C**).

The recommendation for practice is that one immediate precordial thump may be considered after a monitored arrest if a defibrillator is not immediately available (**Class Indeterminate**).

CPR before defibrillation

One study that employed a retrospective control group[85] (**Level C**) and one prospective study[86] (**Level B**) showed that 1.5–3 minutes of CPR before attempted defibrillation improved ROSC and survival in adults with out-of-hospital VF or VT when the response interval was ≥4–5 min. Another randomized trial reported that adults with VF or

VT outside hospital did not benefit from 1.5 min of CPR[87] (**Level B**). Animal studies of VF of ≥5 min duration report that CPR before defibrillation (very often with concomitant adrenaline) improved survival rates[88–91] (**Level C**).

The ILCOR recommendation reflects this evidence: 1.5–3 min of CPR before attempted defibrillation may be considered in adults with out-of-hospital VF or VT where EMS response times are greater than 4–5 min (**Class IIb**). There was no evidence to support or refute the strategy in hospital.

Defibrillator electrode–patient interface

No studies have investigated the influence of electrode position on the outcome of human cardiac arrest. The subject has been investigated during conversion of stable atrial fibrillation or by the use of surrogate endpoints such as transthoracic impedance (TTI). Cardioversion of perfused myocardium in stable atrial fibrillation (AF) may not be the same as defibrillation of ischemic myocardium and caution is required when extrapolating from such studies. Many studies in AF have investigated the influence of electrode position and have lead to current recommendations. For references see [92] (**Level B or C**).

One human study documented higher success with larger electrodes[93]; 12.8 cm pads were superior to 8 cm (**Level B**). Several studies have confirmed lower TTI with increased electrode size (**Level B or C**). One animal study reported increased myocardial damage in dogs with smaller electrodes (4.3 cm compared with 8 or 12 cm)[94] (**Level C**).

The recommendation is that electrodes should be placed on the exposed chest in an anterolateral position (**Class IIa**). Acceptable alternatives are the anteroposterior and apex-posterior position (**Class IIa**). Placing the electrode on the female breast increased TTI[95] and in consequence the electrode should be placed underneath or lateral to the left breast (**Level C**).

Self-adhesive defibrillation pads versus paddles

One randomized trial[96] and two retrospective series[97,98] showed that the TTI was similar with both types of electrode (**Level B, C**). One randomized study showed similar effectiveness in converting AF[99] (**Level C**).

Self-adhesive pads are safe and effective and are an acceptable alternative to standard defibrillation paddles (**Class IIa**). There are important practical advantages with pads for routine monitoring and for perioperative or prehospital use.

Waveform analysis

Analysis of the VF waveform has the potential to improve the timing and effectiveness of countershocks. Evidence

comes from retrospective analysis of human series and animal models (**Level C**). The technology is advancing rapidly but is not yet available in routine clinical practice.

Defibrillator shock waveform

A major advance in defibrillator technology in recent years has been the introduction of biphasic waveforms. Randomized clinical studies in human cardiac arrest[100–102] (**Level B**), reanalysis of the data in one study,[103] two observational studies[104,105] (**Level C**) and many animal studies show that biphasic waveforms using equal or lower energy levels are superior to or at least as effective as monophasic waveforms for terminating VF. A meta-analysis of seven randomized trials in patients in the electrophysiology laboratory[105] concluded that biphasic waveforms defibrillate with similar efficacy at lower energies than monophasic 200 J shocks, and greater efficacy than monophasic shocks of the same energy (**Level A**). No specific biphasic waveform has yet been demonstrated to be superior. One retrospective study[106] showed a higher hospital discharge rate with a monophasic truncated exponential (MTE) waveform compared to a biphasic truncated exponential (BTE) waveform. Survival was a secondary endpoint, however, and there were many confounding factors, not least the higher incidence of bystander CPR in the MTE group.

The recommendation for practice is that biphasic shocks are safe and effective for the termination of VF when compared with monophasic defibrillators (**Class IIa**).

First shock energy levels

Many clinical studies have compared initial biphasic shock energies of 100–200 J without clearly showing an advantage for either[100–102,104,106,107] (**Level B, C**). These studies also investigated subsequent energy levels ranging from 150 J to 300 J for VF refractory to the initial shock but without clearly demonstrating an optimal level. Other laboratory studies of stable patients evaluated termination of induced VF by energy levels of 115–200 J No clinical or laboratory study has convincingly shown greater benefit or harm from any currently used energy level. A hospital study compared first shock efficacy of monophasic damped sinusoidal (MDS) waveforms of low (100–240 J), intermediate (300–320 J) and high (400–440 J) without demonstrating a statistically significant benefit for any level.[108]

There is currently insufficient evidence to recommend a specific energy level for the first or subsequent biphasic shock. ILCOR recommend that with a biphasic defibrillator it is reasonable to use 150–200 J with a BTE waveform or 120 J with a rectilinear waveform (**Class IIa**). For a monophasic defibrillator an initial shock of 360 J is considered a reasonable option (**Class IIa**).

Second and subsequent shocks

Fixed versus escalating energy levels
Only one small human study compared fixed energy with escalating energies for subsequent shocks from a biphasic defibrillator. There was no clear benefit for either strategy[109] (**Level C**). No recommendation for either strategy could therefore be made.

One shock versus three shock sequence
No clinical or animal studies have compared a protocol that employs a single shock with one that employs three successive shocks before the resumption of chest compressions. Many studies have investigated the efficacy of first or subsequent shocks; success is defined as the termination of VF for ≥5s after the shock. This is an assessment made on the ECG, however, and does not necessarily indicate the return of the circulation.

The efficacy of the first shock given by a variety of waveforms and energy levels has been investigated in several trials of out-of-hospital VF.[92] A summary of the results is as follows.
• With a 200 J MDS waveform first shock success was 77–91%.
• With a 200 J MTE waveform, the rate was 54–63%.
• With a 150 J BTE waveform (four studies) and one using a 200 J BTE waveform, first shock success was 86–98%.
• With a 120 J rectilinear biphasic waveform first shock success rate was 85%.
Although the first shock success at converting the rhythm was relatively high, the average rate of ROSC with the first shock for all three waveforms was only 21% (range 13–23%).

Second and third shock success rate

Where the patient remained in VF after the first shock:
• with the MDS waveform with increasing energy levels (200 J to 200–300 J to 360 J), the combined success of the second and or third shocks was 68–72%
• with the MTE waveform with increasing energy levels (200 J to 200–360 J) the combined success of the second and/or third shocks was 27–60%
• with the fixed (non-escalating) 150 J BTE waveform, the combined success of the second and or third shocks was 50–90%.
The single study that used a rectilinear escalating waveform (120 J to 150–200 J) reported combined success of second and/or third shocks of 85%.

In the absence of any evidence for a clearly superior strategy, ILCOR recommended that practice should concentrate on procedures that optimize the chances of successful defibrillation regardless of the precise energy, waveform or shock sequence. These priorities were to rec-

ognize the potential need for defibrillation as soon as possible, provide CPR until a defibrillator is available and minimize interruptions to chest compressions (**Class I**).

A one-shock strategy may improve outcome by reducing interruptions in chest compressions. A stacked sequence of three shocks can be optimized by the immediate resumption of effective chest compressions after each shock (irrespective of the rhythm) and by minimizing the "hands-off" periods for rhythm analysis or other procedures.

Advanced life support: other considerations

Airway and ventilation

Methods to secure and maintain the airway and the different strategies and devices used to provide ventilation during resuscitation attempts are evaluated in detail during the ILCOR evidence evaluation process. Detailed consideration of these topics is outside the scope of this chapter and the reader is referred to the original ILCOR documents.[110]

Drugs used in the management of cardiac arrest

Vasopressors

Despite the widespread use of vasopressors, principally adrenaline/epinephrine during resuscitation attempts, and several trials involving vasopressin, there is no placebo-controlled trial showing that the routine use of any vasopressor during human cardiac arrest increases survival to hospital discharge.

Vasopressin Despite promising preliminary data and numerous animal studies, two large randomized trials of cardiac arrest in humans did not show a benefit (in terms of ROSC or survival) for vasopressin 40 U (repeated in one trial) compared with adrenaline 1 mg (repeated) as the initial vasopressor whether in hospital[111] or out of hospital[112] (**Level A**). In one of the trials,[112] *post hoc* analysis suggested an improvement to hospital discharge for the subset of patients initially in asystole in patients receiving vasopressin compared to adrenaline, but neurologically intact survival was not different in the two groups. Subsequently, meta-analysis of five randomized trials[113] showed no statistically significant differences between vasopressin and adrenaline for ROSC, death within 24 hours or death before hospital discharge. Subgroup analysis based on presenting cardiac rhythm did not show any benefit in terms of death before hospital discharge (**Level A**).

Alpha-methyl noradrenaline When vasopressors like adrenaline that possesses both alpha- and beta-adrenergic effects are administered during cardiac arrest, the beta effects increase myocardial oxygen consumption with the risk of increased myocardial ischemia. Alpha-1 but not alpha-2 receptors have been identified in the ventricular myocardium, and it has been suggested that the selective alpha-2 agonist alpha-methyl noradrenaline may offer advantages by producing vasoconstriction (with attendant increase in coronary perfusion) while avoiding the positive inotropic and chronotropic effects of adrenaline. Animal work has been encouraging but no human study has been reported (**Level C**).[114–116]

Endothelin Several animal studies have demonstrated improved coronary or cerebral perfusion pressure with endothelin-1. This did not result in improved myocardial blood flow, however. No human trial has been reported.

Conclusions Despite the lack of placebo-controlled trials, adrenaline has been the standard vasopressor and remains the drug of choice. It is considered appropriate to administer a 1 mg dose of epinephrine IV/IO every 3–5 minutes during adult cardiac arrest (**Class IIb**). Current evidence does not support or refute the use of any other vasopressor or combination during human cardiac arrest. There is insufficient evidence to support the use of vasopressin either alone or in combination with adrenaline in any cardiac arrest rhythm (**Class III**).

Antiarrhythmic drugs

There is no evidence that the administration of any antiarrhythmic drug during resuscitation increases survival to hospital discharge.

Amiodarone

Two randomized clinical trials in adults have shown that the administration of of amiodarone by paramedics to adult patients in out-of-hospital cardiac arrest with shock-refractory VF/pulseless VT improved survival to hospital admission (but not to hospital discharge) when compared to placebo[117] or lidocaine[118] (**Level A**). Other lower level studies in humans or animals document a consistent improvement in the response to defibrillatory shocks in VF or VT.

Despite the lack of long-term outcome data, it is deemed reasonable to use amiodarone for VF/VT refractory to initial shocks (**Class IIb**).

Other drugs and fluids

There is no evidence that buffers, aminophylline, atropine, calcium or magnesium given routinely during human cardiac arrest increase survival to hospital discharge (**Class III**). There are reports that fibrinolytic agents may have a role when the arrest is caused by pulmonary embolism (**Class IIa**).

Aminophylline Ischemia is a potent stimulus for the release of adenosine which may slow the heart and possibly produce or maintain asystole. Methylxanthines like aminophylline block adenosine receptors and on this basis a role for the use of aminphylline in the management of bradysystolic arrest has been proposed. In a small case series, 15 consecutive patients with cardiac arrest due to asystole or to non-perfusing bradyarrhythmias, who failed to respond to intravenous atropine and epinephrine, were treated with aminophylline (rapid intravenous injection of 250 mg). Establishment of a stable heart rhythm with sufficient blood pressure to allow discontinuation of closed-chest cardiac massage was achieved in 11 of 15 (73%) patients. All 11 patients were alive 60 minutes after resuscitation. One patient survived, without neurologic damage[119] (**Level C**). Subsequently, three randomized trials of its use were unable to show any increase in ROSC[120–122] but the numbers recruited into the trial were small. No trial has shown an effect on survival to hospital discharge. There is no evidence of harm following its use, but overall there is insufficient evidence to advocate a role for its routine use (**Class IIb, Level B**).

Atropine Five prospective but non-randomized studies in adults[123–127] and one retrospective case[128] series failed to show any consistent benefit following the use of atropine (**Level C**). The use of atropine has not been associated with harm, however, and there have been anecdotal reports of survival following its use in asystolic cardiac arrest. In the absence of agents with more evidence to support their use, atropine maintains a role in the management of asystole (**Class Indeterminate**). Atropine remains the first-line drug treatment for acute symptomatic bradycardia (**Class IIa**).

Buffers Sodium bicarbonate has been widely used in the past in the management of cardiac arrest. There are no randomized controlled trials to support its use and recent resuscitation guidelines have curtailed its unrestricted use. Retrospective reports of its uncontrolled use are largely inconclusive although one study reported that EMS systems that gave sodium bicarbonate earlier and more frequently had increased rates of ROSC, hospital discharge and better long-term neurologic survival[129] (**Level C**). Animal studies are also inconclusive. The drug has been used successfully to treat hypotension and arrhythmias complicating tricyclic overdosage, but only one report described the successful treatment of VF arrest[130] (**Level C**).

The routine use of sodium bicarbonate during cardiac arrest (especially outside hospital) or after ROSC is not recommended (**Class III**). It may be considered for life-threatening hyperkalemia or cardiac arrest associated with hyperkalemia, tricyclic overdosage or pre-existing metabolic acidosis (**Class IIb**).

Magnesium Randomized trials of magnesium in adult cardiac arrest [131–4] (**Level B**) and lower degrees of evidence including animal studies have not shown an increased rate of ROSC when magnesium was given during CPR. One small case series reported benefit in patients in shock-resistant and adrenaline/lidocaine-resistant VF.[135]

There are insufficient data to recommend or refute the use of magnesium in cardiac arrest. It should be given in hypomagnesemia and retains a place in the management of torsades de pointes (**Class IIa**).

Fibrinolytic drugs Up to 70% of patients with sudden cardiac arrest have underlying acute myocardial infarction or pulmonary embolism. Both conditions are potentially responsive to fibrinolytic therapy. Adult patients have been successfully resuscitated following the administration of fibrinolytic drugs after the initial failure of standard resuscitation procedures, particularly when the cause has been pulmonary embolism. One large clinical trial, however, failed to show a significant treatment effect when administered to patients with pulseless electrical activity (PEA) outside hospital.[136] Other small studies or case reports were inconclusive with regard to improving outcome, but did not report an increase in bleeding complications (**Level C**).

In the Thrombolysis in Cardiac Arrest (TROICA) trial 1050 patients suffering from witnessed out-of-hospital arrest of presumed cardiac origin were randomly assigned to tenecteplase (TNK) or placebo, plus standard therapy. Interim data analysis showed that the addition of TNK to standard CPR did not increase the 30-day survival rate (18.2% vs 20.2%, P = NS) nor the hospital admission rate (59.0% vs 59.5%, P = NS). The symptomatic intracranial hemorrhage (1% vs 0%) and major bleeding (8.9% vs 7.4%) rates were not significantly different between groups. This preliminary data analysis showed that the probability that the study would demonstrate overall superiority of tenecteplase over placebo was low and the recruitment was suspended[137] (**Level B**).

Thrombolysis should be considered in cardiac arrest caused by proven or suspected pulmonary embolism (**Class IIa**). The data do not support its routine use in other situations.

Techniques and devices to assist the circulation during cardiac arrest

Because CPR is often of poor quality and deteriorates with time, and because interruptions of chest compressions are common, a variety of approaches has been adopted to improve the quality of CPR by the use of prompt devices or by other techniques. A separate approach is to use mechanical methods to undertake chest compressions, thereby eliminating dependence on rescuers.

Transcutaneous pacing for asystole

Three randomized trials[138–140] have failed to demonstrate an improvement in the rate of hospital admission or survival to discharge when pacing was attempted in asystolic patients in the prehospital arena or the emergency department (**Level A**). Pacing is therefore not recommended for this group of patients (**Class III**). It retains its established role in the treatment of bradycardia (**Class I**).

CPR prompt devices

Unprompted CPR is often of poor quality and interruptions to chest compressions are frequent[42,44,45,63] (**Level C**). Studies in adults, children or experimental animals or with manikins have consistently shown improvement in end-tidal CO_2 or quality of CPR when feedback is provided to guide the rescuer[141–151] (**Level C**). Several such aids are now available either as stand-alone devices or incorporated into the AED or electrodes. Further studies are required to investigate the effect on patient outcomes resulting from the introduction of these devices into practice. In the meantime, it is considered that CPR prompt devices may be useful in both out-of-hospital and in-hospital settings (**Class IIb**).

Active compression decompression (ACD) CPR

ACD devices are designed to adhere to the chest (usually by a suction cup) so that after chest compression is complete, lifting the device actively expands the chest. This causes a greater reduction in intrathoracic pressure than would result from passive expansion and thereby increases venous return and cardiac output during subsequent chest compressions. Initial studies were promising, reporting improved survival[152–4] (**Level A, B**).

However, subsequent Cochrane meta-analysis of 10 trials (in 4062 patients) comparing ACD with standard CPR outside hospital did not show an improvement in either short-term survival or hospital discharge[155] (**Level A**). Similarly, analysis of two hospital-based trials (826 patients) comparing ACD with standard CPR after arrest in hospital did not show improvement in either short-term survival or hospital discharge[155] (**Level A**). At present there is insufficient evidence to recommend for or against the use of ACD.

Load-distributing band CPR

This chest compression device features a backboard and a band that is placed circumferentially around the chest. The band is constricted pneumatically to produce chest compression. Case control[156,157] and laboratory studies[158,159] with encouraging results prompted the conduct of two larger clinical studies of the device. One study, comparing results before and after the introduction of the device into an EMS system, reported improvements in ROSC, hospital admission and discharge rates[160] (**Level C**). The second study, a randomized multicenter trial, was stopped prematurely as patients in the device group showed worse neurologic outcomes and a trend toward worse survival than with manual CPR[161] (**Level A**). An accompanying editorial[162] tried to reconcile the apparently contradictory results. Further randomized trials of the device are planned and until more data are available, the device cannot be recommended for routine practice. At present it is recommended that properly trained personnel may use the device as an adjunct to CPR for patients with cardiac arrest in the out-of-hospital or in-hospital setting (**Class IIb**).

Mechanical (piston) CPR

Although this method of providing mechanical CPR has been around for several years, published evidence to support its use is scanty. Prospective randomized studies in humans have demonstrated improvement in surrogate outcomes like end-tidal CO_2 or mean arterial blood pressure when it has been employed both in and outside hospital.[163–6] The device has proved capable of performing chest compressions that adhere more closely to guidelines than manual compressions, particularly during the transport of patients. Reports of its effect on immediate resuscitation or ultimate survival when used in clinical practice are lacking. At present the recommendation is that mechanical piston CPR may be considered for patients in cardiac arrest in circumstances that make manual resuscitation difficult (**Class IIb**).

Lund University Cardiac Arrest System (LUCAS) CPR device

This is a gas-driven device that incorporates a suction cup to apply chest compressions and to achieve active decompression. Promising improvements in hemodynamics were reported in pigs when compared to manual CPR.[167,168] A small case series reported promising results[169] although outcome data were incomplete (**Level C**). The device has been used successfully during the transport of severely hypothermic patients to a center with cardiopulmonary bypass[170,171] and during prolonged resuscitation from PEA complicating anaphylaxis[172] (**Level C**).

A prospective randomized clinical trial comparing the device with manual CPR in out-of-hospital cardiac arrest reported no significant difference in ROSC, hospital admission or discharge[173] (**Level B**). The LUCAS device was applied late, however (18 min after arrest) and the trial highlighted the complexity of conducting such evaluation. Further trials are planned and will help establish the place of the device. Important injuries have been noted in a small number of patients in whom the device was used.[174]

Conclusion

The principles of evidence-based medicine are increasingly applied to the management of cardiac arrest. International collaboration to agree upon the scientific basis of practice is well established. The formulation of sound guidelines for practice is limited, however, by a lack of robust scientific evidence in many areas. There are additional problems with the conduct of clinical trials that might help this process: the population studied is heterogeneous, different treatment strategies are common, recording data is difficult under the circumstances and many confounding factors are usually present. The design and conduct of trials with sufficient statistical power to evaluate potentially small benefits present further challenges. The low levels of evidence often quoted in this chapter attest to these problems but by critically examining the evidence base in this way, areas of ignorance and potentially poor practice may readily be identified. That is a necessary stage toward obtaining better evidence and providing more effective management.

Arrhythmias due to monogenic disorders

Dawood Darbar, Prince Kannankeril and Dan M L Roden
Departments of Medicine, Pediatrics, and Pharmacology, Vanderbilt University School of Medicine, Nashville, TN, USA

Introduction

Monogenic diseases are caused by single genetic defects, follow Mendelian inheritance, and are classified as autosomal dominant, autosomal recessive or X-linked. Over 5000 monogenic diseases have been identified, and more than 1000 genes responsible for these disorders are known. The prevalence of monogenic diseases ranges from 1 in 1000 individuals in the most common forms to 1 in 200 000 in the rarest. The identification and study of the genetic substrates of these diseases are important not only because they contribute to the development of diagnostic tests for affected individuals but also because they promote understanding of the function of different proteins in humans. Consequently, genetic testing is currently applied not only for diagnostic evaluation, but also as a research tool for the study of pathophysiology of inherited arrhythmia syndromes. In cardiology, there are two major clusters of monogenic disorders: the cardiomyopathies due to alterations in sarcomeric and in cytoskeletal proteins, and the arrhythmogenic diseases that are caused by mutations in ion channels and ion channel-controlling proteins, e.g. the congenital long QT syndromes (LQTS), the Brugada syndrome, catecholaminergic polymorphic ventricular tachycardia (CPVT), Andersen–Tawil syndrome, conduction system disease, and atrial fibrillation (AF).

What we have learned from the genetics of monogenic arrhythmia syndromes

The identification of genes responsible for the inherited arrhythmia syndromes has contributed greatly to our understanding of the substrate for arrhythmia development. More importantly, it has provided practical information when managing affected patients with these disorders. The identification of a mutation allows us to suspect the diagnosis independent of the clinical features of the syndrome. When screening family members of a genotyped proband, an unexpectedly large number of carriers is identified among relatives initially considered unaffected based on clinical phenotyping. For example, up to 32% of carriers of LQTS-related mutations can have a normal QTc.[1] As silent carriers have a 50% probability of transmitting LQTS to their offspring and they are more likely to develop cardiac arrhythmias compared to an age-matched population,[2] knowing the genotype status of an individual has practical implications. In addition, silent carriers of a LQTS-related genetic defect still have a 20% risk of becoming symptomatic.[2] Thus, the most immediate contribution of genetic information to clinical practice is that of providing a novel and useful parameter for risk stratification that can be used alone or in combination with other clinical variables. Currently, only in the congenital LQTS do we have data on hundreds of genotyped patients with long clinical follow-up but emerging data for other diseases such as CPVT are becoming available. As progress is made in our understanding of the links between DNA defects and clinical phenotype, genotyping patients with inherited arrhythmia disorders is even more likely to contribute to the clinical management of patients.

Complexity beyond monogenic arrhythmia disorders

Since the initial discovery of mutations in *KCNQ1*, *KCNH2*, and *SCN5A* cardiac ion channel genes by Keating and colleagues over a decade ago,[3–5] hundreds of mutations have been identified in various ion channel subunits and in proteins important for the proper functioning of cardiac ion channels. Although it was initially assumed that all carriers of pathogenic mutations would manifest the

corresponding phenotype, it soon became apparent that the clinical consequences of genetic defects are far more variable than expected. Some of this variability is related to incomplete penetrance and variable expressivity. The penetrance of a monogenic disease is defined as the percentage of individuals with a mutant allele who develop the phenotype of the related disease and it can vary from 10% to 100%. The expressivity of a disease is defined as the different phenotypical manifestations that can be observed among carriers of the same genetic defect. Consequently, the combination of variable penetrance and expressivity dictates that carriers of a DNA mutation may manifest either no clinical phenotype or phenotypes that are not the classic "textbook" type. Thus, genotyping patients affected by "simple" monogenic diseases is more complicated than initially envisioned.

Another important concept when considering monogenic diseases is genetic heterogeneity. Analogous to the genetics of inherited cardiomyopathies, in arrhythmia disorders the "same" phenotype is associated with multiple genetic defects. At present, nine genes are known to cause the phenotype of the congenital LQTS and explain 60–75% of the clinically diagnosed cases. Similarly, two genes have been associated with CPVT and they account for half of the patients with the phenotype.[6] Two genes are known to cause the Brugada syndrome, but several other genes are likely to be implicated because so far only 20% of clinical diagnoses result in positive results at genetic testing.[7] Perhaps an obvious question that stems from these considerations is whether we should refer to all genetic variants with the same name, such as LQTS. Should all individuals with the same ECG marker, e.g., prolonged QT interval, ST segment elevation in the right precordial leads, adrenergically driven polymorphic ventricular tachycardia (VT), be grouped under the same diagnosis, when we know that

each genetic variant has a distinguishing clinical phenotype? This may be more than semantics as there are emerging data that the genetic substrate is a major determinant of prognosis in patients harboring different genetic mutations.[2]

In the future we may consider each genetic variant as a separate disease based on the specific defect as this would avoid the difficulty of trying to fit the complex and overlapping phenotypes into clinical categories. This would not only simplify the categorization of overlapping syndromes but also the clinical profiles: Brugada syndrome with conduction defects, Brugada syndrome with atrial arrhythmias, conduction defects with sinus abnormalities, Brugada syndrome with prolonged QT interval, etc. All these conditions could be grouped in the category of sodium channel disease and its full spectrum of abnormalities. This is complicated even further as it is now established that mutations in one gene may lead not only to variable phenotypes within the same disease, but also to profoundly different diseases. The most emblematic example of this diversity is represented by mutations in the lamin A/C gene, which are known to cause at least eight phenotypes (allelic diseases) as different as dilated cardiomyopathy, Emery–Dreifuss muscular dystrophy, familial partial lipodystrophy, Charcot–Marie–Tooth disease, mandibuloacral dysplasia, Hutchinson–Gilford progeria, lipoatrophy with diabetes, and hepatic steatosis hypertrophic cardiomyopathy. In inherited arrhythmia disorders, three diseases have been associated with mutations of the cardiac sodium channel gene (LQTS, Brugada syndrome, and progressive conduction disturbances)[4,8] and three diseases (LQTS, short QT syndrome and familial AF) have been associated with mutations in the *KCNQ1* gene encoding for the alpha-subunit of the potassium channel conducting the slow component of the delayed rectifier (I_{Ks}).[5,9,10] It is therefore

Table 44.1 Atrial arrhythmias due to monogenic disorders

Phenotype	Rhythm	Inheritance	Locus	Ion channel /protein	Gene
AF	AF	AD	10q22–24	–	–
			11p15	I_{Ks}	KCNQ1
			6q14–16	–	–
			21q22	I_{Kr}	KCNE2
			17q23	I_{K1}	KCNJ2
			12p13	I_{Kur}	KCNA5
	AF	AR	5p13		
SND	Sinus bradycardia, AF	AD		HCN4	HCN4
Atrial standstill	SND, AF	AD	3q21	I_{Na}	SCN5A
WPW syndrome	AVRT	AD			PRKAG2
Progressive conduction disease	AVB	AD	19q13 3q21	I_{Na}	SCN5A

AD, autosomal dominant; AF, atrial fibrillation; AR, autosomal recessive; AVRT, atrioventricular re-entrant tachycardia; AVB, atrioventricular block; SND, sinus node dysfunction; WPW, Wolff–Parkinson–White.

obvious that the identification of a mutation in a given gene cannot establish the diagnosis of a single disease and the identification of a mutation in an individual with a known disease is not enough to predict the phenotype of that individual.

We will now discuss individual inherited monogenic arrhythmia disorders.

Atrial fibrillation

Atrial fibrillation (AF), the most common cardiac arrhythmia in clinical practice, affects approximately 2% of the United States population and results in substantial morbidity and mortality.[11] The increasing prevalence of AF parallels the increasing age of the general population.[12] AF is also the most common arrhythmia requiring drug therapy. The limited success of current interventions for AF is partially the result of heterogeneity of the underlying electrical substrate and incomplete understanding of fundamental mechanisms in disease pathogenesis. Although some of the risk factors associated with AF have been identified, relatively little is known about the underlying molecular events leading to the arrhythmia.[13] One approach to unraveling the molecular pathogenesis of AF is through the identification of genes responsible for familial forms of the disease. Evidence for the heritability of AF has come from several sources including the study of AF kindreds who exhibit the arrhythmia as a primary disease, the analysis of AF presenting in the setting of another familial cardiac disease, and the analysis of common population genetic variants, i.e. DNA polymorphisms, that may predispose to AF.

Monogenic forms of lone AF

Monogenic familial AF was first reported in 1943[14] and while it may be uncommon, there has been no attempt to determine the prevalence of familial AF. Heritability of AF is further suggested by two recent population-based studies demonstrating that AF in first-degree relatives was associated with an increased risk of developing AF.[12,15] One study showed that 5% of patients with AF and up to 15% of individuals with lone AF may have a familial form of the disease.[16,17]

A gene locus for AF was first reported in 1997, based on genetic mapping in three Spanish families.[18] However, the gene responsible for AF in these kindreds has not yet been identified, but resides within a relatively large chromosomal region spanning 14 centiMorgans (cM). In addition, three other loci on chromosomes 6q14–16,[19] 5p13[20] and 10p11-q21[21] have been reported, with no genes yet identified. In 2002, a novel AF locus on chromosome 5p15 was identified by genome-wide linkage analysis of a

four-generation kindred.[22] Importantly, this study established an abnormally prolonged P-wave (>155 ms) determined by signal-averaged ECG analysis as an "endophenotype" that improved statistical power of the linkage study in this family. Collectively, these reports support the idea that familial AF is a genetically heterogeneous disease much like many other inherited arrhythmia syndromes.[16]

Recently, the first genes for AF have been identified, providing a link between ion channelopathies and the arrhythmia. In a four-generation Chinese family in which LQTS and early-onset AF co-segregate, a mutation (S140G) in *KCNQ1* gene on chromosome 11p15.5 has been reported.[10] Functional analysis of the S140G mutant revealed a gain-of-function effect in KCNQ1/KCNE1 and KCNQ1/KCNE2 currents, which contrasts with the dominant negative or loss-of-function effects of *KCNQ1* mutations previously associated with LQTS. More recently, the same group established a link between *KCNE2* and AF by identification of a mutation in two families with AF.[23] The mutation R27C also caused a gain-of-function when co-expressed with *KCNQ1* but had no effect when expressed with *KCNH2*. Recently, a truncating mutation in *KCNA5* encoding a voltage-gated potassium channel (K_V1.5) underlying the ultra-rapid delayed rectifier current (I_{Kur}) was associated with familial AF.[24] These studies firmly establish the role of potassium channels in the pathogenesis of some forms of familial AF, but resequencing studies in large cohorts suggest that mutations in these channels are a rare cause of the arrhythmia.[25]

AF associated with other monogenic diseases

Studies of other cardiac monogenic disorders have also provided evidence for the genetic contribution to the etiology of AF. These include diseases such as hypertrophic cardiomyopathy, skeletal myopathies, familial amyloidosis, and atrial myopathies. It is likely that AF in these cases is related at least in part to non-specific structural changes in the atria caused by the underlying cardiac pathology, but AF is uniquely prominent in some kindreds with each of these conditions.[26] AF can also present in other ion channelopathies like congenital LQTS type 4,[27] Brugada syndrome[28] and short QT syndrome.[29] The high incidence of atrial arrhythmias in patients with short QT syndrome and gain of function mutations in I_{Ks}[30] point to an important role for shortening of the action potential in the development of AF. Sodium channel gene (*SCN5A*) defects have also been associated with a syndrome of early-onset dilated cardiomyopathy and AF.[31] Moreover, mutations in the gene for the nuclear membrane protein lamin A/C (LMNA) have pleiotropic non-cardiac and cardiac manifestations including dilated cardiomyopathy, AF, and conduction system disease.[32] Collectively, these studies

attest to the heterogeneous nature of AF and strongly suggest that defects in many more genes remain to be identified.

AF associated with cardiac or systemic diseases

Most patients with AF have one or more identifiable risk factors, but many or even most patients with these same risk factors do not develop AF. Thus, it is likely that genetic determinants favor AF in some individuals with identifiable risk factors. Studies comparing cases of non-familial AF to age- and gender-matched controls (association studies) have provided insight into the genetic basis of "acquired" AF. One study evaluated a polymorphism in *KCNE1* and AF and identified an association with the 38G allele. While the 38G allele appears to reduce I_{Ks},[33] mice lacking *KCNE1* are prone to AF due to an unexpected increase in I_{Ks},[34] suggesting that the consequences of ion channel mutations are not always straightforward. In addition, common DNA polymorphisms in *GNB3*,[35] *KCNE5*,[36] and *SCN5A* have all been associated with AF.[37] Over the last several years increasing evidence has arisen that renin-angiotensin-aldosterone (RAAS) activation may be an important risk factor for the development of AF. Retrospective analyses suggest that angiotensin-converting enzyme (ACE) inhibitor therapy is associated with a lower incidence of AF and a placebo-controlled trial found a similar beneficial effect of adding the angiotensin receptor blocker (ARB) irbesartan to amiodarone.[38] Additionally, a case–control study of 250 Taiwanese subjects with AF and 250 controls identified polymorphisms in this pathway as risk factors for AF.[39] Added support for the role of RAAS activation in the pathophysiology of AF comes from a recent study which demonstrated a pharmacogenetic interaction between the ACE *I/D* polymorphism and efficacy of antiarrhythmic drug therapy in patients with lone AF.[40]

The above studies in aging patients with non-familial AF in the presence of underlying heart disease suggest some form of heritable contribution to the pathogenesis of the more common forms of AF. These data are promising and may help clarify why some people develop AF under specific circumstances while others may not.

Uncovering common genes for AF

A logical consequence of the availability of comprehensive genomic maps is the advent of high-density genome-wide searches for modest gene effects using large-scale testing of single nucleotide polymorphisms (SNPs). Such an approach has been suggested to tackle complex human diseases such as AF. Early proponents suggested the study of coding or promoting variants with potential functional significance. Collins *et al* subsequently proposed that non-coding or evenly spaced SNPs with high density could be used to track disease loci through linkage disequilibrium.[41] The availability of high-density mapping of marker SNPs and assessment of genomic structure, together with emerging information on functional pathways, have begun to provide powerful means of identifying genetic susceptibilities to AF. In the first genome-wide association study of AF, a novel locus on chromosome 4q25 has recently been identified which confers a 1.6–2.0 (95% confidence interval)-fold increased risk of the arrhythmia across multiple different populations.[42]

Atrial flutter

While there is significant overlap among the risk factors for AF and atrial flutter, in general these arrhythmias exhibit quite distinct biology and electrophysiology.[13] Atrial flutter is commonly associated with the later stages of a broad range of congenital heart disease (CHD). There is extensive heterogeneity particularly in the most profound structural disorders, but increasing evidence of a heritable component to many forms of CHD is accumulating. The association of CHD with atrial flutter has been attributed to abnormal atrial patterning, which may range from the extreme to the subtle, often with no other obvious manifestations. Interestingly, atrial flutter was found to be more strongly associated with the locus on chromosome 4q25 than AF, at least suggesting that there may be common factors underlying the clinical presentation of some forms of these two arrhythmias.[42] Given the intrinsic biases of genome-wide association studies, these links might be far downstream of the primary causation, but nevertheless may have substantial effects on a population basis.

Sinus nodal failure

Classic Mendelian genetics have revealed several distinctive mechanisms for sinus nodal disease. Mutations in the cardiac transcription factors Nkx 2.5 and Tbx 2.5 both cause defects in the differentiation and maintenance of specialized conduction tissues (particularly those of the AV node) and each causes subtle abnormalities of sinus impulse generation.[8,43–45] Similarly, several primary arrhythmic syndromes including some forms of the LQTS also result in perturbations of sinus rhythm.[46] While in many instances potential mechanisms have been framed in terms of effects on transmembrane ion currents, data from genetic models of *SCN5A* and AnkB disease suggest that subtle trophic effects on myocardial structures may also play a role.[47,48] Genetic models may also inform human studies at an earlier stage. Murine null alleles of the pacemaker channels *HCN2* and *HCN4* first directly implicated these channels in normal sinus rhythm, and subsequent human genetic

Table 44.2 Genetic arrhythmia syndromes associated with ventricular arrhythmias

Syndrome	Inheritance	Locus	Ion channel/protein	Gene

studies have identified mutations in the *HCN4* gene in sinoatrial disease.[49–52]

Other atrial arrhythmias

Virtually every known myocardial disease has been associated with some form of atrial arrhythmia. However, there are some rare associations which appear to be considerably more specific. A number of metabolic disorders, including mitochondrial diseases, glycogen or other storage disorders, are strongly associated with prominent evidence of AV conduction disease, often with overt ventricular preexcitation as well as frequent macro re-entrant and other atrial arrhythmias. For example, dominant mutations in the AMP-activated protein kinase gamma subunit (PRKAG2) have been shown to result in massive myocardial thickening, AV conduction system disease and ventricular pre-excitation.[53] These families had previously been included under the rubric of hypertrophic cardiomyopathy on the basis of their inheritance patterns, adult-onset and echocardiographic features. AF and atrial flutter are common, but high-grade AV block is the dominant clinical arrhythmia in these kindreds. Clinical studies suggest that in many cases asymptomatic individuals are maximally pre-excited at rest, and therefore probably dependent on accessory AV connections from an early age.[54] These data defined a novel subset of "hypertrophic cardiomyopathy" illustrating the

potential utility of molecular nosology for cardiac disease, but also offer some unique insights into the mechanisms of normal AV electrical development.[53]

Ventricular arrhythmias

Congenital long QT syndromes

The congenital LQTS are a group of genetic disorders that affect cardiac ion channels, characterized by prolongation of the QT interval, and risk for the life-threatening ventricular tachycardia torsades de pointes. Shortly after the autosomal recessive syndrome of congenital deafness, prolongation of the QT interval, and sudden death was described by Anton Jervell and Fred Lange-Nielsen in 1957,[55] Romano and Ward each independently described an "autosomal dominant" form without congenital deafness.[56,57] In the late 1990s the first five LQTS genes were identified, all of which encode ion channel subunits that underlie the cardiac action potential.[3–5,58] The most commonly affected genes, *KCNQ1* and *KCNH2* (underlying LQT1 and LQT2 respectively), encode proteins that form the alpha-subunits of two major repolarizing potassium currents, I_{Ks} and I_{Kr}. Two other LQTS genes encode for the corresponding beta-subunits (*KCNE1* and *KCNE2* underlying LQT5 and LQT6, respectively). The other major LQTS gene, *SCN5A* (underlying LQT3), encodes the alpha-subunit of the cardiac sodium channel. It is now accepted that patients with "Romano–Ward syndrome" carry a single mutation, while homozygous mutations (or compound heterozygotes) of *KCNQ1* or *KCNE1* cause Jervell–Lange-Nielsen (JLN) syndrome.[59,60] The extracardiac finding of congenital deafness requires the presence of two mutant alleles, and results from lack of functioning I_{Ks} in the inner ear.[61] JLN syndrome patients are also highly susceptible to arrhythmias; thus arrhythmia risk seems partly dependent on "gene dosage."[62] These five classic forms of congenital LQTS result from mutations which reduce outward currents (I_{Ks} or I_{Kr}) or enhance inward current (I_{Na}), thereby prolonging action potential duration and, in turn, prolonging the QT interval.

Additional ion channel mutations have been associated with rare arrhythmia syndromes (Andersen–Tawil syndrome, *KCNJ2*, and Timothy syndrome, *CACNA1C*) which may include QT prolongation, as well as significant extracardiac phenotypes.[63,64] Andersen–Tawil syndrome patients do not uniformly display prolonged QT intervals, and due to clinical features that differ from LQTS, this syndrome is better termed ATS1 rather than LQT7.[65] The previously termed LQT4 has been linked to mutations in *ANK2*, encoding the structural protein ankyrin-B, which when mutated results in altered localization and expression of ion channels.[27] Patients with *ANK2* mutations

do not uniformly have prolonged QT intervals, and it has been suggested that LQT4 be renamed "sick sinus syndrome associated with bradycardia" or "ankyrin-B syndrome."[66]

The incidence of congenital LQTS has been estimated at 1 in 5000, and the incidence of JLN syndrome estimated as 1 in 500 congenitally deaf individuals. Without treatment, 13% of LQTS patients will suffer cardiac arrest or sudden death prior to 40 years of age; when syncopal events are included, 36% will have symptoms by age 40.[2] The JLN syndrome is more severe, with 90% experiencing syncope, cardiac arrest or sudden death by age 18, and mortality exceeding 25% even with therapy.[62] Important clinical differences among affected patients depending on the underlying affected gene have been observed – so-called genotype-phenotype correlation. As the majority (>90%) of genotyped LQTS patients have LQT1, LQT2 or LQT3,[67] most of the differences are observed among these genotypes and include different ECG T-wave patterns,[68] clinical course,[69] triggers of cardiac events,[70] response to sympathetic stimulation,[71,72] and effectiveness and limitations of beta-blocker therapy.[73]

Pharmacologic therapy for LQTS

Despite the genotype-specific aspects mentioned above, evidence-based therapeutic recommendations, for the most part, disregard the underlying genotype.[74] This is practical, as approximately one-third of patients with an unambiguous clinical diagnosis of LQTS do not have mutations in any of the known LQTS genes. Beta-blockers and lifestyle modifications, including restriction from vigorous exercise and avoidance of drugs which prolong the QT interval, are recommended for all patients with a clinical diagnosis of LQTS[73] (**Class I, Level B**). While there are no placebo-controlled clinical trials of beta-blockers in LQTS, the data from retrospective comparisons of cohorts with and without therapy, event rates before and after beta-blocker therapy, and data from the International Registry provide convincing evidence (60% reduction in risk for cardiac events, and LQTS-related death).[73,75,76] Aside from beta-blockers no pharmacologic intervention has been supported by enough data to warrant evidence-based recommendations. Sodium channel blockers seem a logical choice for patients with LQT3, and mexiletine has been shown to shorten the QT interval both in *in vitro* models of LQT3 and in a small cohort of LQT3 patients.[77,78] Concerns about the safety of flecainide were raised when intravenous flecainide elicited a Brugada syndrome phenotype in six out of 13 LQT3 patients.[79] However, in eight LQT3 patients with a specific *SCN5A* mutation, oral flecainide shortened the QT and was safely tolerated chronically.[80] Elevating serum potassium, both acutely[81] and chronically with oral potassium and spironolactone, shortens the QT interval in LQT2.[82] Despite these potentially beneficial effects on repo-

larization, a reduction in cardiac events has yet to be demonstrated with any drug other than beta-blockers.

Non-pharmacologic therapy for LQTS

Patients who have suffered a cardiac arrest should receive an implantable cardioverter-defibrillator (ICD), as 14% of those individuals will experience cardiac arrest or sudden death within 5 years, even with beta-blocker therapy[73] (**Class I, Level B**). Patients with recurrent syncope on beta-blocker therapy also should undergo ICD implantation, as 19% will have subsequent cardiac arrest, appropriate ICD shock or death[83,84] (**Class IIa, Level B**). Patients who do not meet the above criteria may be considered for prophylactic ICD implantation if they are in a category associated with a higher risk of cardiac arrest[74] (**Class IIb, Level B**). A combination of risk factors, including age, gender, genotype, history of syncope, and QT duration, contributes to an individual's risk.[2]

The largest LQTS study to date investigates predictors of life-threatening events during the high-risk period of adolescence (2772 patients between age 10 and 20 years).[85] In this group, male gender (between age 10 and 12), QTC ≥530, and recent syncope increased the risk for cardiac arrest or sudden death, while genotype was not predictive. In a recent large study of adults (812 patients >18 years), female gender, QTc ≥500, and interim syncope increases the risk of life-threatening events.[75] Genotype did not increase risk of cardiac arrest or sudden death, but LQT2 patients were at increased risk of any cardiac event. Previous studies suggested that patients with LQT2 or LQT3 had a higher risk of symptoms or death on beta-blockers compared to LQT1 patients.[2,70,73] The JLN syndrome would be considered a high-risk category, with 27% suffering cardiac arrest or sudden death on beta-blocker therapy, and 51% remaining or becoming symptomatic on therapy[63] (**Class IIb, Level B**). Timothy syndrome (LQT8), associated with syndactyly and multiorgan dysfunction, is perhaps the most severe form of LQTS, with 10 of the first 17 described children dead at an average age of 2.5 years.[64] Left cardiac sympathetic denervation (LCSD) may be considered for patients with LQTS and syncope or cardiac arrest despite beta-blocker therapy, those intolerant to beta-blockers or those with ICDs to reduce appropriate shocks (**Class IIb, Level B**). The published experience with LCSD is from 147 "high-risk" patients – 75% with cardiac events despite beta-blockers, nearly half with a history of cardiac arrest, and an average QTc of 543 ± 65 ms.[86] LCSD was highly effective in reducing the frequency and occurrence of syncope and cardiac arrest in this high-risk group, with a 91% reduction in cardiac events. The 5-year survival was 95%, and 65% were asymptomatic or had only a single episode of syncope during 7 years of follow-up. Protection was not complete, however, as 34% had cardiac arrest or sudden death after LCSD.

Short QT syndrome

Just as abnormally long QT intervals increase the risk of sudden death, it has been recognized since the 1990s that excessively short QT intervals are also associated with increased mortality.[87] In 2000, a new genetic arrhythmia syndrome was suggested when persistently short QT intervals were noted in a family with atrial fibrillation and in an unrelated patient who suffered sudden death.[88,89] Subsequently, two other families with short QT intervals, short atrial and ventricular effective refractory periods and inducible ventricular fibrillation (VF) at electrophysiology study were reported.[30] The ECG in these patients with "short QT syndrome" reveals not only a short QT interval, but an absence of the ST segment and abnormally tall T-waves in many. In short QT syndrome patients, identification of "gain-of-function" mutations in *KCNH2*, *KCNQ1*, and *KCNJ2* followed only 4–5 years after the initial description of the syndrome.[29,90,91]

The true prevalence of short QT syndrome is unknown, but it appears to be exquisitely rare. In two separate population studies of 10–12 000 subjects, a QTc <320 was observed rarely (0–0.1%), and those with the shortest QT values did not have higher mortality than the rest of the population.[92,93] No ECGs with QTc <300 were observed in a hospital-based study of >100 000 patients.[94] The rarity of the syndrome, and the fact that it is relatively newly recognized, results in a small cohort of published cases (29 in the largest study).[95] The reported cases of short QT syndrome have absolute QT intervals between 210 and 320 ms, and corrected QT intervals between 250 and 340 ms, as well as a personal or family history of sudden death or aborted sudden death.[95,96] Cardiac arrest is the most frequent symptom (31%) and, unfortunately, is often the first clinical presentation. As with any new syndrome, the initially recognized cases are the most severe, therefore the high incidence of sudden death in these patients is not terribly surprising. The risk for VF in short QT syndrome may stem from an increased transmural dispersion of repolarization.[97] Other symptoms include presyncope, syncope, palpitations, and atrial fibrillation. Electrophysiology study may be useful to confirm the diagnosis, as short atrial and ventricular refractory periods accompany the syndrome; however, the predictive value of inducible VF is poor (only three of six patients with a history of VF had inducible VF at electrophysiology study).[95] Defibrillator therapy has been recommended for these patients, but is complicated by the potential for frequent inappropriate shocks due to oversensing of the high-amplitude T-waves in this disorder[98] (**Class IIa, Level C**). As more patients with short QT syndrome are identified, clinical heterogeneity will likely be uncovered and risk stratification may become possible. Multiple drugs, including flecainide, sotalol, ibutilide, and quinidine, have been tested in a few short QT syndrome

patients.[99] Quinidine significantly prolonged the QT interval and ventricular refractory period, and prevented inducibility of VF. Interestingly, quinidine seems to prolong the QT to greater degrees in patients with *KCNH2* mutations.[95] At this time, there are no data on the efficacy of quinidine to reduce symptoms or clinical events, but the effects in patients and in *in vitro* models suggest that quinidine may be useful to reduce appropriate ICD shocks or in those who refuse an ICD[100] (**Class IIb, Level C**).

Catecholaminergic polymorphic ventricular tachycardia

Catecholaminergic polymorphic ventricular tachycardia (CPVT) is a genetic arrhythmia syndrome that may lead to syncope or sudden death in young children with normal hearts.[101] Linkage of CPVT to chromosome 1q42-q43[102] was followed by identification of mutations in the cardiac ryanodine receptor (RYR2).[103] Mutations in calsequestrin 2 (*CASQ2*) have also been identified in an autosomal recessive form of CPVT.[104,105] A third locus has been linked to chromosome 7p14-p22 in a family with autosomal recessive CPVT, but the gene has not yet been identified.[106] Abnormal calcium release from the SR seems to be a common mechanism underlying CPVT mutations. Experimental studies simulating adrenergic stimulation in the setting of abnormal calcium release reveal epicardial origin of ectopic beats increasing transmural dispersion of repolarization, providing the substrate for catecholaminergic VT. Furthermore, bidirectional VT results as a consequence of alternation in the origin of ectopic activity between endocardial and epicardial regions.[107]

The familial transmission, risk of physical or emotional stress, and benefits of beta-blocker therapy have been recognized since the early reports of CPVT.[101,108] Swimming-triggered events, previously thought to be specific for LQT1, have been associated with CPVT as well.[109] The incidence of CPVT is unknown, but it is likely underdiagnosed. A high index of suspicion is necessary, with exercise testing often required to make the diagnosis. In contrast to LQTS, the baseline ECG is normal, although resting sinus bradycardia has been noted.[110] Exercise induces a characteristic bidirectional VT, which may be asymptomatic; however, polymorphic VT and ventricular fibrillation may also occur.[111] Electrophysiology study with programmed ventricular stimulation usually does not provoke any arrhythmias. The disease is highly lethal, with a mortality rate in untreated individuals of 30–50% by age 40.[112] Beta-blockers are recommended for all patients with CPVT[74] (**Class I, Level C**). In one series, 98% of patients were symptom free for 2 years on beta-blockers[110] but a second study with longer follow-up (40–50 months) revealed arrhythmias in 18/39 CPVT patients on beta-blockers.[111] Defibrillator therapy is recommended for CPVT patients who have survived cardiac arrest (**Class I, Level C**) and for those with syncope or sustained VT on beta-blockers[74] (**Class IIa, Level C**).

Brugada syndrome

Brugada syndrome refers to a typical ECG pattern (ST elevation in the right precordial or, rarely, inferior leads) associated with a risk of ventricular arrhythmias and sudden death.[113] With improved recognition of the syndrome, it is now apparent that most, if not all cases of sudden unexplained nocturnal death syndrome (SUNDS)[114] and some sudden infant death syndrome (SIDS) cases are due to Brugada syndrome.[115,116]

The first Brugada syndrome gene to be identified was *SCN5A*, the same gene underlying LQT3.[9] Brugada syndrome *SCN5A* mutations result in reduced sodium current, as opposed to augmented late sodium current in LQT3. Experimental studies have revealed that loss of sodium current leaves the transient outward current (I_{to}) unopposed, resulting in the characteristic ECG as well as an increased risk for ventricular tachycardia and fibrillation.[117] Interestingly, fever has been reported to unmask the ECG findings and elicit storms of ventricular tachycardia in Brugada syndrome.[118,119] Correspondingly, some mutations have temperature-dependent functional consequences.[120] Only 20% of Brugada syndrome patients have *SCN5A* mutations, suggesting that other genes are also important. In one large Brugada syndrome family, a mutation in glycerol-3-phosphate dehydrogenase 1-like gene (*GPD1L*), which also affects sodium current, has been identified.[121] Additionally, mutations in *CACNA1C* have been identified in patients with Brugada syndrome and shorter than normal QT intervals.[122]

The electrocardiographic findings in Brugada syndrome are dynamic and may be concealed, but can be unmasked by sodium channel-blocking drugs such as flecainide, ajmaline or procainamide.[123] This makes determination of the true prevalence difficult. Large population studies from Japan estimate the prevalence at between 0.1% and 0.7%, but it is likely lower in North America and Europe.[124,125] The prevalence is lower among schoolchildren (0.02%), who may not yet manifest ECG changes.[126] The disease expression is significantly affected by gender as well, as 90% of diagnosed patients are male. An ICD is the only proven effective therapy and is recommended for patients with Brugada syndrome and a previous cardiac arrest as they are at the highest risk for a recurrence (69% at 54 months of follow-up)[74,127] (**Class I, Level B**). A single randomized controlled trial comparing an ICD to beta-blockers was performed in survivors of SUNDS, most of whom had Brugada syndrome. In total there were seven deaths (18%) in the beta-blocker group and no deaths in the ICD group but there were a total of 12 ICD patients who received ICD

discharges due to recurrent ventricular fibrillation.[128] An ICD is also recommended for patients with a spontaneous Brugada-pattern ECG who have a history of syncope, as these patients have a recurrence rate of 19% at 26 months of follow-up[129] (**Class IIa, Level C**). Patients with no history of syncope, and who require drug challenge to elicit the Brugada ECG are at minimal risk, and may be clinically monitored (**Class IIa, Level C**). Although quinidine, likely by blocking I_{to}, has demonstrated some protective effects,[130,131] recommended use in Brugada syndrome is an adjunct to ICD or for the treatment of electrical storm[74] (**Class IIb, Level C**). The role of electrophysiology study for risk stratification is controversial, with differing results in separate large cohorts.[132–134] The negative predictive value in asymptomatic individuals appears high, while the positive predictive value is poor in all cohorts studied. At this time, an electrophysiology study may be considered in asymptomatic individuals with a spontaneous Brugada ECG, as they have an intermediate risk of sudden death[74] (**Class IIb, Level C**).

Hypertrophic cardiomyopathy

Hypertrophic cardiomyopathy (HCM) represents a genetically diverse group of disorders associated with a variety of cardiac arrhythmias. HCM typically displays an autosomal dominant pattern of inheritance, with most cases attributable to defects in various components of the cardiac sarcomere.[135] Mutations in PRKAG2 underlie a specific phenotype consisting of HCM, Wolff–Parkinson–White (WPW) syndrome, premature conduction disease, and the presence of glycogen vacuoles in myocytes.[136] Various arrhythmias are observed in HCM, including atrial fibrillation and flutter, ventricular tachycardia and ventricular fibrillation. HCM is covered in detail in Chapter 50; here we will limit our discussion to risk stratification and treatment of ventricular arrhythmias and sudden death.

It is important to recognize that treatment strategies for relief of left ventricular outflow obstruction and associated symptoms such as exercise intolerance and chest pain are independent of arrhythmia and SD management. The SD risk in HCM varies with age (2–4% per year in children, 1% per year in adults), and HCM is the leading cause of sudden death in young athletes in the United States.[137] Various major risk factors for sudden death have been identified, including prior cardiac arrest (ventricular fibrillation), spontaneous sustained ventricular tachycardia, family history of SD, history of syncope, septal thickness >3 cm, abnormal blood pressure response to exercise, and non-sustained ventricular tachycardia.[138] An ICD is indicated for patients with a history of sustained ventricular fibrillation or tachycardia, as these patients have a high rate of appropriate ICD discharge (11% per year)[74,139] (**Class I, Level C**). Additionally, an ICD is recommended for patients

with two or more major risk factors, and should be considered for patients with one major risk factor (**Class IIa, Level C**). Amiodarone has shown survival benefit in non-randomized studies[140] but is likely inferior to ICD, and is therefore indicated only when an ICD is not feasible[74] (**Class IIa, Level C**). Patients with symptoms suggestive of arrhythmias such as palpitations or syncope or presenting with sustained supraventricular arrhythmias should undergo comprehensive invasive electrophysiology testing, as should patients with WPW on ECG. Electrophysiology testing for risk stratification is controversial, with one group presenting data suggesting poorer outcome in patients with inducible VT[141] (**Class IIb, Level C**). Many feel that the electrophysiology study adds little to non-invasive means of risk stratification.[142]

Arrhythmogenic right ventricular cardiomyopathy

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is a genetic cardiomyopathy characterized by ventricular arrhythmias and structural abnormalities of the right ventricle, resulting from progressive fibrofatty infiltration of right ventricular myocardium.[143] It may be a relatively common cause of ventricular tachycardia in young patients with previously unrecognized heart disease, and accounts for up to 10% of unexpected sudden death,[144] though its prevalence may vary by geographic location.[145] The diagnosis of ARVC is based on clinical criteria including structural abnormalities, tissue characterization, abnormalities in depolarization or repolarization, arrhythmias, and family history.[146] These criteria are often subjective and may be too stringent, especially for family members of patients with known ARVC.[147] Familial occurrence of ARVC is well recognized, most commonly with autosomal dominant inheritance.

Genetic heterogeneity has been firmly established, and linkage analysis has identified nine distinct genetic loci. To date, five genes have been identified in autosomal-dominant ARVC: the cardiac ryanodine receptor (*RYR2*) in ARVC2,[148] desmoplakin (*DSP*) in ARVC8,[149] plakophilin-2 (*PKP2*) in ARVC9,[150] desmoglein-2 (*DSG2*)[151] and desmocollin-2 (*DSC2*).[152] ARVC2 is a rare and atypical form, with only mild structural abnormalities and a characteristic bidirectional VT very similar to CPVT. It is still unclear whether such patients fulfil the diagnostic criteria for ARVC. Mutations in the non-coding region of the transforming growth factor β3 have been identified in one kindred with ARVC1.[153] One form of ARVC, inherited in an autosomal-recessive fashion, is associated with wooly hair and palmoplantar keratoderma (Naxos disease) and caused by mutations in plakoglobin (JUP).[154] Five of the seven identified genes encode key components of the desmosome – protein complexes which provide structural and functional integrity to

adjacent cells, suggesting that ARVC is a disease of the desmosome.

Management is problematic in patients with ARVC. Patients may simultaneously be at risk for lethal arrhythmias, yet experience frequent, short episodes of minimally symptomatic arrhythmias. The annual incidence of sudden death ranges from 0.08% to 9%, and ARVC is the top cause of SD in athletes in one Italian series.[155] Patients with ARVC who have a history of aborted sudden cardiac death or sustained ventricular tachycardia warrant placement of an ICD[74] (**Class I, Level B**). Otherwise, there is currently little information available to help decide which patients merit placement of a prophylactic ICD. Several clinical features have been proposed as markers of an increased risk of sudden death, including disease severity, history of syncope, family history of sudden death, and left ventricular involvement; an ICD can be considered in these patients[74] (**Class IIa, Level C**). Adjunctive medical or attempted ablation therapy is often necessary to limit the frequency discharges, especially for minimally symptomatic arrhythmias. Response to beta-blockers is variable, but sotalol or amiodarone can be effective for prevention of VT[74,156] (**Class IIa, Level C**). Catheter ablation may be used as adjunctive therapy, but remains unproven as long-term therapy in this condition (**Class IIb, Level C**). The role of electrophysiology testing is unclear at this time, but had excellent negative predictive value in one study among individuals with "probable ARVC" (three Task Force criteria), suggesting that low-risk individuals may be identified[157] (**Class IIb, Level C**).

Conclusion

In the last decade the identification of gene defects in a vast array of monogenic disorders has revolutionized our understanding of the basic mechanisms underlying numerous disease processes. Mutations in cardiac ion channels have been identified as the basis of a wide range of inherited arrhythmia syndromes, including congenital long and short QT syndromes, Brugada syndrome, Lenegre syndrome, Andersen–Tawil syndrome, and familial atrial fibrillation. More recently, it has been observed that not only transmembrane cardiac ion channels cause cardiac arrhythmias, but also intracellular channel and non-ion conduction proteins that may be pathophysiologically linked to inherited arrhythmias. The identification of genes underlying the inherited arrhythmia syndromes has greatly contributed to our understanding of the substrates for arrhythmia development but an unexpected complexity has emerged in the genotype/phenotype relationship. Phenotypic expression of a given mutation does not always appear to be uniform in patients, implying a contribution from environmental factors and/or presence of other genetic modifiers. The marked clinical heterogeneity associated with these inherited arrhythmia syndromes has led to the development of a multifactorial ("multiple hits") concept of arrhythmogenesis in which causal gene mutations have a major effect on disease that is further modified by factors such as age, gender, autonomic tone, and environmental triggers.

45 Arrhythmogenic right ventricular cardiomyopathy

Deirdre Ward[1] and Perry M Elliott[2]
[1]Trinity College, Dublin, Ireland
[2]University College London, London, UK

Introduction

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is a disorder characterized clinically by ventricular arrhythmia, heart failure and sudden death, and histologically by cardiomyocyte loss and replacement with fibrous or fibrofatty tissue. The estimated prevalence of ARVC is 1 in 5000 of the population. It is an important cause of sudden cardiac deaths in athletes and in people under 35 years. In many individuals, the disease is caused by mutations in genes that encode different components of the intercalated disc of cardiomyocytes. Clinically, ARVC is difficult to diagnose, usually requiring integration of data from family members, electrocardiography and a range of imaging techniques. Management of ARVC focuses on treatment of symptomatic arrhythmia, prevention of sudden cardiac death and, in the later stages of the disease, heart failure management.

History

In 1952 Dr Henry Uhl described a case of "almost total absence of the myocardium of the right ventricle" in an 8-month-old girl.[1] The case was characterized by complete heart block and right ventricular failure. At post mortem the myocardium of the left ventricle was normal and there was a sharp demarcation line between this and the very abnormal right ventricle in which there was virtually complete loss of the myocardium. There was no evidence of ischemic change or inflammation and the cause was assumed to be a maldevelopment or dysplastic process.

The first description of an ARVC was in 1978, when detailed electrocardiography readings of four French

patients with right ventricular dysplasia associated with arrhythmia were reported.[2] In the same journal there was a report of two French patients in their sixth decade of life presenting with recurrent ventricular tachycardia of left bundle branch bock (LBBB) morphology resistant to medical therapy. Clinical examination, angiography and ultimately post-mortem examination identified what was described as "the parchment right ventricle syndrome of the adult."[3]

A case series of 24 patients published 4 years later identified the characteristics of the typical patient with what is now called arrhythmogenic right ventricular cardiomyopathy. The mean age at presentation (in those who had symptoms) was 39 years, and the male/female ratio was 2.7:1. Almost 90% of the patients had T-wave inversion in the right precordial leads. Ventricular postexcitation waves (epsilon waves) were present in one-third of patients. All but one of the patients had spontaneously occurring ventricular tachycardia with a LBBB configuration. In those who underwent echocardiography, the ratio of right to left ventricular size was increased, and wall motion abnormality of the right ventricle was seen in the majority. One patient had a wall motion abnormality of the posterior wall of the left ventricle. Morphologic findings were confirmed in 13 patients during surgical intervention. The right ventricle was invariably enlarged and there were discrete areas of segmental dilation associated with dyskinetic wall motion and aneurysms. The authors reported the most common location of these right ventricular aneurysms to be the anterior surface of the right ventricular outflow tract, apex and inferior wall, and coined the term "the triangle of dysplasia." There was frequently an increase in subepicardial fat over these areas and depletion in the numbers of muscle fibers. The amount of fibrosis was variable. On microscopy some hypertrophy of the remaining myofibers was noted, and there was a varying degree of lymphocytic infiltration.[4] One of the patients came from a family reported 4 years earlier in a description of seven cases of familial ventricular tachycardia.[5]

The first gene mutation to be associated with ARVC was identified in patients with a recessive cardiocutaneous syndrome characterized by wooly hair, palmoplantar keratoderma and ARVC common on the Greek island of Naxos.[6] The locus for Naxos disease was mapped to chromosome 17 (17q21), and subsequently a deletion in the gene encoding plakoglobin was identified as the disease-causing mutation.[7,8] Plakoglobin is a constituent protein in both adherens and desmosomal cell–cell junctions. Subsequent evaluation of other related desmosomal genes in ARVC patients with more typical autosomal dominant disease has identified disease-causing mutations in a further four genes encoding other desmosomal proteins.

The structure of the right ventricle renders it inherently more difficult to image than the left ventricle, but improvements in imaging techniques over the past decade have broadened the clinical spectrum of the disease by identifying patients at an earlier, often asymptomatic stage. Cardiac magnetic resonance imaging in particular has demonstrated a high prevalence of left ventricular involvement in many patients, illustrating the heterogeneity in disease expression.[9–13]

Epidemiology

In most populations the prevalence of ARVC is unknown. An apparent cluster of disease is reported in the Veneto region of Italy, with a frequency of 1 per 5000, but it is unclear whether this is a true clustering or a reflection of local interest and expertise in the disease. Nevertheless, the limited information available suggests that ARVC is an important cause of premature sudden cardiac death. A retrospective review of a French post-mortem series identified ARVC as a likely cause of death in 10% of the population aged 1–65 years.[14] Prospective studies of an Italian cohort aged 12–35 years found evidence of ARVC in 12% of those who suffered a sudden cardiac death.[15] A population-based study from the USA identified pathologic changes of ARVC in 17% of sudden death victims under 40 years of age.[16] Other authors report that up to 25% of sudden deaths in athletes are due to ARVC.[17]

Pathology

In the early stages, abnormal pathologic findings are localized to the apical, inflow and infundibular areas of the right ventricle.[4] With disease progression, the left ventricle, particularly the posterolateral wall, is often involved, with relative sparing of the interventricular septum. In some cases, the pathologic abnormalities may be confined to the left ventricle.[18,19]

Macroscopic examination of the heart shows diffuse or focal thinning of the right ventricular wall, affecting the subepicardium more than the subendocardium, with aneurysm formation in up to 50% of cases.[18,20] Histologically, there is myocardial atrophy and fibro-fatty replacement. Islands or strands of surviving myocytes exhibit a combination of degenerative change with myocyte vacuolation, often associated with focal mononuclear inflammatory cell infiltrates.[21–24] In some cases, typical histologic findings may be present in the absence of any macroscopic features.[25] A second histologic pattern, characterized by transmural infiltration of adipose tissue without fibrous replacement or wall thinning, has been considered to be an earlier stage of the condition[22,26] but this can be a normal finding, particularly in older women.[20]

A number of studies have reported evidence of apoptosis in ARVC which is not found in normal controls, patients undergoing post-transplant surveillance or in patients with structurally normal hearts and VT arising from the RV outflow tract.[27–30] Apoptosis is more common in patients with a short (less than 6 months) clinical history and acute symptoms and signs.[27] Apoptosis is present to an equivalent degree in children and adults with ARVC.[28]

Endomyocardial biopsies from some ARVC patients have been found to contain enteroviral RNA with homology to Coxsackie virus type B. In one study similar proportions of patients with myocarditis or dilated cardiomyopathy were positive for viral RNA but none of the control patients with non-inflammatory cardiac disorders.[31] Other studies have failed to confirm these findings, which may reflect patient selection and differences between inherited and sporadic, non-familial forms of ARVC.[32–37]

Genetics

Systematic family studies have shown that ARVC is inherited in up to 50% of cases.[38] Numerous genetic loci have been identified (Table 45.1). The mode of transmission is usually autosomal dominant with variable penetrance, but autosomal recessive forms are well recognized and provided the first insights into the genetic basis of ARVC. In 1986, an autosomal recessive syndrome characterized by cardiomyopathy, wooly hair and palmoplantar keratoderma was described in families from the Greek island of Naxos.[6] The cardiac phenotype of this syndrome replicates the clinical and histopathologic characteristics of typical ARVC.[39] Subsequent molecular genetic investigations in families with Naxos disease revealed a homozygous mutation in the gene encoding plakoglobin, a member of the armadillo protein family found in adherens and desmosomal junctions between cardiomyocytes. Families with a similar cardiocutaneous phenotype are reported from other Mediterranean areas,[40–43] India[44] and South America.[45] The

Table 45.1 Genetic loci identified in association with ARVC

Subtype	Loci	Reference
ARVC 1	14q23–24	Rampazzo, 1994[53]

cause in many of these families is an autosomal recessively inherited mutation in the gene encoding desmoplakin.

The intercalated discs are end-to-end connections between cardiomyocytes that maintain mechanical and electrical integrity between cells. They consist of three main components: the adherens junction, the desmosome, and gap junctions. Desmosomes are the secondary mechanical intercellular junctions, present in abundance in epithelial tissues and the myocardium. Plakoglobin links the intermediate filament network to the cytoplasmic tails of the cadherin proteins which extend into the intercellular space and have adhesive functions, although the precise mechanism by which they achieve this function is unknown. Desmoplakin is a protein of the plakin family of cytolinkers and is located deeper in the cytoplasmic plaque of the desmosome. It appears to be an obligate component of the desmosomal junction.[37]

The involvement of plakoglobin and desmoplakin genes in these recessive forms of ARVC led to the examination of these and other desmosomal protein genes in the more common dominant ARVC phenotype. Plakoglobin has only been associated with autosomal recessive ARVC to date. Desmoplakin, on the other hand, accounts for 16% of dominant ARVC cases. Genes implicated only in autosomal dominant disease include plakophilin 2 (PKP2) accounting for 25–43% of cases,[46–48] desmoglein (DSG2) (10% of cases), and desmocollin (DSC2).

The discovery that many cases of ARVC are "desmosomal" diseases has led to a simplistic theory of pathogenesis in which disruption of desmosomal integrity causes separation of myocardial cells under conditions of mechan-

ical stress. Detached myocytes die and are replaced by fibro-fatty tissue. The predilection for the right ventricle can be explained by the relative thinness of the RV walls in comparison with the left ventricle; the tendency for lesions to develop in the "triangle of dysplasia" is explained by the fact that the RV inflow, apex and outflow are the regions of maximal mechanical stress.

While this theory may explain the ultrastructural changes associated with ARVC and, indeed, the apparently aggressive form of the disease in those who partake in endurance training,[49] it does not account for the disproportionate tendency to arrhythmia. Evaluation of a small number of patients with Naxos disease has shown that expression of connexin 43, a major gap junction protein, is markedly reduced in both the left and right ventricles, even at an early age of disease development. A reduction in the number and size of the gap junctions may result in an electrical coupling defect which increases the propensity to arrhythmia and may explain the occurrence of sudden death in patients without marked morphologic changes.[50]

Two non-desmosomal genes have been associated with ARVC. Mutations in the ryanodine receptor gene (RYR2) were reported in association with a localized form of ARVC, but mutations in this gene more typically cause catecholaminergic polymorphic VT (CPVT) and are no longer classified as a subtype of ARVC.[51,52] A mutation in the transforming growth factor beta 3 (TGFβ3) gene has also been described, but the mutation occurs in an intronic region of the gene and only one of the three originally described ARVC1 families has a TGFβ3 mutation. Functional studies have shown an alteration in the expression of the TGFβ3 gene resulting in increased fibrosis. Whether this represents true ARVC or not remains controversial.[53,54]

Natural history

The natural history of ARVC can be divided into four phases.[38] In phase one (the "concealed" phase) patients are asymptomatic with few if any morphologic abnormalities. In the absence of systematic post-mortem evaluation of the right ventricle, the diagnosis may be missed at this stage and so the incidence of sudden death in this phase may be underestimated. In the second (electrical) phase, symptoms of arrhythmia occur and morphologic structural and functional abnormalities are easier to identify. The third phase is marked by the classic right ventricular functional abnormalities that can progress to right ventricular failure with relatively preserved left ventricular function. The final or end-stage is associated with the development of biventricular systolic impairment. Although a useful disease paradigm, it is not inevitable that affected persons will progress through all phases as described. Moreover, multiple (mostly unknown) factors influence the clinical mani-

festations and natural history of the condition. It is generally thought that physical training and exercise both increase the risk of arrhythmic events in affected individuals and result in more aggressive disease progression.[17,49,55–57] Some patients demonstrate left ventricular involvement early in the disease, and may have predominant left ventricular disease.[58–60]

Clinical features

The first presentation of the disease is often sudden cardiac death in previously asymptomatic individuals, including young children and teenagers.[14,55,61,62] Occasionally, patients will have experienced syncope in the months preceding their death.[14,56,63] An imbalance of adrenergic activity has been suggested as a possible factor in the genesis of lethal ventricular arrhythmias; thus exposure to catecholamines (particularly during exercise) may increase the risk of sudden death.[64]

Patients usually present with symptoms between the second and fifth decades of life. Syncope, palpitations and chest pain are common, but family studies have shown that most affected individuals are asymptomatic, particularly in the early stages.[65,66] With disease progression, features of right and later biventricular failure may be present.

Diagnosis

Accurate diagnosis of ARVC is notoriously difficult at post mortem and in living patients. The gold standard for making the diagnosis is the demonstration of transmural fibro-fatty replacement of right ventricular myocardium. However, endomyocardial biopsy has a substantial false-negative rate caused by the patchy distribution of the disease and the fact that the interventricular septum, which is the site of choice for endomyocardial biopsy, is often relatively spared. In an attempt to address this difficulty, a task force of international experts was convened, under the auspices of the Scientific Council of the International Society and Federation of Cardiology (ISFC) and the European Society of Cardiology Working Group on Myocardial and Pericardial Diseases. The Task Force reviewed the evidence available at the time in order to agree a set of clinical diagnostic criteria. They grouped clinical criteria into six categories, and assigned either major or minor status to each criterion depending on the degree of specificity for the diagnosis. A cumulative scoring system was devised with agreed thresholds for making a clinical diagnosis. The presence of two major criteria from different categories, or one major and two minor, or four minor criteria, all from different categories, is considered diagnostic of ARVC[67] (Box 45.1).

BOX 45.1 Criteria for diagnosis of ARVC (adapted from McKenna *et al*[67])

1. Family history

Major
- Familial disease confirmed at necropsy or surgery

Minor
- Family history of premature sudden death (<35 years) due to suspected right ventricular cardiomyopathy
- Family history of clinical diagnosis based on the present criteria

2. Tissue characterization of walls

Major
- Fibro-fatty replacement of myocardium demonstrated on endomyocardial biopsy

3. Global and/or regional dysfunction and structural alterations

Major
- Severe dilation and reduction in systolic function of RV with no (or only mild) impairment of LV
- Localized RV aneurysms (akinetic or dyskinetic areas with diastolic bulging)
- Severe segmental dilation of the RV

Minor
- Mild global RV dilation and/or reduction in ejection fraction with normal LV
- Mild segmental dilation of RV
- Regional RV hypokinesia

4. Depolarization/conduction abnormalities

Major
- Epsilon waves or localized prolongation of the QRS complex in V1–V3 (>110 ms)

Minor
- Late potentials demonstrated on signal-averaged ECG

5. Repolarization abnormalities

Minor
- Inverted T-waves in right precordial leads (V2 and V3)
- (individuals >12 years of age; in the absence of right bundle branch block)

6. Arrhythmias

Minor
- Sustained and non-sustained ventricular tachycardia with LBBB morphology (documented on ECG, Holter or exercise testing)
- Frequent ventricular extrasystoles (>1000 over 24-hr Holter monitoring)

Imaging

Morphologic abnormalities of the right ventricle are challenging to identify *in vivo*, particularly when they are relatively subtle. At the time of publication of the Task Force criteria the most commonly used imaging modality was cine-angiography of the right ventricle. This has been largely replaced by transthoracic echo which, in addition to the detection of ARVC, has a major role in the exclusion

of congenital heart disease such as partial anomalous venous drainage, Ebstein's anomaly and other causes of isolated right ventricular abnormalities.[68,69] The major challenge when using echo to assess the right ventricle is the chamber's complex three-dimensional structure. Together with the segmental nature of the disease, this means that structure and function should be assessed using multiple views.[70] The echocardiographic features of ARVC include: right ventricular dilation and hypokinesia; aneurysms; regional wall motion abnormalities, including dyskinesia of the inferobasal right ventricular segment; increased echogenicity of the moderator band; and right ventricular apical hypertrabeculation.[63,68,71–73] Tricuspid annular early diastolic velocities are reduced[70,74] but strain rate imaging has not yet been found to be a reliable diagnostic tool in ARVC. Three-dimensional echo may be a more accurate method of assessing right ventricular systolic function[75] but larger studies are needed to validate the technique.

Cardiac magnetic resonance imaging is generally considered to be the imaging modality of choice in ARVC, but unfamiliarity with normal right ventricular morphology and function has led to high interobserver error and poor reproducibility in some series.[76,77] The presence of intramyocardial fat deposition in the right ventricle must also be interpreted with caution, as fat in the right ventricle is present in a large proportion of "normal" individuals (up to 85%), and the frequency and severity increase with age, body weight and female gender.[20,23,78] Diagnostic accuracy can be improved by using standardized acquisition and analysis protocols. Using genetic status as the gold standard, a single-center experience has suggested that magnetic resonance imaging has a sensitivity of 96% and a specificity of 78%.[13]

In the current Task Force criteria, right ventricular abnormalities were only considered significant in the absence of significant left ventricular disease. However, gadolinium-enhanced cardiac MR imaging has reported evidence of LV involvement in 84% of patients.[79] It is likely that the next iteration of the Task Force guidelines will be modified to take into account the biventricular nature of disease in patients with ARVC.

ECG

The most frequent electrocardiographic marker of ARVC is the presence of precordial T-wave inversion. Studies have reported a very wide range in prevalence (19–94%),[80–83] with the lowest prevalence rates in evaluations of large families, reflecting incomplete penetrance, and the highest rates in case series of probands where selection bias may lead to an overestimation of the true prevalence of this disease marker.[66,82]

The presence of epsilon waves on the ECG (any electrical potential in V1–V3 occurring after the QRS complex where the Q–epsilon interval exceeds the QRS duration in V6 by more than 25 ms)[72] may be highly specific for a diagnosis of ARVC but they are found in only one-quarter to one-third of patients.[81,84] A modified method of lead placement may enhance detection of epsilon waves.[72]

Localized QRS prolongation (in excess of 110 ms) in the right precordial leads is considered a major criterion for ARVC. More recently, investigators have looked at QRS dispersion (the numeric difference in QRS duration between the right precordial leads and V6) which is a strong independent predictor of sudden death if the value is greater than 40 ms.[84]

Signal-averaged ECG

The presence of late potentials on signal-averaged ECG is consistent with ARVC, but they are also found frequently after myocardial ischemia. The prevalence in case series varies which may reflect a wide range of disease severity as late potentials have a positive correlation with the extent of ventricular fibrosis, reduced right ventricular systolic function and significant morphologic abnormalities on imaging.[85,86]

Ventricular arrhythmia

The occurrence of VT with left bundle branch morphology is a non-specific finding, but in the context of other diagnostic features, it is supportive of the diagnosis. In addition to ARVC, left bundle morphology VT occurs in myocardial ischemia, dilated cardiomyopathy and right ventricular outflow tract VT. The presence of ventricular ectopy above a threshold of 1000 ectopics in 24 hours should raise suspicion of ARVC in an appropriate clinical scenario, but merits minor status only as a result of low specificity.

Diagnosis in relatives

In the early years following the first description of the disease, ARVC was thought to be almost always sporadic. Case reports emerged subsequently describing families with clinical evidence of ARVC with wide variation in disease characteristics and severity between family members.[57,87–90] In a later series of seven families, over 50% of evaluated relatives were affected with a slight male predominance (63% of men and 53% of women affected), autosomal dominant transmission with incomplete penetrance and variable clinical expression.[91]

Systematic evaluation of relatives of 67 index cases found evidence of familial disease in 28% of cases using the Task Force criteria. A further 11% of families had non-diagnostic abnormalities on ECG, ambulatory ECG monitoring or echocardiography. The authors proposed a modification of the diagnostic criteria to be applied to first-degree relatives of an index case where ARVC is proven. In this scheme, the

presence of late potentials on signal-averaged ECG or a single minor criterion on ECG, echocardiography or ambulatory monitoring should be considered diagnostic. The authors also proposed that, in the setting of a positive family history, a threshold of 200 ventricular ectopics over a 24-hour monitoring period is sufficiently sensitive to diagnose ARVC (Box 45.2).[92] These criteria have been tested in a small number of studies in genetically characterized families, where application of the Task Force criteria would identify 54–66% of gene carriers. Use of the proposed modified criteria increased this figure to between 70% and almost 100%.[59,93]

Genetic testing was not possible at the time of the Task Force review. DNA screening for desmosomal gene mutations identifies disease-causing mutations in over 40% of probands who have a clinical diagnosis of ARVC.[94] In the setting of familial disease, with 50% risk of mutation inheritance and variable age-related penetrance which mandates repeated clinical evaluation of all adult relatives, mutation analysis in the proband and predictive testing in relatives is probably cost-effective if a disease-causing mutation is identified. Co-existence of two distinct desmosomal gene mutations within families has been reported, although the frequency of this occurrence has not yet been clarified.[94] Screening of all desmosomal genes in all probands is therefore required, rather than concentrating on "hotspot" genes or exons. As with any inherited condition, the potential clinical, psychologic and financial implications of mutation identification in an asymptomatic individual mean that

formal genetic counseling and informed consent are mandatory prior to gene testing.

Management

Patients with proven or suspected ARVC are discouraged from active sports participation or endurance training. Other simple measures include avoidance of stimulants and abstention from recreational drug usage, although there are no data to prove an association between either activity and sudden death.

Pharmacologic therapy is generally recommended in patients with well-tolerated VT or symptomatic ventricular ectopy. The only comparative study of pharmacologic agents in spontaneously occurring and inducible VT identified sotalol as the most efficacious agent[95] (**Class IIB, Level C**). In practice, both sotalol and amiodarone are widely used, although long-term side effects of amiodarone therapy in relatively young patients are a cause for concern. These agents may also be useful in patients with implantable cardioverter defibrillators (ICD) who have had recurrent therapies.

Before the advent of radiofrequency and cryoablation therapies, surgical disarticulation of the RV and surgical resection of segments of RV myocardium were advocated for the suppression of recurrent or incessant arrhythmia.[96,97] In the modern era, success rates of 60–90% for catheter ablation of re-entry circuits have been reported, although up to 60% of patients relapse, probably due to the development of new arrhythmic foci.[98] The number of lesions required for successful therapy may be up to 38 per patient, which is a cause for concern in patients with thinned and fibrosed RV myocardium.[99] Catheter ablation has a more accepted role in patients with ICDs who experience recurrent appropriate therapies (**Level C**).

Current joint ACC/AHA/ESC guidelines for ICD implantation are summarized in Box 45.3.[100] Much of the information on risk identification is provided by retrospective analysis of discharge rates from ICDs implanted for primary and secondary prophylaxis in patients with advanced disease. Data from three separate populations identify a prior cardiac arrest, a history of VT with hemodynamic compromise, major morphologic abnormalities of the right ventricle and left ventricular involvement as independent risk predictors. Programmed ventricular stimulation has also been advocated as a risk predictor, but results vary. In one study, electrophysiology testing had poor positive and negative predictive accuracy, was the only independent predictor of rapid (>240 beats/min) VT in another, and was predictive of appropriate ICD therapy in patients with a history of sustained ventricular arrhythmia in a third. None of the patients in these studies were genetically characterized.[101–104]

BOX 45.2 Proposed modification of Task Force criteria for the diagnosis of familial ARVC (adapted from Hamid et al[92])

Proven ARVC in a first-degree relative plus one of the following:

1. **Structural or functional abnormality of the right ventricle:**
   - Mild global RV dilation of the RV and/or reduction in ejection fraction with normal LV
   - Mild segmental dilation of the RV
   - Regional RV hypokinesia
2. **Arrhythmia:**
   - Ventricular tachycardia with LBBB morphology (documented on ECG, Holter monitoring or during exercise testing)
   - >200 ventricular extrasystoles over 24 hours (Holter monitor)
3. **ECG:**
   - T-wave inversion in the right precordial leads (V2 and V3)
4. **Signal-averaged ECG:**
   - Demonstration of late potentials

One small study has identified QRS dispersion on standard ECG as a predictor of risk. ARVC patients in whom the difference between maximum and minimum QRS duration in any ECG leads was > 40 ms had a higher risk of sudden death.[84] The presence of late potentials on signal-averaged ECG has not yet been found to identify a higher risk population. The use of three-dimensional voltage mapping during EP studies may become a useful tool for risk stratification. In one study, a borderline association between the occurrence of significant arrhythmia and reduced and fractionated voltage signals has been demonstrated. The location of these areas of altered signal intensity correlated well with endomyocardial biopsies.[105] Definite or probable indications for ICD implantation in ARVC are summarized in Box 45.3.

Patients with symptomatic arrhythmia may be managed differently in North America compared with European centers, with a lower threshold for device implantation in the former. Whether the common practice of ICD implantation in all those diagnosed clinically with ARVC can or will be extended to those with a genetic diagnosis in the future is uncertain. In addition to the usually encountered device complications at implant and revision, progressive fibrosis and wall thinning can make it difficult to achieve satisfactory lead position and may increase the risk of perforation.

The incidence of inappropriate device therapy in patients with ARVC ranges from 10% to 23%.[101,102,106] The use of cardiac resynchronization has not been evaluated specifically in ARVC. Cardiac transplantation may be necessary in patients with advanced heart failure, and occasionally for intractable arrhythmia.

Future directions

Research is ongoing to improve our ability to diagnose and risk stratify ARVC patients. Advanced imaging techniques, electrical mapping technologies and identification of new genes are likely to provide new insights. Stem cell therapy does not look promising, not least because cells that differentiate into contracting myocardial cells have not been able to generate gap junctions, which is already a fundamental problem in ARVC. Disease-modifying therapy may be a promising area for progress, particularly if we can gain better understanding of the various genetic, infective, environmental and lifestyle factors that currently influence disease penetrance and progression.

Epidemiology of heart failure

Despite the considerable burden of heart failure (HF), its epidemiology is still poorly defined, especially in primary care.[1] A precise analysis of the epidemiology must take into account the difficulty in defining the syndrome itself, particularly in a predominantly elderly population in whom symptoms and signs are less specific. An ideal estimate of the true epidemiology would be based on surveys in random samples of the general population, using validated questionnaires and targeted physical examinations in conjunction with objective measures of left ventricular systolic dysfunction (LVSD) such as imaging and possibly supported by validated biomarkers. Broadly speaking, contemporary studies can be divided into those analyzing the prevalence and incidence of "symptomatic" HF (further divided into those with preserved and reduced LV ejection fraction [LVEF]) and those investigating the prevalence of LVSD (of which a significant proportion of patients will be asymptomatic).

Prevalence of symptomatic HF (Table 46.1)

Studies utilizing a range of designs suggest that the prevalence of HF is around 2–5% of the population of the developed world, increasing considerably with age. Whilst age-adjusted incidence has remained stable in the last two decades, prevalence may be increasing.[2] Furthermore, approximately half of all patients with symptomatic HF have preserved LVEF.[3] Prevalence varies widely from 0.4% to 19% in older age groups based on general practice (GP)

studies in the UK. The GP Research Database, involving 211 general practices in England and Wales (representing 2.6% of the national population), reported an overall prevalence (physician diagnosis) of 12.2/1000 in men and 15.8/1000 in women, increasing to 190/1000 in those over 85 years.[4] The substantial increase in prevalence with aging has been confirmed in additional UK primary care studies.[5,6]

Several population-based observational studies have been undertaken in North America and continental Europe (see Table 46.1). The prevalence of symptomatic HF in the USA is reported to be of the order of 2.2% and similarly increases considerably with age.[7,8] The European EPICA study of 5434 individuals attending general practices in Portugal reported that prevalence was 44.6/1000 in those >25 years and increased noticeably in the elderly.[9] These data are supported by contemporary data from across Northern and Southern Europe.[10–14] A significant proportion of patients with symptomatic HF have preserved LVEF. In the Olmsted County Study, 55% of symptomatic patients had preserved LVEF, an observation which is consistent with several other epidemiologic studies (Fig. 46.1).[3]

Prevalence of LVSD (Table 46.2)

A number of studies have used an objective measure of LVEF to estimate the population prevalence of LVSD. The Glasgow MONICA Study included 1640 subjects aged 25–74 who were assessed by questionnaire, electrocardiography and transthoracic echocardiography (TTE).[15] Prevalence of LVSD (LVEF <0.30) was 2.9% and increased with age. A cohort of 2267 subjects from the Rotterdam Study (which used a combination of clinical criteria and prescribing patterns to define HF) underwent echocardiography.[10] Prevalence of LVSD (defined by fractional shortening <25%) was 5.5% in men and 2.2% in women. Similar data come from the UK, USA and Australia.[7,16,17]

Incidence of symptomatic HF (Table 46.3)

An estimate of the incidence of HF is more difficult to define, but there are considerable data, particularly from large population-based studies. In the Framingham Heart Study, at 34 years follow-up, incidence was approximately 2/1000 person-years in subjects aged 45–54, increasing to 40/1000 in men aged 85–94.[18] Similar rates are reported from the Olmsted County Study and UK and Finnish pop-

ulation studies.[4,19,20] In the UK, Cowie and colleagues reported incidence in referrals from primary care. They identified new cases from a population of 151 000 in London, through surveillance of hospital admissions and through referrals to a rapid-access HF clinic.[21] Diagnosis of HF was determined by a panel of cardiologists and supported by echocardiography. Incidence was 1.3/1000 overall for those ≥25 years. Incidence increased with age and was higher in men than women. Overall, only 29% of

patients referred had an adjudicated final diagnosis of HF, illustrating the difficulty of classification on the basis of clinical assessment alone.

The age-adjusted incidence of HF appears to be stable. In the Resource Utilization Among Congestive Heart Failure (REACH) Study, which was a retrospective study using administrative databases of outpatient visits and hospitalizations in Michigan, USA, the incidence of HF in 1999 was 3.7/1000 person-years in men and 4.2/1000 person-years in women of all ages with no changes between 1989 and 1999.[22] In a similar analysis of the Framingham Heart Study, incidence was examined in four periods: 1950–69, 1970–79, 1980–89 and 1990–99.[18] When compared with the rate for the period from 1950 to 1969, incidence remained virtually unchanged among men in the three subsequent periods but declined by 31–40% among women.

Incidence of HF with preserved ejection fraction

The body of evidence suggests that approximately 40–50% of patients have preserved EF (HF-PEF). An analysis of the Olmsted County Study identified 6076 patients with incident HF identified from the general population between 1987 and 2001 and suggested that about half had preserved EF (47%) whereas studies in patients hospitalized with HF suggest lower proportions (e.g. 31% in a study undertaken in Ontario, Canada).[23,24] The EuroHeart Failure Survey reported on the characteristics and outcome of 6806 patients admitted to 115 European hospitals with HF between March 2000 and May 2001.[25] Forty-six percent of patients had HF-PEF (LVEF ≥40%); these patients were more likely to be older, hypertensive and have a history of chronic atrial fibrillation, whereas coronary artery disease (CAD) was more prevalent in the systolic HF group ($P < 0.001$). The observed variations in the reported propor-

tion of HF-PEF in these studies are partly explained by the differing thresholds for differentiating HF-PEF from systolic HF and the proportion of patients undergoing quantitative assessment of LVEF. Nevertheless, these data indicate that a significant proportion of patients have HF-PEF.

HF morbidity: hospitalizations

Despite the limitations of administrative databases, there is evidence that age-adjusted hospitalization rates have significantly increased in the developed countries over the last two decades (Fig. 46.2), emphasizing the growing global nature of this problem.[1] In the USA and UK, HF is the most common cause of hospitalization in people aged ≥65 years.[26,27] In Scotland, the number of hospital admissions for HF increased by 16% in men and 12% in women between 1990 and 1996, with some apparent plateauing by 1993–94.[28] Similar data have been reported in The Netherlands.[29]

Men tend to be younger than women at index admission, but because of greater female longevity, overall admission numbers are roughly equal. The NHS Heart Failure Survey determined that 50% of patients with admissions for HF were male but that female patients were older (mean 80 v 75 years, $P < 0.001$).[30] Overall, the typical HF patient is getting older. In The Netherlands between 1985 and 1995, mean age rose from 71.2 to 72.9 years in men and from 75.0 to 77.7 years in women.[30] Elderly patients are more likely to have prolonged admissions, be managed by non-specialists, and be burdened by co-morbid conditions prolonging their admission.[31] An admission to hospital with HF is frequently prolonged and in many cases followed by readmission within a relatively short time, particularly amongst the very elderly. In England and Wales, mean length of stay is 7 (IQR [interquartile range] 4–14) and 8 (IQR 4–14) days
Figure 46.2 Comparison of heart failure admissions rates per annum (recorded hospital admission/10 000 population at risk) in Western developed countries, 1978–1993. (Adapted with permission from data in McMurray *et al*, Heart 2000;83:596–602.)

for men and women respectively.[31] Transfer to a non-specialist unit adds another 2 days. Readmission to hospital is both common and costly. In Scottish hospitals in 2002, the average 30-day readmission rate was 5.3% (lowest 3.3%, highest 7.3%) and may be even higher in the USA.[26,32]

HF mortality

HF prognosis remains poor despite considerable therapeutic advances. However, official statistics continue to specifically attribute only a small proportion of deaths to HF. This reflects a common policy of coding the cause of death as the underlying etiology (e.g. CAD) rather than as HF itself. Population level data suggest that HF-related mortality is comparable to that of cancer; in the Framingham Heart Study the 5-year mortality was as high as 75% in men.[33] Similarly, in a UK study, 1- and 5-year mortality following a first hospitalization was 43% and 73% respectively, with increasing relative risks with increasing age.[34] In Scotland between 1986 and 1995, crude mortality rates in incident HF were 19.9% at 30 days, 44.5% at 1 year and 76.5% at 5 years.[35] Median survival was 1.47 years in men and 1.39 years in women.

In the Rotterdam Study, survival rates from *prevalent* cases of HF were more favorable, with 1- and 5- year survival rates of 89% and 59% respectively.[36] This still, however, represents a threefold increase in the age- and gender-matched risk of death compared to the general population. However, prognosis appears to be improving. In 2000, MacIntyre *et al* demonstrated a fall in 30-day case fatality rates by 26% in men and 17% in women between 1986 and 1995.[35] Similar reductions were seen with longer term mortality. In the Framingham Study, 1- and 5-year mortality rates in men declined from 30% to 70% in 1950–69 and to 28% and 59% in 1990–99, with similar decreases in women.[33] In the Olmsted County Study, age-adjusted 5-year survival improved from 43% in 1979–84 to 52% in 1996–2000. Similar compeling reductions in mortality were identified in data from nearly 300 000 hospitalizations from the Swedish Hospital Registry between 1988 and 2000.[37] These improvements in outcome temporally correlate with the emergence of evidence-based therapies offering potential incremental benefits.

Prognosis of HF-PEF

With respect to hospitalization rates, in the Olmsted County Study, 24% of patients with HF-PEF were never hospitalized, 51% hospitalized once, and 25% hospitalized more than twice over a 5-year period.[38] Patients with systolic HF had significantly more hospitalizations (41% once and 49% more than twice over the same 5-year period). In hospital cohort studies, the reported rates of rehospitalization are similar between those with low and preserved EF. In the aforementioned Canadian EFFECT Study, there was no significant difference in either 30-day (4.5% v 4.9% for HF-PEF and systolic HF respectively, P = 0.66) or 1-year readmission rates (13.5% v 16.1% for HF-PEF and systolic HF respectively, P = 0.09) in patients who survived the index HF admission.[39]

Similarly, in the EuroHeart Failure Survey, rates of early (within 12 weeks) readmission were almost identical (and impressively high) between both groups (22% and 21% for HF-PEF and systolic HF respectively, P = 0.47), indicating that, regardless of LV EF, approximately one in five patients may experience an early (and costly) readmission to hospital.[25]

In terms of mortality, in the Framingham Study, patients with systolic HF had an annual mortality rate of 18.9% compared to 4.1% in age- and sex-matched controls with HF-PEF (over 6.2 years follow-up).[40] Median survival was 4.3 years in those with systolic HF and 7.1 years in those with HF-PEF. A contemporary insight into comparative prognosis comes from the Candesartan in Heart Failure Reduction in Mortality (CHARM) Study which enrolled 7601 patients with symptomatic HF (over 25% of whom had preserved LVEF). The CHARM investigators related baseline LVEF to outcome in 7599 patients with symptomatic HF (of whom 55% were receiving a beta-blocker) randomized to receive candesartan or placebo.[41] Over a median follow-up of 38 months, the hazard ratio (HR) for all-cause mortality increased by 39% for every 10% reduction in LVEF below 45% (HR 1.39; 95% confidence interval (CI) 1.32–1.46).

In contrast to the aforementioned population-based and clinical trial data, two contemporary hospital-based cohort studies suggest that there is little difference in outcome between these patient groups. In the Canadian EFFECT Study, both 30-day (7.1% v 5.3%, P = 0.08) and 1-year mortality (25.5% v 22.2%, P = 0.07) rates were broadly similar between systolic HF and HF-PEF respectively.[39] Similarly, 5-year survival rates were only marginally better in those with HF-PEF in the Olmsted County Study (HR 0.96, 95% CI 0.93–1.00, P = 0.03).[23] It is difficult to accurately explain the differences between these data and those observed in the CHARM population which may suggest the need for care in extrapolating clinical course from trials to the general population.

Epidemiology of HF in the developing world

Data describing the epidemiology of HF in the developing world are scarce and are somewhat limited to single-center hospital-based studies. This reflects the relative difficulty of conducting large-scale studies in communities with finite resources. Furthermore, studies often lack objective measures of LV function and accurate determinants of etiology principally because of inaccessibility to specialist

tests. Whereas cardiovascular disease is the principal cause of death in the developed world, it represents only around a quarter of deaths in the developing nations. In contrast, whereas mortality rates have generally declined in the developed world, cardiovascular events are accelerating elsewhere (particularly Asia), in parallel with the emergence of industrialization, "Western" lifestyle and greater longevity.[42] This is often referred to as "epidemiologic transition". Current projections predict that in the next two decades, cardiovascular disease (and undoubtedly associated HF) will emerge as the dominant cause of death in these regions.

In the early 1980s a case series of 315 HF patients admitted to a regional hospital in Nigeria suggested that HF accounted for 7% of all admissions.[43] Almost half were deemed attributable to "cardiomyopathy" (in many cases undefined) and 10% due to rheumatic heart disease. There was also regional variation between Northern and Southern Nigeria, where hypertension accounted for 13% and 35% of cases respectively. Accurate analyses of the contribution of coronary disease were lacking. In contrast, in a small single-center case series undertaken in Kenya in 1999, HF accounted for only 3.3% of hospital admissions.[44] Rheumatic heart disease was attributed in 32% of cases followed by undefined cardiomyopathy in 25%. Only 2.2% of cases were attributed to coronary disease (the assumption made in the presence of ECG features of previous myocardial infarction).

The Heart of Soweto Study mapped the emergence of cardiovascular disease in a geographically stable impoverished population in South Africa.[45] A total of 1593 cases of newly diagnosed cardiovascular disease were identified during 2006. HF was the most common primary diagnosis (44%), of whom 53% had moderate-to-severe LVSD. Approximately one-third (35%) were attributed to cardiomyopathy, a further third (33%) to hypertension and only 9% to ischemic etiology and 8% to primary valvular disease (predominantly rheumatic heart disease). Nevertheless, 59% of all patients had modifiable cardiovascular risk factors, which could influence future risk and illustrates the changing epidemiology in this region.

Profound epidemiologic transitions have taken place in many parts of the Middle East, Central and Southern America and Asia with a resultant increase in the burden of cardiovascular disease. In Oman between 1992 and 1994, the prevalence of HF was 5.17/1000.[46] Ischemic heart disease was the most commonly attributed cause (51.7%) followed by hypertension (24.9%) and idiopathic cardiomyopathy (8.3%). Overall, only 15.7% of patients had HF-PEF (defined as LVEF ≥50%).

In Central and Southern America several case series indicate that the incidence of HF is higher (up to 9.4% of medical admissions in one Brazilian study) and often attributed to modifiable causes, particularly CAD (around a third) and hypertension (around 20%).[47,48] The relative contribution of Chagas' disease varied between 4% and 20%. In Asian countries such as China, India and Malaysia, cardiovascular disease is now the leading cause of death and in a similar fashion to the West, CAD and hypertension have now replaced rheumatic valve disease as the dominant cause of HF which accounts for up to 6% of medical admissions.[49–51]

Epidemiology of asymptomatic left ventricular systolic dysfunction

Prevalence of asymptomatic left ventricular systolic dysfunction (ALVSD)

In a systematic review, Wang and colleagues identified 11 studies estimating the prevalence of ALVSD.[52] After adjustment for factors including the definition of LVSD, they suggested 3–6% as a reasonable estimate. Prevalence appears to be 2–8-fold greater in men than in women, and increases significantly with age. Therefore, the prevalence of ALVSD is at least twice that of symptomatic HF.

Prognosis of ALVSD

Randomized controlled trials provide the largest source of data on prognosis in ALVSD but are limited by their under-representation of the "average" patient. In the Survival and Ventricular Enlargement (SAVE) trial of post-myocardial infarction (MI) LVSD, 13% of patients developed overt HF during median follow-up of 37 months.[53] Similarly, during a median 3-year follow-up, 16% of the placebo-treated patients in the Study of Left Ventricular Dysfunction-Prevention (SOLVD-P) died, with 5% dying within the first year following randomization.[54] Nearly one-third progressed to overt HF and 5% died suddenly. Mortality and HF risk were associated with the degree of baseline systolic dysfunction (mean LVEF was 28%). Several population-based observational studies have confirmed that ALVSD is associated with an increased risk of cardiovascular mortality, all-cause mortality and non-fatal cardiovascular events, including the development of symptomatic HF.[55]

Etiology of heart failure

Heart failure is a classic illustration of the cardiovascular disease continuum, where multiple overlapping mechanisms are involved in disease progression and the disease progressively worsens, providing the opportunity to influence the process. The greatest opportunity for reducing the incidence and excessive mortality and morbidity of HF is through preventive strategies. The ACC/AHA staged

approach recognizes that there are established risk factors and behaviors known to be associated with increased risk (Fig. 46.3). Interventions designed to interrupt these processes could slow or halt disease progression and are therefore potential preventive targets. Table 46.4 illustrates the common risk factors identified as preventive targets in the ACC/AHA and CCS guidelines.

LVSD progresses gradually, often beginning with an index myocardial injury (such as MI) which leads to a progressive loss of functioning myocytes. The loss of

cardiac function occurs as a consequence of ventricular remodeling, a process by which ventricular shape, dimension and function are altered. Remodeling consists of a multitude of maladaptive pathophysiologic processes including myocyte hypertrophy, necrosis and apoptosis and myocardial interstitial fibrosis and is exacerbated by activation of neurohormonal and inflammatory pathways.[56] The remodeling process may persist despite any further discrete myocardial injury and is accelerated in the face of ongoing risk factors such as hypertension, diabetes mellitus, cigarette smoking and elevated cholesterol.

In the developed world, CAD, either alone or in combination with hypertension, appears to be the dominant cause of HF.[1,57] It is, however, difficult to definitively determine the primary etiology in a patient with multiple risk factors. Earlier studies which relied on non-invasive methods may have been unable to precisely determine the etiology (CAD in particular). In the Bromley Heart Failure Study, the percentage with unknown cause declined from 42% to 10% after cardiac catheterization and nuclear perfusion scanning.[57] Variations in the frequencies of causes of HF can also be explained by differences in the study population and in the methods used to allocate HF diagnosis and underlying precipitant.

Coronary artery disease and myocardial infarction

In the original Framingham cohort, monitored until 1965, hypertension appeared to be the most common cause of HF (in 30% of men and 20% of women, and as co-factor in a further 33% and 25% respectively). However, in subsequent years, CAD emerged as the dominant etiology (increasing from 22% in the 1950s to almost 70% in the 1970s).[58] Similarly, in the Glasgow MONICA Study, 95% of symptomatic individuals had evidence of CAD.[15] Those with symptomatic HF were also more likely to have a past history of MI and ongoing angina pectoris. In asymptomatic individuals, 71% had evidence of CAD. As such, preventive strategies for CAD are also likely to be effective in preventing HF.

There are surprisingly few data describing the epidemiology of HF following acute MI. This again reflects the heterogeneous characteristics of the population. Clinical trials may provide a comprehensive data source but are confounded by bias related to inclusion criteria. Multivariable analyses from the Argatroban in Acute Myocardial Infarction (ARGMI)-2 trial suggest that risk of post-MI HF increases with age, anterior and Q-wave infarcts and in those with prior history of MI.[59] Those with significant LVSD were also more likely to have symptomatic HF on presentation and have associated co-morbid conditions. The Worcester Heart Attack Study (MA, USA) has systematically evaluated the community incidence of MI and sub-

sequent HF in a stable population over a 26-year period (1975–2001).[60] Over this period the incidence of first MI decreased although the proportion of HF complicating MI rose from 40.1% in the mid 1970s, peaking in the early 1980s at 45.5%. Since then, there has been a gradual reduction in the proportion of HF, with a rate of 39.9% in 2001. Whilst the risk of death from HF declined in a parallel fashion, the adjusted odds ratio (OR) in the 2001 cohort was significantly higher (OR 1.37, 95% CI 1.13–1.64 compared with 1975–8). This has been confirmed by the most recent analyses, reflecting an MI population that is typically older and more often burdened by co-morbid conditions, particularly diabetes, and thus reflecting the evolution of the epidemiology of HF as a whole.

Hypertension

The measurable contribution of hypertension appears to have declined; Kannel and colleagues demonstrated a decline in the contribution of hypertension per decade through 1950–87 of approximately 5% in men and 30% in women.[61] This may reflect the parallel introduction of efficacious antihypertensives, as well as improved diagnostic discrimination in the assessment of suspected CAD (with the advent of coronary angiography). Nevertheless, whilst the risk of HF associated with hypertension is measurably smaller than that associated with CAD, hypertension contributes considerably to the epidemiology of HF as it occurs more frequently.[59] Additionally, ECG evidence of left ventricular hypertrophy in the presence of hypertension carries an approximate 15-fold increased risk of HF.[62]

Diabetes mellitus

Dysglycemia is directly implicated in HF pathophysiology with accumulating evidence that diabetes is associated with accelerated myocardial fibrosis, hypertrophy and progressive dysfunction.[63] Diabetes confers a twofold increased risk of HF, and this may be proportionately greater in younger individuals and in women.[64] Those most at risk are generally older, with higher baseline $HbA1_c$ and Body Mass Index (BMI), established diabetic microvascular complications, longer duration of disease and on insulin, and experiencing coronary disease.[65–67]

In an analysis of the Randomized Evaluation of Strategies for Left Ventricular Dysfunction (RESOLVD) Study, 27% of patients had documented diabetes, 8% had undiagnosed diabetes, and a further 9% had abnormal fasting glucose levels.[68] Further compeling evidence of the negative contribution of diabetes comes from the CHARM program. Diabetes emerged as one of the most powerful predictors of outcome, with an approximate doubling of risk of death or the composite outcome of cardiovascular death or HF hospitalization.[69] Recent evidence indicates

that elevated fasting glucose alone is an independent predictor of future HF hospitalization, suggesting that impaired glucose tolerance and insulin resistance is prognostically significant even without overt diabetes.[70]

Obesity and cardiometabolic risk factors

Cardiometabolic risk factors include: abdominal adiposity, hypertriglyceridemia, high total cholesterol, low HDL cholesterol, hypertension and fasting hyperglycemia. The relationship between lipid abnormalities and atherosclerosis is well established. Similarly, both elevated triglycerides and high ration of total to high-density lipoprotein (HDL) cholesterol have been found to be associated with increased risk of HF.[71] In an analysis of the Framingham Heart Study, each incremental increase in BMI of $1\,kg/m^2$ was associated with a 5% and 7% increased risk of HF in men and women respectively, with 11% of cases of HF in men and 14% in women being directly attributed to obesity.[72] Similarly, the NHANES-I follow-up study suggested that obesity was associated with a 30% higher risk of incident HF.[62]

Tobacco smoking

Multivariable analyses from epidemiologic studies and clinical trial registries indicate that tobacco smoking is an independent risk factor for the future development of HF. A prior history of cigarette smoking was found in 42% of men and 24% of women who developed HF from the Framingham Study and approximately 17% of all incident cases could be attributed to cigarette smoking in the NHANES-I survey.[18,62] There is both a direct and independent relationship between smoking and the development of ALVSD as well as a dose–response relationship strongly supporting causality.[73]

Special circumstances

Valvular heart disease

Although the measurable contribution of valvular heart disease has decreased (secondary to the decreased incidence of rheumatic heart disease in the developed nations), patients with HF frequently have valvular abnormalities. In the Glasgow MONICA Study, 25% of patients with symptomatic LVSD had abnormalities on echocardiography which may contribute to morbidity.[15] Nevertheless, as discussed above, even in the developed world, atherosclerotic disease now dominates.

Other causes of cardiomyopathy

Long-term heavy alcohol consumption (>11 units per day) is a particularly important (and largely preventable) cause of dilated cardiomyopathy, especially in men in their late forties.[74] An ever increasing list of candidate drugs (both therapeutic and recreational) is implicated in HF etiology.[75]

Special attention should be given to individuals receiving anthracycline and immunotherapy-based cancer treatment. In survivors of childhood cancer, the relative risk of HF is 15.1 times greater than siblings and is greatest with previous anthracycline-based chemotherapy or thoracic irradiation. Trastuzumab is a monoclonal antibody directed against the HER-2 receptor (expressed in around 25% of breast cancers). Although very effective in the management of these cancers (which are often more aggressive) trastuzumab has been linked with an increased risk of cardiomyopathy (prevalence of up to 11% in some studies).[76] With broadening clinical indications for its use, we may see more reports of trastuzumab-related cardiotoxicity (particularly when used in combination with other cardiotoxic agents).

Recently, concern has been directed towards the thiazolidinediones (TZDs), insulin-sensitizing agents used in the management of type-2 diabetes, with both case report and clinical trial data suggesting an increased incidence of fluid retention and possibly decompensation of HF.[77]

In Latin America, Chagas' disease is an important and preventable cause of HF. Chagas' is caused by the protozoan parasite *Trypanosoma cruzi,* and transmitted through its principal vector, the triatomine bug, which is endemic in Latin America. Infection is closely linked to socio-economic status, with the impoverished and those in rural communities being most at risk. It is estimated that 25 million people worldwide are infected or at risk of Chagas', with seroprevalence rates as high as 40%.[78] These estimates may underestimate the true prevalence and the population at risk (which includes up to 500 000 immigrants in the USA). Dilated cardiomyopathy occurs in up to 30% of infected individuals between 10–20 years after initial infection and is associated with a typically worse prognosis than "idiopathic" cardiomyopathies.[79]

Renal disease

Renal impairment is strongly associated with the development of cardiovascular disease and death. End-stage renal disease is associated with a CVD risk 20–30 times that of the general population. In particular, microalbuminuria is a well-characterized risk factor for HF in diabetics, in whom the presence of elevated urine albumin excretion increases risk by 3–5-fold.[67] In the Heart Outcomes Prevention Evaluation (HOPE) trial, microalbuminuria was a predictor of HF and other cardiovascular events in both diabetics and non-diabetics.[80]

Preventive strategies

Preventive strategies include public health policy, the specific targeting of high-risk individuals and secondary prevention in those with established cardiovascular disease (ACC/AHA Stage A). Many patients have more than one

risk factor; therefore, optimal treatment of all risk factors may produce benefits that are at least additive, if not synergistic. Interpretation of clinical trial data may be difficult. Whilst some treatment strategies may appear to be intuitively effective (e.g. reperfusion therapy following MI), direct evidence of reduction of HF risk may be lacking and therefore, assigning appropriate evidence recommendations may be difficult. Tables 46.5 and 46.6 summarize the best available clinical trial data directly supporting treatments for the prevention of HF and supporting evidence recommendations for these strategies.

Treatment of hypertension

Treatment of both systolic and diastolic hypertension is associated with a considerable reduction in the incidence of HF with several randomized controlled trials and meta-analyses demonstrating reductions of the order of 30–50% across the spectrum of disease severity and in all age groups (see Table 46.6).[81–85] Indeed, the elderly may have most to gain, with considerable reductions in cardiovascular events; particularly HF.[86] Is there a difference between antihypertensive agents or is adequate BP reduction enough? The most compeling data support the use of diuretics, inhibitors of the renin-angiotensin-aldosterone system (RAAS) and beta-blockers, whereas calcium channel blockers appear somewhat less effective and alpha-antagonists may be potentially detrimental.

The International Nifedipine GITS (INIGHT) Study compared long-acting nifedipine with the thiazide diuretic co-amilozide.[87] There was a significantly higher rate of HF amongst patients treated with nifedipine (0.8% v 0.3%, $P = 0.028$) although again there was no significant differ-ence in other cardiovascular outcome measures. The Nordic Diltiazem trial (NORDIL) randomized patients to diltiazem or "conventional" beta-blocker or thiazide-based therapy.[88] Incidence of HF was approximately 20% higher in those treated with diltiazem (2.5/1000 per year v 2.1/1000 per year) although this difference was not statistically significant.

The Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) remains the largest randomized controlled antihypertensive trial conducted to date and allowed direct comparison of several regimens (see Table 46.6).[89] The doxazosin arm of the study was terminated early because of an increased incidence of cardiovascular events, particularly HF, relative to chlorthalidone (relative risk (RR) 2.04, 95% CI 1.79–2.32). This differential effect on HF was consistently observed amongst all subgroups. Previous smaller trials have suggested that alpha-antagonists increase plasma volume and plasma norepinephrine levels, adding biologic plausibility to the potential detrimental effects of doxazosin.[90] The remaining arms of the ALLHAT study included 33 357 patients assigned to chlorthalidone, lisinopril or amlodipine.[91] At 5 years, systolic BP was significantly lower in the chlorthalidone-treated group. The amlodipine group had a 35% higher risk of hospitalized and fatal HF compared with chlorthalidone (RR 1.35, 95% CI 1.21–1.50, $P < 0.001$) and a 23% higher risk compared with the lisinopril group (RR 1.23, 95% CI 1.09–1.38, $P < 0.01$). There was no significant difference between lisinopril and chlorthalidone.

These findings are supported by the Blood Pressure Lowering Treatment Trialists' Collaboration (BPLTCC) meta-analysis of 29 trials involving over 162 000 patients which demonstrated superiority of ACE inhibitor, beta-

Table 46.5 Evidence-based practice recommendations for the prevention of heart failure

Preventive strategy	ACC/AHA	HFSA*	Australian*	Canadian	ESC

Table 46.6 Clinical trials providing evidence for prevention of heart failure

Study	Inclusion criteria	Intervention	HF event relative risk reduction
Antihypertensive agents			
STOP[82]	Hypertension – 70–84 y	Beta-blocker v placebo	53% (P = 0.031)
SHEP[83]	Isolated systolic hypertension –>60 y	Chlorthalidone 12.5 mg (plus atenolol 25 mg) v placebo	51% (P < 0.01)
Syst-Eur[84]	Isolated systolic hypertension –>60 y	Nitrenidipine 10–40 mg (plus enalapril 5–10 mg + hydrochlorothiazide 12.5–25 mg) v placebo	29% (P = 0.12)
ALLHAT[89,91]	Hypertension –>55 y	Chlorthalidone 12.5–25 mg v amlodipine 2.5–10 mg v lisinopril 10–40 mg v doxazosin 2–8 mg	See text
VALUE[94]	Hypertension –>50 y	Valsartan 80–160 mg v amlodipine 5–10 mg	37% (P = 0.004)
JIKEI[85]	Hypertension – 20–79 y	Valsartan 40–160 mg v + "conventional" treatment v "conventional" treatment alone	47% (P = 0.0293)
Secondary prevention of coronary artery disease			
HOPE[80]	Vascular disease or diabetes + risk factors	Ramipril 10 mg v placebo	23% (P < 0.01)
EUROPA[101]		Perindopril 8 mg v placebo	39% (P = 0.002)
PEACE[102]		Trandalopril 2–4 mg v placebo	25% (P = 0.02)
CURE[112]	Acute coronary syndromes	Clopidogrel 75 mg v placebo	18% (P = 0.03)
Optimizing diabetic care			
UKPDS[65]	Type 2 diabetes (T2DM)	Glycemic control	See text
RENAAL[97]	T2DM, hypertension, nephropathy	Losartan 50–100 mg v placebo	32% (P = 0.005)
IDNT[95]	T2DM, hypertension, nephropathy	Irbesartan 300 mg v amlodipine 10 mg v placebo	28% (P = 0.048)
Hyperlipidemia			
4S[104]	Stable coronary artery disease	Simvastatin 20–40 mg v placebo	21% (P < 0.015)
TNT[107]		Atorvastatin 10 mg v atorvastatin 80 mg	26% (P = 0.01)
CARE[105]		Pravastatin 40 mg v placebo	21% (P = 0.10)
VA-HIT[106]		Gemfibrozil 1200 mg v placebo	22% (P = 0.04)
PROVE-IT[108]	Acute coronary syndromes	Atorvastatin 80 mg v pravastatin 40 mg	45% (P = 0.008)

blocker or diuretic-based regimens over calcium channel blockers in reducing the risk of HF, despite almost identical BP reductions.[92] Indeed, for every outcome other than HF, the differences in the observed risk were directly related to degree of blood pressure reduction.

The newest class of antihypertensive drug showing efficacy in prevention of HF are the angiotensin receptor blockers (ARBs). This group has shown particular efficacy in reducing major cardiovascular events in diabetics with established nephropathy (and in many cases, associated hypertension). The Losartan Intervention for Endpoint reduction in hypertension (LIFE) study compared losartan and atenolol in 9193 patients with significant hypertension (BP 160–200/95–115 mmHg).[93] After mean follow-up of just under 5 years the primary composite endpoint of cardiovascular morbidity and death was lower in the losartan group (HR 0.87, 95% CI 0.77–0.98, P = 0.021) with a trend towards a reduction in HF admissions. The Valsartan Antihypertensive Long-term Use Evaluation (VALUE) trial ran-

domized 15 235 high-risk patients to a regimen based on the ARB valsartan or CCB amlodipine, with the addition of hydrochlorothiazide to each as necessary.[94] Primary outcome was time to first cardiac event (a composite which included hospitalization or death due to HF). Whilst there was no difference in the primary outcome between either group, in a subsequent analysis of the 46% receiving monotherapy, valsartan emerged as superior in reducing incident HF (HR 0.63, 95% CI 0.461–0.962. P = 0.004).

These studies illustrate the substantial benefits of antihypertensive therapy across a spectrum of hypertension severity, with even modest reductions in BP among patients with stage 1 and 2 hypertension producing tremendous benefits. Amongst diabetics and patients with established atherosclerosis, inhibitors of the RAAS have been particularly effective.[92,95–97] It is estimated that only 52% of Americans with established hypertension are receiving treatment, and only 23% are adequately controlled.[98] Similarly almost half of patients with previous MI have uncontrolled

hypertension.[99] There is therefore, considerable room for improvement and prevention in such high-risk individuals. Optimal BP control in line with contemporary guidelines should be the primary goal, the choice of drugs guided by concomitant medical problems (e.g. CAD, diabetes or renal disease) (**Class I, Level A**).

Treatment of atherosclerosis and prevention of myocardial infarction

ACE inhibitors

ACE inhibitors play a pivotal role in the secondary prevention of MI and in patients with chronic stable atherosclerosis. The ACE Inhibitor Myocardial Infarction Collaborative Group undertook a systematic review of trials of ACE inhibition in the early (0–36 hours) phase of acute MI.[100] Data were available from four randomized controlled trials involving nearly 100 000 patients. Results were consistent, with a significant 7% relative risk reduction in 30-day mortality and a significant but small 1.4% absolute risk reduction in the incidence of non-fatal HF.

In patients with established cardiovascular disease, long-term treatment with an ACE inhibitor may decrease the risk of death and further major cardiovascular events, including HF, although studies have yielded variable results. The aforementioned HOPE trial randomized 9297 patients aged 55 years or older with diabetes mellitus or established vascular disease (but without evidence of HF) to receive ramipril or placebo.[80] Ramipril decreased the incidence of HF by 23% (OR 0.77, 95% CI 0.67–0.97, $P < 0.001$). This benefit appeared independent of blood pressure. Similar results were observed with perindopril in the EURopean trial On reduction of cardiac events with Perindopril in stable coronary Artery disease (EUROPA) Study.[101] Perindopril was associated with a significant 20% relative risk reduction in the primary endpoint (OR 0.8, 95% CI 0.09–0.29, $P = 0.0003$) with a 39% relative risk reduction in HF hospitalizations (OR 0.69, 95% CI 0.17–0.56, $P = 0.002$). In contrast to HOPE and EUROPA, the Prevention of Events with Angiotensin Converting Enzyme inhibition (PEACE) trial failed to show any incremental benefit of adding ACE inhibitor (trandolapril) to otherwise optimal therapy on the composite endpoint of cardiovascular death, MI or coronary revascularization.[102] There was, however, a significant reduction in the composite rate of death or hospitalization due to HF (OR 0.75, 95% CI 0.59–0.95, $P = 0.02$). To control for apparent differences in risk profiles, baseline therapies and follow-up between the different trials, two comprehensive meta-analyses have combined the findings of these and smaller studies and persuasively demonstrate a significant reduction in all-cause mortality, cardiovascular mortality and hospitalization for HF (OR 0.77, 95% CI 0.67–0.90, $P = 0.0007$).[96,103] As such, all patients with stable CAD should be considered for treatment with an ACE inhibitor (**Class I, Level A**).

Lipid-lowering therapy

The Scandinavian Simvastatin Survival Study (4S) randomized 4444 patients (mean age 60 years) with known CAD and serum cholesterol 5.5–8.0 mmol/L, and without clinical evidence of HF, to receive simvastatin (20 mg initially, increased to 40 mg if cholesterol remained >5.2 mmol/L) or placebo.[104] Primary endpoint was total mortality. After 5-years follow-up there was a significant 30% reduction in total mortality ($P < 0.0003$) with a 21% relative risk reduction in the incidence of HF ($P < 0.015$). The relative risk reduction for major coronary events was independent of baseline cholesterol and similar across all subgroups. Risk of HF was closely related to ischemic events, particularly MI and comorbid diabetes. The Cholesterol and Recurrent Events (CARE) trial randomized 1283 elderly patients aged 65–75 years (mean 69 years) with prior history of MI and total cholesterol <6.2 mmol/L to receive pravastatin 40 mg or placebo.[105] There was a significant reduction in the primary composite endpoint of non-fatal MI or CAD death (39% relative risk reduction, $P = 0.001$) and a trend towards reductions in incident HF (23% relative risk reduction, $P = 0.10$).

The Veterans' Affairs Co-operative Studies Program High-density Lipoprotein Cholesterol Intervention trial (VA-HIT) randomized 2531 male patients with established CAD, low HDL cholesterol and no more than moderately elevated LDL cholesterol to receive either the fibrate gemfibrozil 1200 mg or placebo.[106] Primary endpoint was non-fatal MI or death from CAD. After 5.1 years follow-up gemfibrozil was associated with a significant reduction in the primary endpoint and a 22% relative risk reduction in HF hospitalization (OR 0.78, 95% CI 0.62–0.98, $P = 0.04$).

In a meta-analysis of six recently conducted randomized controlled trials comparing intensive with moderate lipid-lowering therapy (with a statin) in patients with recent acute coronary syndrome (ACS) and stable CAD, intensive therapy showed greater efficacy in reducing total mortality, although this was restricted to patients with recent ACS.[107] Nevertheless, intensive therapy was associated with a significant reduction in risk of HF hospitalization in both patient groups (RR 0.63, 95% CI 0.46–0.86 and OR 0.77, 95% CI 0.64–0.092 respectively). These substantial reductions in heart failure admission rates may be independent of ischemic events. In the Pravastatin or Atorvastatin Evaluation and InfecTion (PROVE-IT) trial, 4162 patients with low baseline rates of HF were randomized to receive intensive (atorvastatin 80 mg) or moderate (pravastatin 40 mg) statin therapy following stabilization for a recent ACS.[108] Hospitalization rates for HF were significantly reduced in the intensive therapy group (HR 0.55, 95% CI 0.35–0.85, $P = 0.008$) and this benefit appeared independent of recurrent ischemic events. Consequently, lipid-lowering therapy (in accordance with local primary and secondary prevention guidelines) is strongly recommended in all patients with CAD to prevent HF (**Class I, Level A**).

Antiplatelets

Antiplatelet drugs, notably aspirin, have been shown to produce short-term benefits in preventing mortality and cardiovascular events after MI and in patients with cardiovascular disease.[109] Aspirin is universally accepted as first-line treatment of CAD. However, two prospective outcome trials, including patients with HF, have failed to demonstrate significant beneficial effects on mortality specifically related to HF.[110,111]

Clopidogrel exerts its antiplatelet effects through antagonism of adenosine diphosphate-induced platelet aggregation. Combination of clopidogrel with aspirin, which acts via the thromboxane-mediated aggregation pathway, may have an additive effect, producing incremental clinical benefits, particularly in high-risk patients. The Clopidogrel in Unstable Angina to Prevent Recurrent Events trial investigators randomized 12 562 patients who had presented within 24 hours of onset of ACS (excluding ST elevation MI) to receive aspirin and clopidogrel (loading dose of 300 mg followed by 75 mg daily) or placebo for 12 months.[112] Clopidogrel was associated with a significant 20% relative risk reduction in the primary composite outcome measure of death from cardiovascular causes, non-fatal MI or stroke (HR 0.80, 95% CI 0.72–0.90, $P < 0.001$). There was also a significant reduction in incidence of in-hospital HF (HR 0.82, 95% CI 0.69–0.98, $P = 0.03$). This was of a similar magnitude to the reduction in ischemic events, suggesting that through prevention of recurrent ischemia, intensive antiplatelet therapy can prevent heart failure following ACS (**Class IIa, Level B**).

Optimizing treatment of diabetes

Considering diabetes as an integral part of the cardiovascular risk continuum, strategies to prevent HF should largely focus on optimal treatment of hypertension, reducing ischemic events and optimizing diabetes care as a whole. It is difficult, however, to determine if improving glycemic control reduces heart failure incidence *per se*, largely due to a paucity of good data from large trials. In the UK Prospective Diabetes Study Group (UKPDS), every 1% reduction in $HbA1_c$ was associated with a 16% reduction in risk of incident HF (95% CI 3–26, $P = 0.016$).[65] Whilst several observational and interventional studies have demonstrated a linear relationship between percentage $HbA1_c$ and subsequent risk of HF, the converse, that aggressive reduction in $HbA1_c$ modifies risk of heart failure, remains largely unproven.[66,113] Nevertheless, glycemic control in patients with diabetes is recommended to reduce future heart failure risk (**Class I, Level A**).

Treatment of obesity

Effective weight reduction strategies have been shown to improve many of the adverse effects of obesity. Some small studies specifically investigating bariatric surgery in the management of morbid obesity have demonstrated measurable reductions in LV mass with tandem improvements in LV systolic and diastolic function.[114,115] Nevertheless, there is no firm evidence on which to base recommendations for weight loss targets as a preventive strategy for HF. Contemporary practice guidelines suggest a BMI of <30 as a clinical target (**Class I, Level C**).

Smoking cessation

There is considerable evidence that smoking cessation prevents subsequent cardiovascular events in those with established coronary disease.[116,117] Similarly, smoking cessation appears to have substantial benefits on decreasing morbidity and mortality in patients with established heart failure.[73] In the SOLVD study, non-smokers or former smokers showed improved outcome when compared with current smokers. These and other observational data suggest that smoking cessation may positively impact on HF outcome, particularly in those with established cardiovascular disease (**Class I, Level A**).

Others

In patients at risk of "cardiomyopathy", clinical vigilance and early treatment of asymptomatic LVSD is the key. Precipitating causes should be sought and corrected. Drug-induced LVSD may be responsible for only a small proportion but may be easily overlooked and relies on a thorough history and clinical awareness of potential culprits. In those receiving high-dose anthracycline chemotherapy regimens, a variety of cardioprotectant strategies have been attempted but without much success.[118] The most promising is the free radical scavenger dexrazoxane which may reduce the incidence and severity of cardiomyopathy associated with doxorubicin.[118]

In 2007 the WHO launched a "Global Network for Chagas' Elimination" with the primary goal of eliminating Chagas' disease by 2010. This complements national programs to control Chagas' such as the "Southern Cone Initiative" which, through a combination of housing improvements and insecticide spraying, have resulted in significant reductions in transmission.[119] The use of antiparasitic therapy (principally benzidazole) has been evaluated in several small randomized and non-randomized controlled trials. These studies have been evaluated by the Cochrane Collaboration which suggests potential for asymptomatic patients.[120] Large-scale randomized controlled trials are indicated, with one under way.[121]

The prevention of rheumatic heart disease relies on accurate diagnosis and effective administration of secondary prophylaxis. The WHO recommends a program based upon monthly injections of penicillin after a first episode of acute rheumatic fever, and continued until the third

decade as an effective (and affordable) strategy to prevent rheumatic heart disease.[122] Despite this, many impoverished nations have no national secondary prophylaxis program. The prevention of these infectious causes of HF is perhaps more closely tied to national public health policy than specific therapeutic interventions.

Management of asymptomatic left ventricular systolic dysfunction

Neurohormonal activation is evident in ALVSD and therefore, therapeutic manipulation may provide clinical benefits. ALVSD is more often managed in primary care and by non-specialists, and therefore, may go unrecognized or untreated. Patients with ALVSD may also be reluctant to commit to a lifetime of medication in the absence of symptoms, especially when faced by side effects and prescription costs. Most of the existing evidence comes from studies in patients with CAD incidentally found to have ALVSD. There are only limited data for non-ischemic etiologies. Table 46.7 summarizes the evidence-based recommendations.

ACE inhibitors

The milestone trials in the treatment of ALVSD using ACE inhibitors are the SOLVD-P and the SAVE trials.[53,54] The SOLVD-P trial randomized 4228 asymptomatic or mildly symptomatic patients with LVEF ≤35%, primarily with CAD (83%), to receive enalapril or placebo. After median follow-up of 37 months, patients receiving enalapril showed a trend toward increased survival and a significant reduction in the risk of development of HF. Extended 12-year follow-up demonstrated a statistically significant 14%

reduction in mortality.[123] The SAVE trial randomized 2231 patients with ALVSD (LVEF ≤40%) following MI to receive placebo or captopril. Mean baseline LVEF was 31%. After median follow-up of 19 months there was a significant 22% relative risk reduction in HF hospitalization and a 36% relative risk reduction in death due to worsening HF.

Finally the Trandolapril Cardiac Evaluation (TRACE) study randomized 1749 patients with MI and LVEF <35% (31% of whom were asymptomatic) to trandolapril or placebo for up to 50 months.[124] Trandolapril produced a 22% relative risk reduction in total mortality and a 29% relative risk reduction in death due to worsening HF.

Taken together, these trials unequivocally support the use of ACE inhibitors in ALVSD, particularly in patients with CAD. Consequently, ACE inhibitors are indicated in all patients with ALVSD post MI (**Class I, Level A**) and in patients with ALVSD even if they have not experienced MI (**Class I, Level A**).

Beta blockers

Treatment with beta-blockers has been shown to provide significant incremental benefits in symptomatic patients treated with an ACE inhibitor. Moreover, beta-blockers have been demonstrated to induce reverse remodeling, reducing LV dimensions and increasing LVEF. In a *post hoc* analysis of the SOLVD-P trial, the benefit of adding beta-blockers to ACE inhibitors in ALVSD became apparent.[125] Those patients receiving both agents (25%) had significantly lower rates of mortality and hospitalization for HF. Similarly, a retrospective analysis of the SAVE trial found that the 35% of patients who were receiving both agents had a 30% lower risk of death and a 21% lower risk of progression to symptomatic HF that was independent of

Table 46.7 Evidence-based recommendations for the management of ALVSD

	ACC/AHA	HFSA*	Australian*	Canadian	ESC

* "Is recommended" (HFSA) and "should be treated with" (Australian) are considered equivalent to Class I recommendation.

[†] No specific distinction made between prior MI and no prior MI.

[§] "In acute MI with signs of heart failure *or* LVSD".

captopril use.[126] The Australia-New Zealand Heart Failure trial randomized 415 patients with LVSD (LVEF <45%) due to CAD (30% of whom were asymptomatic) to carvedilol or placebo.[127] Most patients were concurrently treated with an ACE inhibitor (86%). After a median 19-month follow-up there was a 26% relative risk reduction in mortality or HF hospitalization with carvedilol. Carvedilol also produced significant improvements in LVEF.

The Carvedilol Post-Infarct Survival Control in LV Dysfunction (CAPRICORN) trial randomized 1959 patients with LVEF ≤40% (mean 33%) post MI to receive carvedilol or placebo.[128] Fifty-three percent of patients were asymptomatic and nearly all received ACE inhibitors (98%). Although there was no difference in the primary composite endpoint of all-cause mortality or cardiovascular hospital admission, there was a significant 23% relative risk reduction in all-cause mortality with carvedilol. In a subgroup analysis of the asymptomatic patients, carvedilol treatment produced a 31% relative risk reduction in all-cause mortality. In an echocardiographic substudy of the same study, carvedilol resulted in statistically significant reductions in LV volumes and superior improvements in LVEF indicating a reversal of LV remodeling.[129]

The more specific effects of ACE inhibitors and beta-blockers on LV remodeling were evaluated in the Carvedilol ACE Inhibitor Remodelling Mild CHF Evaluation (CARMEN) trial which assigned 572 patients with heart failure (LVEF ≤40%) to enalapril, carvedilol or combination of both;[130] 8% of patients were asymptomatic. Primary endpoint was change in LV end-systolic volume at 6 and 8 months. Carvedilol alone and the combination of both drugs appeared to be most efficacious. Patients who were treated with ACE inhibitor alone had no change in LV dimensions and a small, late increase in LVEF. The recently published Reversal of Ventricular Remodelling with Toprol-XL (REVERT) trial has extended these data, demonstrating that beta-blocker therapy can ameliorate LV remodeling.[131] When considering that initiation of a beta-blocker is better tolerated in asymptomatic or mildly symptomatic individuals, an early approach to combined beta-blocker and ACE inhibitor therapy in these patients seems most appropriate. Consequently, beta-blockers are indicated in all patients with ALVSD post MI (**Class I, Level B**) and in patients with ALVSD without history of MI (**Class I, Level C**).

Angiotensin receptor blockers (ARBs)

Clinical trial evidence supporting the use of ARBs in ALVSD is currently limited to the post-MI population. The Valsartan in Acute Myocardial Infarction (VALIANT) trial randomized 14 703 patients with LVSD (mean LVEF 35%) 0.5 to 10 days post MI to receive the ARB valsartan (target dose 160 mg bd) the ACE inhibitor captopril or a combination of both.[132] Twenty-eight percent had no symptoms of HF. After a median follow-up period of nearly 25 months, valsartan was as effective as captopril in reducing the primary endpoint of total mortality, even in asymptomatic patients. The combination of both drugs conferred no additional benefit, whilst increasing the risk of adverse events.

The Optimal Trial in Myocardial Infarction with the Angiotensin II Antagonist Losartan (OPTIMAAL) trial randomized 5477 patients 50 years of age or older with either clinical HF or echocardiographic evidence of LVSD post MI to receive the ARB losartan (at target dose 50 mg once daily) or captopril (at target dose 50 mg three times daily).[133] The primary endpoint was all-cause mortality. Approximately one-third of the study population were asymptomatic. There was a non-significant trend in mortality favoring captopril, although losartan was better tolerated. These results suggest that the efficacy of an ARB in post-MI LVSD either varies depending on agent used (valsartan being efficacious and losartan not) or by dosing. In the VALIANT trial, valsartan was more rapidly titrated and reported equivalent non-inferior reductions in events when compared with captopril. In contrast, the OPTIMAAL investigators observed a significantly higher early event rate in this high-risk population, suggesting that the dosing regimen of losartan may have been suboptimal.

Consequently, ARBs are indicated in patients with ALVSD post MI who are intolerant of ACE inhibitors (**Class I, Level B**) and may be beneficial in ALVSD in patients without a history of MI who are intolerant of ACE inhibitors (**Class IIa, Level C**).

Aldosterone antagonists (AA)

The Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS) randomized 6632 patients LVEF ≤40% and clinical or radiologic HF (or diabetes mellitus) after MI to receive the selective AA eplerenone 50 mg once daily or placebo (in addition to standard therapy).[54,134] There was a significant 15% relative risk reduction in all-cause mortality with further benefits in reducing hospital admissions. These benefits were achieved despite high baseline use of ACE inhibitors and beta-blockers, demonstrating the incremental advantage for these high-risk patients; 10% of patients were asymptomatic (all diabetics). In a recent cardiac magnetic resonance imaging study, eplerenone significantly reduced LV remodeling (assessed by LV systolic volume index) over a 6-month period compared with placebo in 100 patients with ALVSD post MI (RAP Weir, presentation at the American Heart Association Scientific Congress, Orlando, 2007). These patients were otherwise optimally treated in accordance with contemporary guidelines.

Consequently, the AA eplerenone should be considered in diabetic patients with ALVSD post MI although a level of recommendation cannot be made on the basis of the available evidence. Further adequately powered clinical endpoint studies are indicated to explore the broader application of aldosterone antagonists in ALVSD, particularly in such high-risk groups.

Implantable cardioverter-defibrillators (ICDs)

Despite advances in pharmacologic treatment, patients continue to experience significant mortality. In the SOLVD-P trial, 5% of patients suffered sudden cardiac death that was not preceded by worsening HF and in the Framingham population, 43% of patients with ALVSD died suddenly.[54,55] It is presumed that a significant proportion of these sudden deaths are arrhythmic in etiology. This has led to the investigation of ICDs as a preventive strategy in high-risk patients. Early studies targeted therapy to those considered most at risk on the basis of electrophysiologic testing, and confirmed a significant reduction in mortality. Subsequently, "primary prevention" devices have been proven to be efficacious in preventing sudden cardiac death in patients without electrophysiologic testing and in patients with both ischemic and non-ischemic LVSD. A considerable proportion of asymptomatic patients were included in the landmark studies.

The Multicenter Automatic Defibrillator Implantation Trial II (MADIT-II) randomized 1232 patients with past history of MI (at least 1 month) and LVEF ≤30% to receive conventional medical therapy or medical therapy plus ICD.[135] Median follow-up was 20 months. Approximately one-third of each group were asymptomatic. ICD was associated with a 31% relative risk reduction in death compared with medical therapy alone. Asymptomatic patients were conferred the same survival benefits as those with overt symptoms. The Defibrillators in Non-ischemic Cardiomyopathy Treatment Evaluation (DEFINITE) Study investigated the role of ICD in patients with non-ischemic cardiomyopathy.[136] Four hundred and fifty-eight patients (22% of whom were asymptomatic) with LVEF ≤36% were randomized to receive conventional medical therapy or medical therapy plus ICD. Device implantation produced a non-significant 35% relative risk reduction in total mortality ($P = 0.08$). In contrast to the MADIT-II population, only symptomatic NYHA III patients received mortality benefit.

Consequently, ICD implantation should be considered in patients with ALVSD and LVEF ≤30% post MI on optimal medical therapy and in whom a reasonable survival with good functional status of more than 1 year can be expected (Class IIa, Level B). Implantation may be considered in patients with non-ischemic cardiomyopathy with LVSD but this remains an area of debate (**Class IIb, Level C**).

Conclusion

Heart failure affects approximately 2–5% of the population and is associated with considerable morbidity and mortality. Whilst the age-adjusted incidence appears to have remained stable, prevalence is thought to be increasing, principally as a consequence of aging of the population and improved survival from CAD. The prevalence of ALVSD may be even greater, indicating that many patients go unrecognized and untreated. Therapies aimed at modifying the abnormal neurohormonal activation that is characteristic of LVSD have been proven to prevent progression of ALVSD to overt HF, particularly post MI.

Early identification of those at risk and modification of risk factors is critical to reduce the population burden. Future strategies may include the use of devices and novel therapeutic agents as well as screening for asymptomatic patients. Together with effective preventive measures, this may decelerate this growing epidemic.

47 Management of overt heart failure

Paul J Hauptman[1] and Karl Swedberg[2]
[1]Saint Louis University School of Medicine, St Louis, MO, USA
[2]Sahlgrenska University Hospital/Östra, Göteborg, Sweden

Introduction

The heart may be exposed to various forms of injury brought about by ischemic, hemodynamic, metabolic or toxic insults. Progression to the clinical syndrome of congestive heart failure (CHF) occurs through a complex series of neurohormonal and hemodynamic interactions that results in a common cardiovascular phenotype, characterized by fluid overload, low cardiac output syndrome or a combination of both. Treatment paradigms developed over the past 20 years have increasingly focused on the attainment of long-term survival benefit rather than on improvements in presumptive surrogates for survival such as the hemodynamic profile. While symptom improvement is a goal of therapy, the relationship between symptom relief (for example, with diuretic therapy) and longevity is often non-linear; that is, interventions that may improve symptoms can have a negative or neutral effect on survival, while those that improve survival (for example, the beta-adrenergic receptor antagonists) may have neutral effects on important clinical markers like exercise tolerance.

Since the publication of the last edition of this chapter, the advent of device therapy (in particular implantable cardioverter defibrillators and biventricular pacemakers) has shifted the focus of management. However, the approach to the patient with heart failure must continue to be seen as multidimensional, multidisciplinary and predominantly pharmacologic. Given the morbidity and mortality associated with the condition, and its increasing prevalence, the need to define evidence-based medical therapies has become even more urgent. In this chapter we review contemporary standard-of-care approaches for both chronic and acute overt CHF with a focus on pharmacology, and offer an overview of new challenges ahead.

Pharmacologic therapy

Cardiac glycosides

Digitalis is the oldest of the drugs used in the treatment of CHF today. The main action of the drug is thought to be exerted by inhibition of the plasma membrane Na^+/K^+-ATPase, increasing intracellular concentrations of Na^+ and Ca^+. A variety of autonomic effects have been shown in acute experimental studies and sympatholytic effects have been described.

Acute effects in CHF

Older uncontrolled studies have suggested that digitalis produces beneficial hemodynamic effects in patients with decompensated heart failure, expressed as a decrease in pulmonary capillary wedge pressure, an increase in cardiac output, and a fall in heart rate.[1,2] It appears that the effect of digitalis on hemodynamics is dependent on the hemodynamic state of the patient. Whereas positive effects have been observed in decompensated heart failure, the effects in normal subjects are largely negligible.[3,4] Although the slowing of heart rate would be of benefit in diastolic heart failure without systolic dysfunction, there are limited data about this effect.[5] Acute administration of digitalis restores baroreceptor function and causes a decrease in sympathetic activity[6,7] though not all findings have been reproduced.[8]

Chronic digitalis therapy

The first double-blind placebo-controlled trial with chronic digoxin treatment was published in 1977.[9] Subsequently a series of small short-term trials provided conflicting data about digoxin efficacy,[10–13] with some studies suggesting favorable effects of digoxin on clinical heart failure symptoms, echocardiographic parameters, and exercise capacity, in particular in patients with more advanced left ventricular dysfunction.

In the first large study, the Captopril-Digoxin Multicenter Research Group trial, 300 patients with relatively mild heart failure were compared using captopril, digoxin or placebo. Digoxin and captopril were equally effective in

preventing hospitalization or an increase in diuretic dosages. Although digoxin-treated patients showed a significant increase in ejection fraction, in contrast to the captopril group, digoxin did not improve exercise capacity as much as captopril. The German and Austrian Xamoterol Study Group investigated the effect of digoxin together with xamoterol and placebo. Digoxin improved clinical indices of heart failure but not exercise capacity.[14]

Several trials have used a withdrawal design to evaluate digoxin efficacy. In the PROVED trial a randomized double-blind withdrawal of digoxin was investigated in 88 patients with stable NYHA class II–III maintained on digoxin and diuretics.[15] More placebo patients had worsening heart failure with an increase in the need for diuretics and hospitalization, and an impairment in exercise capacity and LV function. In a similar study, the RADIANCE trial, 178 patients with CHF were investigated during digoxin withdrawal compared with maintained digoxin therapy;[16] both groups were also on angiotensin-converting enzyme (ACE) inhibitors. The results were similar to those of the PROVED trial, with placebo patients showing a statistically significant deterioration in cardiac function, hospitalization, quality of life and exercise capacity.

It should be noted that the withdrawal study design is inferior to prospective treatment studies and provides only inferential data about efficacy. In contrast, the Digitalis Investigators Group (DIG) study, the only survival study of digoxin, was a multicenter, prospective, randomized, placebo-controlled, double-blind trial in 7788 patients with mild to moderate heart failure and sinus rhythm.[5] Among the investigated patients, 6800 had signs of systolic dysfunction expressed as ejection fraction of <45%. The remaining patients might be considered to have had only diastolic dysfunction. There was no effect on the primary endpoint of all-cause mortality but digoxin significantly reduced the number of hospitalizations from worsening heart failure.

In clinical practice, the use of digoxin appears to be declining[17] as part of a secular trend as opposed to a reaction to the publication of the DIG trial results. However, other factors may be contributing. One substudy has garnered attention because of a putative increase in mortality in women assigned to receive digoxin.[18] Subsequently, data from the DIG trial supporting the relationship between serum digoxin concentration (measured at 4 hours post dose) and outcomes were published. A survival benefit was observed for serum digoxin concentrations of 0.5–0.8 ng/dL compared to a neutral effect for concentrations between 0.9 and 1.1 ng/dL and an increase in mortality for higher concentrations (greater than 1.1 ng/dL).[19] In an analysis that synthesized these two important observations, Adams *et al* determined that the increased mortality observed in women was likely an effect of higher serum digoxin concentrations, given that women tend to have smaller volumes of distribution of the drug than men.[20]

BOX 47.1 Documented value of digoxin

Proven indication: always acceptable **Level A**
Symptomatic left ventricular systolic heart failure and sinus rhythm on maximal medical therapy: symptomatic improvement, improved exercise capacity and decreased hospitalization for heart failure*

Acceptable indication but of uncertain efficacy and may be controversial **Level B**
CHF with atrial fibrillation: heart rate control

Acceptable indication but of uncertain efficacy and may be controversial **Level A**
Symptomatic heart failure due to diastolic dysfunction

Not proven: potentially harmful (contraindicated) **Level A**
Bradycardia and atrioventricular block
Significant ventricular arrhythmias
Renal dysfunction
Electrolyte disturbances, hypokalemia in particular

*Target serum digoxin level less than 1.0 ng/dL (see text for details)

Taken together, present data on digoxin suggest that this drug induces small but beneficial effects on cardiac function, morbidity, and symptoms. There is a neutral effect on all-cause mortality. However, the therapeutic window is narrow, and the potential risk for serious arrhythmias cannot be ignored. The need to monitor serum drug levels appears to be heightened by recent analyses and in that context practitioners must be vigilant about the possibility that drug–drug interactions may elevate digoxin concentration. Further, the applicability of the data derived from digoxin withdrawal trials to contemporary practice that includes beta-blockers is unclear; the efficacy of digoxin in stable patients with mild heart failure on combined ACE inhibition and beta-blocker has not been established.

Diuretics

Fluid retention is a consistent finding in patients with CHF. The need for reduction of blood volume in patients with edema was recognized several hundred years ago. Historically, drugs with mild diuretic effects, such as mercury salts, carbonic anhydrase inhibitors, and thiazides, have been used.

A more substantial and conventional way to achieve diuresis is the use of loop diuretics.[21] Compensatory fluid retention, as a response to lower cardiac output and reduced kidney perfusion,[22] might be of short-term benefit in restoring optimal preload in the earlier states of CHF. However, a further increase in intracavitary pressure increases wall stress in the myocardium with a parallel increase in oxygen consumption and energy expenditure.

In the classic physiologic description, the elevation of venous pressure shifts the hydrostatic balance across the capillary wall toward a net filtration of fluid to the extracellular space, and finally to the formation of edema. The decrease in renal blood flow that commonly accompanies heart failure stimulates the renin system, which leads to secretion of angiotensin and aldosterone. Other neurohormones that promote retention of sodium and water include vasopressin, norepinephrine, and prostaglandins.[23] In contrast, endogenous sodium excretion is promoted by natriuretic peptides and prostacyclin.

Neurohormonal and hemodynamic effects of loop diuretics

In patients with pulmonary edema, intravenous furosemide is normally followed by a prompt response and relief of symptoms. However, findings are not consistent regarding the mode of action of loop diuretics in the acute phase of decompensated heart failure. A reduction in filling pressures occurs even before diuresis is initiated[24–26] and has been attributed to vasodilation. However, acute arterial vasoconstriction has also been found, alone or in combination with venodilation,[27–29] potentially related, at least in part, to acute upregulation of neurohormones such as aldosterone. Similarly, cardiac output may increase, remain unchanged or decrease. Although furosemide is the most thoroughly tested loop diuretic, there are others available and commonly used, including bumetanide[30] and torsemide.[31]

Most long-term studies have involved a small number of patients and used a variety of drugs and doses; chronic neuroendocrine effects are less well studied. Oral furosemide treatment has been associated with a reduction in norepinephrine concentration and a profound increase in plasma renin activity, angiotensin, and plasma aldosterone concentration.[32,33]

Effects on clinical outcomes and survival

No prospective randomized study has been performed in the ACE inhibitor era examining the effect of diuretics on long-term survival. One meta-analysis of (small) randomized trials with active controls suggests that diuretics improve exercise capacity and the risk of worsening disease.[34] Further, despite concerns regarding the potential neurohormonal activation by diuretics, it should be kept in mind that studies showing positive survival effects of ACE inhibitors, beta-blockers or vasodilators in heart failure have all permitted diuretics as background treatment.

Clinical management

Diuretics reduce symptoms in CHF. The effect on symptoms has been formally tested in trials with furosemide and torsemide.[35] Further, it has been observed that the effects of ACE inhibitors may require the co-administration of diuretics.[36,37] Diuretics are also more effective in relieving edema and congestive symptoms than ACE inhibitors when given as single therapy.[38]

Through an increase in urinary excretion of electrolytes, diuretics are prone to induce metabolic abnormalities such as hypokalemia, hyponatremia, hypocalcemia, hypomagnesemia, and metabolic alkalosis.[39] The need for potassium supplements can be diminished by using potassium-sparing diuretics, such as amiloride or triamterine. However, ACE inhibitors act synergistically with potassium-sparing diuretics, which may produce hyperkalemia; diabetic patients with proteinuria and renal tubular acidosis are at particularly high risk. The addition of a potassium-sparing diuretic to a loop diuretic may further increase diuresis but in the case of spironolactone, the therapeutic effects seen in heart failure are likely mediated by aldosterone blockade rather than direct diuresis. Additionally, the diuretic effect of a loop diuretic can be augmented by other diuretics acting at different sites in the nephron, especially if clinically apparent diuretic resistance has developed. In particular, the combination of a loop diuretic with a thiazide enhances the diuretic effect, when the former is administered slightly after (e.g. 30 minutes) the latter.

Alternative to diuretic therapy: ultrafiltration

It is difficult to foresee a future situation when diuretics are no longer needed in the treatment of CHF. However, recent data using ultrafiltration show promise, albeit with an invasive approach that is likely to be limited to patients with significant or refractory edema or diuretic resistance. Specifically, the UNLOAD trial demonstrated that ultrafiltration led to greater weight loss (5.0 ± 3.1 kg) than diuretics alone (3.1 ± 3.5, $P = 0.001$) in a cohort of 200 patients hospitalized with symptomatic heart failure. Reductions in patient-reported dyspnea were the same. There were fewer subsequent heart failure hospitalizations at 90 days though it is important to highlight the fact that the trial had an open-label design. Mitigating this confounder to some degree was the companion finding of fewer unscheduled visits for heart failure during extended follow-up.[40]

Diuretics summary

The need for relief of edema and fluid retention and the generic status of most diuretics will prevent the initiation and completion of a classic placebo-controlled randomized long-term survival study. However, given concerns about the metabolic and neurohormonal effects of the diuretics and recognizing that peripheral edema is more a cosmetic nuisance than a life-threatening condition, it is advisable to keep the diuretic dosages as low as possible.

Aldosterone receptor blockers

Aldosterone plays an important role in the pathophysiology of heart failure, facilitating sodium retention and

<table>

</table>

potassium loss. Further, it activates the sympathetic nervous system, stimulates myocardial and vascular fibrosis, and is a component of the circulating renin–angiotensin–aldosterone system.[41–44]

Although aldosterone antagonists have diuretic effects, they differ from other diuretic agents in that they are neuroendocrine antagonists and thereby have a potential to be effective in the long-term treatment of patients with CHF. In particular, spironolactone was evaluated in the RALES study in which 1663 patients in NYHA class III or IV were randomized to active drug or placebo.[45] Spironolactone was initiated at 25 mg/day with adjustments to 12.5 or 50 mg depending on serum potassium. Ninety-five percent of the patients were on ACE inhibitors but only 11% had a background therapy of beta-blockers. The trial was discontinued early after a mean follow-up period of 24 months because of beneficial effect of spironolactone. There were 386 (46%) deaths in the placebo group and 284 (35%) in the spironolactone group; the relative risk attributed to spironolactone was 0.70 (95% confidence interval (CI) 0.60–0.82, $P < 0.001$) attributed mostly to a lower risk from sudden cardiac death. The RALES trial demonstrates that improved antagonism of the renin–angiotensin system by spironolactone reduces the risk of both morbidity and mortality in CHF. However, shortly after the publication of the RALES trial results, there was an apparent increase in admissions for hyperkalemia attributed to initiation of the drug,[46] highlighting the challenges of translating RCT data into sound clinical practice (e.g. appropriate patient selection and protocol-based monitoring of potassium levels).

Subsequently, in a different population (early post myocardial infarction (MI) with left ventricular dysfunction or heart failure), the selective aldosterone receptor blocker eplerenone was shown to reduce all-cause mortality and cardiovascular deaths, with effects most noticeable within the first 30 days following MI. This early effect suggests that the benefit may be mediated more by protection against hypokalemia than through inhibition of aldoste-

rone. In fact, while cases of serious hyperkalemia were more common with study drug compared with placebo (5.5% versus 3.9%), the incidence of hypokalemia was decreased by more than half (from 8.4% to 3.1%).[47,48]

Vasodilators: acute therapy

Vasodilation reduces left ventricular afterload and preload and these beneficial effects were observed as early as 1956,[49,50] but it was not until the 1970s that the concept was widely accepted.[51,52] The first drugs used were pure vasodilators, such as nitroprusside, nitroglycerin, and phentolamine. Later, agents with combined effects were developed. Examples of combination therapies are the inotropic drugs with simultaneous vasodilation, such as milrinone, and the ACE inhibitors, both of which are reviewed in other sections of this chapter.

Reduction of afterload and preload in CHF improves left ventricular performance according to the Frank–Starling relation with less myocardial oxygen demand and increased cardiac output.[53,54] Further, vasodilation might theoretically reduce valvular regurgitation by means of afterload reduction and may improve organ dysfunction by acting directly on selected vascular beds, such as the coronary and renal vasculature.

Nitroglycerin, nitroprusside and, in the United States, nesiritide have been used for acute short-term vasodilation therapy in heart failure. However, the clinical trials data for these drugs are either limited or controversial.

Nitroglycerin
Nitroglycerin causes smooth muscle cell relaxation and vasodilation of arterial and venous vessels through action on guanylate cyclase and the generation of cyclic guanosine monophosphate.[55] Nitrates are conventionally used

topically or as an intravenous infusion; administration causes reduction in left ventricular filling pressures within 3–5 minutes, mainly by venodilation and lowering of preload.[56–61] Further, nitroglycerin reduces systemic vascular resistance and afterload, with ensuing improvement in cardiac output. It is also conceivable that nitrate therapy favorably affects myocardial perfusion and oxygen supply/demand ratio.[62,63] However, tolerance occurs early and may limit effectiveness.

Nitroprusside

Nitroprusside generates nitric oxide and nitrosothiols, which stimulate guanylate cyclase to increase intracellular cGMP. Smooth muscle cell relaxation is rapidly induced after administration. Sodium nitroprusside is converted to cyanide and is metabolized to thiocyanate, which may accumulate and lead to thiocyanate toxicity during prolonged nitroprusside therapy. Toxicity is rare during short-term administration ($<3\,\mu g/kg/min$ for less than 72 hours) in the absence of renal failure. As compared to nitroglycerin, nitroprusside is more potent and causes a more pronounced arterial vasodilation; there are minor effects on the renal and hepatosplanchnic vasculature.[59] In contrast to nitroglycerin, nitroprusside may induce a coronary steal phenomenon.[64] Owing to its potent vasodilation property, nitroprusside may cause adverse hypotension, especially in cases of inadequate filling pressure.

Nesiritide

Brain natriuretic factor, or nesiritide, was shown in early studies to lower filling pressures and improve patient report of symptoms. Colucci and investigators demonstrated a dose-dependent reduction in pulmonary capillary wedge pressure at 6 hours in a double-blinded placebo-controlled study.[65] Subsequently, the VMAC trial demonstrated improvements in PCWP at 3 hours compared to placebo (and comparable to nitroglycerin), with greater reductions compared to nitroglycerin (TNG) seen at 24 hours, perhaps reflecting tachyphylaxis to the nitrate therapy. Patient self-report of dyspnea also favored nesiritide.[66]

Following approval by the Food and Drug Administration in the United States, a series of controversial papers that included retrospectively reanalyzed published and unpublished data suggested that the drug might exacerbate renal dysfunction and worsen 30-day mortality rates.[67,68] The mechanism by which these effects occur was not clearly delineated but the impact on clinical practice was swift, leading to a marked decrease in use.[69] As a result, a panel of experts and the FDA reiterated that the major benefit is relief of dyspnea and the dose used to achieve this benefit is $0.01\,\mu g/kg/min$. In response to the concerns raised by the studies, a large randomized double-blinded outcomes clinical trial has been initiated. At the same time, other natriuretic peptides are either in clinical use (caperitide in Japan) or in clinical trials (ularitide, CD-NP).

It is important to note that data are lacking to support the use of nesiritide as an intermittent outpatient therapy[70] and in that context the data parallel what is known about the use of intermittent inotropic therapy.

Newer vasodilators

A number of other novel agents are in clinical trials for use in the acute phase including adenosine antagonists[71,72] and relaxin,[73] a naturally occurring peptide that modulates cardiovascular responses to pregnancy.[73] In addition, a direct myosin activator, CK1827452, will be studied both acutely using intravenous delivery and then, on conversion to oral formulation, chronically upon discharge, following the paradigm established in the EVEREST trial.

Effects of long-term vasodilator therapy

Nitrates and hydralazine Oral nitroglycerin and hydralazine have been studied, either alone or in combination. The effects on left ventricular function and hemodynamics are similar to the acute effects of vasodilators described above.[74,75]

Hydralazine was available as an antihypertensive agent when vasodilator therapy was adopted as a therapeutic strategy in CHF. Hydralazine acts as a dominant arterial vasodilator but has probably also mild inotropic properties, which might be due to a reflex activation of sympathetic activity.[76,77] This inotropic action might be responsible for a less favorable effect on myocardial oxygen consumption counteracting the unloading effects of vasodilation.[78,79]

The addition of a nitrate to hydralazine causes a greater effect on the reduction in filling pressures than can be achieved by hydralazine alone.[80] In view of the beneficial action of nitrates on coronary dynamics, a nitrate should be added to hydralazine therapy in patients with significant coronary artery disease.[81] However, despite the focus on direct venous and arterial vasodilation, current thinking about mechanism has focused on the nitrate component as a nitric oxide donor and hydralazine as an agent that mitigates nitrate tolerance through a complex mechanism mediated by NADH oxidase.[82] This mechanism has been used to explain the possible race-based differential clinical effect seen among African Americans compared with Caucasians, inferred from the first two V-HeFT trials.

V-HeFT-I was the first placebo-controlled clinical trial to study the effect of any vasodilator on survival in patients with chronic heart failure. The study randomized 642 patients with mild to moderate heart failure to placebo, prazosin or the combination of hydralazine and isosorbide dinitrate. Two years after randomization, the survival in the hydralazine-isosorbide treated group was significantly better than the placebo group ($P < 0.028$); for the entire follow-up, the difference trended toward significance ($P = 0.093$). Of note, the mortality rate in the prazosin group was not different from the placebo group.[83]

The second V-HeFT study compared the efficacy of hydralazine and isosorbide with that of enalapril. Two

years after randomization, the all-cause mortality was 18% in the enalapril group as compared with 25% in the hydralazine-isosorbide group ($P = 0.016$). For the total follow-up, the difference was not significant ($P = 0.08$).[84]

A retrospective analysis of both V-HeFT-1 and V-HeFT-2 suggested that African Americans derived benefit from the hydralazine-nitrate combination, whereas Caucasians, presumably most of European descent, did not.[85] Conceptually, this analysis was based on a series of observations that suggested a relative deficiency of nitric oxide in African Americans, though the exact nature of the defect(s) has not been established.

To test this hypothesis, 1050 self-identified African Americans with NYHA class III or IV heart failure were randomized in a survival trial with a three times daily formulation of hydralazine and nitrate.[86,87] A composite endpoint was used, combining mortality, quality of life as measured on the Minnesota Living with Heart Failure Questionnaire and time to first hospitalization; each component was statistically significant in favor of the combination therapy. Most pronounced was the impact on mortality, which declined from 10.2% in placebo-treated patients to 6.2% in patients on active therapy. The cohorts were well managed, with high percentages on conventional treatment with ACE inhibitor, angiotensin receptor blocker and beta-blocker. The magnitude of this change parallels or exceeds almost all other double-blinded placebo-controlled trials and as such represents a significant achievement. However, while providing an opportunity to advance medical therapy for CHF, the controversial approval based on race by the US Food and Drug Adminstration and other factors such as three times daily therapy have negatively impacted its adoption by practitioners.

Calcium channel blockers The role for calcium channel blockers remains very limited in patients with CHF. With the first-generation calcium channel blocker nifedipine, vasodilatory effects are counterbalanced by negative inotropy and additional deleterious effects on hemodynamics, neurohormonal activation and, not surprisingly, disease progression.[88,89] The effects of diltiazem were unfavorable in patients with CHF in conjunction with myocardial infarction in a large placebo-controlled trial in 1237 patients.[90] Second-generation calcium channel blockers have not been extensively studied in patients with heart failure, but there are indications of a risk for clinical deterioration with drugs such as nisoldipine and nicardipine.[91,92] The second-generation calcium channel blocker felodipine caused vasodilation and an increase in cardiac output during 8 weeks of treatment in a placebo-controlled trial[93] but the effect on survival was neutral.[94]

Amlodipine, a third-generation calcium channel blocker, was investigated in the PRAISE trial.[95] Among more than 1100 patients with NYHA III–IV heart failure, the overall effect on mortality as well as on the combined endpoint mortality and hospitalization was neutral but there were significantly fewer endpoints in the non-ischemic group treated with amlodipine as compared to patients on placebo (22% vs 35%, $P < 0.001$). As a consequence, patients with non-ischemic etiology in NYHA class IIIb or IV heart failure (n = 1652) were randomized to placebo or amlodipine 10 mg/day.[96] There was no significant difference in all-cause or cardiac mortality and cardiac event rates between the two groups. The data from PRAISE and the felodipine trials suggest therapeutic neutrality; however, it is likely that both amlodipine and felodipine may be used safely to treat concomitant angina or hypertension in patients with CHF, if other proven drugs such as ACE inhibitors and beta-blockers are ineffective or not tolerated. All other drugs in this class are not indicated in any treatment algorithm for heart failure.

Other vasodilators Other potent vasodilators, such as prazosin and minoxidil, are not indicated in the short- or long-term management of CHF. Several other drugs with multiple effects including vasodilation have failed in clinical trials. For example, flosequinan, a vasodilator with a combined venous and arterial effect and possible positive inotropic and chronotropic effects, was associated with increased mortality in a large multicenter trial (PROFILE).[97] Additionally, the prostacyclin epoprostenol, which might improve hemodynamics, has been shown to have an adverse effect on mortality in severe heart failure.[98]

Drugs affecting the renin–angiotensin system

ACE inhibitors

ACE inhibitors were introduced for the treatment of heart failure within the last 25 years. Their potential value was

---

BOX 47.4 Documented value of vasodilators

Proven indication: always acceptable Level A
Short-term reduction of afterload in cases with acute heart failure
The combination hydralazine-isosorbide dinitrate can be used for long-term treatment in patients who do not tolerate ACE inhibitors or ARBs as add-on therapy in African American patients

Acceptable indication but of uncertain efficacy and may be controversial Level B
Third-generation calcium channel blockers may be used for symptomatic treatment of concomitant conditions such as angina pectoris or hypertension

Not proven: potentially harmful (contraindicated) Level C
Vasodilators other than hydralazine-isosorbide dinitrate and third-generation calcium channel blockers may increase mortality during long-term treatment
Treatment of patients with concomitant significant aortic or mitral stenosis

suggested by studies showing attenuated LV remodeling after myocardial infarction[99,100] and improved symptoms,[101] hemodynamics[102,103] and survival.[104] Multiple landmark studies have reported effects of ACE inhibitors on survival in patients at risk for heart failure and those with clinically manifest disease. In a similar way, these trials have demonstrated benefit across NYHA classes I–IV.[105] As a consequence, the use of ACE inhibitors is supported by all contemporary published clinical practice guidelines.

Effects on exercise capacity and hemodynamics An extensive review of these data[106] suggested that ACE inhibitors improve exercise capacity, consistent with changes in symptoms. In addition, ACE inhibitors were documented in early studies to induce beneficial hemodynamic responses. These effects included a vasodilatory effect and an increased cardiac output, increased stroke volume, and reduced pulmonary wedge pressure.[102,103]

Survival trials The first major trial, CONSENSUS, included 253 patients in NYHA class IV randomized to receive placebo or enalapril. After a follow-up of 6 months (primary objective), the overall mortality was reduced by 27% (*P* = 0.003). The number of days of hospital care was reduced and NYHA classification significantly improved with enalapril.[104] In the Studies of Left Ventricular Treatment (SOLVD) trial, 2569 patients with symptomatic heart failure NYHA class II–III received placebo or enalapril besides conventional heart failure therapy.[107] After an average follow-up of 41.4 months, mortality was significantly reduced from 40% to 35% (*P* = 0.0036), most notably reducing deaths attributed to progressive heart failure. Hospitalizations for heart failure were also reduced and symptoms and quality of life assessed by questionnaire were improved.[108]

The early post infarct cohort was examined in the Survival and Ventricular Enlargement (SAVE) trial, in which 2231 patients with ejection fraction of 40% or less, but without overt heart failure or symptoms of myocardial ischemia, were randomly assigned treatment with captopril or placebo.[109] Mortality from all causes was 20% in the captopril group and 25% in the placebo group (relative risk (RR) 19%, *P* = 0.019). In a similar evaluation (the TRACE study) with trandolapril, 1749 patients with left ventricular dysfunction were randomly assigned to treatment with placebo or active study drug.[110] Treatment was initiated 3–7 days from the onset of myocardial infarction. All-cause mortality in the placebo group was 42.3% and 34.7% in the trandolapril group, a 22% relative reduction of mortality (*P* = 0.00065). Finally, in the AIRE study, 2006 patients with clinical evidence of heart failure any time after the index infarction were randomly allocated to treatment with ramipril or placebo on day 3–10 from the onset of infarction.[111] Mortality from all causes at the end of the study was

17% in the ramipril group and 23% in the placebo group (RR 27%, *P* = 0.002) with a mean follow-up of 15 months. Taken together, these studies provide incontrovertible support for the use of ACE inhibitors in post-MI patients with left ventricular dysfunction.

Dose and class effects: clinical questions remain Uncertainties about the importance of dose of ACE inhibitor and class effects have stimulated debate and clinical evaluation. Two dose ranges of lisinopril were compared in the ATLAS trial. Patients with CHF (n = 3164) and ejection fraction <30% were randomized to a low dose of lisinopril (2.5–5.0 mg/day) or a high dose (32.5–35 mg/day) for a median of 45.7 months.[112] There were 717 deaths in the low-dose group versus 666 in the high-dose group (hazard ratio (HR) 0.92; *P* = 0.128) for the high dose. The combined endpoint of all-cause mortality or hospitalization for any reason showed a hazard ratio of 0.88 (95% CI 0.82–0.96, *P* = 0.002). The side effects and tolerability were similar in the two groups.

These findings indicate that patients with heart failure should generally be titrated up from low doses of an ACE inhibitor, but suggest that a difference in efficacy between intermediate and high doses of an ACE inhibitor is likely to be small. Thus, patients should be titrated to dose levels achieved in the clinical trials. The value of additional dose levels such as greater than 20 mg per day of lisinopril remains uncertain but can be viewed as supported in part by the results of the ATLAS trial.

With regard to the relative benefits of different ACE inhibitors, there are no large comparative studies that provide definitive evidence of the superiority of one ACE inhibitor over another. Nevertheless, it is widely acknowledged that these drugs differ in a number of fundamental respects: the ability to bind to tissue ACE, chemical structure, pharmacodynamics, pharmacokinetics and the supporting clinical trials data.[113] In an attempt to address the clinical relevance of different ACE inhibitors, Pilote and investigators compared 1-year survival among elderly post-MI patients using data from hospital discharge records and pharmacy databases in the province of Quebec, Canada.[114] Attempts were made to correct for the propensity to receive a particular ACE inhibitor and to the extent accomplished, the data suggest a significant difference among the seven options for ACE inhibitors available on the provincial formulary, favoring ramipril. These data support the concept but do not provide absolute confirmation that the different ACE inhibitors have different long-term clinical benefits.

Trials on prevention A reduced incidence of heart failure by ACE inhibitors has been demonstrated in several trials. In the prevention arm of the SOLVD study,[107] the incidence of heart failure and the number of hospitalizations were

reduced and similar findings were reported in SAVE.[109] In an overview of ACE inhibitor trials,[108] the preventive potential of ACE inhibitors is clearly demonstrated.

Three landmark studies have been performed among patients at risk for heart failure: HOPE,[115] EUROPA[115] and PEACE.[116] These trials, when considered together, suggest a role for ACE inhibitors in heart failure prevention,[117] a topic covered in more detail elsewhere in this book.

Overall, it is clear that the number needed to treat to save one life in a year is significantly higher when heart failure prevention is the goal rather than treatment of established disease. Nevertheless, while the exact role for ACE inhibitors as a component of contemporary primary prevention is not absolutely clear, use of this class of drug in defined subgroups is highly justified. Those most at risk, including diabetics and hypertensives not at goal, should be strongly considered for ACE inhibitors as part of a comprehensive approach to risk factor modification.

Cost effectiveness In asymptomatic patients with left ventricular dysfunction after an acute myocardial infarction (SAVE), captopril was cost-effective in patients aged 50–80 years compared to other interventions.[119] Ramipril therapy for patients with clinical heart failure after acute myocardial infarction appears highly cost effective when assessed using data from the AIRE study.[120] ACE inhibitor treatment was also considered cost-effective in an economic evaluation of five independent studies.[121] For example, enalapril therapy for patients with heart failure was cost-effective in SOLVD. Given the fact that many of the ACE inhibitors are available in lower cost generic formulations, the cost effectiveness now even more strongly favors this class of drug.

Clinical perspective All patients with documented left ventricular systolic dysfunction (ejection fraction <35–40%) should be treated with an ACE inhibitor unless contraindications exist (including systolic blood pressure less than 80 mmHg, pronounced renal dysfunction, history of angioneurotic edema and important valve stenosis). Treatment should be continued long term. The dosage to be used should be titrated from a low dose and increased to the levels employed in clinical trials. If no hypotension or renal dysfunction develops, titration up to enalapril 10 mg 2×/day, captopril 50 mg 3×/day, ramipril 10 mg/day, trandolapril 4 mg/day and quinapril 10 mg 2×/day will be most effective.

Angiotensin II receptor (AT₁) antagonists

As ACE inhibition does not provide complete blockade from the synthesis of angiotensin II, a more effective blockade has been postulated by specific antagonism at the

receptor (AT₁) level. One of the early ARB trials was ELITE-II, conducted in 3152 class II–IV patients with ejection fractions (EF) of <40%, randomized to losartan 50 mg/day or captopril 50 mg 3×/day.[122] There was no significant difference in all-cause mortality or sudden death (hazard ratio 1.13; 95% CI 0.95–1.35, $P = 0.16$). Significantly fewer patients in the losartan group discontinued study treatment because of adverse effects (9.7 vs 14.7%; $P < 0.001$). In the small RESOLVD trial, there were no differences between groups receiving candesartan and enalapril in exercise tolerance, ventricular function or symptomatic status over 43 weeks.[123] However, combined therapy with candasartan plus enalapril markedly reduced ventricular volumes and improved EF compared to either agent alone.

The major series of ARB trials began with Val-HeFT, a study of 5010 patients in class II–IV and EF of <40% randomized to placebo or valsartan.[124] Dose levels were increased to 160 mg twice a day. Background therapy with an ACE inhibitor was present in 93%. There was no effect on all-cause mortality (484 in the placebo group vs 495 in the valsartan group; RR 1.02, 95% CI 0.90–1.15, $P = 0.8$). In the other primary endpoint, mortality or hospitalization, there was a significant reduction from 801 (32.1%) to 723 (28.8%) (RR 0.87, 95% CI 0.79–0.96, $P = 0.009$).

The CHARM Program was designed to study the effects of candesartan in a broad spectrum of patients with CHF. Three component trials included patients with reduced

BOX 47.5 Documented value of ACE inhibitors

Proven indication: always acceptable Level A
Symptomatic chronic heart failure and documented systolic myocardial dysfunction. Improved survival and reduced morbidity have been demonstrated. Symptoms will be attenuated and exercise capacity improved
Following acute myocardial infarction with clinical signs of heart failure or systolic dysfunction (ejection fraction <40%). Improved survival and reduced morbidity have been demonstrated
Prevention of cardiovascular events, including heart failure, in patients with atherosclerotic disease or in patients with diabetes mellitus and additional risk factors

Acceptable indication but of uncertain efficacy and may be controversial Level A
Heart failure from diastolic dysfunction

Not proven: potentially harmful (contraindicated) Level C
Treatment of patients with significant aortic or mitral stenosis
Treatment of patients with hypotension (systolic blood pressure <80 mmHg)
Treatment of patients with pronounced renal dysfunction

systolic LV function (EF <40%) in two (CHARM-Alternative and CHARM-Added) and patients with preserved LV (EF >40%) in one (CHARM-Preserved). The primary outcome in each component trial was cardiovascular death or hospital admission for heart failure. In CHARM-Overall, the trials were combined and the effect on all-cause mortality was assessed.

Symptomatic patients with CHF intolerant to ACE inhibitors because of cough, symptomatic hypotension or renal dysfunction were included in CHARM-Alternative (n = 2028). Candesartan significantly reduced cardiovascular death or hospital admission for heart failure by 23% (P = 0.0004), whereas the rate of discontinuation of the study drug was similar to placebo.[125] In CHARM-Added (n = 2548), candesartan on top of ACE inhibitors significantly reduced the primary outcome of cardiovascular death or hospital admission for heart failure by 15% (P = 0.011). Hospitalizations for heart failure were also reduced significantly (P = 0.014).[126] In CHARM-Preserved (n = 3023), there was a non-significant effect on mortality. Hospitalizations for heart failure as reported by the investigators were reduced by 15% (P = 0.017).[127]

In all patients with symptomatic heart failure (n = 7599), irrespective of background ACE inhibitor or beta-blocker therapy, candesartan reduced all-cause mortality by 9% (P = 0.055), particularly among those with left ventricular systolic dysfunction (HR 0.88; P = 0.018).[128] Among these patients, the effects on mortality were seen early; the HRs were 0.67 and 0.82 (both P < 0.001) at 1 and 2 years respectively. Further, hospital admissions for heart failure were reduced significantly by 21% (P < 0.001).

ARB and background therapy

In the Val-HeFT trials, a *post-hoc* analysis suggested that the treatment effect with valsartan was attenuated by background beta-blocker therapy. This could not be confirmed in CHARM-Added where a similar effect of candesartan was observed regardless of background beta-blocker. In a meta-analysis, the effect of ARBs may be attenuated by background beta-blocker treatment.[129] In contrast, based on Val-HeFT and in particular CHARM-Added, the effect of valsartan and candesartan was additive on top of background ACE-inhibitor therapy with reduction of the composite primary outcome in both trials.

ARB summary

The trials with ARBs provide definitive proof that this class of drug can be used for treatment of patients with symptomatic heart failure who do not tolerate ACE inhibitors. The treatment effect is at least of similar magnitude as that achieved by ACE inhibitors. There is also an added, albeit modest effect on morbidity and mortality on top of ACE inhibitor therapy.

BOX 47.6 Documented value of angiotensin receptor blockers

Proven indication: always acceptable Level A
Symptomatic treatment of patients with heart failure who do not tolerate ACE inhibitors to improve morbidity and mortality

Acceptable indication: Level A
Add-on therapy in patients with heart failure on background therapy of ACE inhibitor

---

Non-digitalis inotropic drugs: short-term therapy but no long-term role

Vast efforts have been expended to develop drugs that might increase contractility or the state of inotropy. However, it has become increasingly evident that these drugs are associated with important negative effects in both the short and long term.

Inotropic agents differ according to their mode of action.[130] Several of these drugs increase the intracellular level of cyclic adenosine monophosphate (cAMP), either by receptor stimulation (beta-adrenergic agonists) or by decreasing cAMP breakdown (phosphodiesterase inhibitors). One class of agents affects intracellular calcium mechanisms by release of sarcoplasmic reticulum calcium or by increasing the sensitivity of contractile proteins to calcium. Further, there are inotropic drugs with multiple mechanisms of action.

Dobutamine

Drugs with beta-receptor agonist properties induce an increase in intracellular cAMP activity by stimulation of cellular receptors. Nearly 50 years ago, patients with cardiogenic shock were treated with beta-receptor agonists isoproterenol and norepinephrine.[131] It was realized that both drugs had potential negative effects, such as an increased risk for arrhythmias or, in the case of norepinephrine, untoward vasoconstriction. Dobutamine, a drug that is a modification of the isoproterenol molecule, has beta-1, beta-2 and alpha-1 adrenergic activity.[132] Dobutamine induces vasodilation in combination with an increase in contractility, leading to an increase in stroke volume and cardiac output.[133–135] An enhancement of contractility is usually associated with an increase in myocardial oxygen consumption.[136] Side effects, such as arrhythmias or an unfavorable blood pressure response, are usually modest. Dobutamine can only be administered intravenously, in doses from 2 μg/kg/min up to 20–25 μg /kg/min.[137] It has been noticed that dobutamine may decrease beta-receptor sensitivity,[138,139] and prolonged infusion over 96 hours has been associated with a decrease in the hemodynamic effect by as much as 50%[140] ("tachyphylaxis"). The role of dobutamine is

limited to hemodynamic support for patients in or near a state of cardiogenic shock. The use of the drug on an intermittent basis is not recommended though it has been used continuously for palliation in end-stage patients.[141]

Dopamine

Dopamine is an adrenergic agonist with predominantly beta-1 receptor activity.[142,143] This drug increases contractility with minor effects on heart rate or blood pressure. At low doses (0.5–2.0 μg /kg/min), dopamine acts on dopaminergic receptors, while at doses above 5.0 μg /kg/min it has effects mediated through beta-1 receptors, and at higher doses also through alpha-receptors. Infusion at low doses causes dilation of smooth muscles in renal, mesenteric, and coronary arteries, leading to an increase in diuresis[144,145] though this therapy remains highly controversial.[146]

Milrinone

Through inhibition of cAMP breakdown, the phosphodiesterase inhibitors bypass the beta-receptor pathway. Milrinone, related to amrinone (which fell into disfavor because of thrombocytopenia), enhances myocardial contractility and has potent vasodilatory effects,[147–149] without thrombocytopenia.[150] Whereas short-term administration may improve myocardial performance and clinical condition in CHF,[149,151] the long-term effects of an oral formulation were discouraging. Specifically, in the PROMISE trial, 1088 class III–IV patients were given milrinone or placebo. There was a 28% increase in mortality in patients treated with milrinone (95% CI 1–61%, $P = 0.038$).[152]

Nevertheless, in those instances when an inotrope is required and selected, the choice of agent may be dictated, at least in part, by concomitant therapy with beta-blockers. In particular, use of milrinone should be strongly considered because the drug bypasses the beta-receptor. Indeed, Lowes and colleagues demonstrated that while dobutamine can bring about a comparable acute increase in cardiac index, it did so only at doses that are not usually used to treat heart failure: 15–20 μg /kg/minute).[153]

Other inotropic agents: a history marked by failure

The list of inotropes (or drugs with both inotropic and other effects) that have failed in clinical trials is large. Interested readers are referred to an earlier iteration of this chapter (second edition) and various clinical reviews for more detailed descriptions.[154,155] The list of drugs includes ibopamine (an orally active dopaminergic agonist), xamoterol (beta-adrenergic blocking and high partial agonist activity), pimobendan (multiple actions including phosphodiesterase [PDE] inhibition), milrinone (oral formulation), vesnarinone (multiple effects) and flosequinon (multiple effects). More recently, levosimendan and enoximone (see below) were extensively studied but also failed in pivotal studies. Although drug development efforts continue, as for example

with the novel drug CK-1827452, the goal of finding an inotropic drug that does not have proarrhythmic effects or increase energy expenditure may prove to be futile.

Levosimendan A calcium-sensitizing agent with properties similar to pimobendan, levosimendan looked very promising from the standpoint of hemodynamics and clinical outcomes in a number of early moderately sized clinical trials.[156–158] The drug and one active metabolite with a prolonged half-life demonstrate a novel mechanism of action: calcium-dependent binding to troponin C, facilitating and prolonging actin-myosin protein cross-bridge formation without an increase in calcium flux or energy requirement. In addition, vasodilation is achieved through smooth muscle cell relaxation. However, in two large multicenter international trials, the outcomes were mixed. While the drug attained its primary novel composite endpoint in the short-term REVIVE study,[159] safety issues including hypotension, ventricular tachycardia and atrial fibrillation were more apparent in the active study arm compared with placebo. In the companion SURVIVE trial in which the drug was compared to dobutamine,[160] there was no difference in survival through 180 days with only a 2% absolute difference between the two treatment groups. In retrospect, it was likely not realistic to expect that an infusion of an intravenous drug during a heart failure hospitalization would result in improved outcomes at 6 months. Currently, the lack of demonstrable efficacy, combined with concerns over safety, have stalled the clinical development program of this novel drug.

Enoximone In several Phase II/III trials, enoximone failed to achieve the primary endpoints. For example, in the EMOTE trial, enoximone did not significantly increase the likelihood of weaning from dobutamine versus placebo though there were favorable trends in time to death or reinitiation of intravenous inotrope. In the pivotal ESSENTIAL trial, the hazard ratio for time to first cardiovascular hospitalization or all-cause mortality was near unity and there were no differences in patient global assessments.[161]

Beta-adrenergic blockade

Clinicians have generally been cautious in using betablockers in patients with CHF, even though investigators in the early 1970s were already proposing a possible beneficial effect of beta-blockers in such cases.[162,163] Rigorous clinical trials data gathered during the last 15 years have incontrovertibly confirmed the beneficial role of betablockers in mild, moderate and severe heart failure.

Hemodynamic and neurohormonal effects

The short-term effects of beta-adrenergic blockade differ markedly from the long-term effects. After IV administra-

tion, there is a rapid reduction in heart rate, contractility, and blood pressure, with ensuing fall in cardiac output.[164–166] Intraventricular volumes, stroke volume, and ejection fraction are unaffected.[164] Beta-blockers with vasodilating properties cause an acute reduction in afterload with reduction in filling pressures.[164–167]

During 1–3 months of treatment, positive diastolic effects have been observed and these effects probably precede full effects on cardiac systolic function.[165,168] During longer-term treatment (3–12 months), beta blockers induce myocardial improvement, as expressed by an increase in ejection fraction, cardiac output, and exercise capacity.[170–174] Eichhorn and colleagues documented decreases in echocardiographically measured indices of left ventricular function during the initiation phase of therapy but improvements thereafter.[171] Similar to ACE inhibitors, beta-blockers attenuate left ventricular remodeling.[169,175–177]

Acute administration of metoprolol causes a reflex increase in peripheral catecholamines without alteration of the transmyocardial gradient.[165] Some studies suggest a beneficial reduction in peripheral norepinephrine level.[178–182] A decrease in renin–angiotensin activity has been noted, while the levels of atrial natriuretic peptides might increase on a short-term basis.[175]

Effects on quality of life and hospitalizations

Studies have demonstrated a reduction of the need for hospitalizations with bisoprolol,[183] metoprolol,[184] and carvedilol,[185] improvement in quality of life[186] and both patient and physician global assessments of heart failure symptoms. However, quality of life scores were not improved in the US carvedilol studies or in the MERIT-HF study.[187–189]

Effects on survival

One of the first studies of beta-blockers in chronic heart failure showed a reduced mortality in patients treated by beta-blockade as compared with historical controls.[162] Not until 1993, when the MDC trial was published, did additional information on clinical outcome become available. This study demonstrated a 34% reduction in the combined endpoint deaths and need for heart transplantation ($P = 0.058$) in 383 patients with idiopathic dilated cardiomyopathy, treated with placebo or metoprolol.[186] A late follow-up of this study showed that this trend was maintained or possibly reinforced, regarding all-cause mortality and actual cardiac transplantations 3 years after randomization.[190] In the CIBIS study, bisoprolol was used in a placebo-controlled trial in 641 patients; overall there was a non-significant reduction in mortality (RR 0.80, 95% CI 0.56–1.15, $P = 0.22$).[191] Data from four pooled carvedilol studies in the USA were combined in an analysis that demonstrated a markedly lower mortality in the carvedilol group (22 of 696 [3.2%] vs 31 of 398 [7.8%] deaths; RR 65%, 95% CI 39–80, $P < 0.01$).[192] However, there was no statistically beneficial effect of carvedilol regarding survival in the smaller Australia–New Zealand trial of 415 patients with chronic heart failure of varying etiology.[193] None of the aforementioned trials was designed to specifically study mortality, and the number of events in each trial was relatively modest.

Subsequently, a series of landmark studies were prospectively designed to test the potential survival benefits of long-term beta-blockade. The first major study was CIBIS-II in which the beta-1 selective antagonist bisoprolol was tested versus placebo in 2647 patients in NYHA III–IV and an ejection fraction of <35.[183] Study drug was initiated at a dose of 1.25 mg/day and was progressively increased to 10 mg/day over 3 months. The study was stopped by the safety committee after a mean follow-up of 1.3 years. All-cause mortality was significantly lower with bisoprolol than with placebo (156 [11.8%] vs 228 [17.3%]; HR 0.66, 95% CI 0.54–0.81, $P < 0.0001$). There were significantly fewer sudden deaths among patients on bisoprolol than in those on placebo (3.6% vs 6.3%; HR 0.56, $P = 0.001$).

In the MERIT-HF trial, metoprolol controlled release/extended release (CR/XL) was compared in 3991 patients with chronic heart failure in NYHA class II–IV and an ejection fraction of <0.40. Background therapy including an ACE inhibitor or an ARB was present in 95% of the patients. Treatment was initiated with metoprolol CR/XL 12.5–25 mg/day and titrated for 6–8 weeks up to target dose of 200 mg/day. This study was also stopped early on the recommendation of the independent safety committee. At a mean follow-up time of 1 year, all-cause mortality was lower in the metoprolol group than in the placebo group: 145 (7.2% per patient-year of follow-up) versus 217 deaths (11.0%) (RR 0.66, 95% CI 0.53–0.81, $P = 0.0009$). There were fewer sudden deaths in the metoprolol CR/XL group than

in the placebo group (79 vs 132; RR 0.59, P = 0.0002) and fewer deaths from worsening heart failure (30 vs 58; RR 0.51, P = 0.0023).[184]

The COPERNICUS trial was performed in 2289 patients with symptomatic chronic heart failure with symptoms at rest or at minimal exertion.[185] Carvedilol was initiated with 3.125 mg ×2/day and titrated to 25 mg ×2/day. There was a significant reduction in all-cause mortality from 190 (18.5% per patient-year) to 130 (11.4%) with a hazard ratio of 0.65 (95% CI 0.52–0.81, P = 0.0001). The effect was consistent among a number of prespecified subgroups. In particular, the outcomes in a high-risk subgroup, defined by multiple antecedent hospitalizations or recent need for intravenous inotrope or very low ejection fraction, were as favorable as in the main study cohort when examined during both early and late follow-up.[194] It is important to note that most if not all of these patients would have been excluded from the early beta-blocker trials (including the US Carvedilol trials).

In a *post-hoc* subgroup analysis of patients in the MERIT-HF study with similar characteristics as the patients in the COPERNICUS trial, including an EF of <0.25 and NYHA class III–IV, there was a comparable reduction in all-cause mortality (45 [11%] vs 72 [18%] deaths; HR 0.61, 95% CI 0.11–0.58, P = 0.0086).[195]

All three large beta-blocker studies (CIBIS-II, MERIT-HF, COPERNICUS) had been stopped early because of clear evidence of benefit. In contrast, in the BEST trial, the effects of the non-selective beta-blocker bucindolol compared with placebo in 2708 patients with CHF in NYHA class III–IV were modest and not statistically significant.[196] Bucindolol was initiated with 3 mg 2×/day and titrated up over 6–8 weeks to 50–100 mg 2×/day. The study was prematurely terminated by the safety committee. Mortality was reduced from 447 deaths to 409 deaths (RR 0.91, 95% CI 0.88–1.02, P = 0.12). In a subgroup analysis, there was a heterogeneous response among groups analyzed. For example, patients with NYHA class IV or ejection fraction below 20% did not appear to benefit. Furthermore, among African Americans there was a 17% excess mortality, suggesting a lack of benefit among these patients. However, these were *post-hoc* analyses and not prespecified endpoints. The analysis has raised interesting questions about the reasons for the lack of a significant overall survival benefit, including the particular drug studied, the dose used and the population under study. Of note, patients at highest risk for mortality had the most marked reductions in plasma norepinephrine levels, paralleling findings with the centrally acting sympatholytic agent moxonidine (see below).

Subsequently, a study of genetic polymorphisms for the beta-1 receptor has suggested that patients homozygos for beta(1)-arg 389 had large and statistically significant reductions in both mortality and the combination of mortality and hospitalizations compared with placebo (38% and 34% respectively). In contrast, carriers of beta(1)-gly 389 had no benefit.[197] This effect is presumably mediated through differences in signal transduction. Whether these observations will translate into meaningful clinical decision making and establish a pharmacogenomic approach to therapeutics remains to be seen.

Further in the SENIORS trial,[198] the beta-1 selective blocker nebivolol, which has the ancillary property of vasodilation mediated through nitric oxide modulation, was evaluated in a heterogeneous older cohort of patients (mean age 76) with 35% having an ejection fraction exceeding 35%. As with other trials, the drug was uptitrated (from 1.25 mg to 10 mg with mean dose of active study drug achieved at 7.7 mg). At a mean follow-up of 21 months, somewhat longer than most placebo-controlled beta-blocker trials, the combined primary endpoint of all-cause mortality or cardiovascular hospitalization was decreased from 35.3% to 31.1% (HR 0.86, 95% CI 0.74–0.99, P = 0.039). However, mortality alone was not statistically impacted (HR 0.88, 95% CI 0.71–1.08, P = 0.21). The mixed picture has many possible explanations, though the population studied most likely explains some, if not all, of the reasons underlying the modest effects.[199]

Comparison of beta-blockers

Given the variability in clinical data and the known differences among the beta-blockers in terms of receptor blockade, half-lives and lipophilicity, it is reasonable to assume that not all drugs in this class are appropriate for patients with heart failure. At present, only three beta-blockers can be recommended (bisoprolol, metoprolol succinate and carvedilol) though an argument can be made for nebivolol. Are there differences among these agents? The data are confined to comparisons of metoprolol tartrate and carvedilol. For example, an early crossover study suggested that there are differences with respect to receptor effects, while long-term clinical effects were comparable.[200]

This issue was further explored in the COMET trial in which carvedilol and metoprolol were compared in 3042 patients with NYHA class II–IV heart failure and a prior admission for cardiovascular reasons. The mean age was 62 years and mean ejection fraction was 0.26 (±0.07). At a mean follow-up of 58 months (longer than in the placebo-controlled trials because both arms received active therapy), the primary endpoint of all-cause mortality was favorably impacted by carvedilol (target dose 25 mg bid) over metoprolol tartrate (target dose 50 mg bid), with a HR of 0.83 (95% CI 0.74–0.93, P = 0.0017). Median survival was 1.4 years longer with carvedilol. There was also a trend toward improvement in the combination of all-cause mortality and all-cause hospitalization.[201]

The results of the trial were widely debated: was this a true difference or an issue related to dose or the formula-

tion of metoprolol? At the very least, the results suggest that the concept of class effect is dubious, especially when COMET is also interpreted in the context of the BEST result which did not parallel the outcomes described for the other major beta-blocker trials.[202–204]

Beta blockers and ACE inhibitors in d*e novo* heart failure: which to start first?

For *de novo* patients with heart failure or for established patients with heart failure who are ACE inhibitor and beta-blocker naïve, it is appropriate to ask which drug should be started first. The CIBIS 3 Trial randomized 1010 patients in open-label fashion to receive bisoprolol or enalapril for 6 months followed by combination therapy from months 6 to 24.[205] The two strategies appeared to be similar when the endpoints of all-cause mortality and all-cause hospitalization were analyzed in blinded fashion. In reality, the trial may not markedly affect practice, largely because of its design. First, beta-blocker trials were all performed in patients with background ACE inhibitor therapy, leading to the common practice of initial initiation of this drug followed by the beta-blocker. Second, *de novo* patients may present with fluid overload, in which case ACE inhibitor therapy is safer as a first line agent. Finally, current guidelines do not advocate a waiting period of 6 months before initiation of combination therapy for heart failure; rather, both the ACE inhibitors and beta-blockers should be used early during initiation of medical therapy.

Beta blockers in the post-MI setting: preventing heart failure

Data from several older large post myocardial infarction trials suggested that beta-blockers would be beneficial when symptoms of heart failure are present.[206–208] These findings were first extended prospectively in the CAPRI-CORN study, in which carvedilol or placebo was given to 1959 patients with a recent myocardial infarction and signs of left ventricular dysfunction (EF <40%)[209] in a study design conceptually similar to SAVE, AIRE, TRACE and EPHESUS. There was no effect on the primary endpoint of mortality or cardiovascular hospitalization (HR ratio 0.92, 95% CI 0.80–1.07), but there was a statistically significant reduction in all-cause mortality with 166 (15%) versus 151 (12%) deaths (HR 0.77, 95% CI 0.60–0.98, $P = 0.03$). The risk reduction was of similar magnitude compared with previous post myocardial infarction trials with beta-blockers.

Clinical perspective: drug titration and intolerance

Due to initial negative inotropic effects, treatment with beta-blocker requires a titration procedure. Experience from the clinical trials suggests that it is possible to initiate drug therapy with high tolerability. Patients with both marked hypotension and tachycardia, and/or expressing severe decompensation, may not tolerate beta-blockers.

BOX 47.8 Documented value of beta-blockers

Proven indication: always acceptable Level A
To improve long-term survival in patients with mild to severe heart failure
To improve cardiac function and symptoms in patients with symptomatic chronic heart failure, already on conventional treatment with ACE inhibitors (or ARBs), diuretics or digitalis
To improve outcomes in patients with acute myocardial infarction and left ventricular dysfunction with or without symptomatic heart failure
Symptomatic treatment of patients with heart failure who do not tolerate ACE inhibitors

Acceptable indication but of uncertain efficacy and may be controversial Level B
Symptomatic heart failure from diastolic dysfunction

Not proven: potentially harmful (contraindicated) Level C
Acute decompensated heart failure
CHF with pronounced hypotension and/or bradycardia

Clinical euvolemia remains critical at the time of initiation or dose uptitration. In cases with significant bronchospastic disease, beta-blockers should be used with caution, and a selective beta-blocker would be preferred.

Overall, reports of intolerance have been uncommon in randomized trials, comparable to those of ACE inhibitors, though it is important to note that the trial with the most pronounced mortality effect (the *post hoc* evaluation of data from the US Carvedilol family of trials) had an open-label run-in phase. The low starting doses with different beta-blockers have been: bisoprolol 1.25 mg/day; carvedilol 3.125–6.25 mg 2×/day; metoprolol 12.5–25 mg/day; and nebivolol 1.25 mg/day. Doses are increased every 1–2 weeks, until maintenance doses of full conventional beta-blockade are achieved.

Although resting basal heart rate probably is probably important, it has not been possible to adequately identify responders from non-responders to beta-blocker therapy.

Central nervous system modulators

Moxonidine

Reduction of sympathetic nervous system activity can also be achieved by stimulating receptors within the central nervous system. Studies in this area have been performed with clonidine[210] and moxonidine. Moxonidine has been documented in several Phase II and III trials. In a study over 12 weeks in 97 patients, Swedberg and co-workers demonstrated a significant attenuation of plasma norepinephrine levels.[211] With a sustained-release preparation of moxonidine, a more prolonged and effective reduction of

plasma norepinephrine of the order of 40–50% was achieved within 3 weeks of initiation.[212] However, in a large Phase III trial with moxonidine sustained release (MOXCON), an early increase in death rate and adverse events in the moxonidine SR group led to premature termination of the trial because of safety concerns after 1934 patients had been entered.[213] Final analysis revealed 54 deaths (5.5%) in the moxonidine SR group and 32 deaths (3.1%) in the placebo group. Survival curves revealed a significantly (P = 0.005) worse outcome in the moxonidine SR group. Hospitalization for heart failure, acute myocardial infarction, and adverse events were also more frequent in the moxonidine SR group. This trial terminated the efforts to explore whether CNS inhibition of adrenergic activation could be an alternative to beta-adrenergic blockade in heart failure.

Antiarrhythmic drugs in heart failure

Although progressive pump dysfunction is a common cause of death in heart failure, sudden death is probably the most common reason, and has been considered responsible for 25–50% of all deaths.[214–217] The majority of sudden deaths are due to ventricular arrhythmias[218] rather than primary asystole (though in patients dying of pump dysfunction, terminal bradycardia is common). The issue of antiarrhythmic therapy in heart failure patients has therefore been of major interest.

However, while frequent and complex ventricular arrhythmias may be predictive of sudden death, left ventricular dysfunction is a more powerful predictor.[219] Unfortunately, most antiarrhythmics cause a depression of left ventricular function. Furthermore, these drugs may have proarrhythmic effects, especially in cases of left ventricular dysfunction, prolonged QT and metabolic abnormalities such as hypokalemia and low serum magnesium that may accompany acute or chronic diuretic therapy.

In the landmark CAST study the efficacy of antiarrhythmic drugs in patients with left ventricular dysfunction after myocardial infarction and with complex ventricular arrhythmias was evaluated. Patients who responded with attenuation of arrhythmias after drug testing were randomized to encainide, flecainide or moricizine. The results showed an increase in mortality in patients treated with the first two of these agents.[220]

Subsequently, interest in amiodarone, a class III antiarrhythmic drug with no or little negative inotropic effect, increased. However, despite a promising, albeit mixed set of results in smaller trials,[221–225] the SCD-HeFT trial suggested that the drug had no impact on survival when used for primary prevention of sudden death in patients with left ventricular dysfunction and heart failure.[226]

Similarly, sotalol, a beta-blocker with class III antiarrhythmic properties, has not been found to reduce deaths

from ventricular arrhythmias. On the contrary, a study with the non-beta blocker isoform d-sotalol in postmyocardial patients had to be terminated in advance because of an increased mortality in the sotalol group.[227]

Without question, the most impressive effects on sudden deaths have been found in the large survival studies with beta-blockers. Consistent effects were found with all three agents: bisoprolol, metoprolol, and carvedilol.[183–185] In addition, both aldosterone antagonists (spironolactone and eplerenone) as well as the angiotensin receptor blocker candasartan have been shown to play a role in reduction of sudden death, the former likely mediated in part by protection against hypokalemia.[45,47,228] Implantable cardioverter defibrillators are also widely used for prevention of sudden death from ventricular arrhythmias. The appropriate indications and selection of patients for these therapeutic devices are dealt with elsewhere in this book.

Other pharmacologic approaches

Given the success of ACE inhibitors, beta-blockers and aldosterone antagonists, the search for effective therapies that antagonize the effects of other neurohormones or by extension cytokines and inflammatory mediators that are upregulated in heart failure has been an ongoing focus of drug development. Although the knowledge gained from negative trials can be significant, a plethora of recent studies has not led to meaningful changes for patients. We review data from three classes of drug that have failed to improve clinical outcomes and are not part of the contemporary treatment algorithm for patients with heart failure.

Anti-TNF therapy

Two anti-TNF therapies have failed in clinical studies, despite a wealth of basic, preclinical and early phase human studies that suggested a potential role for the anti-cytokine anti-inflammatory treatment paradigm. In the RENEWAL program, etanercept, a soluble TNF antagonist, was studied in two companion placebo-controlled trials (RECOVER

and RENAISSANCE).[229] The former randomized patients to study drug in two different dosing regimens (25 mg once or twice weekly) versus placebo; the latter evaluated dosing at 25 mg twice or three times weekly. Clinical status, a composite of death, heart failue hospitalization, patient global assessment and NYHA class, was measured. However, the trial was stopped early when the relative risk for the combination of mortality and heart failure hospitalization crossed unity, suggesting a lack of benefit. Another agent, infliximab (a chimeric monoclonal antibody to TNF), was evaluated in advanced (NYHA III–IV) heart failure in two doses versus placebo.[230] A trend toward an increase in a combined endpoint of death or heart failure hospitalization at 28 weeks was observed.

Vasopressin antagonism

Vasopressin antagonists, both V2 and combined V1/V2 antagonists, have been studied. Most clinical data come from tolvaptan, an oral non-peptide V2-receptor antagonist. Preliminary data derived from ACTIV, a Phase II dose-ranging study, demonstrated that tolvaptan elicited a statistically significant change in body weight at all doses examined compared to placebo.[231] However, there were no differences in clinical outcomes such as death or hospitalization though the study was underpowered to detect such a difference.

The lowest dose from ACTIV was selected for EVEREST which randomized patients within 48 hours of admission to receive active drug versus placebo.[232,233] A short-term outcomes trial with endpoints of body weight on day 7 or discharge and scoring on a global visual analog scale (VAS) was embedded in a long-term survival study, as patients were continued on medical therapy on discharge. The endpoints were all-cause mortality (superiority and non-inferiority) and a composite of cardiovascular death or heart failure hospitalization (superiority). In the short-term trial, loss of weight favored tolvaptan, albeit with modest changes. There was no change on the global VAS though relief of dyspnea was greater with tolvaptan on day 1. There were no statistically significant differences in the primary endpoints of the long-term trial. These findings seriously jeopardize the concept that long-term vasopressin antagonism has a role in the management of chronic heart failure.

At least one other vaptan, lixivaptan, another oral non-peptide V2 selective agent[234] is in clinical trials.

Endothelin antagonism

Despite the fact that endothelin and precursors are elevated in heart failure and correlate with prognosis,[235] several endothelin antagonists have been tested and have failed in clinical trials. In particular, both oral bosentan for chronic heart failure[236] and intravenous tezosentan for acutely decompensated heart failure[237] have not improved outcomes. These trials have raised significant questions about therapeutic strategies that target particular neurohor-

mones, especially in light of the failures of other similar drug development programs.[238–240]

Adjunctive therapies

HMG CoA enzyme inhibitors

The HMG CoA enzyme inhibitor class ("statin") has been evaluated as a potential adjunct to heart failure management on the basis of retrospective data.[241] The proposed mechanisms of action include prevention of downstream ischemic events and an anti-inflammatory effect; however, clinically there is now a large prospective trial that has not confirmed the earlier favorable reports. In CORONA, 5011 patients with ischemic cardiomyopathy and NYHA class II–IV heart failure were randomized to receive rosuvastatin 10 mg versus placebo. Over a mean period of 32.8 months, a combined endpoint of cardiovascular death, non-fatal MI and non-fatal stroke was not significantly reduced (HR 0.92, 95% CI 0.83–1.02).[242] A secondary endpoint of cardiovascular hospitalizations was positive with a statistically significant reduction and there were no major safety concerns. The lack of a positive overall finding likely reflects the challenge of interpreting competing risks. In the case of statins, the impact of this class of drug on outcomes related to coronary artery disease is attenuated by the heightened importance of myocardial dysfunction and neurohormonal activation in patients with advanced heart failure. In addition, the lowering of LDL cholesterol may not necessarily be advantageous; the paradoxic observation that low cholesterol levels in chronic heart failure is associated with increased risk[243] is supported by CORONA.

Nevertheless, major questions remained including the possibility that the statins work by preventing ischemic complications in long-term survivors of dilated non-ischemic cardiomyopathy,[244] which was not addressed in CORONA. However, the GISSI-HF trial failed to demonstrate any difference between rosuvastatin and placebo in time to death or the combined endpoint of time to death or hospitalization for cardiovascular causes after 3.9 years of follow-up in over 4500 patients with chronic HF. Of note, there was a slight absolute reduction in mortality risk in patients randomized to receive omega-3 fatty acid supplementation, raising interesting questions about mechanism of action.[245]

Exercise rehabilitation

A large multicenter trial, HF-ACTION, demonstrated that a structured exercise program for patients with heart failure is safe.[246] However, there was only a nonsignificant trend in reduction of mortality or hospitalization due, perhaps in part, to the reduction in adherence to exercise over time. A variety of important secondary endpoints, such as health status as measured by the Kansas City Cardiomyopathy Questionnaire, may provide insight into other long term effects on outcomes.

Heart failure management

Physician or nurse-directed disease management has been increasingly recognized as an important component of heart failure care. Multiple studies have suggested that various interventions, including telemanagement, intensive discharge planning and other multidisciplinary interventions, can reduce overall costs and improve measurable outcomes in the quality of care.[247–251]

Device and surgical therapy

Implantable cardioverter defibrillators and biventricular pacing (cardiac resynchronization therapy)

In addition to a background of pharmacologic therapy, the addition of implantable cardioverter defibrillators (ICD) for primary prevention of sudden cardiac death and cardiac resynchronization therapy for mortality reduction in patients with symptomatic heart failure has dramatically impacted management approaches.[226,252–256] Defining appropriate candidates and providing meticulous longitudinal care are hallmarks of successful therapy, given the high degree of technical complexity, associated costs and impact on patients and patients' families.[257–259] The role of device therapy is covered in detail elsewhere in this book.

Ventricular assist devices

Support with ventricular assist and other circulatory support devices has been an area of considerable focus for the subgroup of patients with medically refractory and often near terminal heart failure. Different kinds of left ventricular mechanical assist devices (LVADs) have been studied for several years and they have been in clinical use since at least the early 1990s.[260] Newer and smaller generations of pumps are under clinical evaluation. They differ in size, flow patterns (centrifugal versus axial flow), method of implantation, durability, and intended clinical use (cardiogenic shock, post cardiotomy shock, bridge to transplant and destination). Long-term effects have been unclear.

In REMATCH (Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart failure), 129 patients with a mean age of 67 years and ejection fraction of 0.17 with advanced symptomatic heart failure (NYHA class IV) ineligible for transplantation were randomized to optimal medical management (mostly intravenous inotropic drugs) or LVAD (HeartMate).[261] Kaplan–Meier survival analysis showed a reduction of 48% in the risk of death from any cause in the group that received LVADs as compared with the medical therapy group (RR 0.52, 95% CI 0.34–0.78, $P = 0.001$). The rates of survival at 1 year were 52% in the device group and 25% in the medical therapy group ($P = 0.002$); the rates at 2 years were 23% and

8% ($P = 0.09$), respectively. The frequency of serious adverse events in the device group was nearly 2.4 times (95% CI 1.86–2.95) that in the medical therapy group, with a predominance of infection, bleeding, and malfunction of the device. Quality of life was significantly improved at 1 year in the device group assessed as SF-36 and Beck Depression Inventory but this was an unmatched survivors analysis.

In a more recent study, a newer generation axial flow pump (HeartMate 2) was assessed as a device for bridge to transplant. Three possible favorable outcomes were defined as transplant, recovery or ongoing support. Median survival on pump was 126 days (range 1–600 days) with 68% 1-year survival.[262] Other devices are under investigation; the focus is to define appropriate subgroups and to provide sustained support with a low incidence of thromboembolic and mechanical complications.

Key clinical challenges remain, highlighted by a report by Yacoub and colleagues in which the viability of LVAD weaning was demonstrated in a series of patients with non-ischemic cardiomyopathy at a mean of 320 ± 186 days of support facilitated by the use of the beta-2 agonist clenbuterol.[263] Of 15 patients examined, 11 were weaned; there was one death within 24 hours. To what degree this study has applicability to patients with long-standing advanced heart failure is not clear, nor is the durability of the recovery.

These studies demonstrate the viability of mechanical support and the fact that LVADs have the potential to prolong life and improve quality of life in severe heart failure. Based on REMATCH, treatment effect is limited in time although since publication of the trial results, refinements in the technology, patient selection and surgical technique have occurred. Important questions will require further study, including the degree to which long-term durability can be achieved, the identification of patients with a likelihood of recovery, the durability of that recovery, and cost-effectiveness.

Other surgical options

There are several surgical approaches to heart failure including revascularization, left ventricular reconstruction, cardiomyoplasty, constraining devices, mitral valvular repair and heart transplantation. Most of these techniques have not been subjected to rigorous evaluation in clinical trials, reflecting at least in part the difficulties inherent in defining control groups in surgical intervention trials.[264–266]

Heart failure with preserved left ventricular function

The evidence base for heart failure with preserved LV function is limited, reflecting uncertainties about the underly-

ing heterogeneous pathophysiology, difficulties with trial design including standardization of definitions and endpoints, and lack of focused interest by industry. Nevertheless, recent trials have provided some important insight into several treatment options.

In the DIG trial, a subgroup of 988 patients had ejection fractions greater than 45%. Treatment with digoxin did not impact mortality but as in the main study group, hospitalizations were reduced by study drug. As mentioned in the section on angiotensin receptor blockers, candesartan did not impact mortality in CHARM-Preserved but hospitalizations were reduced.[127] Specifically, the composite primary endpoint of cardiovascular death or admission to hospital for CHF occurred in 22% of patients treated with candesartan and 24% of patients on placebo (HR 0.89, 95% CI 0.77–1.03, P = 0.118). The minor difference was driven entirely by a reduction in hospitalizations which, taken alone, reached statistical significance. A second large ARB trial, i-PRESERVED with irbesartan, failed to demonstrate a salutary effect of irbesartan versus placebo in over 4100 patients over the age of 59 with HF symptoms and left ventricular ejection fraction of at least 45%. The primary endpoint (a composite of death from any cause or hospitalization for HF, myocardial infarction, unstable angina, arrhythmia or stroke) was associated with a hazard ratio that was near unity.[267]

In the PEP-CHF study, patients with a diagnosis of heart failure treated with diuretics but demonstrating essentially preserved LV systolic function (EF 64% and 65% in placebo and active study arms respectively) were randomized to receive perindopril 4 mg or placebo for a period of at least 1 year. The cohort was elderly (mean age 76), predominantly female (55%) and hypertensive (prior hypertension in 79% and mean SBP at randomization approximately 139 mmHg). A high withdrawal rate at 1 year with crossover to open-label ACE inhibitor reduced the power of the study, though when analyzed at 1 year, the composite endpoint of all-cause mortality and unplanned heart failure hospitalization approached statistical significance, driven largely by a reduction in hospitalizations.

In the SENIORS trial with a novel beta blocker nebivolol,[198] approximately 35% of study patients had an ejection fraction over 35%; a proportion of these likely had preserved LVF. The effect on the primary endpoint of all-cause mortality or cardiovascular hospitalization was similar to the cohort with lower EFs; that is, ejection fraction did not appear to modify the effect of nebivolol. Nevertheless, the endpoint was largely driven by the reduction in hospitalizations.

What can one conclude about these trials and treatment approaches to patients with heart failure despite preserved or nearly preserved LVF? As in all patients, risk factor reduction including control of blood pressure is key. This concept has been supported by multiple clinical trials in hypertension among patients at risk for heart failure including the landmark SHEP trial in which antihypertensive treatment in elderly patients with isolated systolic hypertension reduced heart failure events with a dramatic relative risk reduction of 0.51.[268] The potential utility of drugs in the ACE inhibitor, ARB and beta-blocker classes (especially those that have been shown to be effective in systolic heart failure) seems clear. Nevertheless, as outlined, clinical trial results are limited in scope and magnitude and as such do not permit the same high-level recommendations that are currently used in treatment guidelines for patients with systolic heart failure.

Challenges and controversies

Challenges for future clinical trials of therapeutics in heart failure

A key challenge for clinical trialists is the definition of endpoints in trials of both acutely decompensated and chronic heart failure. For the former, surrogates for mortality have not been well defined nor accepted. Although event rates are high, in-hospital mortality is under 5%, meaning that additional and often composite endpoints that include assessment of patient well-being need to be developed. For the latter, ACE inhibitors, beta-blockers and aldosterone blockers have seriously impacted power calculations and hence the ability of conventionally sized trials to detect meaningful differences in mortality. Further, non-pharmacologic trials (i.e. evaluation of devices) are limited in size by the expense and scope of the interventions. The need for trial designs that can pass regulatory requirements in the absence of survival endpoints is pivotal.

Heart failure monitoring

Acute
The role of invasive hemodynamic monitoring during hospitalization for decompensated heart failure was critically evaluated in the ESCAPE Trial in which 433 patients across 26 sites were randomized to receive usual clinical care or care supplemented by the placement of a pulmonary artery catheter.[269] Inotropic therapy was discouraged but not proscribed. The primary endpoint was days alive outside the hospital which did not differ between the two groups (HR 1.0); there were more adverse events in the group treated with the invasive approach. These results suggest that most patients can be managed without invasive hemodynamic monitoring in the acute setting.

Chronic
Multiple technologies have been considered for remote monitoring of patients with chronic heart failure, many using telemonitoring.[270–272] The range of options is significant from simple weight scales[273] to biomarkers[274] to inva-

sive physiologic monitors.[275] As a whole, the data have not been consistent or convincing.

For example, the use of the natriuretic peptides (BNP/NT-proBNP) for guiding treatment during follow-up has been supported by observational experience from large clinical trials[276] and more focused primary data from small controlled trials.[277] In the latter, 220 patients were randomized to control or treatment modifications based on target BNP concentrations <100 pg/mL. During a 15-month follow-up the primary endpoint of death or admissions for worsening heart failure was significantly reduced in the BNP-guided group. However, this group had an increase in non-heart failure-related admissions, largely negating the presumptive benefit of biomarker-based treatment. Further, the limited study size and open design make the results difficult to interpret. Other randomized trials are ongoing.[278]

In the example of chronic hemodynamic monitoring, the largest study to date using an implantable monitor of pulmonary capillary wedge pressure (COMPASS-HF) did not reach its primary endpoint.[279] The fact that outcomes were not favorably impacted raises questions about the underlying hypothesis that an improved hemodynamic profile is a key therapeutic goal. Nevertheless, despite these mixed results, interest remains in defining appropriate types and intensities of monitoring. In that context, it will be necessary to define the nature of clinical decision making in response to fluctuating or worsening markers of heart failure.

Performance measures

The standardization of heart failure care has been a focus of professional societies, health insurers and other stakeholders,[280,281] largely based on the recognition that there is great variability in the quality of care delivered to patients with heart failure.[282] Multiple initiatives have been developed[283] in attempt to improve quality. At the same time, the performance measures used to gauge quality may not in fact reflect outcomes,[284] an issue of enormous importance if hospitals and providers are to be judged by process measures related to the delivery of heart failure care.

Conclusion

In the pharmacologic treatment of CHF there are two main classes of drugs – ACE inhibitors and beta-blockers – with solid and consistent documentation for reduction of morbidity and mortality. Furthermore, aldosterone antagonists and hydralazine/nitrate in combination have demonstrated efficacy in defined subgroups. Several ARBs have a role, most clearly as a substitute when patients are not tolerating an ACE inhibitor (Table 47.1) and in some patients as add-on therapy. Ancillary approaches continue to be defined. The reader is also referred to the major published guidelines in Europe and the USA for additional

Table 47.1 Key recommendations

Aim of treatment	Class of drug	Level of evidence
Symptomatic improvement of congestion, improvement of exercise capacity	Diuretics	**Level A**
Reduction of mortality in mild to moderate heart failure	ACE inhibitors Beta-adrenergic blockers	**Level A** **Level A**
Reduction of mortality in severe heart failure	ACE inhibitors Beta-adrenergic blockers Spironolactone	**Level A** **Level A** **Level A**
Reduction of mortality in patients not tolerating an ACE inhibitor	ARBs	**Level A**
Reduction of morbidity and symptoms in mild–severe heart failure	ACE inhibitors Beta-adrenergic blockers ARBs Spironolactone Digoxin	**Level A** **Level A** **Level A** **Level A** **Level A**
Short-term improvement of symptoms in patients with severe CHF	Non-digitalis inotropic drugs	**Level B**
Surgical treatment of end-stage CHF	Cardiac transplantation	**Level B**
Bridging towards heart transplantation in terminal heart failure	Left ventricular assist device	**Level B**

background and classification of standard approaches to HF management.[285,286]

The challenges for the next decade are manifold. They include the need to: better define subgroups that benefit the most from different drug combinations; fulfill the mandate to ensure dissemination of the findings of clinical trials into practice; and develop appropriate metrics to gauge physician competencies in the treatment of patients with heart failure. In addition, the need to define strategies that can be used to translate and effectively implement clinical practice guidelines is significant, as many patients are not offered comprehensive contemporary treatments. Heart failure care must be structured, given its complexity and the importance of drug titration and close clinical follow-up. Finally, given an increasing prevalence, deleterious effects on patient morbidity and mortality and pronounced impact on the finances of healthcare systems, we need to continue to pursue a greater understanding of the mechanisms underlying cardiac failure and the methods that can be applied in order to prevent the development of and progression to symptomatic end-stage disease.

48 Acute myocarditis and dilated cardiomyopathy

Leslie T Cooper Jr and Oyere K Onuma
Mayo Clinic College of Medicine, Rochester, MN, USA

Introduction and historic perspectives

"Is the inflammation of the heart always very sharp and acute, or does it not sometimes affect an insidious, hidden progress and which it appears, if not impossible, at least very difficult to distinguish?" Jean Corvisart, personal physician to Napoleon Bonaparte[1]

Myocarditis is usually defined by histologic criteria as inflammation of the myocardium, often with damage or injury to cardiac myocytes. The histologic Dallas criteria allow for two categories of myocarditis: active, in which myocyte damage is evident, and borderline, in which a cellular inflammatory infiltrate is not associated with myocyte injury or necrosis (Plate 48.1).[2] However, the diagnosis of myocarditis is frequently presumed if a compatible clinical scenario is associated with new abnormalities on non-invasive cardiac imaging and/or elevated serum biomarkers of cardiac injury. Clinically, myocarditis most often presents as an acute or occasionally fulminant illness with new-onset dilated cardiomyopathy (DCM). However, manifestations range from subclinical disease to sudden death, new-onset atrial or ventricular arrhythmias, complete heart block or an acute myocardial infarction-type syndrome. The known causes of myocarditis are as varied as the disease presentations and include infectious causes (including coxsackie B virus, parvovirus B19, adenovirus, *T. cruzi*), toxic agents, and cardiac manifestation of a systemic autoimmune disease (Box 48.1).

DCM is a common phenotype that results from many forms of myocardial injury and is both an acute and long-term consequence of viral myocarditis.[3] Usually a careful family history and a history of an antecedent viral prodrome in the weeks prior to cardiac symptoms permit the clinical distinction between familial and postviral cardiomyopathy. However, a small pedigree may confound the assessment of an inherited predisposition to DCM and inherited abnormalities of cytoskeletal proteins may actually predispose to more severe viral myocarditis, as is the case with Duchenne's muscular dystrophy and coxsackie B virus infection, both of which affect dystrophin. Therefore a clear distinction between primarily familial and primarily acquired DCM is not always possible.

This chapter focuses on primary DCM in which histologic evidence of myocarditis or persistent viral infection is present. In the USA, the estimated prevalence of all forms of DCM is 36.5 cases per 100 000.[4] DCM is important because it constitutes the leading cause (45%) of heart transplantation in the United States.[5] In a review of 1230 cases of initially unexplained DCM, only 9% were thought to be due to myocarditis when the Dallas criteria were applied.[6] Although standard histologic criteria for myocarditis are usually absent in chronic DCM, other markers of inflammation including ICAM, VCAM, and major histocompatability complex (MHC) antigen expression are present in up to 40% of cases.[7] Thus the prevalence of myocarditis in DCM varies widely depending on the histologic criteria used to establish the diagnosis.

Incidence, natural history and prognosis of acute myocarditis

The incidence of myocarditis in the community is unknown because many cases probably have minimal if any acute symptoms, and escape diagnosis only to present months or years later with a non-ischemic DCM. The incidence may also be underestimated due to the highly variable presentation of the disease which ranges from subclinical to fulminant heart failure, and includes sudden death, syncope, and acute myocardial infarction-like syndromes. Furthermore, the histologic diagnosis of patients with acute clinical symptoms and suspected myocarditis is confounded by a lack of sensitivity in the traditional Dallas Criteria.[8] For example, in the Myocarditis Treatment Trial, which used the Dallas criteria for study entry, only 10% of 2333 patients

Infectious
- Viral – common
  - Parvovirus B19, increasing since 1994
  - Adenovirus, most common 1995 to 2005
  - Enterovirus (coxsackie B), decreasing since 2004
  - HCV (in Japan)
  - Human immunodeficiency virus
- Bacterial – consider in immunosuppressed hosts
  - Mycobacteria
  - Streptococcal sp.
  - *Treponema palladum*
  - *Borrelia burgdoferi*
- Fungal – consider in immunosuppressed hosts
  - *Aspergillus*
  - *Candida*
  - *Cryptococcus*
  - *Histoplasma*
  - *Coccidioides*
- Protozoal
  - *Trypanosoma cruzi*

Toxins
- Cocaine
- Anthracyclines
- Imatimib mesylate
- Interleukin-2

Hypersensitivity
- Clozapine
- Methyldopa
- Cephalosporins
- Penicillins
- Tricyclic antidepressants

Systemic/autoimmune
- Systemic lupus erythematosus
- Inflammatory bowel disease
- Giant cell myocarditis
- Sarcoidosis (idiopathic granulomatous myocarditis)
- Takayasu's arteritis
- Hypereosinophilic syndrome
- Endomyocardial eosinophilic diseases

Figure 48.1 Transplant free survival of lymphocytic myocarditis versus giant cell myocarditis. Kaplan–Meier curves showing the duration of transplant-free survival from the onset of symptoms in 63 patients with giant cell myocarditis and 111 patients with lymphocytic myocarditis from the Myocarditis Treatment Trial. *P* < 0.001 by log-rank test. (Reproduced with permission from Cooper *et al*.[15])

with suspected myocarditis and recent-onset DCM met these criteria.[9] The rate was somewhat higher at 17% in the European Study of Epidemiology and Treatment of Cardiac Inflammatory Diseases Study (ESETCID), which used less restrictive immunohistologic criteria.[10]

The prognosis in myocarditis is variable and depends partly on clinical, hemodynamic, and histologic variables. Presentation with syncope, heart block on EKG, lower left ventricular ejection fraction, and higher pulmonary artery pressures are associated with shorter transplant-free survival.[11] In the series from Massachusetts General Hospital, Dallas Criteria myocarditis was associated with shorter

transplant-free survival than borderline myocarditis.[12] In a Mayo Clinic series from the early 1990s by Grogan *et al*, the five-year survival in acute myocarditis was 56%, comparable to survival in patients with idiopathic DCM without myocarditis.[13] Immunoperoxidase based diagnostic criteria have higher sensitivity than the Dallas criteria and may have prognostic value.[14]

Histologic patterns that influence survival are limited to several uncommon disorders including giant cell myocarditis (GCM), acute necrotizing eosinophilic myocarditis, and cardiac sarcoidosis (CS).[15] The five-year transplant-free survival rate in GCM is less than 20% (Fig. 48.1).[16] In a large clinical series, subjects with either GCM or CS had a worse transplant-free survival than those with lymphocytic myocarditis.[17] Paradoxically, patients with the clinical pathologic entity of fulminant lymphocytic myocarditis, although severely ill at presentation with marked hemodynamic compromise, are more likely to recover than those with acute (2 weeks to 3 months duration) myocarditis who do not have a distinct viral prodrome.[18]

A few serologic and imaging biomarkers have been associated with poor clinical outcome. Higher concentrations of serologic markers such as Fas ligand (FasL) and interleukin 10 (IL-10) may predict increased mortality.[19,20] Right ventricular function on echocardiogram was an independent predictor of death or cardiac transplantation in a study of 23 patients with biopsy-confirmed myocarditis.[21] In this study, multivariate analysis revealed that right ventricular dysfunction as quantitated by right ventricular descent was the most powerful predictor of death or cardiac transplantation. In a separate study, Naqvi *et al* demonstrated that contractile reserve assessed by dobutamine

echocardiography predicted left ventricular functional recovery in 22 patients with new-onset DCM, some of which may have been due to myocarditis.[22]

Pathogenesis of myocarditis

Studies in mouse and rat models of myocarditis have investigated the pathogenesis of autoimmune and viral myocarditis and enhanced our understanding of the relationship between direct viral injury and the host immune response to viral infection. Coxsackie B virus-induced myocarditis (CVB) is thought to progress in three temporal stages:

1 acute myocarditis characterized by viremia and a high fatality rate in animal models

2 subacute myocarditis with lymphocytic infiltrates in the myocardium, rising antibody titers and release of inflammatory cytokines including IL-1-beta, tumor necrosis factor (TNF)-alpha, interferon (IFN)-gamma and IL-2

3 chronic myocarditis characterized by fibrosis, progressive ventricular dilation and heart failure.[3]

It is this third stage of "chronic myocarditis" that is thought to result in "idiopathic" dilated cardiomyopathy.

Myocardial injury in CVB and encephalomyocarditis virus (ECMV) myocarditis occurs through several mechanisms.[23,24] Viral infection can lead within hours to days to myocyte death and release of sequestered intracellular antigens, which trigger an innate and adaptive immune response in the myocardium. Antibodies that cross-react with CVB, human cardiac myosin, and the beta-adrenergic receptor have been observed in cases of myocarditis. Cytokines, such as TNF-alpha, and autoantibodies associated with this inflammatory reaction impair cardiac myocyte contractility, and released cellular products such as major basic protein (MBP) can lead directly to myocyte cell death. T cell-deficient mice show a muted response or progression to myocarditis as compared to normal mice.[25] Long-term myocardial damage may also occur through an apoptotic mechanism, especially in the absence of active inflammation. In the Lewis rat model of autoimmune myocarditis, T cells also are a key mediator of myocardial damage. Myocardial damage may occur independently of any immune reaction. For example, protein products of the enteroviral genome, including viral protease 2a, can cleave host proteins, including dystrophin, and lead to cardiomyopathy.[26,27] Environmental variables such as selenium deficiency can affect viral virulence and individual susceptibility to cardiotopic viral infection.[28,29]

Genetic susceptibility to myocarditis is strongly suggested by animal models in which spontaneous myocarditis occurs.[30] A genetic component of DCM has also been well characterized in studies of familial association and linkage studies. Twenty to 40% of patients with DCM have a first-degree relative with some degree of left ventricular

dysfunction.[31] A positive association of DCM with the MHC HLA DR4 has been identified in several independent studies. However, specific genes that predispose patients to myocarditis have not yet been identified.

Clinical presentation and diagnosis

The clinical presentation in myocarditis varies from asymptomatic ECG findings to cardiogenic shock or even sudden death. Although a non-specific viral prodrome with fevers, myalgias, and respiratory or gastrointestinal symptoms is classically associated with myocarditis, the published rates of reported symptoms are highly variable.[32] Cardiac symptoms include fatigue, decreased exercise tolerance, palpitations, precordial chest pain, and syncope. Of the 3055 patients in the ESETCID study, 72% had dyspnea, 33% had chest pain, and 18% had arrhythmic events.[10] Most studies of acute dilated cardiomyopathy and suspected myocarditis have a slight a male predominance. For example, 62% of the 111 patients enrolled in the Myocarditis Treatment Trial were male.[9]

Cardiac enzyme elevations are seen in a minority of patients with acute myocarditis and can help confirm the diagnosis. Standard markers of myocardial damage including troponin-I have a high specificity (89%) but limited sensitivity (34%) in the diagnosis of myocarditis, especially with a shorter duration (less than four weeks) of symptoms.[33] Clinical and experimental data suggest that cardiac troponin-I is increased much more frequently than creatnine kinase MB (CK-MB) in patients with myocarditis.[34] Other circulating biomarkers including cytokines, complement components and anti-heart antibodies have not been prospectively validated and are not in widespread clinical use.

Troponin I or T should be measured in suspected acute myocarditis (**Class I, Level C**).

The ECG in acute myocarditis may show sinus tachycardia with non-specific ST segment and T-wave abnormalities. Occasionally, the ECG changes are suggestive of an acute myocardial infarction and may include ST segment elevation in two or more contiguous leads (54%), widespread ST segment depressions (18%) and pathologic Q-waves (18–27%).[35] In a small proportion of patients, various degrees of heart block may occur. In the Myocarditis Treatment Trial, pacemaker implantation occurred in approximately 1% of subjects. Ventricular arrhythmias may also be present, but occur more commonly in cardiac sarcoidosis and giant cell myocarditis.[36]

An ECG should be performed in suspected acute myocarditis (**Class I, Level C**).

The most common echocardiographic features of acute myocarditis are unfortunately not specific; however, echocardiography is useful to exclude other causes of acute

heart failure. Echocardiographic patterns of dilated, hypertrophic, restrictive, and ischemic cardiomyopathies have been described in histologically proven myocarditis. Segmental or global wall motion abnormalities can simulate myocardial infarction in myocarditis.[37] In the Myocarditis Treatment Trial, increased sphericity and left ventricular volume occurred in acute, active myocarditis. Left ventricular cavity size may be normal in very early myocarditis and increase over time due to remodeling. Fulminant myocarditis may be distinguished from acute myocarditis by echocardiographic criteria as suggested by Felker *et al.*[38] These authors performed echocardiography on 11 fulminant and 43 acute myocarditis patients at presentation and after six months. Patients with fulminant myocarditis had near normal LV diastolic dimensions with increased septal thickness at presentation, while those with acute myocarditis had increased diastolic dimensions but normal septal thickness.

An echocardiogram should be performed in suspected acute myocarditis (**Class I, Level C**).

Due to its availability and low risk, cardiac magnetic resonance imaging (CMR) is being used with increasing frequency as a diagnostic test in suspected acute myocarditis and may be used to localize sites for endomyocardial biopsies.[39,40] CMR may also be useful to differentiate ischemic from non-ischemic cardiomyopathy. McCrohon *et al* performed gadolinium-enhanced CMR in 90 patients with heart failure and LV systolic dysfunction, of whom 63 had idiopathic DCM. Subendocardial or transmural enhancement was seen in ischemic cardiomyopathy. In contrast, the DCM group had three patterns of enhancement: no enhancement, myocardial enhancement indistinguishable from the patients with CAD and patchy or longitudinal mid wall enhancement.[41] Results from similar studies suggest that diffuse and/or heterogeneous involvement with combined enhancement is highly suggestive of myocarditis. Histopathologic evaluation of biopsies directed by contrast CMR with delayed enhancement by Mahrholdt *et al* demonstrated active myocarditis in 19 of 21 patients. In contrast, only one in seven patients showed active myocarditis in biopsies guided by non-myocardial delayed enhancement (MDE) CMR.[42] Serial CMR using T1-weighted images with gadolinium have also been used to visualize the myocardial injury in myocarditis and track its progression.[43] The prognostic value of CMR to predict future cardiac events in acute myocarditis is under investigation.

CMR can be useful in suspected acute myocarditis (**Class IIa, Level C**).

The gold standard for the diagnosis of myocarditis is histopathology on endomyocardial biopsy (EMB). The histopathologic classification called the Dallas criteria[44] was used in the Myocarditis Treatment Trial and is widely cited, but the average incidence of positive right ventricular biopsy findings in acute dilated cardiomyopathy is only around 10%.[9,45] This is likely due to sampling error secondary to the patchy nature of myocardial inflammation[46] and interobserver variability.[8,47] Newer diagnostic criteria that rely on immunoperoxidase techniques are coming into broader clinical use. Expression of MHC antigens is a more sensitive marker than the Dallas criteria for myocardial inflammation, and this is detected using immunoperoxidase-based stains for HLA-ABC and HLA-DR antigens. Indeed, the sensitivity and specificity of MHC expression for detecting biopsy-proven myocarditis has been reported as high as 80%. Viral genomes can be detected using molecular methods like the polymerase chain reaction (PCR) to identify viral RNA and DNA from endomyocardial biopsy samples. The clinical value of viral genome analysis, immunoperoxidase stains, and transcriptome based biomarkers is being evaluated in ongoing clinical trials.

Currently, the risks of cardiac perforation and death associated with EMB preclude its routine use in the diagnosis of myocarditis. The 2007 AHA/ACCF/ESC scientific statement on the role of endomyocardial biopsy in cardiovascular disease lists 14 clinical scenarios in which EMB may be considered, and gives a class I recommendation to two of these 14 (Table 48.1).[49]

Management

Myocarditis presenting as acute DCM

Myocarditis should be treated according to the guidelines for the presenting clinical syndrome. For example, acute DCM should be managed according to the current AHA/ACCF, ESC, and HFSA guidelines.[48–51] The mainstay of therapy for acute myocarditis is supportive therapy for left ventricular dysfunction. Most patients will improve with standard heart failure regimen that includes ACE inhibitors or angiotensin receptor blockers, beta-blockers such as metoprolol or carvedilol, and diuretics, if needed. In patients who deteriorate despite optimal medical management, case series suggest a role for mechanical circulatory support such as ventricular assist devices or extracorporeal membrane oxygenation (ECMO) as a bridge to transplantation or recovery.[52,53]

Heart failure therapy

Angiotensin-converting enzyme inhibitors/angiotensin receptor blockers (ACEI/ARBs)

Although the utility of ACEI/ARBs in the treatment of symptomatic and asymptomatic heart failure with left ventricular dysfunction is well established, evidence for their specific use in myocarditis is limited to studies in animal models. Early treatment with captopril, starting on day 1

Table 48.1 The role of endomyocardial biopsy in 14 clinical scenarios

Scenario number	Clinical scenario	Level of evidence (A,B,C)	Class of recommendation (I, IIa, IIb, III)
1	New-onset heart failure of less than 2 weeks duration associated with a normal size or dilated left ventricle and hemodynamic compromise	B	I
2	New-onset heart failure of 2 weeks to 3 months duration associated with a dilated left ventricle, and new ventricular arrhythmias, Mobitz type II second- or third-degree heart block, or failure to respond to usual care within 1–2 weeks	B	I
3	Heart failure of greater than 3 months duration associated with a dilated left ventricle and new ventricular arrhythmias, second- or third-degree heart block, or failure to respond to usual care within 1–2 weeks	C	IIa
4	Heart failure associated with a dilated cardiomyopathy of any duration associated with suspected allergic reaction in addition to eosinophilia	C	IIa
5	Heart failure associated with suspected anthracycline cardiomyopathy	C	IIa
6	Heart failure associated with unexplained restrictive cardiomyopathy	C	IIa
7	Suspected cardiac tumors except for typical myxomas	C	IIa
8	Unexplained cardiomyopathy in children	C	IIa
9	New-onset heart failure of 2 weeks to 3 months duration associated with a dilated left ventricle, without new ventricular arrhythmias, Mobitz type II second- or third-degree heart block, and that responds to usual care within 1–2 weeks	B	IIb
10	Heart failure of greater than 3 months duration associated with a dilated left ventricle, without new ventricular arrhythmias, or Mobitz type 2 second- or third-degree heart block, and that responds to usual care within 1–2 weeks	C	IIb
11	Heart failure associated with unexplained hypertrophic cardiomyopathy	C	IIb
12	Suspected AVRD/C	C	IIb
13	Unexplained ventricular arrhythmias	C	IIb
14	Unexplained atrial fibrillation	C	III

AVRD/C, arrhythmogenic right ventricular dysplasia/cardiomyopathy
Reproduced with permission from Cooper et al.[49]

of infection, has beneficial effects in murine models of myocarditis in the reduction of inflammatory infiltrates, myocardial necrosis and calcification.[54] In a second study by Rezkalla et al, delayed captopril therapy, initiated 10 days after viral inoculation, was still found to result in a reduction of left ventricular mass and liver congestion.[55]

Studies of the ARB candersartan in a murine model of viral myocarditis showed a significant improvement in seven-day survival (60% versus 18%) in the candersartan group as compared to controls.[56] Studies in angiotensin receptor 1 (AT1) knockout mice demonstrate that AT1 signaling is important in the pathogenesis of viral cardiomyopathy through an NF-kB dependent pathway.[57] However, there are no specific studies of ACEI/ARBs in clinical myocarditis; therefore the applicability of these findings in human disease remains unknown. ACEI/ARBs should be used in patients with myocarditis and LVEF less than 40% (**Class I, Level C**).

Beta-adrenergic receptor blockers

The use of beta-blockers in murine models of myocarditis has been studied in acute, subacute and chronic models of myocarditis. In a murine model of coxsackie myocarditis using the BALB/C and DBA/2 strains of mice, carteolol, a non-selective beta-blocker, was shown to improve histopathologic measures including cell necrosis, cellular infiltration, reduction in wall thickness, fibrosis and clacification.[58] A previous study comparing metoprolol with saline in a murine model of acute coxsackie myocarditis resulted in increased mortality (60% vs 0%) in metoprolol-treated mice with an accompanying increase in the viral replication and myocyte necrosis.[59] Metoprolol treatment was started on the day of viral inoculation and continued for 10 days. These studies thus suggest that beta-blocker therapy, while useful in the management of chronic heart failure, may be harmful if initiated very early in acute myocarditis. Non-selective beta-blockers may be

preferable. As with ACE inhibitors, there have been no trials of beta-blockers in human myocarditis. Recommendations for the use of beta-blockers in myocarditis rely on extrapolation from randomized trials of beta-adrenergic blocking drugs that demonstrated benefit for the treatment of heart failure with decreased left ventricular systolic function.

We recommend that beta-blockers that have been shown to improve mortality and heart failure symptoms should also be used in that subset of heart failure patients with myocarditis in accordance with current heart failure guidelines (**Class I, Level C**).

Aldosterone inhhibitors

In the Randomized Aldactone Evaluation Study (RALES), 1663 patients with severe heart failure, of whom 46% were non-ischemic in etiology, NYHA class III–IV and EF <35% were randomized to aldactone or placebo. The majority of the patients were concurrently on loop diuretics, ACE inhibitors and digitalis. There was a 30% reduction in the primary endpoint of all-cause mortality in the aldactone groups versus placebo, a 35% reduction in the rate of hospitalizations for worsening heart failure as well as a significant improvement in the symptoms of heart failure.

The risk reduction seen in reduction in hospitalizations may be related to the role of the aldosterone receptor antagonist in preventing myocardial fibrosis and decreasing sodium retention.[60] Aldosterone antgonists have not been studied in experimental or human myocarditis.

We recommend that aldosterone inhibitors that have been shown to improve mortality and heart failure symptoms should also be used in that subset of heart failure patients with myocarditis in accordance with current heart failure guidelines (**Class I, Level C**).

Digoxin

In a mouse model of viral myocarditis, digoxin worsened myocardial injury and increased mortality, possibly by increasing the production of proinflammatory cytokines in the myocardium.[61] There are no published studies evaluating digoxin for the specific treatment of myocarditis in human disease.

Therefore digoxin should be reserved for that subset of heart failiure patients with myocarditis who also have NYHA class II symptoms and other criteria set forth in the current heart failure guidelines (**Class I, Level C**).

Calcium channel blockers

In a study by Wang *et al*, amlodipine improved survival, heart weight to body weight ratio and the histopathologic grades of myocardial lesions in a murine model of viral myocarditis.[62] Diltiazem or verapamil may be used for rate control on patients with atrial fibrillation in whom beta-blockers have proven inadequate or are not tolerated.

There are no published data regarding the benefit or risk of calcium channel blockers in human myocarditis. Therefore, their use should be limited to other clinical indications for which their benefit has been demonstrated that might co-exist or develop concurrently with acute myocarditis, such as supraventricular tachycardia or hypertension. The lack of published data does not allow a recommendation for or against their use in acute myocarditis.

Specific therapy

Antiviral treatment

Data regarding the use of antiviral agents for the treatment of acute myocarditis is limited to animal models and small case series. In murine viral myocarditis, antiviral therapy with ribavarin and interferon-alpha was found to reduce the severity of myocardial lesions and mortality.[63,64] However, antiviral therapy was only effective if applied at the time of inoculation with the virus or soon thereafter, a timeline that is not practical in human cases of acute myocarditis. Antiviral therapy has been used in one case series of fulminant myocarditis[65] and therefore could be considered in laboratory-acquired cases or possibly institutional outbreaks. However, most cases of fulminant and acute myocarditis have a high rate of spontaneous improvement and in the absence of any human data, antiviral therapy cannot be recommended for the treatment of acute myocarditis at this time (**Class III, Level C**).

Antiviral therapy may be best utilized in patients with viral persistence in the setting of chronic dilated cardiomyopathy. In a study by Kuhl *et al*, 22 patients with persistent LV dysfunction, symptomatic heart failure and evidence of myocardial persistence of enteroviral or adenoviral genome by PCR were treated with beta-interferon for 24 weeks.[66] Viral clearance/eradication was achieved in all patients after antiviral treatment, with a significant increase in LV function and a significant decrease in LV dimensions in the treatment group. There have also been reports of treatment of enterovirus-induced cardiomyopathy with interferon-alpha[67]; however, no randomized trials of interferon treatment have been published. Pleconaril is being studied in an onging clinical trial for the treatment of enteroviral myocarditis in children (NCT00031512). An unpublished multicenter trial of beta-interferon for viral cardiomyopathy suggested a benefit for treatment of enteroviral and adenoviral but not parvovirus B19-related cardiomyopathy (**Class IIb, Level C**).

Immunosuppressive treatment

In an early study by Parillo *et al*, subjects with unexplained dilated cardiomyopathy were randomized to treatment

with prednisone (initially 60 mg daily) or to placebo.[68] Subjects were categorized as reactive (patients with fibroblastic or immune deposition on EMB, with a positive gallium scan) or non-reactive if they lacked these features. Although patients in the prednisone group had a statistically larger chance at improvement in LVEF at three months, the increases in EF were small (4.3% in the treatment group) and were not sustained after the steroid dose was lowered at six or nine months. In the Myocarditis Treatment Trial, 111 patients with heart failure of less than two years' duration, histopathologic diagnosis of myocarditis according to the Dallas criteria and LVEF less than 45% were randomized to three treatment groups: prednisone and azathioprine, prednisone and ciclosporin, or placebo. Patients were treated for 24 weeks with concurrent conventional heart failure treatment. In the placebo and combined treatment groups, there was an improvement in the LVEF from an average of 25% to 34% and the combined endpoint of death or transplantation at five years was 56%. There was no significant change in LVEF in treated versus untreated patients and similarly, no significant difference in survival or need for cardiac transplantation between groups. A higher LVEF at baseline, less intensive conventional drug therapy at baseline, and a shorter duration of disease, but not the treatment assignment, were positive independent predictors of the LVEF at week 28.[9] These studies suggest that immunosuppression is not beneficial in the routine treatment of acute DCM due to lymphocytic myocarditis or unexplained DCM (**Class III, Level B**).

A recent meta-analysis of immunosuppression and immunomodulation trials found that trials performed in DCM of less than six months' duration were negative, while those in DCM of greater than six months duration were generally positive due to the large improvement in the placebo groups in subjects with acute myocarditis.[69] For example, in a trial of 84 patients with DCM of less than two years in duration and cardiomyocyte HLA expression on EMB, who were randomized to azathioprine and prednisone or placebo, Wojnicz *et al* showed an improvement in the secondary endpoints of LVEF, NYHA functional class, left ventricular volume and left ventricular end-diastolic diameter.[70] However, there was no difference in cardiac death, hospitalization or readmission rates. Today the use of immunosuppressive drugs for patients on optimal medical management with evidence of ongoing myocardial inflammation and persistent left ventricular dysfunction is controversial, and these should be considered for enrollment in clinical research trials when feasible (**Class IIb, Level B**).

Intravenous immunoglobulin (IVIG)

The antiviral and immunomodulatory effects of IVIG suggest that it might play a role in the management of viral and postviral autoimmune myocarditis. In the Immune

Modulation for Acute Cardiomyopathy (IMAC) trial, patients with recent-onset myocarditis or dilated cardiomyopathy (less than six months) in duration were randomized to IVIG or placebo. Overall, there was an improvement in the LVEF at six months, from 25% to 40% in both cohorts, but there was no significant difference between the treatment group and placebo.[71] A recent systematic review that included IMAC and other smaller studies concluded that there is insufficient evidence to recommend its use in acute myocarditis in adults.[72] Therefore, the routine use of IVIG for acute myocarditis in adults is not recommended (**Class III, Level B**). However, case series suggest that IVIG confers benefit in acute pediatric myocarditis,[73,74] and its use is common in this clinical setting. Furthermore, the role of IVIG in chronic inflammatory cardiomyopathy remains to be determined.

Non-steroidal anti-inflammatory drugs

In several murine models, non-steroidal anti-inflammatory drugs (NSAIDS) have not shown any efficacy in the treatment of myocarditis, despite histologic evidence of inflammatory infiltrates in myocarditis. In fact, they may lead to increased mortality by exacerbating the inflammatory process in the myocardium and increasing the virulence of the infectious agent.[75–77]

The use of NSAIDS should be avoided in acute myocarditis (**Class III, Level C**).

Antiarrhythmics

Given the occurrence of both tachyarrhythmias and bradyarrhythmias in patients with myocarditis, patients with acute myocarditis should be hospitalized for ECG monitoring. Therapy for arrhythmias is supportive since they usually resolve after the acute phase of the disease. The 2006 ACC/AHA/ESC guidelines for the management of arrhythmias recommended that acute arrhythmic emergencies be managed conventionally in the setting of myocarditis.[78] Further recommendations for the management of arrhythmias in myocarditis are as follows.
- Temporary pacemakers should be considered in acute myocarditis for patients with symptomatic bradycardia or complete heart block (**Class I, Level C**).
- For patients with sustained supraventricular tachycardias (SVT) or symptomatic NSVT and acute myocarditis, the restoration of sinus rhythm is the recommended approach and antiarrhythmic therapy may be appropriate (**Class IIa, Level C**).
- For patients with life-threatening ventricular arrhythmias, ICD therapy may be appropriate if they are *not* in the acute phase of myocarditis and are on optimal medical therapy with reasonable prognosis for recovery of functional status (**Class IIa, Level C**).

- ICD implantation is *not* recommended for patients with acute myocarditis (**Class III, Level C**).

When antiarrhythmic therapy is indicated, amiodarone or dofetilide should be considered. Due to their proarrhythmic and negative inotropic effects, other class I and class III antiarrhythmics should be avoided in patients with acute myocarditis.

Mechanical support

In non-randomized case series and case reports, mechanical circulatory support has been shown to be an effective bridge to recovery or to transplantation in fulminant and acute myocarditis.[79,80] (**Class I, Level C**).

Cardiac transplantation

The overall five-year survival rate following cardiac transplantation is about 74%.[5] Although early case series suggested that cardiac transplantation for myocarditis was associated with a poorer survival and an increased risk of rejection, more recent and larger case series suggest that the overall survival for cardiac transplantation for myocarditis is similar to survival for other causes of cardiac transplantation.[5] Cardiac transplantation may be an effective treatment for myocarditis that is refractory to medical management and mechanical circulatory support (**Class I, Level C**).

Non-pharmacologic interventions

Exercise
Current recommendations with regard to the resumption of athletic activity are that athletes with a definite or presumed diagnosis of myocarditis refrain from competitive sports for a period of six months after the clinical onset of disease. Furthermore, the resumption of training should only occur if echocardiographic measures of LV function, wall motion and dimensions return to baseline in the absence of clinically relevant arrhythmias, a normal 12-lead ECG and normalization of serum biomarkers.[81] These recommendations are based on animal models in which exercise following acute myocarditis increases mortality. Therefore, we recommend that patients with acute myocarditis refrain from aerobic exercise for a period of months following the acute illness (**Class I, Level C**).

Prevention

There are no specific strategies for the prevention of myocarditis. However, the widespread use of vaccination in developed countries has made myocarditis secondary to measles, mumps, rubella, poliomyelitis and influenza quite rare. As such, vaccinations against other cardiotropic viruses may prevent viral myocarditis as shown in murine models.[82] At this time, there are no specific recommendations for the use of vaccinations to prevent viral myocarditis.

Specific etiologies of myocarditis and their management

Certain idiopathic or infectious causes of myocarditis have specific treatments. These are uncommon, but certain clinical clues can lead to a directed investigation and appropriate management.

Giant cell myocarditis

Giant cell myocarditis (GCM) is a rare but usually fatal autoimmune form of myocarditis, characterized by the presence of giant cells in the myocardium (Plate 48.2). Its pathogenesis is unknown; however, in animal models, a GCM-like inflammation is induced by immunization with cardiac myosin.[83] The clinical course is usually one of rapid deterioration in spite of usual clinical care, with frequent ventricular arrhythmias and complete heart block. The prognosis in GCM is significantly worse as compared to lymphocytic myocarditis, with a median survival of 5.5 months from the onset of symptoms and an 89% rate of death or cardiac transplant at five years.[16]

Management
Unlike acute lymphocytic myocarditis, transplant-free survival is prolonged in patients with acute GCM treated with a combination of ciclosporin and steroids. We recommend that immunosuppression that includes steroids and ciclosporin be used for patients with histologically proven, acute GCM of less than three months symptom duration (**Class I, Level C**). Despite a 20–25% rate of GCM recurrence in the allograft, transplantation is also an effective therapy for GCM. We recommend that heart transplantation be considered for patients with GCM who fail to respond to standard management of heat failure and immunosuppression (**Class I, Level C**).[16,84]

Hypersensitivity and eosinophilic myocarditis

Drug-induced hypersensitivity reactions can sometimes affect the myocardium. Numerous medications, including some antidepressants, antibiotics and antipsychotics, have been implicated in hypersensitivity myocarditis. Patients are generally older and are often on multiple medications and often present acutely with rash, fever, and occasionally liver function test abnormalities. ECG changes are similar to those with lymphocytic myocarditis, including sinus tachycardia, non-specific T-wave abnormalities and ST elevations.

Eosinophilic myocarditis is characterized by a predominantly eosinophilic infiltrate in the myocardium and may occur in association with systemic diseases such as hypereosinophilic syndrome (HES), Churg–Strauss syndrome and Löffler's endomyocardial fibrosis or in association with parasitic or helminthic or protozoal infections.[85–87] Clinical manifestations of eosinophilic myocarditis include endocardial fibrosis, fibrosis of the cardiac valves leading to regurgitation, right and left congestive heart failure and formation of thrombi on the endocardial surface. Acute necrotizing eosinophilic myocarditis is an aggressive form of eosinophilic myocarditis with acute onset and high mortality rates.

Management

In general, the treatment for eosinophilic myocarditis depends on the underlying cause and includes withdrawal of the offending agent, if known. High-dose corticosteroids may be beneficial in the setting of systemic disease-associated eosinophilic myocarditis, while surgical treatment may also play a role in the management of endomyocardial fibrosis (**Class IIa, Level C**).[15,88]

Lyme myocarditis

Myocarditis can occur in association with the infection by the spirochete *Borrelia burgdorferi* (Lyme disease). Lyme myocarditis should be suspected in patients who have a history of travel to the endemic regions or who give a history of a tick bite. Clinical presentation may include several degrees of atrioventricular conduction abnormalities, including transient or permanent heart block or cardiac arrhythmia.[89] The diagnosis of Lyme disease is confirmed by serologic testing but this does not establish the diagnosis of myocarditis. EMB, if indicated, may show a lymphocytic myocarditis with a prominent plasmacytic component and the organism may be visualized in the section with special stains. In a patient with suspected Lyme disease after a tick bite, the possibility of co-infection with *Ehrlichia* (ehrlichiosis) and *Babesia* (babesiosis) should be considered as both can also cause myocarditis. Serologic tests are available for both disorders.

Management

The treatment of Lyme myocarditis consists of supportive clinical care for left ventricular dysfunction and treatment of the underlying infection using appropriate antibiotics such as doxycycline and ceftriaxone. Permanent pacing may be required for symptomatic heart block (**Class IIa, Level C**).

Chagas' myocarditis

Trypanosoma cruzi infection in the heart can present as an acute myocarditis or as a chronic cardiomyopathy and is a leading cause of dilated cardiomyopathy and congestive heart failure in the endemic areas of rural Central or South America. Chagas' cardiomyopathy may present with symptoms of cardiac arrhythmia or heart block in 10–20% of infected persons. These symptoms may be related to congestive heart failure due to left ventricular dysfunction or ventricular arrhythmia resulting from progressive damage to the heart. An additional 20–30% of affected persons have asymptomatic cardiac involvement. The disease is clinically suspected if the patient has a strong history of environmental exposure, and the diagnosis is confirmed by serologic testing or polymerase chain reaction. The ECG may show evidence of conduction system disease including right bundle branch block or left anterior fascicular block. Echocardiography or contrast ventriculography may reveal a left ventricular apical aneurysm, regional wall motion abnormalities, or diffuse cardiomyopathy.

Management

There is no specific treatment for Chagas' cardiomyopathy. Antiparisitic treatments directed against *T. cruzi* may eradicate the disease in acute or subacute infection and congestive heart failure can be managed symptomatically with ACE inhibitors at high doses, diuretics and digoxin. Ventricular arrhythmias may respond to electrophysiology-guided treatments. Although heart transplantation for Chagas' cardiomyopathy has been successfully performed, reactivation of *T. cruzi* is common.[90] The best treatment is the institution of prevention measures. Improvements in housing and the use of pesticides may eradicate the reduviid bugs that transmit the disease, thus reducing infection and disease rates.

HIV myocarditis

Myocarditis is the most common cardiac pathologic finding at autopsy of HIV-infected patients, with prevalence as high as 70%. HIV-associated myocarditis is often characterized by a focal non-specific myocardial infiltrate in the presence of left ventricular dysfunction. HIV1-RNA has also been detected in the myocardial tissue of patients with acquired immunodeficiency syndrome (AIDS). Nevertheless, the pathogenesis of myocarditis and left ventricular dysfunction in immunocompromised patients is unclear, as the myocardial inflammation could be secondary to HIV itself, other opportunistic viruses and co-infections, or even due to the medications used in treatment. The prognosis for HIV-associated myocarditis is significantly poorer than that of lymphocytic myocarditis and in a large cardiomyopathy cohort, HIV-related myocarditis was the strongest predictor of death.[91]

Conclusion

Acute myocarditis presenting as dilated cardiomyopathy should be treated according to the current AHA/ACCF, ESC, and HFSA heart failure guidelines.[48–50] Arrhythmias should be managed according to the current ACC/AHA/ESC guideline.[77] Additionally patients should abstain from vigorous exercise for a period of up to six months, based on experimental data that indicates a greater mortality if animals exercise during the period of acute myocardial inflammation (**Class I**). If EMB reveals acute giant cell myocarditis, granulomatous or eosinophilic myocarditis, immunosuppressive treatment should be added (**Class I**). Mechanical circulatory support may provide a bridge to transplantation or recovery in patients with fulminant or acute myocarditis who deteriorate despite optimal medical management (**Class I**).
