49 Management of hypertrophic cardiomyopathy

Barry J Maron

Hypertrophic Cardiomyopathy Center, Minneapolis Heart Institute Foundation, Minneapolis, MN, USA

Over the last 50 years,[1] hypertrophic cardiomyopathy (HCM) has proven to be a genetic heart disease with heterogeneous phenotypic expression, unique pathophysiology, and a diverse clinical course caused by several distinct disease-provoking mutations in genes encoding proteins of the cardiac sarcomere.[2–12] HCM may cause disability and death at virtually any age, including early childhood and infancy, and is the most common cause of sudden death in the young (including competitive athletes).[13]

The first modern description of HCM was in 1958 by Teare.[14] Since then, our understanding of the diagnosis, natural history and management of this heterogeneous disease has evolved dramatically with the development of novel diagnostic tests and treatment modalities. Although literally thousands of papers have been published on HCM,[4] because this disease is relatively uncommon in cardiovascular practice and so diverse in its genetic substrate and clinical presentation, it has not been possible to develop large prospective and randomized clinical trials to test particular treatment modalities.[3] Therefore, most of the data available in HCM come from retrospective and observational studies often composed of relatively small numbers of patients that do not meet the evidence-based threshold achieved by the controlled trials carried out in patients with atherosclerotic coronary artery disease largely over the last 15–20 years. This is an important and unavoidable distinction that must be drawn between genetic heart diseases such as HCM and the much more common acquired coronary heart disease that essentially represents the core of cardiologic practice. For that fundamental reason, the guideline-assigned grades for the various treatments discussed here are usually Class IIa and IIb indications and C1 and C2 levels of evidence.

Indeed, the only truly randomized trials in the HCM literature include a cross-over drug comparison of a beta-blocker versus calcium channel blocker[15] and three pacemaker studies in the early 1990s in which individual patients acted as their own controls by virtue of alternating the pacing mode to either the on or off position.[16–18] Nevertheless, over the last 10–15 years the strategy of assembling multicenter populations from HCM centers of excellence has allowed for much larger HCM patient cohorts to be studied, thereby producing evidence concerning the disease that would not be possible with single institution populations.

Prevalence and epidemiology

A number of epidemiologic studies are now available showing that HCM occurs in at least 0.2% of the general population (e.g. 1 : 500).[8,19–22] This prevalence is greater than previously regarded, although HCM remains relatively uncommon in general cardiology practice.[23] This paradox strongly suggests that most individuals affected by HCM do not achieve clinical recognition. Furthermore, there is growing evidence that HCM is truly a global disease,[20] although to date the most intense interest and reporting of cases has been in North America, Western Europe and Asia (Japan and China). HCM occurs equally in the genders and has been reported in many racial groups, including African-Americans.[24]

Definition and nomenclature

HCM is characterized by a thickened but non-dilated left ventricle (LV) in the absence of another cardiac or systemic disease capable of producing the magnitude of hypertrophy evident (e.g. aortic valve stenosis, systemic hypertension, and some phenotypic expressions of athlete's heart).[2–8] For the past 35 years, the clinical diagnosis of HCM has usually been made by echocardiographic imaging.[3] Cardiovascular magnetic resonance (CMR) has an expand-

ing role in the non-invasive diagnosis of HCM. For example, CMR may visualize areas of segmental hypertrophy, specifically in the anterolateral free wall and LV apex, not reliably identified with echocardiography.[25]

Left ventricle morphology

Hypertrophy

The distribution of LV hypertrophy is characteristically asymmetric, in which some portion of the LV wall is thicker than other areas.[7] Frequently, the pattern of hypertrophy is strikingly heterogeneous, with contiguous segments of LV wall differing greatly in thickness. Hypertrophy may be diffuse, involving substantial portions of ventricular septum and LV free wall, including patients with the most substantial hypertrophy observed in any cardiac disease.[7] However, in about one-third of patients, LV hypertrophy may be relatively mild and confined to small areas of the chamber such as basal anterior septum or apex. Furthermore, genotype-phenotype studies in HCM families have documented the association of HCM mutant genes with near-normal or even normal LV wall thicknesses.[12,26] Therefore, virtually any LV wall thickness is compatible with the clinical and/or genetic diagnosis of HCM.

Histopathology

Cardiac muscle cells (myocytes) in ventricular septum and LV free wall have increased transverse diameter as well as bizarre shapes, often maintaining intercellular connections with several adjacent cells.[27,28] Frequently, these myocytes are arranged in a chaotic, disorganized pattern at oblique and perpendicular angles to each other; myofibrils within cardiac muscle cells may also be in disarray. Disorganized cardiac muscle cells occur in about 95% of patients dying of HCM and usually occupy substantial portions of the LV, about 33% of septum and 25% of free wall.[27,28]

Microvascular abnormalities of intramural coronary arteries are present in about 80% of patients studied at necropsy, most commonly in the ventricular septum.[29] These vessels commonly have thickened arterial walls due to increased intimal and/or medial components, associated with apparent luminal narrowing. This form of "small vessel disease" may be responsible for regional myocardial ischemia,[11] necrosis, and ultimately replacement fibrosis with grossly visible extensive (or even transmural) scars. It is likely that disorganized myocardial cells and architecture, as well as areas of replacement fibrosis dispersed throughout the LV wall, impair normal transmission of electrophysiologic impulses, predispose to disordered patterns and increased dispersion of electrical depolarization

and repolarization, and probably serve as an electrically unstable arrhythmogenic substrate with the potential to trigger lethal ventricular tachyarrhythmias and sudden death.[30] Myocardial disorganization and fibrosis could also contribute to diastolic dysfunction and progression of heart failure.

LV outflow obstruction

Dynamic subaortic obstruction in HCM is usually produced by systolic anterior motion (SAM) of the mitral valve, resulting in contact between mitral valve and ventricular septum.[6] Subaortic obstruction in HCM may fluctuate in response to a number of provocations (including exercise)[31,32] but represents true mechanical impedance to LV outflow. The markedly increased intraventricular pressures that result may be detrimental to LV function by increasing myocardial wall stress and oxygen demand. LV outflow tract obstruction (gradient ≥30 mmHg) is a proven determinant of progressive heart failure symptoms and cardiovascular death over many years[9] (9) (Fig. 49.1). Furthermore, fully 70% of an HCM cohort has the propensity to develop LV outflow obstruction either at rest or with physiologic exercise.[10]

Genetics

HCM is a Mendelian trait with an autosomal dominant pattern of inheritance. Molecular studies with clinical genotype-phenotype correlations have convincingly demonstrated that HCM is caused by mutations in any one of 11 genes, each encoding a protein component of the cardiac
Figure 49.1 Long-term significance of LV outflow tract obstruction. Probability of progression to severe heart failure (NYHA III or IV) or death from heart failure or stroke among 224 patients with LV outflow tract obstruction (gradient at rest ≥30 mmHg), and 770 patients without obstruction. (From Maron *et al*[9] with permission of the Massachusetts Medical Society.)

sarcomere (of either the thick or thin filaments) with contractile, structural or regulatory functions.[12,26,33–38]

Two of the HCM-causing mutant genes, beta-myosin heavy chain and myosin-binding protein C, predominate in frequency. The other nine genes account for far fewer cases of HCM and include troponin T and I, regulatory and essential myosin light chains, titin, alpha-tropomyosin, alpha-actin, alpha-myosin heavy chain and muscle LIM protein (MLP). This genetic diversity is compounded by the considerable intragenic heterogeneity with over 400 mutations now identified (http://cardiogenomics.med. harvard.edu). The characteristic morphologic diversity of the HCM phenotype is largely attributable to the disease-causing mutations, but probably also to the influence of modifier genes and environmental factors on phenotypic expression.

Symptoms

Onset of heart failure symptoms often occurs in early adulthood between 20 and 40 years of age, although symptoms can become evident at any age, from young children to the elderly.[3,39,40] While some degree of heart failure is frequent in HCM, progression to severe functional limitation (i.e. NYHA class III–IV) is uncommon, occurring in about 10–15% of hospital-based patient populations.[3,4] The usual circumstance is characterized by exertional dyspnea and fatigue (and sometimes orthopnea and paroxysmal nocturnal dyspnea), indicative of elevated pulmonary venous pressures in the presence of intact or hyperdynamic systolic function. Such symptoms are related to diastolic dysfunction, outflow tract obstruction, microvascular myocardial ischemia, or a combination of these pathophysiologic variables. HCM patients may also experience syncope (or near-syncope), lightheadedness, palpitations, and chest pain, either typical of midsternal angina pectoris or with more atypical features.

Natural history

Overall patient population

Predicting clinical course and outcome for individual HCM patients continues to be challenging because of the marked variability and heterogeneity in disease expression, particularly for young patients with their long period of potential risk. Annual premature HCM-related mortality rates were initially reported to be 3–6% with the higher range in children.[5,41] However, these are now regarded as outdated estimates derived largely from highly selected HCM cohorts, skewed toward high-risk patients at tertiary referral centers. Greater insight into the clinical course of HCM has been achieved by analysis of unselected community-based patient populations, uncontaminated by tertiary center referral bias. These cohorts have allowed more realistic overall mortality rates of about 1%/year to be established, although somewhat higher for children (i.e. 2%/year)[3,40,41] (Fig. 49.2). Therefore, in adults, HCM does not add to total mortality over that expected for the general population and is compatible with normal life expectancy, often without significant disability or the necessity for major interventions.[3,39,40]

Risk stratification and sudden cardiac death

Demographics

Sudden death in HCM may occur at a wide range of ages, but most commonly during adolescence and young

n=234
Avg. follow-up=8.1 years

HCM

U.S. National Health Statistics
Figure 49.2 Cumulative survival in a community-based adult HCM population. Total mortality in 234 HCM patients (1%/year) does not differ significantly from that expected in general US population after adjustment for age, sex, and race. (From Maron *et al*,[40] reproduced with permission of the American Medical Association.)

adulthood, less than age 30–35 years of age.[3–6,41–45] Indeed, HCM is the most common cause of sudden cardiac death in young people and these events are arrhythmia-based due to primary ventricular tachycardia/fibrillation, with a predilection for the early morning hours.[30,45,46] Sudden death is often the initial disease manifestation in asymptomatic individuals, many of whom are undiagnosed during life. Although most patients die suddenly while sedentary or during normal/modest physical activity, an important proportion do so associated with vigorous exertion, including young competitive athletes in organized sports. This observation is the basis for the standard and prudent recommendation to disqualify young athletes with HCM from intense competitive sports to reduce their risk for sudden death, according to the guidelines of Bethesda Conference #36.[47]

Risk factors[3–5,30,43,44,48–54]

For secondary prevention, risk for sudden death is associated with prior cardiac arrest or sustained ventricular tachycardia. For primary prevention, one or more of the following clinical risk markers are relevant:

• family history of ≥1 premature HCM-related deaths, particularly if sudden and multiple
• unexplained recent syncope, particularly in the young and related to exertion
• hypotensive or attenuated blood pressure response to exercise
• multiple repetitive (or prolonged) non-sustained ventricular tachycardia on serial Holter (ambulatory) ECG monitoring
• massive LV hypertrophy (wall thickness ≥30 mm), most relevant to younger patients.

Each of these risk factors, taken individually, has potential limitations and all are encumbered with relatively low positive predictive value (of about 20%), although with high negative predictive accuracy. For example, the finding of non-sustained ventricular tachycardia (NSVT) on ambulatory Holter may be fraught with particular ambiguity.[48,53,54] A single brief isolated burst of NSVT on a random Holter ECG is no longer regarded as a risk factor which itself would trigger a primary prevention implanted cardioverter-defibrillator (ICD). However, long runs of NSVT (>10 beats) intuitively carry greater weight in these clinical circumstances. One potentially useful (but non-evidence based) strategy utilized following identification of a short run of NSVT on the initial Holter ECG involves expanding the monitoring period to a total of six days by obtaining additional ECG recordings at about 1–2 week intervals.[53,54] This approach allows assembly of an extended profile of ectopy. Thus, a more measured assessment of an individual patient's day-to-day ventricular ectopy (including NSVT) is achieved, potentially clarifying the decision concerning a prophylactic ICD.

It has been proposed that certain mutations responsible for HCM could represent prognostic markers conveying either favorable or adverse outcome, including the risk for sudden death.[12,55] For example, early genotype-phenotype studies identified certain beta-myosin heavy chain and troponin T mutations to be associated with higher frequency of premature death compared to other mutations, such as those involving myosin-binding protein C or alpha-tropomyosin. More recently, however, the prognostic significance of disease-causing mutations for risk stratification and decision-making concerning treatment strategies has been questioned and de-emphasized.[37,38] Due to the substantial genetic heterogeneity in HCM and lack of compelling data, it is now evident that anticipating the future clinical course based on knowledge of the disease-causing mutation is untenable and has been largely abandoned in the management of individual patients.

While the presence of a subaortic gradient (≥30 mmHg at rest) is a strong determinant of progressive heart failure and cardiovascular death, the relationship is much less predictive of sudden cardiac death[9] and LV outflow obstruction should not be regarded as a primary risk marker.

Management

Treatment strategies in individual HCM patients are usually tailored along one of three major prognostic pathways: disabling symptoms due to heart failure, high risk for sudden death, and atrial fibrillation (Fig. 49.3).

Medical management of heart failure

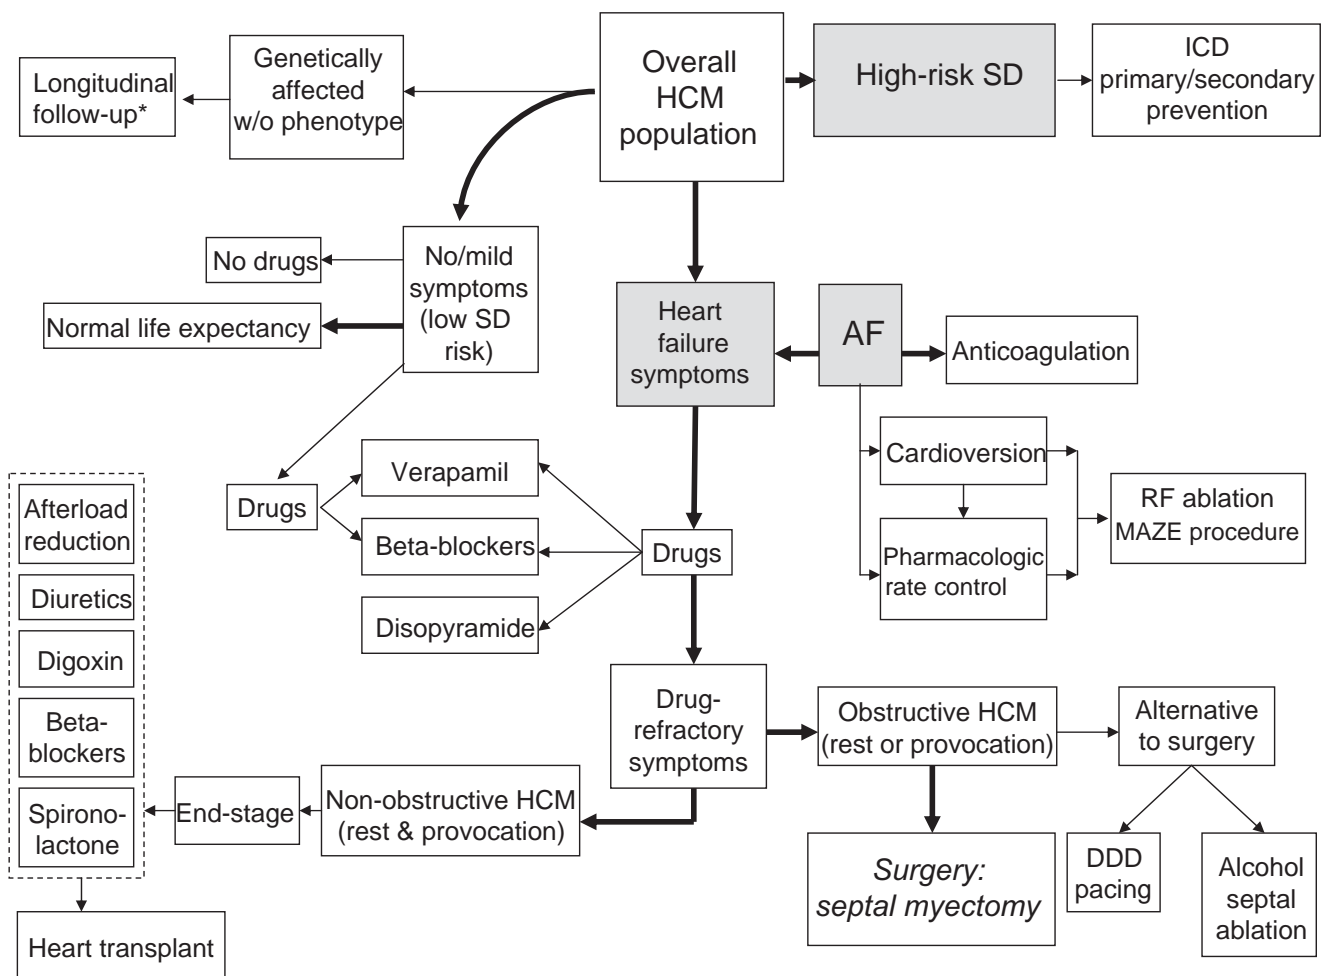
Data dictating pharmacologic treatment of symptomatic HCM patients with heart failure are largely derived from clinical experience in selected patient subsets followed for relatively brief periods of time,[56] with the exception of one double-blind cross-over study in a small patient cohort.[15] When associated with normal or hyperdynamic LV function the response of heart failure symptoms to medical treatment is highly variable; hence, therapy is often tailored empirically to the individual requirements of symptomatic patients. Since the mid-1960s a variety of beta-adrenergic receptor-blocking drugs have been utilized extensively to relieve and control heart failure symptoms in patients with obstructive or non-obstructive HCM.[1] Verapamil may improve cardiac symptoms and exercise capacity (largely in non-obstructive patients) due to a beneficial effect on LV relaxation and filling, but should be avoided in the presence of elevated pulmonary venous pressures and marked outflow obstruction.[3] In patients who fail to benefit from beta-blockers and verapamil, an empiric trial may be initiated with disopyramide (in combination with a beta-blocker).[57]


Figure 49.3 Current treatment strategies for patient subgroups within HCM disease spectrum. Management decisions usually proceed along three major prognostic pathways: disabling symptoms due to heart failure, high risk for sudden death, and atrial fibrillation. *No specific treatment or intervention indicated, except under exceptional circumstances. AF, atrial fibrillation; ICD, implantable cardioverter-defibrillator; RF, radiofrequency; SD, sudden death.

Alternatively, about 3% of HCM patients will manifest the "end-stage" of HCM in which progressive heart failure is associated with LV systolic dysfunction and often remodeling in the form of wall thinning and cavity dilation.[58] Drug therapy in these patients is similar to that employed for congestive heart failure in other cardiac diseases and may include the administration of beta-blockers, ACE inhibitors, angiotensin receptor blockers and diuretics, as well as possibly digoxin, spironolactone, warfarin, and ultimately heart transplant.

Prevention of sudden death

Historically, the management of high-risk HCM patients was first confined to prophylactic pharmacologic treatment with beta-blockers, verapamil, and antiarrhythmic agents (such as procainamide, quinidine, and subsequently amio-

darone). However, in HCM there are virtually no data supporting the efficacy of prophylactic drug treatment in preventing sudden death.[59]

When the level of risk for sudden death is judged by risk factor analysis to be unacceptably high and deserving of intervention, the ICD has proved to be the most effective available prophylactic treatment option, with the potential for absolute protection and alteration in the natural history of this disease by aborting potentially life-threatening ventricular tachyarrhythmias.[30,46,60] Unavoidably, all available ICD data in HCM are observational and by design non-randomized, with patients accessed retrospectively and prospectively.[61–63]

The largest such study cohort is composed of 506 HCM patients in an international multicenter registry, all of whom had ICDs implanted for high-risk status, and were followed for an average period of about 3½ years (up to

16).[30] Appropriate device discharges (either defibrillation shocks or antitachycardia pacing) triggered by ventricular tachycardia/fibrillation occurred in 20% of patients with an overall annual discharge rate of 5.5%. Appropriate intervention rate was 11%/year for secondary and 4%/year for primary prevention. Of note, almost 30% of the young patients implanted at ≤20 years of age subsequently had appropriate ICD discharges at 18 ± 4 years of age. Therefore, the ICD has proven effective in HCM despite the often substantially increased cardiac mass characteristic of this disease, as well as the not infrequent occurrence of LV outflow tract obstruction. Furthermore, about 40% of those patients who received appropriate defibrillator therapy to terminate potentially lethal ventricular tachyarrhythmias in fact experienced multiple such interventions.

Medical treatment is not absolutely protective against the risk of sudden death in HCM. Indeed, in one large study, a substantial proportion of patients were taking amiodarone or other potentially antiarrhythmic drugs at the time of appropriate defibrillator interventions.[59]

There is general consensus and virtually no controversy that secondary sudden death prevention (i.e. with the ICD) is strongly warranted in those patients with fortuitous resuscitation from prior cardiac arrest (with documented ventricular fibrillation (VF)) or sustained and spontaneously occurring ventricular tachycardia (VT). While the presence of multiple clinical risk factors conveys greater comfort in judging increased risk for primary prevention,[43,44] it is also

obvious now that a single risk factor may often be sufficient evidence to justify a recommendation for a prophylactic ICD.[30] A large multicenter international registry found no difference in the likelihood of appropriate shocks when ICDs were implanted for either 1, 2 or ≥ 3 risk markers, and 35% of patients implanted for only one risk factor nevertheless experienced an appropriate shock (Fig. 49.4). Therefore, many investigators, particularly in the US, favor strong consideration of a prophylactic ICD even in the presence of only one major risk factor. Other (largely European) investigators are generally more conservative and restrictive in requiring two or more risk factors before raising consideration for a primary prevention ICD. Also, based on experience, both the end-stage phase and LV apical aneurysm (with regional myocardial scarring)[63] are subgroups at risk for sudden cardiac death and potentially warrant a prophylactic ICD as a bridge to heart transplantation.

While a single risk factor may be sufficient to trigger consideration for a prophylactic ICD, there are numerous clinical circumstances for which ambiguities and gray areas arise with respect to the presence, strength or number of risk factors.[30] For example, there are many elderly patients with a single risk factor (e.g. syncope) who may not be candidates for primary prevention, given that HCM-related sudden death is uncommon in this age group and survival to advanced age without complications itself generally declares lower risk status in HCM. Ultimately, many of the complex clinical scenarios involving only one risk factor
Figure 49.4 ICD therapy in HCM. Cumulative rates for first appropriate implantable defibrillator intervention in HCM patients with 1, 2 or ≥3 risk factors who had received devices for primary prevention. (From Maron et al,[30] reproduced with permission of the American Medical Association.)

NO. at risk

1 risk factor	173	150	119	98	70	48	31	18	16
2 risk factor	143	123	95	71	53	34	28	16	6
3 or more risk factors	59	52	38	32	23	11	9	8	6

may require a measure of physician judgment in the context of the individual patient's clinical profile. Patient autonomy with full physician disclosure allows the fully informed HCM patient to contribute importantly to the resolution of such uncertainties which not infrequently arise in clinical situations with insufficient evidence-based data.[64,65] We also recognize that physician and patient attitudes toward ICDs (and access to such devices within respective healthcare systems) can vary considerably among countries and cultures, and thereby impact importantly on clinical decision making and the threshold for device implant in HCM.[66]

Crucial to understanding the role of the ICD within the broad HCM disease spectrum is an appreciation of certain demographic distinctions from ICD therapy in ischemic heart disease. The latter patients are of relatively advanced age at the time of implant (average about 65 years), often with severe and progressive heart failure as a consequence of prior myocardial infarction and LV dysfunction. In sharp contrast, ICDs in HCM often involve young asymptomatic patients with an extended period of risk for sudden death (mean age at implant and at first appropriate device intervention only 40 years). Therefore, although annual appropriate primary prevention intervention rates for HCM are lower than those reported in coronary artery disease,[67–69] they are nevertheless significant, since that experience must be placed in the context of a much younger patient population usually free of significant heart failure and noncardiac disease. Protected by the ICD, these patients could potentially survive many decades of productive life with few or no symptoms, even achieving normal or near-normal life expectancy if not encumbered by other major HCM-related or other disease complications.

The time interval between implant and first appropriate ICD intervention may be quite variable, with particularly long delays of up to 10 years not uncommon for the initial life-saving intervention.[30] This observation underscores the unpredictable timing of lethal arrhythmias and sudden death in HCM in which the ICD may remain dormant for substantial periods of time before it is ultimately required to intervene appropriately. Conversely, some appropriate shocks occur early after implant, not uncommonly even within the first 12 months.[70] The mechanisms underlying such earlier interventions are unresolved.

Indeed, the decision to prophylactically implant an ICD in an HCM patient is often fortuitously based on the precise time at which risk stratification is undertaken and high-risk status identified. Once potential risk is recognized, it becomes difficult and probably imprudent to temporize or delay potentially preventive treatment. Indeed, a patient identified as high risk at age 20 (and implanted with a device prophylactically) will still be young and at increased risk for an event at age 35, even if the ICD has not been triggered appropriately during that 15-year period. Consequently, once the decision to implant an ICD in a high-risk HCM patient is made it is likely to represent a life-long preventive measure.

Atrial fibrillation

Atrial fibrillation (AF) is the most common sustained arrhythmia in HCM, frequently accounts for unexpected hospital admissions and lost productivity, and often requires aggressive therapeutic intervention.[3] Data directly focused on the natural history and management of AF in HCM are limited, and essentially confined to one large retrospective study.[71] Consequently, treatment guidelines for AF in HCM are not infrequently translated from the experience in acquired cardiac diseases, particularly randomized trials such as AFFIRM.[72]

Paroxysmal episodes or chronic AF occur in about 25% of HCM patients, increasing in incidence with age, and linked to enlargement of the left atrium.[71] AF is reasonably well tolerated by about one-third of patients and has not proved to be an independent determinant of sudden cardiac death. It is associated with embolic stroke, progressive heart failure, disability and possibly heart failure-related death, particularly when associated with outflow obstruction at rest in patients <50 years of age. Paroxysmal AF only occasionally is responsible for acute clinical decompensation, requiring emergent electrical or pharmacologic cardioversion. Amiodarone is regarded as effective in reducing AF recurrences based on inferences from data in non-HCM patients. With chronic AF, beta-blockers and verapamil will usually control heart rate; atrioventricular (AV) node ablation with permanent ventricular pacing is rarely required to institute adequate drug therapy. In the absence of HCM-specific controlled data, AF management decisions regarding rate control versus conversion to sinus rhythm are generally made case by case, based upon the overall clinical profile, and the experience in patients with other cardiac diseases.

Because of the potential for clot formation and embolization, warfarin is indicated in HCM patients with AF. Since only one or two paroxysms of AF have been associated with risk for systemic thromboembolism in this disease, the threshold for initiation of anticoagulant therapy is low. However, such clinical decisions should be tailored to individual patients after considering obligatory lifestyle modifications, risk of hemorrhagic complications, and expectations for compliance. Some success in treating refractory AF complicating HCM has been reported in a small number of patients with the surgical MAZE procedure or by radiofrequency catheter ablation.[3]

Surgery

Based on a series of observational studies from many parts of the world over several decades, operation (surgical

septal myectomy) is the primary treatment option for HCM patients with severe drug-refractory symptoms resulting in functional disability and associated with obstruction to LV outflow under basal conditions or with physiologic exercise (gradient ≥50 mmHg).[73–89] The primary objective of myectomy is reduction in heart failure-related symptoms and improved quality of life. Surgical myectomy is not recommended for asymptomatic or mildly symptomatic patients with outflow obstruction, as there is no evidence at present that prophylactic surgical relief of obstruction has greater long-term benefit with respect to survival or disease progression.

The most successful operative procedure has been the transaortic septal myectomy (Morrow procedure) in which a portion of muscle is resected from the basal septum (usually about 2–10 g).[90] More recently, at some centers, the myectomy has been extended much more distally within the septum.[86,91] Results achieved at several institutions with myectomy over the past 45 years have been excellent, with most patients afforded substantial symptomatic and hemodynamic benefit, but without important compromise in global LV function. Operative mortality has steadily decreased and is now considerably less than 1% at the most experienced centers.[89]

Long-term follow-up studies from surgical centers have demonstrated that basal outflow obstruction does not recur and heart failure is largely reversed by septal myectomy.[73–89] Symptoms are relieved long term in about 85% of patients, followed for up to 26 years, and overall survival has been reported to be 83% over a 10-year follow-up. In a observational study design, operated patients achieved the same longevity as the general population and had significantly better survival than non-operated patients with outflow obstruction (Fig. 49.5). Randomization of patients to surgery versus medical therapy is not practical or ethically feasible.

Alternatives to surgery

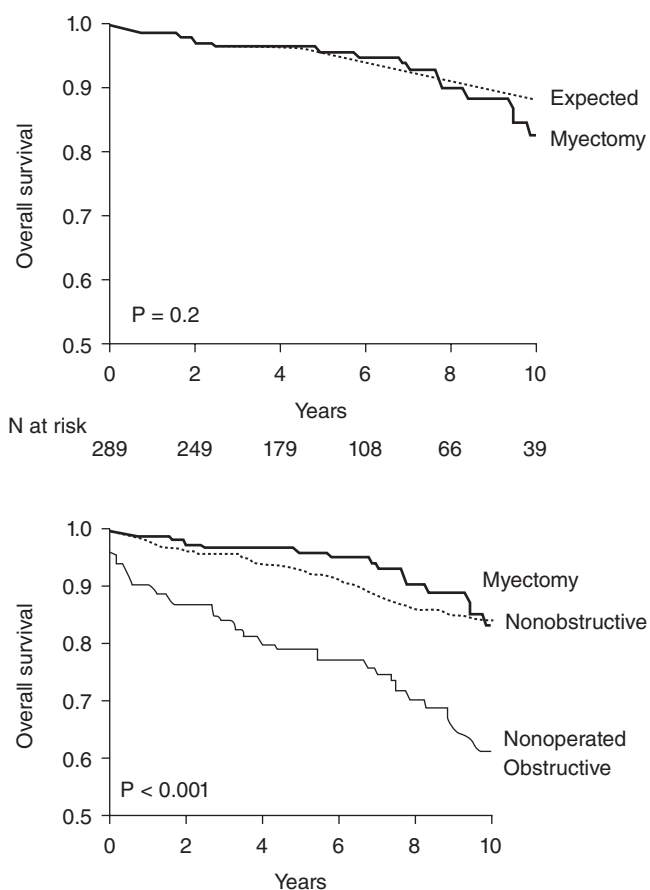
In the late 1990s, permanent dual-chamber pacing was promoted as an alternative to myectomy for patients with obstructive HCM and severe refractory symptoms.[16–18] However, several randomized double-blind, cross-over studies demonstrated that subjectively perceived symptomatic benefit from pacing was not accompanied by objective evidence of improved exercise capacity and appeared to largely represent a placebo effect.[16,18] These studies represent the few controlled investigations available addressing the treatment options for HCM patients since these study designs permitted assessment of patients blindly with the pacing mode on or off. While reduction in subaortic gradient may be induced by pacing in some patients, this benefit is more modest and inconsistent compared to that achieved with myectomy. Although selected patients


Figure 49.5 Long-term survival following surgical septal myectomy. (*Top panel*) Survival free from all-cause mortality after myectomy for obstructive HCM (n = 289) compared with age- and gender-matched US population. (*Bottom panel*) Survival free from all-cause mortality in three HCM patient subgroups: surgical myectomy (n = 289), non-operated with obstruction (n = 228), and non-obstructive (n = 820). Overall log-rank and myectomy vs non-operated obstructive HCM, *P* < 0.001. (From Ommen *et al*,[87] with permission of the American College of Cardiology.)

older than 65 years may more likely benefit from pacing, the overall role for this treatment modality in HCM has become particularly limited.

Percutaneous alcohol septal ablation may reduce LV outflow tract gradient and heart failure symptoms, by virtue of producing a large transmural septal infarct.[92] However, follow-up is necessarily short compared to myectomy (average 2–4 years vs up to 45 years for surgery) and the ultimate role of alcohol ablation in the treatment of patients with obstructive HCM is not yet definitively resolved. Observational studies show gradient and symptom relief from alcohol ablation to be similar although less complete and consistent compared to myectomy, with about 25% of ablation patients incurring major (even life-threatening) complications requiring repeated procedures due to unsatisfactory hemodynamic and symptomatic results.[89–91,93–97]

Table 49.1 Level of evidence for major management options in hypertrophic cardiomyopathy

	Class	Evidence
Surgical septal myectomy	I	C1
Percutaneous alcohol septal ablation	IIa	C2
Dual-chamber pacing	IIb	A
Genetic testing (for diagnosis)	I	C1
Genetic testing (for prognosis)	IIb	C2
Implantable cardioverter-defibrillator (primary and secondary sudden death prevention)	I	C1
Drug therapy for heart failure symptoms	IIa	C1
Control of atrial fibrillation (drugs/cardioversion)	IIa	C1
Heart transplantation (for end stage)	I	C2

Because percutaneous septal ablation has been perceived to be less invasive and more accessible than surgical myectomy, its penetration into cardiologic practice has been extensive, raising the possibility that the threshold for ablation is lower than for operation. Indeed, the American College of Cardiology/European Society of Cardiology expert consensus panel[3] placed surgical septal myectomy as the primary gold standard management option for patients with severe refractory symptoms and marked outflow obstruction. In those guidelines, alcohol ablation is regarded as an alternative treatment strategy for selected patients, i.e. those with co-morbidity or other medical factors which increase operative risk or who are adverse to surgical intervention.

However, long-term issues remain unresolved, most prominently the clinical significance of the alcohol-induced transmural scar (occupying about 10% of the LV wall) which represents a potentially unstable arrhythmogenic substrate and undoubtedly raises the risk for sudden cardiac death in some patients.[98] Reported procedural mortality for alcohol septal ablation at experienced centers (≤2%) is higher than for HCM surgical centers (<1%). A prospective myectomy versus alcohol ablation trial, adequately powered to compare the key issue of long-term outcome, poses myriad practical problems which seem virtually insurmountable, and likely will never occur to resolve these issues.[99]

Conclusion

Hypertrophic cardiomyopathy is an important genetic heart disease, characterized by left ventricular hypertrophy, with a characteristically heterogeneous clinical presentation and course which greatly influences management strategies. Unavoidably, much of the available data concerning treatment options and decision making come from retrospective, observational studies, often composed of relatively small patient cohorts. Because randomized prospective studies are exceedingly uncommon, the level of evidence in HCM (and other genetic heart diseases) rarely reaches that achieved for patients with much more common coronary artery disease.

Treatment options in HCM target control of heart failure or atrial fibrillation, and prevention of sudden death. Heart failure is manifest largely as disability due to exertional dyspnea and is initially treated pharmacologically with a series of drugs (including beta-blockers, verapamil, disopyramide and possibly diuretics). Should limiting symptoms progress despite maximal medical therapy, and substantial obstruction LV outflow be present either at rest or with physiologic provocation, then invasive septal reduction is considered. In such disabled drug-refractory patients with obstructive HCM, surgical septal myectomy is the primary treatment option, with alcohol septal ablation an alternative for selected patients, particularly those of advanced age and/or with significant co-morbidity. Patients who progress to the "end-stage" phase with systolic dysfunction constitute the only HCM subset eligible for heart transplantation. Atrial fibrillation is managed by rate control or cardioversion and anticoagulation and possibly radiofrequency ablation in selected patients.

Recently, the ICD has been employed effectively in HCM, demonstrating that sudden death due to ventricular tachyarrhythmias can be prevented and the natural course of the disease importantly altered. The risk stratification algorithm employed in HCM has proved to be an efficacious and useful guide in selecting patients for defibrillator therapy, although likely incomplete. Management of individual HCM patients is predicated on targeting pathways of prognosis, i.e. heart failure (and progression to the end stage), atrial fibrillation or increased risk for sudden death risk.

50 Infective and infiltrative cardiomyopathies

Stavros Kounas and Perry M Elliott
The Heart Hospital, University College London, London, UK

Infective cardiomyopathies

Myocardial dysfunction is a well-recognized complication of viral, bacterial, fungal and parasitic infections. Worldwide, the most common infective myocarditis is Chagas' disease caused by *Trypanosoma cruzi*, a protozoan organism endemic in rural areas of South and Central America. In the Western world, viral myocarditis caused by enterovirus and adenovirus infection is the most common cause of inflammatory heart muscle disease.

Viral myocarditis

Until quite recently, enterovirus (Coxsackie B) and adenovirus were the most commonly implicated viruses in acute myocarditis in adults and children.[1–4] A causal association between enteroviruses and myocarditis was first suggested in studies showing a relationship between rising serum Coxsackie B antibody titers and acute symptomatic presentation.[3] Subsequently, enteroviral genome has been detected in myocardial biopsy samples of patients with myocarditis and dilated cardiomyopathy using polymerase chain reaction techniques.[4]

More recently, studies suggest that the frequency of enteroviral and adenoviral infection in patients with clinically suspected myocarditis and dilated cardiomyopathy has reduced. Instead, parvovirus B19 infection, which usually causes erythema infectiosum ("slapped cheek" *or* "fifth" disease), seems more common in adults.[5] Childhood parvovirus myocarditis has also been reported,[6] including four cases of sudden cardiac death.[7–10] Many other viruses have been implicated in myocarditis, including cytomegalovirus, hepatitis C virus, and herpes simplex virus[11–14] (see Table 50.1).

HIV-related cardiomyopathy

The human immunodeficiency virus (HIV) infection affects an estimated 39.5 million living people worldwide, with 4.3 million new cases in 2006.[15] Advances in treatment have substantially improved morbidity and mortality, but late cardiac complications are increasing as patients' survival improves.[16] These include myocardial dysfunction, pericardial effusion, endocarditis, malignancy and premature coronary disease. Observational data estimate the annual incidence of HIV-associated cardiomyopathy at 15.9 cases per 1000 HIV-positive patients.[13] Among children with vertically transmitted HIV infection the 2-year incidence of congestive heart failure was 4.7%.[17]

Pathogenesis of the heart muscle dysfunction in HIV infection is still poorly understood. Opportunistic infections, malnutrition and antiviral treatment have been implicated.[18] Some studies have also suggested a direct cardiotoxic effect of HIV and secondary effects caused by autoimmune responses against HIV and other cardiotropic viruses.[12,19] This latter hypothesis is supported by the demonstration of a high frequency of circulating cardiac specific autoantibodies in HIV positive patients in comparison to normal controls.[20]

Clinical presentation and diagnosis

Presentation of infective myocarditis varies enormously. Malaise, low-grade fever, chest pain, transient electrocardiographic changes (T-wave changes, ventricular extrasystoles), left ventricular dysfunction and biochemical signs of myocardial dysfunction are typical. In some cases, the clinical picture mimics acute myocardial infarction with ST segment elevation.[21] Other cases present with fulminant heart failure,[22] arrhythmias,[23] conduction disturbance[24] and sudden cardiac death.[25]

Although the echocardiogram is rarely entirely normal in myocarditis, the findings are non-specific. Evidence of impaired left ventricular systolic performance (with reduced fractional shortening and ejection fraction) is common. Regional wall motion abnormalities occur

Table 50.1 Studies showing viral genome persistence in patients with DCM or myocarditis

Study	Disease spectrum	Investigated viruses	Patients	Controls	Year
Weiss[55]	MC/DCM/controls	EV	1/5 (20%) MC, 0/11 (0%)DCM	0/21	1991

frequently. Left (or right) ventricular thrombus may be present. Evidence of left ventricular diastolic impairment may also be detected in myocarditis. Less often, right ventricular systolic and diastolic function may also be compromised. Echocardiography may show wall thickening caused by myocardial edema.[26]

Magnetic resonance imaging with gadolinium enahancement often demonstrates regions of signal enhancement.[27,28] Mild to severe persistent perfusion defects using thallium-201 myocardial scintigraphy may be present in the acute phase, with partial recovery on follow-up.[29]

Routine blood tests such as full blood count and erythrocyte sedimentation rate are usually unhelpful in confirming or refuting the diagnosis of myocarditis. In a study of 80 patients with suspected myocarditis, 35% had elevated troponin T levels. Troponin T levels greater than 0.1 ng/mL had a specificity of 94% and a positive predictive value of 93%, although the sensitivity for detecting myocarditis was low at 53%.[30] Similarly, troponin I has a high specificity (89%) for diagnosing myocarditis but a sensitivity of only 34%.[31] Creatine kinase and its cardiac isoform CK-MB are less sensitive and specific than troponin, and are not clinically useful as a screening test in suspected myocarditis. Autoantibodies directed against myocardial proteins such as myosin and the adenine nucleotide translocator protein are reported in myocarditis, and correlate with progressive ventricular dysfunction.[32,33]

Endomyocardial biopsy (EMB) theorectically provides the means for establishment of a pathologic diagnosis.[34] Only two clinical scenarios are class I indications: new-onset heart failure of less than 2 weeks' duration associated with a normal sized or dilated left ventricle and hemodynamic compromise; and new-onset heart failure of 2 weeks'

to 3 months' duration associated with a dilated left ventricle and new ventricular arrhythmias, second- or third-degree heart block, or failure to respond to usual care within 1 to 2 weeks. The rationale for these recommendations is that many patients presenting in this way have myocarditis and by determining the histologic type (lymphocytic, giant cell or necrotizing eosinophilic) prognostic information can be obtained and specific therapy initiated. The use of EMB to detect viral persistence is considered to be a research indication.

Management

General principles General principles of stabilization include afterload reduction, anticoagulation, diuresis and inotropic support. Patients with fulminant acute myocarditis may require intensive intravenous hemodynamic support. In severe cases, mechanical assist devices or extracorporeal membrane oxygenation may be necessary.[35–38] Following initial stabilization, treatment should follow standard heart failure guidelines. Patients with left ventricular enlargement may require anticoagulation with warfarin. Patients with intractable and deteriorating heart failure may require cardiac transplantation.

Immunotherapy (Table 50.2) Intravenous immunoglobulin has been extensively used in children with suspected myocarditis.[39] Evidence for its use includes case reports,[40,41] and case series[42,43] of children and adults with acute myocarditis. However, only one double-blind randomized controlled trial of immunoglobulin has been conducted. In 62 patients with recent-onset heart failure and unexplained dilated cardiomyopathy, intravenous immunoglobulin failed to

Table 50.2 Studies or case reports of immunotherapy with IV gammaglobulin (IVGG) for myocarditis

Author	Type of study	Patients	Results	Year
McNamara[44]	Randomized controlled trial	62	No difference in LVEF between patient and controls	2001
Ducker[42]	Retrospective case series	21	Better ventricular function at 12 months	1994
McNamara[43]	Uncontrolled trial	10	1 death – LVEF improved by 17% at 12 months for the 9 discharged	1997

LVEF, left ventricular ejection fraction.

improve all-cause mortality or left ventricular ejection fraction.[44] Furthermore, spontaneous improvement in left ventricular function occurred in both treatment and control groups.[44] A recent Cochrane Database review concluded that current evidence does not support the use of intravenous immunoglobulin for the management of presumed viral myocarditis and that "intravenous immunoglobulin for presumed viral myocarditis should not be part of routine practice"[45] (**Class IIb, Level B**).

Immunosuppression (Table 50.3) The hypothesis that immune responses to viral infection may cause the long-term sequelae of viral myocarditis has led to the use of immunosuppression to reduce the acute inflammatory response.[1,46] A potential danger of this approach is that immunosuppression might impair the ability of the host immune system to eradicate virus.[47] In mice, prednisolone increases mortality in animals with acute viral myocarditis.[48] Observational unrandomized case series in children have reported a beneficial effect of immunosuppression in children with myocarditis.[49–52] In the Myocarditis Treatment Trial, there was no difference in mortality or left ventricular function between the control group and the treatment groups (prednisolone plus either ciclosporin or azathioprine).[53] In another study of patients with major histocompatibility complex expression on endomyocardial biopsy samples randomized to prednisolone and azathioprine or placebo, there was improvement in left ventricular ejection fraction in the immunosuppressed group only, but no difference was observed in mortality, transplantation or rehospitalization rates over a 2-year follow-up period.[54] On the basis of the available data immunosuppression therapy is considered as a **Class IIa, Level C** recommendation for children with myocarditis. For adults the data are **Class IIb, Level B**.

Bacterial infections

Bacterial myocarditis is rare in the modern era but still occurs in high-risk groups such as immunosuppressed patients. Pathogenetic mechanisms include direct bacterial invasion with myocardial tissue destruction, abscess formation and toxin-related cardiac dysfunction. *Staphylococcus aureus* is the most common cause of bacterial myocarditis producing cardiac dysfunction, rhythm disturbances, and myocardial rupture with secondary purulent pericarditis.[81] *Corynebacterium diphtheriae* respiratory infections can proceed to myocardial involvement mediated by elaborated toxins and affecting predominantly the cardiac conducting system. Cardiac tuberculosis can produce miliary or nodular lesions[82] and has been associated with severe heart failure,[83] ventricular arrthymias[84] and sudden cardiac death.[85] *Treponema whippleii* causing intestinal lipodystrophy or Whipple disease may affect cardiac valves, pericardium and myocardium.[86] Myocarditis can also be caused by *Clostridium* species.[87] *Brucella*,[88] *Mycoplasma*, *Chlamydia*,[89] *Salmonella*[90] and numerous other bacteria.

Therapy in the acute phase is supportive. Complete atrioventricular block should be treated with temporary or permanent transvenous pacing.[91] Antitoxins are available and should be used when appropriate. Specialized antibiotic regimens directed against the pathogen usually resolve the infection.

Rheumatic carditis

Rheumatic carditis is a common manifestation of acute rheumatic fever following group A streptococcal (GAS) infection of the tonsillopharynx.[92] The main pathogenetic process is a genetically predisposed autoimmune connective tissue damage, which affects primarily the cardiac valves.[93]

Table 50.3 Studies of immunosuppressive therapy for myocarditis

Reference	Type of study	Agent used	Patients	Results
Mason[53]	Multicenter randomized placebo-controlled	Prednisolone plus either ciclosporin or azathioprine	111	No difference in LVEF
Wojnicz[54]	Single-center randomized placebo-controlled	Prednisolone and azathioprine	84 DCM patients with increased HLA expression in EMB	No difference in composite endpoint of death, heart transplantation or hospital admissions. Statistically significant difference in LVEF
Parrilo[76]	Randomized trial	Prednisone	102	Small increase in LVEF. Marginal clinical benefit
Arbustini[77]	Observational series	6-month tapered steroid and azathioprine protocol	11 treated 9 not treated	10 year follow-up 6 deaths, 2 cardiac transplants, 3 survivals vs 3 deaths, 1 cardiac transplant, 5 survivals
Hosenpud[79]	Observational series	Prednisolone and azathioprine	6	No improvement in LV systolic function indices
Latham[80]	Observational series	Prednisone	52	No survival improvement
Chan[78]	Observational series	Prednisone	13 children	1 death, all survivors improved
Kleinert[49]	Observational series	Ciclosporin and prednisolone	29 children	Improved LV systolic function
Lee[50]	Retrospective review	Corticosteroids	34 children	Authors conclude excellent survival and recovery of LV function
Gagliardi[51]	Observational series	Ciclosporin and prednisone	114 children	Event free survival was 97% and 70% respectively for acute and borderline myocarditis respectively
Camargo[52]	Observational series	Four treatment groups In two prednisone was given with azathioprine *or* ciclosporin	68 children	According to authors immunosuppressive therapy with azathioprine or ciclosporin together with prednisone improves prognosis

LVEF, left ventricular ejection fraction; DCM, dilated cardiomyopathy; HLA, human leukocyte antigen; EMB, endomyocardial biopsy.

Diagnosis traditionally has been based on the constellation of symptoms and signs first introduced by Jones in 1944 and further updated in 1992.[94] The presence of two major or one major and two minor manifestations together with evidence of antecedent streptococcal infection implies a high probability of acute rheumatic fever.

Rheumatic carditis is seen usually within 3 weeks of GAS infection. Prevalence was estimated around 50% of acute RF cases based on clinical findings; however, using modern echocardiographic tools this proportion is somewhat higher.[95] Valvular dysfunction during the acute phase is typically seen as mitral and aortic valve regurgitation caused by ventricular dilation combined with leaflet restriction and thickening from active inflammation.[95] The tricuspid valve can also be affected but the pulmonary valve is spared. Overt heart failure is usually the consequence of acute valvular regurgitation with no significant myocardial contractile dysfunction detected in several series.[96,97] Parietal and visceral pericardial involvement with effusion is also rare. Moderate or severe carditis, recurrent rheumatic fever attacks or low educational level have been related to late valvular fibrosis and scarring causing debilitating hemodynamics and long-term morbidity.[98]

Cardiac troponin levels lie within the normal range, showing no myocardial necrosis despite the intense endocardial and connective tissue inflammation.[99] Acute phase reactants, like C-reactive protein or erythrocyte sedimentation rate, are high, reflecting the rheumatic activity and helping to establish the diagnosis.

Treatment during the acute phase is supportive and anti-inflammatory regimens with salicylates or steroids are dictated by the overall clinical picture. However, there is no convincing evidence supporting corticosteroid or immunoglobin administration during acute rheumatic carditis to prevent late valvular damage[100] (**Class III, Level B**). Antibiotics (penicillin or erythromycin in penicillin allergy) are mandatory to eradicate the causative agent. Secondary prevention to avoid recurrences should be implemented in patients without carditis for 5 years or until the age of 18, in those with mild mitral regurgitation for 10 years or until the age of 25, and life-long prevention is suggested for severe valve disease and after valve surgery.[101] However, the use of penicillin prophylaxis against recurrent rheumatic fever attacks has not always been efficient according to a recent Cochrane Database review (**Class IIb, Level C**). In the same review intramuscular penicillin injections

every 2–3 weeks seem to be more effective than 4-week regimens or oral formulations.[102] (**Class IIa, Level C**).

Rickettsial-spirochetal infections

Myocarditis caused by *Coxiella burnetii* infection may be encountered during the course of Q fever. This may present with precordial pain or heart failure symptoms. The prognosis is generally poor.[103] Myocardial involvement with chest pain, elevated myocardial enzymes and depressed LV function has also been described with *Rickettsia rickettsii* infections, responsible for Rocky Mountain fever.[104] Spirochetal infections including syphilis and Lyme disease (*Borrelia burgdorferi*) can also cause myocarditis. Apart from aortitis, myocardial involvement with left ventricular aneurysms has been reported in secondary syphilis.[105] *Borrelia* infection usually has neurologic, joint and cutaneous manifestations (erythema migrans) with cardiac involvement appearing within 3 weeks in approximately 8% of cases.[106]

Fungal infections

Fungi, as opportunistic pathogens, can cause myocarditis in immunodeficient patients receiving chemotherapy, steroids or immunosuppressive therapy as well as patients with malignancies. The micro-organism may spread from neighboring lung or mediastinal foci or by hematogenous dissemination. Among the various fungal species, cardiac aspergillosis has several case reports in patients with aquired immunodeficiency syndrome and is associated with poor prognosis.[107]

Parasitic infections

Parasitic infections can present with a wide spectrum of cardiac manifestations and remain a major public health issue in developing countries. Helminths or protozoa have the ability to survive and multiply in a variety of mammalian cells including cardiomyocytes, in spite of the host's defensive immune mechanisms. This usually leads to chronic inflammatory responses that ultimately damage the heart muscle, conducting system and pericardial tissue. Chagas' disease, amebiasis, toxoplasmosis, cysticercosis, echinococcosis and trichinellosis are all parasitic infections that commonly affect the heart.[108] For a review of Chagas' disease see Chapter 51.

Infiltrative cardiomyopathies

A number of genetic and acquired disorders result in myocardial infiltration or excessive storage of various substances. Most are associated with extracardiac manifestations and often present exclusively in childhood. A relatively small number present with predominantly cardiac involvement in adults, most notably amyloidosis, hemochromatosis, and Anderson–Fabry disease.

Amyloidosis

Amyloidosis is caused by extracellular deposition in various tissues of proteinaceous material with a characteristic cross-beta sheet quaternary structure, in which strands from different monomers are aligned perpendicular to the axis of the fibril.[109] Amyloid deposits are characterized by a change in the fluorescence intensity (apple green birefringence) under polarized light microscopy of planar aromatic dyes such as Congo red and stain a characteristic color with sulfated alcian blue. The classification of amyloidosis is based on the different protein precursors that make up the amyloid fibrils. Amyloid protein deposition occurs in atria, ventricles, coronary vessels, conduction system and valves. The degree of cardiac involvement varies between each subtype. Hematologic disorders associated with excessive light chain (AL) immunoglobulin production are the most common cause of cardiac amyloid. Familial forms caused by the accumulation of mutant proteins (transthyretin or A-apolipoprotein) have variable cardiac involvement. Secondary amyloidosis, due to deposition of serum amyloid A protein associated with chronic inflammatory diseases, rarely affects the heart to a clinically significant degree.

AL amyloid

Deposition of clonal immunoglobin light chains (with or without multiple myeloma) is the most common cause of amyloidosis. Cardiac involvement occurs in up to 50% of patients with AL amyloid, but clinically isolated cardiac disease is seen in less than 5% of patients.[110] Myocardial wall thickening caused by extracellular deposits without myocyte hypertrophy results in stiff non-dilated ventricles and biatrial dilation.[111] Progressive dyspnea and profound fluid retention dominates the clinical picture. Low cardiac output causes weakness, fatigue and exercise intolerance. Typically, heart failure caused by cardiac infiltration is rapidly progressive with a median survival of less than 1 year.[112]

Chest discomfort or angina pectoris is common, but coronary angiography usually reveals normal epicardial arteries. Perivascular infiltrates and evidence of impaired myocardial flow reserve suggest small vessel disease as the underlying cause.[113] Obstructive intramural coronary amyloidosis has also been reported in autopsy series.[114] Small but persistent cardiac troponin elevations reflecting subtle ongoing myocardial necrosis are also reported.[115]

Syncope is caused by impaired cardiac output, arrhythmia and amyloid autonomic neuropathy.[116] Symptomatic supraventricular arrhythmias associated with atrial enlargement are frequent.[117] Infiltration of the atria may

add to the risk for atrial fibrillation.[118] Infiltration of the sinus node and atrioventricular conduction system causes bradyarrhythmia and complete heart block.[119] Documented complex ventricular arrhythmias are rare, but may underlie some cases of sudden death; sudden death in advanced heart failure cases may also be caused by electromechanical dissociation.[120]

Cardiomegaly and pulmonary congestion with bilateral pleural effusions are seen at late stages on chest radiography. Cardiac troponins and B-type natriuretic peptide reflect the severity of cardiac involvement[121] and are associated with poor prognosis.[115,122] The resting 12-lead electrocardiogram (ECG) usually demonstrates low voltages (<5mV in limb leads) or pseudo-infarction patterns with poor right precordial R-wave progression or inferior Q-waves.[123] Criteria for left ventricular hypertrophy are uncommon, probably because myocardial wall thickening is due to extracellular infiltration rather than true hypertrophy.[124] Atrial fibrillation occurs in 7–25% of patients and poses a significant risk of thromboembolism.[109] Ambulatory ECG monitoring reveals ventricular ectopics, couplets, and non-sustained ventricular tachycardia. Complex ventricular arrhythmias are considered harbingers of lethal arrhythmic events.[125] Sinus node dysfunction, supraventricular arrhythmias and atrioventricular conduction abnormalities may be evident.[119] Late potentials on signal-averaged ECG are common in patients with cardiac amyloidosis and predict sudden death independently of echocardiographic disease markers.[126] Electrophysiology studies may reveal subtle abnormalities of the His–Purkinje system not evident on surface ECG. HV prolongation is common, and is of prognostic significance in some series.[127]

Echocardiography typically shows that global indices of systolic function are preserved until the final stages of the disease. However, decreased longitudinal deformation is common and precedes the onset of heart failure symptoms[128] Two-dimensional echo findings in advanced cardiac amyloidosis are characteristic.[129] Increased biventricular wall thickness with concentric distribution is typical, although asymmetric septal hypertrophy with normal ejection fraction can be encountered. Dynamic left ventricular outflow tract obstruction is extremely unusual. Cardiac valves appear infiltrated and thick, the atria are dilated and the interatrial septum is often thickened. A small pericardial effusion is also common. The peculiar, granular texture of the affected myocardium has traditionally been described as an amyloid feature, but is difficult to quantify without digital image analysis. Transmitral Doppler recordings in advanced cases demonstrate a restrictive left ventricular filling pattern. Diastolic dysfunction indices are better prognostic markers than left ventricular wall thickness.[130]

Other imaging modalities such as cardiac magnetic resonance imaging are used to further assist morphologic description and tissue characterization. Subendocardial late gadolinium enhancement is considered to reflect the transmural distribution of amyloid deposits and cardiac amyloid load.[131] Abnormal gadolinium kinetics are also described, although the sensitivity of this observation is uncertain. Nuclear scans with ^{123}I-labeled serum amyloid P component are highly specific. The isotope localizes selectively in amyloid infiltrates and aids the diagnosis.[132] Other scintigraphic techniques have been used to demonstrate cardiac adrenergic denervation even before the development of clinically apparent heart disease.[133]

The diagnosis of amyloidosis requires a tissue biopsy. This need not be from the heart if the echocardiographic appearances are typical for cardiac amyloidosis. Fine-needle aspiration of the abdominal fat is positive for amyloid deposits in over 70% of patients with AL amyloidosis. If negative, endomyocardial biopsy has a very high sensitivity. Once confirmed, all patients with AL amyloid should be assessed for a plasma cell dyscrasia.

Management of cardiac amyloidosis is directed against symptoms of heart failure. Specific therapies designed to impede precursor production and fibril formation should be implemented whenever possible.[134] Diuretics, often in high dose, are the cornerstone of the palliative heart failure regimen. ACE or angiotensin II inhibitors should be introduced with extreme caution as they are often poorly tolerated and there are no data on their efficacy in cardiac amyloid. Aldosterone inhibitors might be helpful in advanced cases. Sensitivity to digoxin, attributed to enhanced drug binding on amyloid fibrils, demands cautious administration.[135] Although there are no data, the presence of atrial fibrillation in AL amyloidosis should always prompt anticoagulation with warfarin because of a very high rate of thromboembolism.

Management of the underlying amyloid disease process is based mainly on single-center experience with few randomized studies. In AL amyloidosis, progression of systemic disease contributes substantially to poor outcomes even when heart transplant is provided.[136] Heart transplantation followed by high-dose chemotherapy in combination with stem cell transplantation, is promising with short- to intermediate-term survival being now similar to patients receiving cardiac transplant for other indications.[137]

Familial amyloid

Hereditary amyloidosis is most commonly transmitted as an autosomal dominant trait with high penetrance, caused by mutations in the gene encoding transthyretin (TTR). More than 70 mutations in the transthyretin gene have been reported as amyloidogenic but one of the most common is a substitution of isoleucine for valine at position 122 which occurs in 4% of the black US population.[138] TTR amyloidoses usually present after the third decade of life with polyneuropathy and cardiomyopathy. Sometimes cardiac

involvement is clinically confined to atrial arrhythmia and conduction disease. Despite significant myocardial infiltration, heart failure symptoms are less profound and survival is much better than AL amyloidosis.[139] Toxic light chain effects, absent in TTR amyloidosis, may explain the different clinical outcome.[140]

As transthyretin is produced by the liver, the definitive treatment of TTR amyloidosis is liver transplantation. Unfortunately, myocardial wall thickening progresses in some patients with TTR amyloid cardiomyopathy following liver transplantation, probably due to the continued deposition of wild-type transthyretin in the myocardium. Combined liver and heart transplantation or heart transplantation alone has been performed for TTR amyloidosis in small numbers. *In vitro* studies suggests that non-steroidal agents such as diflunisal can stabilize transthyretin.[141] Chemical stabilization to prevent TTR misfolding and decrease amyloidogenesis has also been successful in transgenic mice and human serum during recent *in vivo* studies.[142,143]

Senile cardiac amyloid (SCA)

In senile systemic amyloidosis, cardiomyopathy is caused by deposition of normal wild-type transthyretin. For unknown reasons, the disease nearly always affects elderly men above the age of 70. Presentation is with congestive heart failure, but the clinical course is considerably slower in comparison to other amyloid types (median survival from the onset of heart failure is 7.5 years).[144] Atrial fibrillation and bifascicular block on the ECG are common. Progression to complete AV block necessitating permanent pacemaker implantation is not infrequent. The echocardiographic appearances are indistinguishable from that seen in AL amyloidosis. As extracardiac involvement is rare in SCA, diagnosis usually requires endomyocardial biopsy. Cardiac symptoms predominate, with heart failure and conduction system abnormalities as main features. Atrial fibrillation and associated thromboembolic events are also frequent.[109]

There is no specific treatment for SCA, but as in familial amyloidosis, drugs that stabilize transthyretin are being evaluated.

Sarcoidosis

Sarcoidosis is a granulomatous disease of obscure etiology with multiorgan involvement. The lungs are most commonly involved but lymph nodes, skin, eyes, heart, nervous, musculoskeletal, renal and endocrine systems can be affected. The annual incidence peaks in the third and fourth decade of life and is higher in Japanese, Northern Europeans and African Americans, reaching 40 cases per 100 000 population.[145] Infective (*Mycobacterium tuberculosis*, *Mycoplasma*, *Corynebacteria*, and *Spirochaetes*), environmen-

tal (aluminum, clay) and genetic factors have been implicated in the pathogenesis. The histologic hallmark is the presence of non-caseating granulomas. The frequency of myocardial involvement in patients with sarcoid is difficult to determine, because it is frequently subclinical and patchy in nature. Post-mortem studies suggest that the heart is involved in at least 25% of patients with sarcoidosis[146] and that it accounts for as many as 13–25% of deaths.

Clinical manifestations

Clinical manifestations of sarcoid include congestive heart failure, conduction abnormalities, atrial and ventricular arrhythmias, pericardial effusion, valvular dysfunction and rarely sudden cardiac death. Right heart failure secondary to pulmonary hypertension is caused by extensive fibrotic lung sarcoidosis. Myocardial infiltration by sarcoid granulomata results in restrictive or dilated cardiomyopathy. The most common site is in the lateral wall of the left ventricle. Papillary muscle involvement is responsible for the most common valvulopathy, mitral regurgitation.[147] Granuloma formation in the basal interventricular septum may cause conduction abnormalities.[148] Ventricular arrhythmias are also frequent, generated by re-entry through surviving myocyte bundles around the scarred lesion.[149]

Abnormal Q-waves or repolarization abnormalities are common ECG findings. In one study, right bundle branch block was detected in 57% of patients, and third-degree atrioventricular block in 23–30%.[148,150] Several studies have examined the value of radionuclide scans using thallium-201, gallium-67 and technetium-99 isotopes in the diagnosis of cardiac sarcoid. Positron emission tomography (PET) may have better diagnostic accuracy.[151] Two-dimensional echocardiography may reveal regional wall motion abnormalities, increased LV dimensions, global systolic dysfunction, pericardial effusion, valvular abnormalities, LV aneurysms and raised pulmonary artery pressures.[152] The diagnostic role of magnetic resonance imaging (MRI) is rapidly expanding as regional myocardial enhancement representing focal inflammation or scarring[153] can be detected using contrast enhanced scans.

Demonstration of the typical granuloma on endomyocardial biopsy specimens is pathognomonic for cardiac sarcoidosis but the method lacks sensitivity.[154] In a study of 26 cases with strong clinical suspicion of cardiac sarcoidosis, right ventricular biopsy, with an average of four samples per patient, exhibited non-caseating granulomas diagnosis in only five individuals (19.2%).[154] In an older study, right-sided biopsies had a 63% sensitivity and left-sided 47%, with post-mortem autopsy as the gold standard.[155] The patchy myocardial infiltration with basal or left free lateral wall distribution may account for the low positive rates of endomyocardial biopsy as specimens are usually obtained from the apical septum.

Treatment

Patients with left ventricular systolic dysfunction caused by cardiac sarcoidosis have a poorer prognosis in comparison to idiopathic dilated cardiomyopathy controls.[156] Permanent pacing prevents bradyarrhythmia and ICDs can prevent sudden death by treating malignant arrhythmias.[157] Evidence on the efficacy of corticosteroids is scant and contradictory. Steroids may improve systolic function[158] but are probably most effective if initiated before the occurrence of dilated cardiomyopathy[159] (**Class IIa, Level C**). Some data suggest that steroids may not prevent ventricular arrhythmia[160] (**Class III, Level C**). Pulmonary involvement in advanced cases with progressive and severe heart failure in spite of optimal pharmacologic treatment often precludes cardiac transplantation as an option.[161] Recurrence in the cardiac allograft has been reported in some patients who have been transplanted.[162]

Hereditary hemochromatosis

Hereditary hemochromatosis (HH) is a common autosomal recessive disorder characterized by excessive iron deposition in parenchymal organs, including the liver, spleen, pancreas, endocrine glands and heart. In Caucasians, it has a prevalence of between 1 in 200 and 1 in 500, with an even higher prevalence in the Irish population. The most common form is caused by mutations in the HFE gene. Two common missense mutations account for the majority of disease: a change of cysteine at position 282 to tyrosine (C282Y); and a change of histidine at position 63 to aspartate (H63D). Between 80% and 100% patients of North European origin are C282Y homozygous. Lower rates of C282Y homozygosity occur in Mediterranean and Southern European populations. A minority (11%) of compound heterozygotes (C282Y/H63D) develop clinical symptoms of hemochromatosis. Disease caused by homozygous H63D mutations is very rare because of its much lower clinical penetrance. There are several rare forms of non-HFE-related HH. Juvenile hemochromatosis (HFE2) is the most common, presenting before the age of 30 with cardiac disease and hypogonadism. An autosomal dominant form linked to a mutation in the SLC11A3 gene has been described.[163]

Clinical manifestations

Clinical expression of HFE-related HH is variable. Most patients with classic disease present between the age of 40 and 60 with hyperpigmentation, diabetes mellitus and hepatomegaly. Cardiac disease has been reported on 52% of death certificates of patients with hemochromatosis,[164] and it is estimated that up to 35% of patients with hemochromatosis experience congestive cardiac failure and 36% develop arrhythmias.[165] However, the incidence of lethal cardiomyopathy is variable.[166] As clinical manifestations in HH can be subtle or delayed, a high index of suspicion and early intervention are crucial to avoid severe irreversible complications. Overt cardiac involvement, in the form of restrictive or dilated cardiomyopathy, is seen in late stages[167] as a consequence of chronic cardiac iron accumulation.

Diagnosis

The first-line investigations for HH are serum ferritin and fasting transferin saturation. Elevated ferritin is non-specific as it can be raised in many conditions including inflammatory and neoplastic disorders. However, in combination with transferin saturation, ferritin has a 97% negative predictive value for the diagnosis of HH. When both are elevated, genotyping rather than liver biopsy is recommended to confirm the diagnosis.[168]

Treatment

Treatment for hemochromatosis should be initiated before the emergence of any cardiac abnormalities. However, myocardial iron stores are difficult to assess with non-invasive methods as they correlate poorly with serum ferritin and serum iron levels.[169] Endomyocardial biopsy for direct pathologic examination can be used to measure cardiac iron, but advances in cardiac imaging with novel magnetic resonance techniques appear promising. T2-star sequences provide surrogates of myocardial iron load, allowing early diagnosis and proper treatment monitoring of cardiac hemochromatosis.[170] Regular venesection, until ferritin normalizes or patients become anemic, is the mainstay of therapy.[171] Most clinical features of the disease improve following treatment; in particular, cardiac involvement has been shown to improve[172] (**Class I, Level C**). There are some data showing that chelation therapy clears iron stores quickly and avoids complications of cardiac failure.[173]

Metabolic storage diseases

Metabolic storage diseases comprise a heterogeneous group of genetically determined enzyme deficiencies that result in accumulation of metabolic substrates in various cell types. The most common in clinical practice are the lysosomal storage disorders (LSD), a group of more than 40 diseases caused by a deficiency of lysosomal enzymes, membrane transporters and other proteins involved in lysosomal metabolism. Most are inherited as autosomal recessive traits except for Anderson–Fabry disease, glycogen storage disease (GSD) type IIb (Danon disease) and mucopolysaccharidosis (MPS) type II (Hunter disease). Cardiac disease is particularly important in glycogen storage diseases (Pompe and Danon disease), mucopolysaccharidoses and in glycosphingolipidoses (Anderson–Fabry disease).[174–175]

Pompe disease (acid maltase deficiency, glycogen storage disease IIa) presents as infantile, juvenile and adult variants, that differ with respect to age of onset, rate of disease progression and severity of tissue involvement. Massive cardiac hypertrophy and heart failure caused by myocardial glycogen deposition are characteristic of the infantile and childhood forms. LV outflow obstruction is described in about 6% of patients. The ECG typically shows wide high-voltage QRS complexes and a short PR interval with a pre-excitation pattern. The infantile form is usually fatal before 2 years of age due to cardiorespiratory failure. In the juvenile and adult-onset variants, disease is usually limited to skeletal muscle, with a slowly progressive proximal myopathy and respiratory muscle weakness.[176] Recombinant enzyme replacement in the infantile and childhood forms is associated with regression of LVH and improved survival.[177]

Danon disease is an X-linked disorder caused by deficiency of the lysosome-associated membrane protein type 2 (LAMP-2). The typical presentation includes skeletal myopathy, mental retardation and hypertrophic cardiomyopathy leading to death in affected males between the second and third decade. Heterozygous females have milder disease with later onset cardiomyopathy. The pathologic hallmark of the disease is the presence of intracytoplasmic vacuoles containing autophagic material and glycogen in cardiac and skeletal muscle cells.[178]

Glycogen storage disease type III results from deficient glycogen debrancher enzyme activity. There are two major GSD III subtypes explained by differences in tissue expression of the deficient enzyme: GSD IIIa, which affects both the liver and muscle, accounts for 80% of the cases, and GSD IIIb, affecting only the liver, for approximately 15% of all GSD III cases. Muscle weakness usually coincides with hepatomegaly, hypoglycemia, short stature, dyslipidemia, and occasionally slight mental retardation or facial abnormalities. However, muscle symptoms manifest in some cases long after liver disorders disappeared in childhood.[179] In the majority of GSD IIIa patients cardiac involvement is recognized as ventricular hypertrophy on ECG accompanied by abnormal echocardiographic features.[180] Creatine kinase level is usually increased in patients with skeletal muscle involvement; however, normal levels do not rule out the presence of muscle enzyme deficiency. Treatment for GSD III is primarily dietary and is aimed at maintaining normoglycemia. Liver transplantation to correct the related biochemical abnormalities is an option but with unclear efficacy with regard to muscle or cardiac disease.

Mucopolysaccharidoses

Mucopolysaccharidoses (MPS) are caused by a defect of intralysosomal degradation of acid mucopolysaccharides (glycosaminglycans). Seven main forms and several subtypes are described. Cardiac involvement is detectable in more than two-thirds of affected children, the most common abnormalities being mitral and aortic valve thickening. The prevalence of valve abnormalities ranges from 27% to 90% depending on disease subtype (highest frequency in MPS I, II and VI, lowest in type IV and III). Coronary involvement caused by intimal infiltration by storage cells is reported in more than 40% of patients, but rarely results in clinically evident myocardial ischemia. The aorta may also be affected. Left ventricular hypertrophy, dilated cardiomyopathy and endomyocardial fibroelastosis are described. Conduction system disease is also reported and sudden cardiac deaths are relatively frequent.[181]

Anderson–Fabry disease

Anderson–Fabry disease is an X-linked disorder caused by mutations in the gene encoding the lysosomal enzyme, alpha-galactosidase A. The resultant enzyme deficiency causes intracellular glycosphingolipid accumulation in nervous, renal, gastrointestinal, cutaneous and cardiac tissues. Cardiac involvement usually manifests in the third to fourth decades in hemizygote males and the fourth to fifth decades in heterozygote females.[182] An isolated cardiac variant has been reported, but careful investigations usually reveal subclinical involvement of other systems.[183]

Concentric left ventricular hypertrophy is most typical, although asymmetric septal hypertrophy occurs in approximately 10%. Left ventricular outflow tract obstruction is unusual.[184] Valve thickening results in mild to moderate valvular insufficiency.[185] Reduced coronary flow reserve measured with positron emission tomography may explain angina symptoms in the absence of obstructive coronary disease.[186] Supraventricular or ventricular arrhythmias and conduction abnormalities occur frequently in older patients.[187] The diagnosis in men is obtained by assessment of plasma and leukocyte alpha-galactosidase A activity. Diagnosis in females usually requires genetic analysis as heterozygote females often have enzyme activity levels within the lower normal range.[188] Multicenter randomized placebo-controlled studies have proved the safety and efficacy of enzyme replacement therapies in AFD (**Class I, Level B**). Accumulating data demonstrate encouraging symptomatic and functional amelioration of affected organs including the heart.[189]

51 Chagas' heart disease

J Antonio Marin-Neto,[1] Anis Rassi Jr,[2] Benedito Carlos Maciel,[1] Marcus Vinicius Simões[1] and André Schmidt[1]

[1]Division of Cardiology, Medical School of Ribeirao Preto, University of Sao Paulo, Brazil
[2]Anis Rassi Hospital, Brazil

Historical perspective

Exactly one century ago Carlos Chagas discovered an entirely new infectious entity – Chagas disease, its etiologic agent – *Trypanosoma cruzi,* and the main mechanism of transmission of the disease, through the sting of *Triatominae* bugs.[1] By the early 1920s the most relevant syndrome of Chagas disease – cardiomyopathy – had been characterized, including its florid electrocardiographic disturbances.[2] However, during subsequent decades the disease was practically neglected and its epidemiologic significance was even refuted. Only in the 1950s, with the completion of systematic serologic and necropsy studies, did it became apparent that *T. cruzi* infection was responsible for the triad of cardiomyopathy, megaesophagus and megacolon which afflicted millions of people in Latin America.[3]

Definitions

Chagas' disease is characterized by acute and chronic phases. In the acute phase more than 90% of the patients have the unapparent form, while the remaining infected individuals show a febrile disease and rarely die because of myocarditis or encephalitis. During the chronic phase most patients remain for life with the indeterminate form. Others eventually show the cardiac, the digestive or the mixed form of organic involvement.[4] Cardiac and esophageal chagasic disease is further classified in stages (grades) (Fig. 51.1).

Although megaesophagus and megacolon produce typical clinical conditions in roughly 5–10% of patients, chronic Chagas' cardiomyopathy (CCC) is by far the most serious form of the disease.[5]

The long period of the indeterminate form – several decades before the appearance of clinically manifest disease – constitutes one of its most intriguing features.[6] Its traditional definition by a specialist panel in 1984 requires that asymptomatic patients with positive specific serology show no physical signs of disease, and no abnormalities in the ECG and in the radiologic assessment of the heart, esophagus and colon (barium swallowing and enema).[7] Although not adhering to such strict criteria (for instance, most studies do not allude to performing colon or esophageal X-rays) investigators using more sensitive diagnostic methods have described cardiac abnormalities in the majority of patients with the indeterminate form.[8] More significantly, patients with normal ECG and chest X-rays may have striking alterations in right ventricular biopsy specimens[9] and right ventricular contractile depression.[10] Also, these patients may have mild segmental or global left ventricular (LV) dysfunction as evaluated by the slope of the end-systolic pressure-dimension relationship.[11] In addition, independent of the clinical classification, the presence of minor LV wall motion abnormalities documented at baseline two-dimensional (2D) echocardiography in patients who have normal EKG and normal global systolic function is a predictor of deterioration of ventricular function during follow-up.[12]

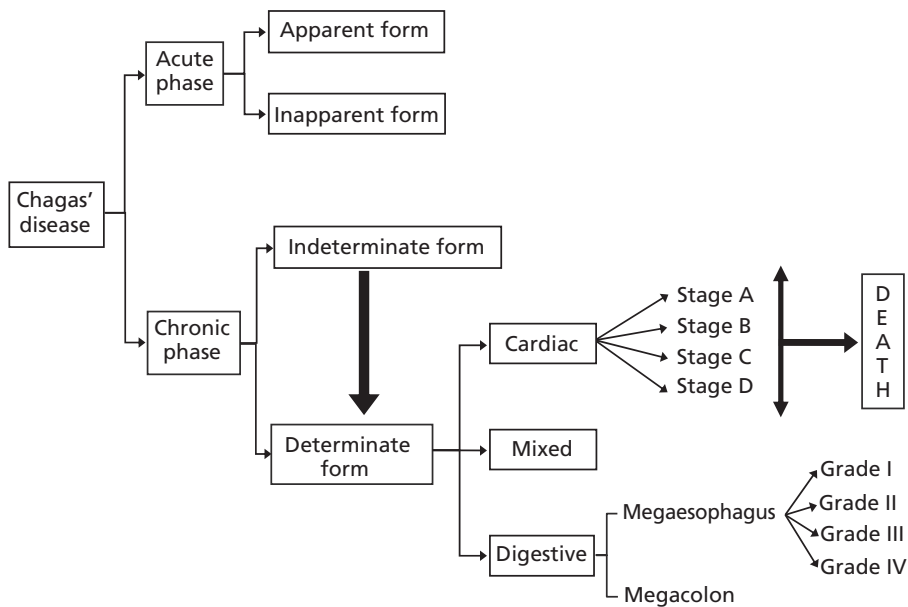
Based on these findings, it has been proposed that seropositive chagasic patients who have minor LV wall motion abnormalities on 2D-echocardiography, despite normal ECG and chest X-rays, should be classified in the cardiac form of the disease. Conversely, patients with the indeterminate form of the disease should have normal global and segmental biventricular systolic function as documented by imaging techniques.[13] Whether every chagasic patient with normal ECG and chest X-rays should routinely undergo other cardiac tests is a distinct and controversial issue. Because the probability of survival of these patients is similar to that of the normal population, the current predominant view is that further initial evaluation is usually unnecessary. Subsequent follow-up of chagasic


Figure 51.1 Chagas' disease: phases, forms, and stages.

patients with normal ECG should rely on annual history, physical examination and repeated ECG.[14]

Epidemiology

Transmission of *T. cruzi* is mainly vectoral, through the feces of infected bloodsucking insects of the family *Reduviidae* (subfamily *Triatominae*). Many case series reports have documented that the infection can also occur by blood transfusion, transplacental transmission, laboratory accident, organ transplantation and ingestion of *Triatominae*-contaminated food or drink.

Although cross-sectional epidemiologic studies assessing clinical manifestations and mortality rates have been reported in scattered areas of several South American countries, the actual prevalence of CCC is unknown, because no recent large-scale screening has been carried out. However, it is unquestionable that the global disease prevalence has steadily reduced. Recent rough estimates are in the range of 8–10 million people who have Chagas' disease in the Americas,[15,16] contrasting with the 1990 estimates of 16–18 million people infected.

In 1991 an initiative for the elimination of the transmission of Chagas' disease was launched in Argentina, Brazil, Bolivia, Chile, Paraguay and Uruguay, covering an area responsible for more than 65% of the global prevalence. As result, Uruguay (1997), Chile (1999) and Brazil (2006) declared themselves free of Chagas' disease transmission due to *Triatoma infestans*.[17] It is estimated that the incidence

of new cases declined from 700 000/year in 1983 to 200 000/year in 2000.[18] Other initiatives are now ongoing in other Latin American countries with results still pending. Nevertheless, CCC is by far the most common form of cardiomyopathy in Latin America countries. Further, because of modern migratory trends, it is likely to become ubiquitous.[19] This tendency can be exemplified by estimates, based on the prevalence of *T. cruzi* infection detected serologically (mostly Latin American immigrants), that 100 000–400 000 infected persons might be living in the United States.[20,21] The FDA recently issued strict surveillance of blood supply regarding *T. cruzi* infection, and in Europe, preventive measures have also been suggested.[22]

In the United States vector-borne transmission is rare[23] but Chagas seropositivity incidence among blood donors is increasing.[24] A recent survey by the American Red Cross, in facilities located in California and Arizona, identified 63 specimens from 61 donors among 148 969 blood donation specimens (nearly one in 2365 donations). Additionally, a systematic review of the literature providing evidence-based recommendations for the evaluation, counseling, and treatment of patients with chronic *T. cruzi* infection in the United States has recently been published.[14]

CCC has a high social impact.[25,26] Over 15 000 annual deaths can be attributed directly to this etiology and 667 000 disability-adjusted life years (DALYs) are lost annually.[18] Chagas' disease constitutes the third largest parasitic disease burden globally, after malaria and schistosomiasis.

Natural history and prognostic factors

There is sound experimental, pathologic, and clinical evidence that *T. cruzi* tissue parasitism produces organ damage acutely (immediately following infection) as well as decades later.[3] Acute infection is often asymptomatic or may be a self-limited febrile illness lasting 4–8 weeks. The case fatality rate in the acute phase is less than 5%, death occurring because of myocarditis and/or meningoencephalitis. Following the acute phase 30–40% of chronically infected individuals develop the clinical manifestations of cardiac and/or digestive disease, the majority 10–30 years after the initial infection.

Cardiac involvement typically produces conduction defects, ventricular arrhythmias, wall motion abnormalities, cardiac failure, pulmonary and systemic thromboembolic phenomena, and sudden death.[5] Megaesophagus and megacolon are also frequently diagnosed in chronic chagasic patients in Brazil, Argentina, and Chile, but not in Mexico, Colombia or Venezuela.[4] The hypothesis that different *T. cruzi* strains, coupled to genetic susceptibilities of infected individuals and to environmental factors, may cause this difference in morbidity has not been evaluated by appropriately designed studies.[27]

The natural history of CCC is relatively well known from observational studies conducted mainly in endemic areas of Brazil, Argentina, and Venezuela since the early 1940s. There is also a wealth of case series reports dealing with acute Chagas' disease acquired through non-vector transmission. Most of these investigations consist of longitudinal or cross-sectional observations of infected people in rural areas. Very few studies have been conducted using case–control populations of chagasic and non-chagasic people. There have also been some observational investigations focusing on the description and follow-up of hospital based cohorts.

Both the rural and the hospital-based studies have limitations. There is usually no adequate identification of cardiac involvement in the rural studies. Furthermore, because of the protracted course of heart involvement, from the acute phase to end-stage heart failure, no studies encompassing the whole span of the disease are available. Conversely, in hospital-based studies the disease is often well characterized but results could not be extended to the whole chagasic population. More recently, several longitudinal studies have been conducted on clinic-based populations at different referral centers in an attempt to establish predictors of death for patients with CCC.[28] These studies have analyzed clinical, radiologic, electrocardiographic, echocardiographic and Holter monitoring variables.

Prognosis in the acute phase

Case series using serologic tests in endemic areas have shown that in less than 10% of the acute cases were clinical manifestations sufficient to make a correct diagnosis.[29] This is a major deterrent for understanding the transition from the acute to the chronic phases. However, the scarce clinical data are in general agreement with findings from experimental models of Chagas' disease.

For the minority of patients in whom the clinical diagnosis was possible, cardiac involvement occurred in 90% of 313 successive cases reported in Bambuí (central Brazil). Of note, in 70–80%, cardiac enlargement was seen on chest X-rays, contrasting with only 50% of cases showing ECG abnormalities.[29] This is in disagreement with other reports showing a predominance of ECG alterations.[30] In the Bambuí study, the severity of myocarditis was inversely proportional to age, heart failure being more intense in children aged up to two years. Mortality in the acute phase, as seen in the 313 cases, was 8.3%. This was higher than the 3–5% reported in similar studies in other endemic areas in Brazil, Argentina, and Uruguay. The ECG was normal in 63.3% of the non-fatal cases and in only 14.3% of those who died in the acute phase. Seventy-five percent of all deaths were seen in children aged <3 years. Heart failure was the constant finding in all fatal cases, with or without concomitant encephalitis.[29]

The typical course of acutely manifested Chagas' disease includes disappearance of symptoms and signs of heart failure within 1–3 months and normalization of the ECG after one year of the infection. However, there is no evidence of spontaneous cure of the infection, as demonstrated by serial xenodiagnosis and serologic tests in studies of several hundreds of chagasic patients. Of 117 patients from Bambuí who were followed for up to 40 years after the acute infection, the development of CCC (based on clinical signs, ECG, and chest X-ray) occurred in 33.8%, 39.3%, and 58.1% for follow-up periods of 10–20 years, 21–30 years, and 31–40 years respectively.[29] In another review from the same cohort, for 268 patients whose acute phase of the disease had been diagnosed an average of 27 years before, the general mortality for the period was 13.8%.[29]

In contrast to the low mortality following the vectoral transmission, recent outbreaks of the disease, caused by ingestion of contaminated food or fluids, were associated with higher mortality rates, probably due to massive parasitic burden.[31]

Prognosis in the indeterminate form

The mechanisms responsible for preventing the progression of disease in more than 50% of cases (i.e. those with

the indeterminate form) remain obscure. A 1–3% annual rate of appearance of CCC has been observed in several studies. Of 400 young adults followed for 10 years in São Felipe (north eastern Brazil), 91 (23%) developed ECG or chest X-ray abnormalities. Of note, eight deaths were recorded in that period, seven of them due to non-chagasic causes and only one occurring because of reactivation of myocarditis.[6]

Another longitudinal study in Bambuí contrasted the evolution of 885 young patients with indeterminate form to that of 911 chagasic patients with initially abnormal ECGs. Survival after 10 years was 97.4% and 61.3% respectively for the indeterminate group and the group with CCC.[32] A third longitudinal study in a rural Venezuelan community, with 47% prevalence of positive serology for Chagas' disease, followed 364 patients for a mean period of four years. Heart involvement appeared at a rate of 1.1% per year in seropositive individuals. Mortality was 3% in the four years of follow-up, CCC being the cause of death in 69% of all fatal cases.[33]

In 1973 a longitudinal study was initiated in Castro Alves (Bahia), a rural community in north east Brazil. In the initial cross-sectional study, of 644 individuals aged >10 years, 53.7% were seropositive. The population initially described in 1973–1974 was re-examined in 1977, 1980, and 1983. The overall rate of development of abnormal ECG was 2.57% in seropositive as compared to 1.25% per year in seronegative individuals, a relative risk of 2.0 for the same geographical area.[34] These results were obtained in chagasic populations with >50% of the patients aged <20 years. It is relevant that fewer indeterminate cases are found in the older age groups because of the evolving nature of the disease (that is, more aging patients presenting clinical signs of cardiac or digestive involvement).

Another study of 160 patients with the indeterminate form was conducted in São Paulo, Brazil, from 1979 to 1994. Patients were followed long term with repeated electrocardiographic and echocardiographic studies at regular intervals. After a mean follow-up of 8.2 years, 34 patients (21.3%) developed ECG changes. However, only in 15 of the 34 patients could the ECG changes be clearly attributed to CCC. In addition, LV ejection fraction remained normal in the entire population throughout the study, certainly contributing to the favorable outlook for these patients.[35] More recently, a longitudinal study in Argentina following 731 patients (mean age 44 years) with the indeterminate form of Chagas' disease for eight years found that 4.6% progressed to clinically manifest cardiomyopathy. Four patients (0.5%) died of cardiovascular causes during this period, but their cardiac status right before the death was not reported.[36] Finally, in the larger series of 4593 chagasic patients followed for an average of 5.3 years in Argentina, those with normal ECG showed a very low sudden cardiac mortality rate (0.004% per year).[37]

Prognosis of chronic Chagas cardiomyopathy

The evidence provided by the studies mentioned above shows that chagasic individuals with a normal ECG, in general, have a very good prognosis. In contrast, the appearance of ECG changes entails an unfavorable prognosis. In a community-based study in rural Brazil, right bundle brunch block and ventricular extrasystoles were each associated with 7–8-fold increase, and the two together with a 13-fold increase in risk of death over a seven-year period, as compared to the infected population with normal ECG.[38]

In another study of 107 chagasic patients followed for 10 years, a significant reduction in life expectancy, as compared to that of 22 control individuals, was detected only in patients with ECG or clinical changes. A mortality rate of 82% over the 10-year follow-up period was seen in the group of 34 patients with signs of heart failure at the beginning of the study. In contrast, a 65% 10-year survival was associated with ECG abnormalities but in the absence of signs of heart failure.[39] In a study of 160 cases, survival two years after the first episode of heart failure was only 33.4%.[40] Another study of 104 male chagasic patients admitted to hospital with heart failure revealed a mortality rate of 52% after five years. The strongest predictors of survival were reduced LV ejection fraction and maximal oxygen uptake during exercise.[41] The data support the concept that mortality associated with Chagas' disease strongly correlates with severity of myocardial dysfunction.

In a series of 42 patients with CCC in the United States, death occurred in 11 patients during a mean follow-up of nearly five years, always in association with global or regional LV dysfunction. Established or developing heart failure was a strong predictor of mortality but aborted sudden death or the presence of sustained ventricular tachycardia were not predictors for mortality in this series.[42] These results contrast with the evidence from 44 chagasic patients followed for a mean period of two years where ventricular tachycardia detected during exercise testing was a marker of increased risk of sudden death.[43] This discrepancy probably reflects the limitations of small number of patients and relatively short follow-up in both studies.

In a recent study of 424 patients with Chagas' heart disease in central Brazil, a mortality risk score based on extensive follow-up data was developed and validated in an external sample, after univariate and multivariate analysis. Six independent predictors of death were identified[44] (Fig. 51.2). Finally, a systematic review of all reports on prognostic factors using multivariate analysis in CCC confirmed that the risk of death is strongly related to the severity of disease, with markers of LV dysfunction, congestive heart failure and complex ventricular arrhythmias carrying the gravest prognosis.[28]

Risk Factor	Points
NYHA class III or IV	5
Cardiomegaly (chest x-ray)	5
Segmental or global WMA (2D echo)	3
Nonsustained VT (24h Holter)	3
Low QRS voltage (ECG)	2
Male sex	2

Total Points	Total Mortality		Risk
	5 years	10 years	
0 – 6	2%	10%	Low
7 – 11	18%	44%	Intermediate
12 – 20	63%	84%	High

Figure 51.2 Risk score for predicting death in chronic Chagas cardiomyopathy. NYHA, New York Heart Association; WMA, wall motion abnormality; VT, ventricular tachycardia.

Key points

- As long as patients remain in the indeterminate form, their prognosis is good. **Level C1**
- After 10 years almost 80% of patients remain with the indeterminate form of the disease and probably 50% of the entire population will have no signs of heart disease throughout their life span. **Level C1**
- There are no clues as to why some chagasic patients remain with the indeterminate form, while others sooner or later undergo severe organic damage.
- The prognosis of patients with Chagas' heart disease is predictable, despite the heterogeneity of clinical manifestations of the disease. **Level C1**
- By univariate analysis many variables indicate a poor prognosis. However, taking into account the relationship among variables (multivariate analysis), impaired LV dysfunction, NYHA class III/IV, cardiomegaly, and non-sustained ventricular tachycardia are consistently and independently associated with higher mortality. **Level C1**
- The combination of non-sustained ventricular tachycardia (NSVT) and LV dysfunction is associated with a substantial increased risk of mortality when compared with patients without any of these risk markers. **Level C1**
- Once overt cardiac failure ensues the prognosis is poor and approaches 50% in four years. **Level C1**
- It is possible, but not proven by good evidence, that ventricular dysrhythmia and sudden death play a more prominent role in mortality due to Chagas' disease than in heart failure due to other etiologies. **Level C2**

Pathophysiology and pathogenetic mechanisms

Organ damage arising during the acute phase is closely related to parasite presence in targets such as the gastrointestinal tract, central nervous system and heart. High-grade parasitemia co-exists with lymphadenopathy, liver and spleen enlargement, markers of widespread immunologic reaction. As the parasitemia abates and the systemic inflammatory reaction subsides, silent relentless focal myocarditis ensues during the indeterminate phase.[45] In predisposed hosts, encompassing approximately 30–50% of the infected population, this chronic myocarditis may evolve to cumulative destruction of cardiac fibers and marked reparative fibrosis. The incessant myocarditis is eventually responsible for myocardial mass loss attaining critical degrees, thereby leading to regional and global ventricular remodeling and chamber dilation, and setting the anatomic substrate for malignant dysrhythmias. This hypothesis is based on several experimental animal models for CCC, but additional evidence has been provided by studies correlating clinical and pathologic findings in autopsied humans dying with all forms and stages of the disease.

The most intriguing challenge for understanding the pathogenesis of CCC lies in the complex host–parasite inter-relationship. In many patients, the myocardial aggression is controlled at low levels, remaining with the indeterminate form, whereas in others the development of fully blown CCC is triggered.[46]

Evidence from pathophysiologic studies in animal models and in humans points to four pathogenetic mechanisms producing myocardial damage in CCC.[45]

1. Cardiac autonomic disturbances

Intense neuronal depopulation has been demonstrated in several independent pathologic studies.[47,48] Also, abnormal autonomic cardiac regulation has been shown in many functional investigations, preceding the development of ventricular dysfunction.[10,49] Because of the dysautonomia, chagasic patients are deprived of the tonic inhibitory action normally exerted by the parasympathetic system on the sinus node, and also lack the vagally mediated mechanism to respond with rapid bradycardia or tachycardia to transient changes in blood pressure or venous return.[50,51] Although sympathetic denervation has also been shown in myocardial regions, even preceding perfusion defects and wall motion abnormalities,[52] on the basis of the striking parasympathetic impairment, the neurogenic theory postulated that a long-lasting autonomic imbalance would lead to a catecholamine-induced cardiomyopathy.[47,53]

However, various kinds of evidence militate against neurogenic derangements being a main pathogenetic mechanism.[45] First, even in endemic areas where cardiac

denervation is readily detectable in some patients, its prevalence and intensity are highly variable. Second, no significant correlation seems to exist between parasympathetic denervation and the extent of myocardial dysfunction or the presence of dysrhythmia. Moreover, the typical chagasic cardiomyopathy is found in geographical regions where the disease is apparently caused by parasite strains devoid of neurotropism.[4] In such regions the typical chagasic digestive syndromes considered to be causally related to parasympathetic denervation of the esophagus and colon are rarely described. Third, no follow-up studies correlating autonomic regulation, myocardial function, and cardiac rhythm assessment have been reported in chagasic patients. Finally, the attractive hypothesis of autonomic impairment triggering sudden death has never been appropriately tested.

2. Microvascular disturbances

There is evidence from studies in experimental models of *T. cruzi* infection, as well as from pathologic and clinical investigations, that microvascular abnormalities causing ischemia contribute to the pathogenesis of CCC. In the experimental murine model of Chagas' disease, occlusive platelet thrombi in small epicardial and microcirculatory coronary vessels have been shown in concomitance with focal vascular constriction and spasm.[54,55] These abnormalities were partly reverted by long-term administration of verapamil, leading to attenuation of the myocardial damage and increased survival for the *T. cruzi* infected mice.[56]

Biopsy and autopsy histopathologic investigations in humans also showed microvascular abnormalities deemed responsible for the focal diffuse myocytolysis and extensive reparative fibrosis known to be related to transient ischemic disturbances of low intensity and short duration.[3,47,57–59]

From the clinical standpoint most chagasic patients have ischemic-like symptoms and ST changes and abnormal Q-waves indicative of regional myocardial fibrosis. They also have prominent LV localized dysynergy and striking myocardial perfusion defects in the absence of epicardial coronary artery obstruction.[60] Of note, these reversible ischemic defects are mostly seen in the apical and inferior-posterior LV segments, i.e. the regions where regional contractile dysfunction prevails in later stages of CCC.[52] In a recent study, 36 chagasic patients with normal coronary arteries were sequentially evaluated regarding progression of left ventricular dysfunction and myocardial perfusion disturbances over a mean period of 5.6 years. The results showed that the decrease of left ventricular ejection fraction over time was correlated to the increase of regional myocardial perfusion at rest, which is indicative of myocardial fibrosis. The appearance of new perfusion defects at rest at the final evaluation was topographically related to the presence of reversible ischemic perfusion defects at the initial scan.[61] Thus, microcirculatory ischemia could

represent an ancillary factor to potentiate and amplify the chronic inflammatory aggression to myocardial tissue, with coalescent microinfarctions leading to the development of aneurysms.[45]

3. Myocardial damage directly related to parasite persistence

Early in the natural history of CCC there is a low-grade but constant focal and diffuse inflammatory process, as shown by studies in experimental models[62] and in human necropsy (chagasics dead from other causes) and biopsy specimens.[9,63,64] Several independent investigators using immunohistochemistry, PCR and *in situ* hybridization methods described tissue *T. cruzi* antigens or its genomic material in the inflammatory foci, first in animal models[64,65] and later in humans.[65–70] There is also evidence of a direct correlation between organic parasite infection and the clinical expression of disease. Thus, *T. cruzi* genetic material could not be detected in the heart from patients who died without signs of cardiac involvement, but it was consistently found in heart specimens from patients with CCC.[69] Moreover, the persistence of *T. cruzi* is directly implicated in the pathology of the chronic phase, as shown by experimental models of Chagas' disease in which parasite load reduction by trypanocidal treatment resulted in attenuation of cardiomyopathy.[71,72] Conversely, in experimental models, enhancement of parasite burden results in exacerbation of the cardiomyopathy course.[73] Finally, in human CCC, during favorable conditions such as immunosuppression treatment to prevent transplant rejection or in patients with acquired immunodeficiency syndromes, intact amastigote parasites undertake active multiplication and cause reactivation of infection and striking recrudescence of myocarditis and esophagitis.[74–79]

4. Immune-mediated cardiac damage

Immunologic factors have been postulated to play a role in the pathogenesis of CCC. The demonstration of predominant mononuclear cells in the inflammatory infiltrates suggests a delayed hypersensitivity reaction, leading to immunoglobulin and complement deposition in myocardial tissue.[80,81] Experimental and clinical data from studies in CCC also show that several of the criteria required for an autoimmune pathogenesis have been fulfilled:[82]
• the identification of heart–*T. cruzi* cell cross-reactive T cell antigens with reproduction of pathobiologic changes by passive transfer of immune cells in murine models
• attenuation of the inflammatory process as a consequence of tolerance induction to myocardial antigens
• the induction of myocardial aggression after immunization with cardiac myosin

• the isolation of cardiac myosin autoreactive T cells in molecular mimicry with *T. cruzi* B13 protein from affected tissue
• *in vitro* immunization with B13 protein eliciting T cell clones cross-reactive with cardiac myosin
• immunization with *T. cruzi* ribosomal antigens inducing cross-reactive antibodies and heart conduction abnormalities
• similar cross-reactive autoantibodies present in sera from patients with CCC disease inducing arrhythmia in explanted hearts.

In summary, there is persuasive evidence of both parasite antigen-driven immunopathology and autoimmunity in cardiac inflammatory lesions. However, the nature of the essential antigen or antigens that elicit destructive immune responses remains elusive.[45]

Key points

- Cardiac dysautonomia is a well-characterized feature preceding myocardial damage, but its role is probably ancillary in the pathogenesis of CCC. **Level B**
- Microcirculatory derangements causing ischemia probably constitute important amplification mechanisms for the inflammatory myocardial aggression. **Level B**
- The low-grade but incessant myocarditis present in CCC is inextricably related to the parasite persistence, with superimposed antiparasite immunity and autoimmune reaction, but the mechanisms triggering exacerbated responses in some cases and deterring significant damage in others still remain to be elucidated. **Level B**
- A corollary of the parasite persistence hypothesis, with potential clinical implication, is that effective measures to control the parasite burden would probably reduce tissue damage and impact on the natural history of CCC.

Clinical features

Cardiac abnormalities may be detected in all phases or forms of Chagas' disease, but their clinical expression is highly variable (Table 51.1). The diagnosis of Chagas' disease in the acute phase is difficult because symptoms are easily mistaken for other infectious diseases and laboratory findings are non-specific, including leukocytosis with an absolute increase in lymphocyte count; ECG may show low-voltage, diffuse ST-T changes and first-degree atrioventricular block; chest X-ray shows variable degrees of cardiomegaly; serologic tests for *T. cruzi* infection are usually negative during the first weeks. In this setting, the diagnosis is based upon detection of circulating parasites by a variety of methods. The diagnosis of acute phase due to blood transfusion requires a high level of awareness, particularly in non-endemic areas This is also necessary for the increasing problem of recognizing reactivation of Chagas' disease in immunocompromised patients who have the chronic form.[79,83]

In the chronic phase, the relative prevalence of symptoms of cardiovascular and/or digestive involvement is variable in different geographical regions, and probably reflects the existence of diverse strains of *T. cruzi*, other environmental or host factors, and the type of laboratory and serologic testing.

Usually, cardiovascular symptoms and physical signs at this stage of the disease arise from three basic syndromes that may co-exist in the same patient: heart failure; cardiac dysrhythmia and thromboembolism (systemic and pulmonary). Of note, it is not uncommon for patients with marked ECG abnormalities to be asymptomatic hard workers, capable of performing strenuous physical exercise under laboratory conditions.[84] When symptoms

Table 51.1 A clinical and functional classification of Chagas' heart disease

| | Clinical phase | | | |
	Acute	**Indeterminate**	**Overt disease**	**Heart failure**
Symptoms	Fairly common	Absent	Minimal	Present
ECG changes	Common	Absent	RBBB, LAHB, AVB, PVCs	+ Q-waves, AF, VT
Heart size (X-rays)	Usually abnormal	Normal	Normal	Enlarged
RV function		May be depressed	Usually abnormal	Abnormal
LV diastolic function	?	Normal or mild abnormalities	Abnormal	Abnormal
LV systolic function	Abnormal	May have mild regional dysynergy	Segmental dysynergy	Global depression
Perfusion defects	?	?	Common	Common
Autonomic function	?	May be abnormal	May be abnormal	Usually abnormal
RV biopsy	Abnormal	May be abnormal	Abnormal	Abnormal

LV, left ventricle; RV, right ventricle; ECG, electrocardiogram; AVB, atrioventricular block; LAHB, left anterior hemiblock; RBBB, right bundle branch block; PVCs, premature ventricular complex; AF, atrial fibrillation; VT, ventricular tachycardia; ? = unknown.

occur they include edema, fatigue and exertional dyspnea, palpitations, dizziness, syncope and chest pain. Such manifestations are the expression of decreased cardiac reserve (including minor early signs of diastolic dysfunction), the presence of ventricular dysrhythmias, sinus node dysfunction, and high-degree atrioventricular block. Chest pain is usually atypical for myocardial ischemia but, in sporadic patients, mimics an acute coronary syndrome. It may also be related to esophageal mechanisms.[85,86]

ECG abnormalities are present in most patients with CCC, mainly in the form of conduction disturbances and ventricular arrhythmias.[5] In more advanced stages pathologic Q-waves and low voltage are found, compatible with extensive areas of myocardial fibrosis. The combination of right bundle branch block and left anterior hemiblock is very typical in CCC.

Many case series reports have documented the peculiar feature of striking segmental wall motion abnormalities in several hundreds of chronic chagasic patients.[87] The most characteristic lesion is the apical LV aneurysm. A few small retrospective studies have evaluated the correlation between ventricular arrhythmia and symptoms in CCC. It is apparent that complex ventricular dysrhythmia may occur in asymptomatic patients, but it is usually associated with poor LV function.[88] The aneurysms are also sources of emboli.[89,90]

Systemic and pulmonary embolism, arising from mural thrombi in the cardiac chambers, is a conspicuous complication of CCC, but post-mortem findings have shown that they are often overlooked: in 1345 necropsies on patients with CCC, 595 cases (44%) had cardiac thrombi and/or visceral thromboembolism. The presence of cardiac thrombi was related to severity of ventricular enlargement. Embolism most frequently involved lungs (36%), kidneys (36%), spleen (14%), and brain (10%).[88] Also, the incidence of cardiac thrombus was higher in cases of heart failure (36%) than in cases of sudden death (15%).

Congestive heart failure, in advanced stage, is more commonly expressed by prominent signs of systemic congestion, with less intense evidence of pulmonary congestion.[91,92] This peculiar feature of CCC is linked to early severe damage of the right ventricle (RV), a chamber frequently neglected in the clinical and echocardiographic evaluation of cardiac performance.[93] Isolated LV failure may also appear in early stages of cardiac decompensation.

Sudden death is the principal cause of death in CCC, accounting for about 55–65% of deaths, followed by pump failure (25–30%), and thromboembolism (10–15%). Sudden cardiac death can occur even in patients previously asymptomatic.[94] It is usually precipitated by physical exercise and associated with ventricular tachycardia and fibrillation or, more rarely, with complete atrioventricular (AV) block. Limited evidence from autopsy studies, in these patients,

indicates variable degrees of inflammatory and neuronal cardiac alterations.[95]

In spite of chest pain being a cardinal complaint in many chagasic patients, coronary angiography is usually normal.[96] However, functional abnormalities in the myocardial blood flow regulation have been described and all types of myocardial perfusion defects have been detected in several small groups of selected patients, possibly implying microvascular coronary disturbances, as discussed above.[52,60]

Cardiac autonomic dysfunction, mainly parasympathetic, has been shown by several independent studies in various groups of chagasic patients (including those with isolated digestive disease), whose response to various autonomic tests was compared to those of control subjects.[49,51,96–99] However, these abnormalities are neither correlated with any symptoms nor cause postural hypotension.[45,51]

Management

Etiologic treatment

Recent developments in basic biochemistry of the parasite allowed identification of potential targets for chemotherapy, such as protein prenylation, sterol, proteases and phospholipids metabolism.[99] However, only two currently available trypanocidal agents have been demonstrated to have acceptable efficacy and safety profiles: nifurtimox and benznidazole. Side effects, warranting discontinuation of therapy in roughly 10% of cases, include dermatitis, polyneuritis, leukopenia, gastrointestinal intolerance and central nervous system adverse symptoms. These untoward reactions are reversible with discontinuation of therapy. Benznidazole is considered the preferred drug at a dose of 5 mg/kg per day for 60 days; the dose in children up to age 12 is 10 mg/kg per day. Nifurtimox is given for 60–90 days at a dose of 8–10 mg/kg per day in adults and 15 mg/kg per day in children. Both drugs should be administered in divided doses at eight-hour intervals. Benznidazole can also be administered at 12-hour intervals.

Assessment of trypanocidal treatment efficacy is still hampered by methodologic issues. Parasitemia is readily demonstrated in the acute phase of Chagas' disease by direct examination of blood or buffy coat, hemoculture or xenodiagnosis but even without treatment, falls to undetectable levels by these methods within three months.[100,101] PCR techniques for detection of *T. cruzi* in blood are useful for monitoring the success of treatment in the acute phase, but also have low sensitivity in the chronic stages.[102] Hence, in the chronic phase of the disease documentation of cure should rely on negativation of IgG serologic tests. There is expert opinion that the length of time after successful treatment required for negative seroconversion is proportional to the duration of *T. cruzi* infection: 3–5 years for those

treated in the acute phase, 5–10 years in those with <10 years, and 15–20 years in those with >10 years duration of infection.[103]

Trypanocidal therapy in the acute phase

There is consensus that in the acute phase, irrespective of the mechanism of transmission (vectorial, congenital, blood transfusion, transplantation, laboratory accident or oral), trypanocidal treatment is mandatory. Parasitologic and serologic cure is thought to occur in 60–85% of those treated in this phase.[102] Unfortunately, no long-term follow-up trials have evaluated the efficacy of trypanocidal therapy for the prevention of chronic organ damage in patients treated during the acute phase.

Trypanocidal therapy in the chronic phase

Etiologic treatment is unanimously recommended for chronic patients with reactivation of acute infection during immunosuppression, including those co-infected with *T. cruzi*/HIV.[104] This indication is supported by observational results of effective trypanocidal therapy for reduction of symptoms and parasitemia in small case series of chagasic patients who received various types of transplants.[105,106]

The prophylactic administration of trypanocidal drugs for women of reproductive age (as an attempt to reduce the possibility of congenital transmission), for anticipated immunosuppression in the future (pre-transplant), and for HIV infection with low CD4+ lymphocyte counts is more controversial.[107] Among experts there is a predominant trend toward recommendation of close monitoring for reactivation after solid organ or bone marrow transplants, and treatment only if infection is demonstrated, based on

the concept that risk of reactivation depends strongly on the degree of immunosuppression.[108]

In the chronic phase, a small prospective non-randomized controlled trial suggested that etiologic treatment may impact favorably on prognosis. It involved 131 patients treated with benznidazole (5 mg/kg/day for 30 days) and 70 untreated patients with a mean follow-up period of eight years; progression of the disease was assessed by ECG changes: treated patients presented fewer ECG changes than control group (4.2% vs 30%) and less deterioration of clinical condition (2.1% vs 17%).[109] More recently the same group reported on a non-randomized, unblinded trial involving 566 patients followed for 10 years; the 283 patients treated with benznidazole (5 mg/kg per day for 30 days) were less likely to develop symptoms, ECG abnormalities, and deterioration of LV function. The study results are limited by missing data during follow-up (20% of patients), the lower than usually recommended treatment dose, and the non-randomized nature of the trial.[110]

Metanalysis of pooled data from observational studies showed that there is insufficient evidence, on the basis of results concerning hard clinical endpoints, to support the use of trypanocidal drugs for the treatment of chronic *T. cruzi* infection, especially if overt heart disease is present.[111] To resolve the current dilemma of treating or not treating adult patients with established CCC with trypanocidal drugs, a multicenter, randomized, placebo-controlled, double-blind study, the BENEFIT trial, is currently under way (http://clinicaltrials.gov/show/NCT00123916).

In asymptomatic patients with chronic Chagas' disease, pooled data derived from a systematic review found only five studies comparing groups of patients submitted to trypanocidal therapy against placebo (Table 51.2).

Table 51.2 General characteristic of randomized clinical trials evaluating trypanocidal therapy in chronic asymptomatic patients with Chagas' disease

Author, country (year)	Participants (% IP)	Interventions (*n* randomized) dose	Outcomes[a] (primary and secondary)
Andrade, Brazil (1996)	School children (90%)	Benznidazole (64) 7.5 mg/kg/day – 8 weeks vs placebo (65)	Seroconversion Antibody changes

A metanalysis of these non-randomized data, involving 756 patients, documented that host–parasite indices of disease were favorably modified by trypanocidal treatment but no results concerning hard clinical outcomes were available.[112] The most important finding in this review was that trypanocidal therapy with benznidazole improved parasite-related outcomes especially in children with asymptomatic *T. cruzi* infection, with approximately 60% apparent cure of infection as measured by conversion of Ig/IgG serologic tests to negative 3–4 years after the end of treatment (Fig. 51.3).[112] Another study, not included in the metanalysis, reported respectively 73% and 86% negativation of PCR and xenodiagnosis three years after treatment with nifurtimox in children.[113]

These studies, together with empiric clinical experience across Latin America, provided the basis for the current recommendation that early diagnosis should be sought and trypanocidal therapy implemented for all infected children.[103,114,115]

<div style="border:1px solid;">

Key points

- Trypanocidal therapy is universally recommended in acute and congenital Chagas' disease, reactivation of acute infection and in early chronic Chagas' disease (children ≤12 years and people whose duration of infection is known or presumed to be <12 years). **Class I, Level B**
- In patients with chronic Chagas' disease with duration >12 years and no established disease (indeterminate form), treatment decisions must be based on an individual basis, only after thorough clinical assessment and with continuous monitoring of potential side effects. **Class IIa, Level C1**
- Until conclusive data are available, etiologic treatment should be considered optional for adults with remote *T. cruzi* infection and definite but not advanced cardiac manifestations. **Class IIb, Level C1**
- Trypanocidal agents may be administered for prevention of reactivation of infection in high-risk patients (e.g. anticipated immunossupression following organ transplantation recipients). **Class IIb, Level B**
- Treatment is contraindicated for patients with class IV heart failure, advanced megaesophagus before surgical intervention, severe renal and liver disease, and during pregnancy. **Class III, Level C2**

Management of rhythm disturbances

Management of rhythm disturbances in the chagasic patient is empirically similar to that recommended for other cardiomyopathies. However, chagasics patients have peculiar characteristics that may interfere with their treatment and deserve specific mention.

Complex ventricular dysrhythmia is the most important disturbance because of its impact on the risk of sudden death.[94] Data from Holter monitoring have shown that episodes of NSVT are present in approximately 40% of patients with mild wall motion abnormalities and in 90% of those with heart failure, an incidence that is higher than that observed in other cardiomyopathies.[83] Not infrequently, ventricular arrhythmias and atrioventricular conduction abnormalities or sinus node dysfunction co-exist in the same patient.

Sustained monomorphic ventricular tachycardia is another important feature of Chagas' heart disease.[116] It is reproducible during programmed ventricular stimulation in approximately 85% of patients, implying a re-entrant mechanism. The anatomic substrate for re-entrant ventricular tachycardia in CCC is the presence of fibrosis with impaired wall motion that is most frequently located at the LV inferolateral region.[117] Histologic analysis of the inferolateral segments showed non-uniform interstitial fibrosis level intermingled with surviving cardiac fibers arranged in random fashion.[118]

Although there is no evidence from randomized controlled trials that antiarrhythmic drugs prolong life or prevent sudden cardiac death in CCC, the use of empiric amiodarone is recommended as first-choice treatment by the guidelines of the Brazilian Society of Cardiology for patients with sustained and non-sustained ventricular tachycardia, particularly in the presence of myocardial dysfunction.[119] Amiodarone is a potent antiarrhythmic drug that markedly reduces the severity and complexity of ventricular arrhythmias, does not have significant negative inotropic properties, is well tolerated (when administered at low doses), has fewer proarrhythmic effects than class I agents, and may reduce total mortality and sudden cardiac death in patients with Chagas' disease according to some observational data. In a series that compared the survival of 34 patients with Chagas' disease and sustained ventricular tachycardia, treated with amiodarone, with an earlier matched cohort of 42 patients not treated or receiving class I agents, survival rate was significantly greater in the amiodarone group at one year (87 vs 57%), four years (65 vs 22%), and eight years (59 vs 7%).[93] In patients failing empiric amiodarone therapy, electrophysiologic guided antiarrhythmic therapy has been advocated by some authors.[120] Electrophysiologic study can also identify patients who may have a poor prognosis when treated with class III antiarrhythmic drugs and be an important tool for risk stratification and patient selection for implantable cardioverter-defibrillator (ICD) selection.[121] Implantation of a cardioverter-defibrillator has been advocated for patients with refractory and hemodynamically unstable sustained ventricular tachycardia or for survivors of sudden cardiac death.[122] In order to reduce frequent shocks, antiarrhythmic drug therapy is required in most patients because of the high prevalence of ambient atrial and ventricular arrhythmias.[88] However, there are no properly

Figure 51.3 Overview of the effect, estimates for data on four outcomes pooled. Estimates are expressed as odds rations or standardized mean differences (SMD) and 95% confidence intervals using the fixed models statistical approach (95% CI fixed). Antibodies mean changes are given in the units originally reported by authors. A negative sign means reduction of levels after being treated. Adapted from Villar et al[112] with permission.

randomized controlled trials to ascertain whether pharmacologic or device therapy improves survival in CCC patients. Such a trial should urgently be conducted, and the indications for ICD therapy in patients with CCC should not be extrapolated from the results of randomized studies obtained in patients with other conditions, such as coronary artery disease or idiopathic dilated cardiomyopathy.[123]

Aneurysmectomy,[124] surgical ablation, transcoronary chemical ablation[125] and epicardial/endocardial catheter ablation[118,126] have been attempted in few patients, but neither efficacy nor impact on survival and arrhythmia recurrence is established.

Severe bradyarrhythmias are treated with pacemakers, as in other cardiac conditions, but the electrode should be placed in the subtricuspid area, not in the right ventricular apex, because apical fibrosis is common and may cause capture failure. The evidence for benefit of pacemaker implantation comes from limited case series reports with historic control series of patients in whom this treatment was not possible.[94]

The common association of sinus node or atrioventricular disturbances and ventricular complex dysrhythmia in the same patient may require pacemaker implantation associated with pharmacologic antiarrhythmic therapy. This management is regarded as prophylactic, although not based on unquestionable evidence.

In the later stages of CCC, with marked cardiac enlargement and heart failure, atrial fibrillation is common but the ventricular rate usually is not elevated because of conduction disturbances.

Key points

- Pharmacologic, surgical, and device-based strategies for the treatment of ventricular dysrhythmia in chagasic patients are empirical and not supported by any large randomized, controlled trial. **Level C2**

Treatment of congestive heart failure

Hemodynamic derangement in chronic chagasic patients with heart failure is similar to that reported in dilated cardiomyopathies of other etiologies. However, there are some peculiarities in the pathophysiology of CCC that may have therapeutic implications. For instance, there is usually marked predominance of systemic congestive manifestations over the pulmonary congestion symptoms and signs. Also, chagasic patients have striking conduction disturbances and tend to have symptomatic bradycardia, that may be aggravated with the use of digoxin, amiodarone, and beta-blockers. Congestive heart failure usually responds to routine management, including sodium restriction,

diuretics, digitalis, and angiotensin-converting enzyme (ACE) inhibitors. For patients with severe cardiac failure, higher doses of diuretics are usually necessary. Small observational studies have documented short-term hemodynamic beneficial effects of these agents and, to a lesser extent, improvement in exercise tolerance in chronic chagasic patients. However, no studies reported improvement in long-term hemodynamic or any hard clinical outcomes.

A prospective multicenter non-controlled trial assessed the impact of adding an ACE inhibitor to conventional therapy in 115 patients with heart failure (of whom 20 were chagasics). At the end of 12 weeks, irrespective of etiology, the NYHA functional class was significantly improved in most patients (85.2%).[127]

A single-blind, cross-over trial of ACE inhibitor and placebo for six weeks each, with a washout period of two weeks, was reported on 18 NYHA class IV chagasic patients.[128] Treatment with ACE inhibitor was associated with significant reduction in neurohumoral activation and amelioration of ventricular arrhythmias. These results indicate a potentially beneficial role for this class of drugs in controlling mechanisms triggering sudden death.

In a recent small trial designed to test the effect of beta-blocker therapy in addition to inhibition of the renin-angiotensin-aldosterone system, 42 chagasic patients NYHA classes I–III received enalapril (up-titrated to 20 mg bid) and spironolactone (25 mg qd).[129] The renin-angiotensin-aldosterone system inhibition was associated with improvement of quality of life score and reduction of neurohumoral activation assessed by brain natriuretic peptide (BNP) levels. Subsequently, 19 patients were randomly assigned to receive carvedilol (up-titrated to 25 mg bid) and 20 patients were allocated to placebo. Beta-blockade with carvedilol was associated to a trend toward LV ejection fraction (EF) increase, and was hemodynamically well tolerated, with no symptomatic bradycardia.

Thus, there is only very limited evidence suggesting benefit of drugs which reduce neurohormonal activation in Chagas' heart disease patients. No long-term controlled study has assessed the impact on survival of chagasic patients treated with ACE inhibitors, spironolactone or beta-blockers. Spironolactone is a theoretically attractive therapy because of the major role that cardiac fibrosis plays in the disease as well as the right heart failure. A randomized double-blind placebo-controlled study has been planned (CHARITY study) to investigate the impact of bisoprolol in a cohort of 500 patients with heart failure secondary to CCC (250 patients per arm), with a follow-up of two years.[130]

Surgical treatment

Procedures such as dynamic cardiomyoplasty and partial left ventriculectomy (Batista's surgery) are now abandoned

and LV geometric reconstruction with apical aneurysmectomy is rarely indicated for chagasic patients. Severe mitral regurgitation, secondary to chamber dilation and to dysynergy of the posterior-inferior wall, contributes frequently to heart failure worsening. A recent retrospective report from a single center in Brazil showed promising results of the implantation of mitral prosthesis in 116 heart failure patients (three being chagasics).[131]

Cardiac transplantation has been performed in small series of patients with refractory heart failure due to CCC. However, transplantation is limited by socioeconomic factors in areas where the disease is endemic and by problems related to the obligatory immunosuppression. Chagas' disease reactivation with acute myocarditis and marked transitory LV systolic depression has previously been reported in small case series as a frequent complication in patients receiving the usual high dose of ciclosporin therapy.[76] Although the reactivation of infection was usually responsive to antiparasite therapy, the possibility of definitive damage to the allograft could not be ruled out and early concern was raised that this could represent a severe limitation or even a contraindication for heart transplantation in Chagas' disease. Nevertheless, the use of immunosuppression regimen with reduced ciclosporin dosing was reported to be effective in circumventing this limitation and the prophylactic treatment of the organ receptor with trypanocidal drugs previous to transplantation was considered not necessary.[105] However, a recent report indicated the occurrence of reactivation during the use of the new immunosuppressant, mycophenolate mofetil.[132]

The long-term impact of heart transplantation in chagasic patients has been described in a subgroup of a large cohort of 792 patients submitted to orthotopic heart transplantation in 16 centers in Brazil.[133] The mean overall follow-up period was 2.87 ± 3.0 years, and 117 patients with chronic CCC constituted the subgroup. The entire cohort population also included 407 patients with idiopathic dilated cardiomyopathy and 196 with ischemic heart disease. Among chagasic patients the reported criteria and contraindication for transplantation were similar to those used for non-chagasic patients, except for the detection of megacolon or megaesophagus, also considered a contraindication for transplantation. The survival rate of Chagas' disease patients at one and 12 years was respectively 76% and 46%. These survival rates were statistically better in comparison with the rest of the cohort group in which the respective survival rates were 72% and 27%. Reactivation of *T. cruzi* infection with myocarditis and meningoencephalitis was rarely reported, and was the cause of death in only 0.3% for the entire chagasic cohort.

A recent retrospective survey from a single center in Brazil reported on the later follow-up after cardiac transplantation, with average of 44.4 ± 55.2 months, in 285 patients of whom 59 had Chagas' disease. The late survival rates were similar in chagasic and non-chagasic patients. The reported *T. cruzi* infection reactivation rate in the initial 10 patients (with conventional ciclosporin dose regimen) was 2.3 episodes per patient. This rate was reduced to 0.25 episodes per patients in the subsequent series of patients for whom the ciclosporin dose was reduced.[105]

Even allowing for the poor control of other relevant characteristics of chagasic and non-chagasic patients in these retrospective observations, the limited available data suggest that heart transplantation is a valid therapeutic option in end-stage CCC, with an expected survival rate at least comparable to that of other patients.

Multisite pacing – cardiac resynchronization

This form of therapy is being widely used for treating chagasic patients, without any supporting evidence of benefit. In fact, there are several concerns about the use of cardiac resynchronization therapy in Chagas' disease patients that need to be resolved before any recommendation can be established. For instance, dysynergy caused by extensive fibrosis is likely to hamper resynchronizing. Also, QRS prolongation in chagasic patients are frequently related to right bundle branch block, and the effect of resynchronization in this setting has not been established.

Stem cell therapy

Preliminary preclinical studies in murine models suggest potential benefit of stem cell therapy in CCC.[134] Two months after treatment a significant reduction in inflammation and fibrosis was seen in recipients of the cell therapy compared to control untreated animals. Another recent observation demonstrated improvement of LV function four weeks after implantation of co-cultured mesenchymal stem cells and skeletal myoblasts in rats.[135]

To date, only one small non-randomized non-controlled clinical study reported the early results of bone marrow cell transplantation delivered by intracoronary injection in 28 chagasic patients with NYHA class III–IV heart failure. A significant increase in LV ejection fraction, assessed by echocardiography, was observed at 60 days after treatment when compared to baseline value (23.0 ± 9.0% vs 20.1 ± 6.8%, $P = 0.02$).[136] There was also improvement of symptoms and functional capacity. However, more studies are needed before this type of treatment can be recommended. A randomized placebo-controlled clinical trial, sponsored by the Brazilian Ministry of Health, is currently ongoing and will test the efficacy of autologous bone marrow derived mononuclear cell therapies in 300 patients with Chagas' heart disease.[137]

Prevention of thromboembolic events

There is very limited clinical information on the risk of embolism in patients with mural thrombosis or apical

aneurysm. A recent study enrolled 305 patients to describe predictors of stroke in various cardiopathies, in a region where Chagas' disease is endemic.[138] Stroke was present in 32 (10.5%) patients, more commonly in chagasics (15.0%) than in other cardiopathies (6.3%; $P = 0.015$). At multivariate analysis only Chagas' disease, cardioversion and diabetes mellitus were predictors of stroke. A prospective cohort study in 1043 chronic chagasic patients found a global incidence of stroke of 5.6 per 1000 person-years. The mortality associated with the acute event was high (19.4%) and the five-year survival was 45%. Only the presence of cardiomyopathy by echocardiographic or radiologic criteria correlated with the occurrence of events.[139]

Because of the high incidence of thromboembolic phenomena in CCC, anticoagulants are recommended for patients with atrial fibrillation, previous embolism, and apical aneurysm with thrombus, even in the absence

of controlled clinical trials demonstrating their efficacy. However, poor social and economic factors may limit the implementation of this therapy, because of the increased risk of bleeding. The use of small doses of acetylsalicylic acid could be a reasonable alternative for these patients.[140]

Figure 51.4 summarizes the cardiovascular interventions useful for the management of various stages of Chagas' heart disease (see Table 51.1 for an explanation of the stages of heart involvement in Chagas' disease).

Prevention

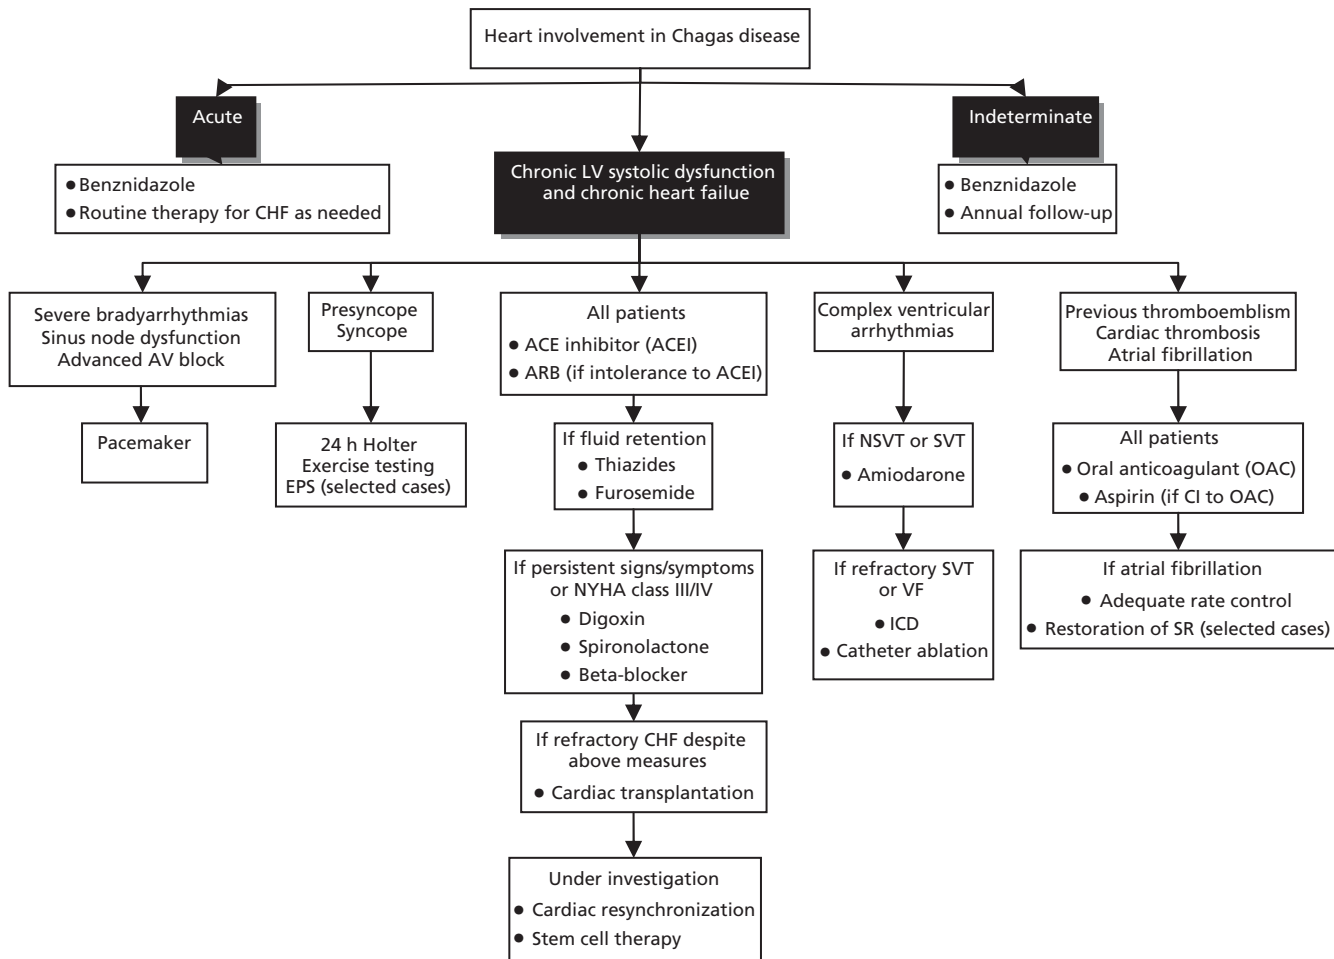
Preventive measures aiming at minimization of the medical and social burden imposed by Chagas' disease include interventions:


Figure 51.4 Treatment algorithm for patients with Chagas' disease. This treatment algorithm represents a summary of the main options available, which are usually empiric and not supported by large randomized controlled trials. ACEI, angiotensin-converting enzyme inhibitor; AV, atrioventricular; CHF, congestive heart failure; CI, contraindication; EPS, electrophysiologic study; ICD, implantable cardioverter-defibrillator; LV, left ventricular; NSVT, non-sustained ventricular tachycardia; NYHA, New York Heart Association; OAC, oral anticoagulant; SR, sinus rhythm; SVT, sustained ventricular tachycardia; VF, ventricular fibrillation.

• designed to prevent the transmission of the disease – primary prevention. The focus of this set of interventions is on the control of vectoral and blood transmission of the infection

• to reduce the chance of developing clinical illness (i.e. to prevent or inhibit disease in cases where infection has occurred) – secondary prevention, which includes trypanocidal therapy, aiming at eradication of *T. cruzi* not only to possibly prevent chronic organ damage, but also to interfere with the epidemiologic chain

• designed to limit human incapacity and to prevent morbidity and mortality, once disease has occurred – tertiary prevention.

Specific cardiovascular disorders: pericardial disease

Bernard J Gersh, Editor

52 Pericardial disease: an evidence-based approach to clinical management

Faisal F Syed[1] and Bongani M Mayosi[2]

[1] Department of Cardiology, University of Newcastle-upon-Tyne, Newcastle, UK
[2] Department of Medicine, Groote Schuur Hospital and University of Cape Town, Cape Town, South Africa

This overview deals with the extent to which the clinical management of the common pericardial diseases (i.e. idiopathic pericarditis, purulent pericarditis, tuberculous pericarditis, and neoplastic pericarditis) is supported by evidence from well-designed prospective studies. The diagnosis of acute pericarditis is based on the presence of typical chest findings, history and the electrocardiogram. The echocardiogram is used to confirm and quantify an associated pericardial effusion. It is generally accepted that oral non-steroidal anti-inflammatory drugs (NSAIDs) or aspirin are effective in most patients with acute pericarditis. Colchicine added to an NSAID or aspirin or as monotherapy appears to shorten the duration of the initial attack, and reduce the risk of recurrent pericarditis. A preliminary study has highlighted the potential benefit of rosuvastatin as adjunctive therapy to NSAIDs in acute pericarditis. Corticosteroids are restricted to cases of autoimmune disease with early introduction of NSAIDs or colchicine during the tapering phase, because of their association with recurrent attacks of acute pericarditis on withdrawal. Recurrent pericarditis is treated with colchicine. Chronic idiopathic pericardial effusion, which is diagnosed on the basis of persistence of effusion for several months in populations with a low prevalence of tuberculosis, is treated by pericardiocentesis and pericardiectomy in the case of recurrence.

A specific cause of pericarditis, such as purulent, tuberculous or neoplastic pericarditis, must be sought in all patients with pericarditis who present with the following clinical features: a fever >38 °C, subacute course over several days or weeks, large effusion with an echo-free space >1 cm anterior to the heart on echocardiography, cardiac tamponade, and failure of aspirin or NSAID therapy within a week. In this context, diagnostic pericardiocente-

sis and other tests are required to make a specific diagnosis. Purulent pericarditis, which is diagnosed on the basis of a neutrophilic pericardial exudate in association with a positive microbiologic culture, requires treatment with antibiotics and pericardial drainage. Preliminary studies using intrapericardial thrombolysis show promise in reducing the incidence of pericardial adhesions and constriction.

A definite or proven diagnosis of tuberculous pericarditis is based on demonstration of tubercle bacilli in pericardial fluid or on histologic section of the pericardium. A probable or presumed diagnosis is based on proof of tuberculosis elsewhere in a patient with otherwise unexplained pericarditis, a lymphocytic pericardial exudate with elevated biomarkers of tuberculous infection, and/or appropriate response to a trial of antituberculosis chemotherapy. Treatment consists of four-drug therapy for at least two months (isoniazid, rifampicin, pyrazinamide, and ethambutol) followed by two drugs (isoniazid and rifampicin) for four months regardless of human immunodeficiency virus (HIV) status. It is uncertain whether adjunctive corticosteroids are effective in reducing mortality or pericardial constriction, and their safety in HIV-infected patients has not been established conclusively. Surgical resection of the pericardium is indicated for calcific constrictive pericarditis or persistent signs of constriction following a 6–8 trial of antituberculosis treatment in patients with non-calcific constrictive pericarditis.

The diagnosis of neoplastic pericarditis rests on sampling of pericardial fluid or tissue for pathologic examination. Treatment of neoplastic pericardial effusion is directed at the relief of immediate symptoms of pericarditis or tamponade, preventing reaccumulation, and the management of the underlying malignancy.

Introduction

A wide variety of conditions may result in pericardial disease, which presents clinically as acute pericarditis,

Table 52.1 Contemporary causes of large pericardial effusion

	South Africa Reuter *et al* 2006[1] (n 233, 1995–2001)	Italy Imazio *et al* 2007[2] (n 453, 1996–2004)
Tuberculous pericarditis	162 (69.5%)	17 (3.7%)
Neoplastic pericarditis	22 (9.4%)	23 (5.1%)
Autoimmune aetiology	12 (5.2%)	33 (7.3%)
Purulent/septic pericarditis	5 (2.2%)	3 (0.7%)
Idiopathic or other causes	32 (13.7%)	377 (83.2%)

pericardial effusion or constrictive pericarditis. The etiologic spectrum depends on the epidemiologic setting of the patient. For example, in industrialized countries, most cases of pericarditis are idiopathic, whereas tuberculosis accounts for the majority of patients in the developing world (Table 52.1).[1,2] In many cases, pericardial disease is associated with a known condition (e.g. malignancy) or underlying cardiac disease, which prove to be the cause of pericardial disease. In patients with no apparent cause of the pericardial syndrome, the presence of inflammatory signs is predictive of acute pericarditis; on the other hand, a large effusion without inflammatory signs or tamponade is predictive of chronic idiopathic pericardial effusion.[3] Tamponade without inflammatory signs is suspicious for neoplastic pericardial effusion. In patients living in tuberculosis-endemic regions, a pericardial effusion without apparent cause is likely to be tuberculous until proven otherwise. The prognosis of pericardial disease is related to the underlying disease, being especially poor in patients with malignancy.[3]

This overview deals with the clinical management of the common pericardial diseases, including idiopathic pericarditis, purulent pericarditis, tuberculous pericarditis, and neoplastic pericarditis. We examine the extent to which existing treatments are supported by evidence from well-designed prospective studies. The findings reported here are based on a comprehensive search of electronic databases and bibliographies of articles on pericarditis.

Idiopathic pericarditis

Epidemiology

Acute idiopathic pericarditis accounts for 80–90% of primary acute pericardial disease (i.e. pericardial syndrome without apparent cause at initial clinical evaluation) in Western countries.[2,4,5] Incidence has been estimated at 28 per 100 000 per year, but the influence of the tested population, mode of presentation and seasonal and geographic variation of viral infections is significant.[6] Acute pericarditis is responsible for ~1% of presentations to emergency departments with electrocardiographic ST elevation, but at least an additional 10% of patients are diagnosed in the absence of electrocardiographic criteria.[7,8]

Etiology

The etiology of idiopathic pericarditis is presumed to be viral or autoimmune. However, in a French study of 136 patients diagnosed with idiopathic pericarditis after standard investigations and pericardiocentesis, serologic antibody evaluation and viral culture of throat swabs yielded alternative diagnoses in 39 (29%); the commonest causes were *Coxiella burnetii* (n = 10), enterovirus (n = 8), Mycoplasma infection (n = 4) and autoimmunity (high antinuclear antibody titer, n = 3).[9] Previously unsuspected hypothyroidism was diagnosed in an additional 14 patients through routine measurement of thyroid-stimulating hormone. The use of more sophisticated methods for examining pericardial fluid and tissue, such as tumor markers, fluorescence-activated cell sorting, polymerase chain reaction and immunohistochemistry, as in the Marburg Pericarditis Registry, means that less than 5% of cases are labeled as idiopathic and a much higher proportion of cases are found to be viral or autoimmune.[10]

Diagnosis

Acute pericarditis is the occurrence of two or more of the following: characteristic chest pain, pericardial friction rub (pathognomonic of acute pericarditis), and an electrocardiogram showing characteristic ST segment elevation or typical serial changes. Transthoracic echocardiography is recommended for all patients.[10,11] Cardiac tamponade is an indication for therapeutic pericardiocentesis. Diagnostic pericardiocentesis is recommended if an infective or malignant cause of effusion is suspected.[10,11] Although there are no absolute clinical differentiators, a history of malignancy or autoimmune illness, high fever with rigors, skin rash or weight loss point to a specific disease. Blood tests may reveal renal failure while a markedly raised white cell count suggests purulent pericarditis.[11]

A recent prospective evaluation of 453 patients identified fever >38 °C (odds ratio (OR) 3.56), subacute course (3.97), large effusion or tamponade (2.15), and failure of aspirin or NSAID therapy (2.50) as predictive of a specific cause being present (noted in 76 patients (17 %)) with identified diagnoses of autoimmune, neoplastic, tuberculous or bacterial pericarditis.[2] In another prospective study of 130 patients, the presence of inflammatory signs (characteristic

chest pain, pericardial friction rub, fever or typical electro-cardiographic changes) in the absence of an identified cause of moderate to large effusion predicted the diagnosis of idiopathic pericarditis (OR 5.4), whereas when these were not present, tamponade predicted neoplasia (OR 2.9).[12] This is in stark contrast to tuberculosis and HIV-endemic areas where the majority of effusions are caused by tuberculosis.[13] The presence of features suggestive of a specific cause should prompt the clinician to investigate the patient further for an infective, neoplastic or autoimmune cause of the pericarditis.

Management

When none of the above features are present to suggest high risk and the presence of autoimmune, neoplastic, tuberculous or bacterial pericarditis, management in a day case unit has been shown to be safe as long as these low-risk patients are observed for a few hours while preliminary investigations are being undertaken and closely followed up thereafter to ensure response to treatment.[8] Acute pericarditis can therefore be triaged based on clinical and echocardiographic criteria and those with high-risk features admitted and thoroughly investigated[2] (**Class I, Level C1**).

It is generally accepted that bed rest and oral NSAIDs are effective in most patients with acute pericarditis, although there are no controlled trials.[4,10,14] Ibuprofen has been recommended over indometacin due to its better side effect profile, larger dose range and anecdotal efficacy.[10,14] Ketorolac is an extremely potent analgesic agent which has been reported to cause rapid resolution of symptomatic acute pericarditis in an uncontrolled study of 20 patients.[15] However, before using expensive NSAIDs, it is appropriate to consider aspirin.[16] In a prospective uncontrolled study of 254 patients with uncomplicated acute pericarditis, aspirin given at a dose of 800 mg every 6–8 hours for 7–10 days (in conjunction with misoprostol or omeprazole for gastric protection) with gradual tapering over 2–3 weeks resulted in a favorable response in 87%.[8] Although similar in presentation to responders, those 33 of 254 patients with poor response to aspirin (defined as persistence of fever, a new pericardial effusion, or worsening of general illness after seven days) were shown to have a higher incidence of autoimmune (39% versus 2%) and tuberculous pericarditis (18% versus 0%). The differences in etiology of pericarditis between responders and non-responders probably explain the reduced incidence of recurrent pericarditis (10% versus 61%) and constriction by one year in responders (0.5% versus 9%).[8] In view of this evidence, response to a trial of aspirin or NSAID can be taken as predictive of good prognosis and no further investigation is routinely required. Conversely, failure of aspirin or NSAID therapy should prompt further investigation for a specific cause of pericarditis[2,8] (**Class I, Level C1**).

A randomized open-label trial of COlchicine for acute PEricarditis (COPE study) in 120 patients with pericarditis due to idiopathic, viral, postpericardiectomy and connective tissue disease demonstrated on intention-to-treat analysis that a three-month course of colchicine in addition to a 3–4 week course of aspirin reduced symptom persistence at 72 hours (from 37% to 12%, P = 0.003) and recurrence rate at 18 months (32% to 11%, P = 0.004, number needed to treat (NNT) = 5).[17] No serious adverse effects of colchicine were seen but the drug had to be discontinued in 8% of patients due to diarrhea. The results of this trial will be supplemented with a larger trial of colchicine versus placebo currently underway.[18] Colchicine (0.5 mg bd)[10] added to an NSAID/aspirin (**Class I, Level B**) or as monotherapy (**Class IIa, Level C2**) appears to be effective for the initial attack and prevention of recurrences of acute pericarditis.

A preliminary study has highlighted the potential benefits of rosuvastatin as adjunctive therapy to NSAIDs in acute pericarditis.[19] The rationale for the use of statins in this setting is based on their known anti-inflammatory effects, as shown by the lowering of C-reactive protein (CRP) independently of their lipid-lowering effect.[19] Fifty five consecutive patients with a first episode of acute pericarditis were randomized to either indometacin plus placebo or indometacin plus rosuvastatin 10 mg, with treatment continued for a week after inflammatory markers normalized. The addition of rosuvastatin resulted in significantly earlier normalization of CRP levels (5.0 versus 6.0 days, P = 0.022), ST segment deviation (3.5 vs 4.5 days, P = 0.001), pericardial effusion (4.5 vs 5.5 days, P = 0.001) and erythrocyte sedimentation rate (ESR) (5.0 vs 6.0 days, P = 0.022). These promising results need to be confirmed in larger studies before application to clinical practice (**Class IIb, Level B**).

Corticosteroids are effective in acute pericarditis but observational data suggest that their use in this setting is associated with an increased risk of recurrence.[16,20] The pain and any associated fever, leukocytosis, and other inflammatory factors resolve rapidly with high-dose corticosteroid administration (e.g. 1–1.5 mg/kg/day), only to return during tapering to a low dose of the steroid.[16] Prospective data from the COPE trial add to these observations.[17] Patients in both arms of the study with aspirin intolerance or contraindication (n = 19, 16%) were treated with corticosteroids for a similar duration to aspirin. Steroid use was an independent risk factor for recurrence on multivariate analysis (OR 4.30, 95% confidence interval (CI) 1.21–15.25). Therefore corticosteroids are restricted to cases of autoimmune or connective tissue disease with early introduction of NSAIDs or colchicine during the tapering phase (**Class IIa, Level C2**).[10] Intrapericardial triamcinolone is one way of reducing systemic side effects which have been shown to be effective in up to 93% of patients with autoimmune pericardial effusion[21] (**Class I, Level C2**).

Recurrent pericarditis

Recurrent pericarditis is the most troublesome complication of acute pericarditis. The criteria for the diagnosis of recurrent pericarditis are a documented first attack of acute pericarditis, and evidence of either recurrence or continued activity of pericarditis despite therapy.[22] Recurrent pericarditis, which affects about 20% of cases,[20,22] is diagnosed in the presence of chest pain and one or more of the following: pericardial friction rub, electrocardiographic changes, echocardiographic evidence of pericardial effusion, and raised inflammatory markers.[22,23] Approximately 40% have multiple attacks and 10% have more than five attacks over several years, although attacks tend to become progressively less severe.[20] The disease process can continue for up to 43 years (mean 5.4 years), with symptom-free periods ranging from one month to 39 years (median three months), but in most it gradually "burns out" after 10 years.[24] Despite this, prognosis is good: cardiac tamponade and pericardial constriction are very rare, myocardial disease is not seen, and atrial fibrillation is an uncommon transient feature of exacerbations.[23–25]

There is no single consistent etiologic factor but evidence of ongoing viral infection, prior corticosteroid use, autoimmunity and familial clustering have all been variably reported.[16,20] Antinuclear antibodies have been reported in approximately 55% and a new diagnosis of connective tissue disease in 10% of 61 patients with recurrent idiopathic pericarditis.[24] Where patients from Mediterranean countries are over-represented, familial Mediterranean fever has been reported in 4%.[26]

In the assessment of patients with recurrence, evaluation for connective tissue disease is appropriate but complex diagnostic procedures, such as invasive endomyocardial or pericardial sampling, are usually not justified.[16,20]

The open-label COlchicine for REcurrent pericarditis (CORE) study randomized 84 consecutive patients with first recurrence of idiopathic, autoimmune or viral pericarditis to aspirin or aspirin and a six-month course of colchicine.[22] On intention-to-treat analysis, treatment with colchicine significantly decreased 18-month recurrence from 51% to 24% ($P = 0.02$, NNT 4) and symptom persistence at 72 hours from 31% to 10% ($P = 0.03$).[10] Colchicine (2 mg/day for one or two days, followed by 1 mg/day)[10] can be recommended as effective therapy for recurrent pericarditis (**Class I, Level B**). Prednisolone was substituted in 30 patients with aspirin contraindication and on multivariate analysis this was an independent risk factor for further recurrences (OR 2.9, 95% CI 1.1–8.3). These findings confirm uncontrolled studies reporting on the use of colchicine as first-line therapy for recurrence[25,27,28] and the deleterious effects of corticosteroids in attenuating its effectiveness[26] and increasing the risk of further recurrence.[20,25] A sustained response on discontinuation of colchicine is

Table 52.2 Therapeutic strategies previously evaluated in recurrent pericarditis (after failure of NSAID)

Study	Patients (n)	Therapeutic strategy evaluated	Remission rate
Fowler[23]	9	Pericardiectomy	2/9 (22%)
Hatcher[32]	24	Pericardiectomy	20/24 (83%)
Asplen[33]	2	Azathioprine	2/2 (100%)
Imazio[25]	2	Azathioprine	2/2 (100%)
Melchior[34]	2	High-dose methylprednisolone as pulse therapy	2/2 (100%)
Marcolongo[35]	12	High-dose prednisolone with aspirin	11/12 (92%)
Peterlana[36]	4	High-dose intravenous immunoglobulin	3/4 (75%)
Tona[37]	2	High-dose intravenous immunoglobulin	2/2 (100%)

seen in 60%, although recurrences are minor and resolve with reinstitution of colchicine (**Class IIa, Level C2**).[28] Relapse on colchicine can be managed effectively in the majority with reinstitution of NSAIDs.[28] Patients with recurrent pain despite NSAIDs and colchicine are challenging yet there is a paucity of evidence to guide management. Corticosteroids are recommended in European guidelines only in patients with poor general condition or frequent crises 10 (**Class IIa, Level C2**). An extended course of low-dose steroids may be superior to regimes utilizing a high dose initially. A nonrandomized retrospective comparison reported a significantly increased risk of recurrence with a higher dose: 33 of 51 patients taking prednisone 1.0 mg/kg/day suffered a recurrence by mean followup of 58 months as compared to 16 of 49 taking 0.2–0.5 mg/kg/day by 54 months (hazards ratio 3.6, $P < 0.001$). Some of this may be related to premature withdrawal of therapy as the higher dose was associated with significantly increased toxicity (osteoporosis and Cushing's syndrome reported in 24% vs 2%).[28a] (**Class IIa, Level C1**) Claims of effectiveness have been made in small uncontrolled studies for pericardiectomy, azathioprine, chloroquine, and intravenous immunoglobulin (Table 52.2) (**Class IIb, Level C2**).

Chronic idiopathic pericardial effusion

Patients with large pericardial effusion of no apparent cause which persists for more than three months constitute 3% of pericarditis and 70% of large chronic effusions in the West.[29] The main concern is the occurrence of tamponade, reported in 30–40% of cases, at times with unexpected decompensation after being asymptomatic for several

years.[29,30] For this reason, drainage is recommended even in the absence of tamponade (**Class IIa, Level C1**). Lasting remission is seen in 33–75% after therapeutic pericardiocentesis alone and 95% after extended catheter drainage.[30] Pericardiectomy offers long-term success whether carried out initially or after failure of percutaneous drainage.[29–31] Survival rates are similar to the background population[30] but a late appearance of malignancy has been reported in 5–10% of cases at 6–80 months following diagnosis.[29,30]

Purulent pericarditis

Epidemiology

Purulent pericarditis is now rare in the developed world, comprising 0.7–5% of pericardial effusions[2,12,38,39] and less than 1% of cases undergoing pericardiectomy.[40–42] In Western series, the most common reported organisms have been staphylococci, streptococci and pneumococci when the predominant associated lesions are empyema (50%) or pneumonia (33%).[43] In a series where over 50% of patients had compromised immunity or thoracic surgery, *Staphylococcus aureus* (30%) and fungi (20%) have predominated.[44] In another unselected retrospective series anaerobes originating from the oropharynx were most commonly found.[45] Seeding may be hematogenous but contiguous spread from less common sites such as the retropharyngeal space, cardiac valves, and below the diaphragm must be excluded.[46] *Neisseria meningitidis* may involve the pericardium in two ways: either through initiating an immune-mediated sterile effusion[47,48] or by direct infection and purulent reaction.[49] The modern era of iatrogenic and HIV-associated immunosuppression has witnessed more unusual organisms and presentations.[50–54]

Diagnosis

A prodrome of 3–10 days precedes presentation with fever, cough, chest pain and tachycardia.[43,44] Pericardial rub is present in 35–45% of patients and tamponade in 40–80%. However, when pericardial involvement is secondary, the underlying sepsis predominates the illness and its outcome.[55] This may partly explain why as many as 30–40% of patients are diagnosed post mortem[43,44] and also stresses the importance of identifying associated foci, with the use of adjunctive investigations as indicated.

Blood tests are in keeping with sepsis whilst radiographic cardiomegaly (75%), lung field shadowing (50%) and pleural effusions (30%) are common. Electrocardiography is usually typical of myopericarditis but may be normal in 10–30% of patients. Echocardiography confirms the presence of effusion; however, in patients with sepsis this is not proof in itself of pericardial infection.[56] Suspicion of purulent pericarditis is an indication for urgent pericardiocentesis,[10] which is diagnostic.[57] The fluid may be frankly purulent. A low pericardial to serum glucose ratio (mean 0.3) and raised pericardial fluid white cell count with high proportion of neutrophils (mean cell count 2.8 per μl, 92% neutrophils) differentiate from tuberculous (ratio 0.7, count 1.7 per μl, 50% neutrophils) and neoplastic (ratio 0.8, count 3.3 per μl, 55% neutrophils) pericarditis.[58] Fluid should be sent for bacterial, fungal and tuberculous studies, blood cultures drawn and other samples taken as guided by the clinical presentation.

Management

Purulent pericarditis should be managed aggressively as mortality is universal if untreated, whereas with comprehensive therapy 85% have been reported to survive the episode and have good long-term outcome.[43] Intravenous antimicrobial therapy should be started empirically until microbiologic results are available. Effective pericardial drainage is crucial.[10] There are no prospective studies comparing one modality over another in purulent pericarditis. Retrospective comparisons with unselected cases feature purulent pericarditis rarely and in small numbers. Central to the choice of modality is the fact that purulent effusions are often heavily loculated and likely to reaccumulate rapidly. Subxiphoid pericardiostomy and rinsing of the pericardial cavity is recommended.[10] This allows more complete drainage of the effusion as loculations can be manually lyzed at the time of surgery. In a Zimbabwean report of 21 cases of purulent pericarditis managed as such, under local anesthesia in most cases, there was one recurrence of effusion (5%), one case of constriction (5%), and four deaths (20%)[59] (**Class IIa, Level C2**).

Intrapericardial thrombolysis through a percutaneous catheter has attempted to address the problems encountered with loculations restricting adequate drainage. Ten studies have reported a total of 35 patients with purulent pericardial effusion treated with percutaneous intrapericardial thrombolysis.[57,60–68] Intrapericardial thrombolysis did not alter systemic clotting parameters and was associated with regression or disappearance of intrapericardial fibrin strands, improvement in hemodynamic status and prevention of constriction. Treatment failure was reported in two patients. Reported complications were intrapericardial haemorrhage (n = 2) and mortality from ongoing sepsis (n = 1). A controlled study of intrapericardial urokinase in 60 patients with tuberculous pericarditis and 34 with purulent pericarditis reported a 13% incidence of intrapericardial haemorrhage.[69] An adequately designed study is required to evaluate the safety and effectiveness of this promising therapy in selected patients with purulent effusion and subacute constriction (**Class IIb, Level C2**). Pericardiectomy is recommended for dense adhesions,

loculated or thick purulent effusion, recurrence of tamponade, persistent infection, and progression to constriction, with up to 8% surgical mortality (**Class IIa, Level C2**).[10] Duration of antimicrobial therapy has to be individualized (**Class IIa, Level C2**).

Tuberculous pericarditis

Epidemiology

Tuberculous pericarditis accounts for less than 5% of pericardial disease in the developed world.[2,4,5] By contrast, tuberculosis is the cause of large pericardial effusions in over 90% of HIV-infected[70–72] and 50–70% of non-HIV infected individuals who live in tuberculosis-endemic regions and communities.[72,70] The disease can occur at any age[73,74] and men are more frequently affected than women, though occasionally a greater proportion of female patients has been reported.[75–78] Clinical presentations are as pericardial effusion (80% of cases), effusive-constrictive pericarditis (15%) or constrictive pericarditis (5%).[79] Tuberculous pericarditis is a serious condition with a mortality of 17–40%; constriction occurs in a similar proportion of cases following tuberculous pericardial effusion.[80]

Tuberculous pericardial effusion

Tuberculous pericardial effusion should be suspected in all instances of pericarditis without a rapidly self-limiting course. Onset is insidious and presentation is with non-specific systemic symptoms, such as fever, night sweats, fatigue, and weight loss.[13] Chest pain, cough, and breathlessness are common, although severe pericardial pain of acute onset characteristic of idiopathic pericarditis is unusual. Right upper abdominal aching owing to liver congestion is also common. In African patients with tuberculous pericardial effusions, evidence of chronic cardiac compression mimicking heart failure is the most common presentation and 10% present with clinical tamponade.[75] While there is marked overlap between the physical signs of pericardial effusion and constrictive pericarditis, the presence of a pericardial friction rub and increased cardiac dullness extending to the right of the sternum favor a clinical diagnosis of pericardial effusion.[81]

Diagnosis

The chest radiograph, which shows an enlarged cardiac shadow in almost all cases,[82] demonstrates features of active pulmonary tuberculosis in 30% of cases and pleural effusion in 40–60% of cases.[75,82–85] The electrocardiogram is abnormal in virtually all cases, usually in the form of non-specific ST T-wave changes.[86] The PR segment deviation

and ST segment elevation characteristic of acute pericarditis are found in only 9–11% of cases. Atrial fibrillation is usually transient. Echocardiographic findings of effusion with fibrinous strands on the visceral pericardium are typical but not specific for a tuberculous aetiology.[87,88] Imaging by CT scanning or MRI can also be used to provide incremental information to echocardiography.[89–91] In addition to features of pericardial disease (i.e. pericardial effusion and thickening of the pericardium), CT of the chest shows typical changes in mediastinal lymph nodes (i.e. enlargement >10 mm with matting and hypodense centers and sparing of hilar lymph nodes) in almost all cases which resolve on treatment.[89] MRI has the added advantage of assessing the extent of pericardial inflammation[91,92] and myocardial involvement.[93,94]

A "definite or proven" diagnosis of tuberculous pericarditis is based on the demonstration of tubercle bacilli in pericardial fluid or on histologic section of the pericardium, and a "probable or presumptive" diagnosis is made when there is proof of tuberculosis elsewhere in a patient with unexplained pericarditis, a lymphocytic pericardial exudate with elevated adenine deaminase (ADA), interferon-gamma (IFN-γ) or lysozyme levels, and/or an appropriate response to antituberculosis chemotherapy.[13] A protocol for the evaluation of a patient with suspected tuberculous pericardial effusion in tuberculosis-endemic and non-endemic communities and regions of the world is presented in Table 52.3.[13,80]

A new diagnostic index score has been developed to predict the diagnosis of tuberculous pericarditis in patients living in an endemic area.[1] Independently predictive of tuberculous pericarditis (with diagnostic index score) were fever (1), night sweats (1), weight loss (2), globulin level >40 g/L (3) and peripheral leukocyte count $<10 \times 10^9$/L(3). A total score of ≥6 indicates tuberculous pericarditis with 86% sensitivity and 85% specificity, which proved to have better diagnostic efficiency than culture or pericardial histology in this study.[1]

Management

In patients living in non-endemic areas, there is no justification for starting antituberculosis treatment empirically when systematic investigation fails to yield a diagnosis of tuberculous pericarditis; such patients should be treated as chronic idiopathic pericardial effusion (as indicated above)[85] (**Class I, Level C1**). By contrast, in tuberculosis endemic regions and communities, after exclusion of other causes of pericardial effusion such as malignancy (**Class I, Level B**), a regimen consisting of rifampicin, isoniazid, pyrazinamide and ethambutol for at least two months, followed by isoniazid and rifampicin (total of six months of therapy), has been shown to be highly effective in treating patients with extrapulmonary tuberculosis; treatment for nine months or

Table 52.3 A step-wise protocol for the evaluation of suspected tuberculous pericardial effusion[13,80]

Stage 1: Initial non-invasive evaluation	Chest radiograph may reveal changes suggestive of pulmonary tuberculosis in 30% of cases.
	Echocardiogram: the presence of a large pericardial effusion with frond-like projections, and thick "porridge-like" fluid is suggestive of an exudate but not specific for a tuberculous etiology.
	CT scan and/or MRI of the chest are alternative imaging modalities where available: for evidence of pericardial effusion and thickening (>3 mm), and typical mediastinal and tracheobronchial lymphadenopathy (>10 mm, hypodense centers, matting), with sparing of hilar lymph nodes.
	Culture of sputum, gastric aspirate and/or urine should be considered in all patients.
	Right scalene lymph node biopsy if pericardial fluid is not accessible and lymphadenopathy present.
	Tuberculin skin test is not helpful in adults regardless of the background prevalence of tuberculosis.
Stage 2: Pericardiocentesis	*Therapeutic pericardiocentesis* is absolutely indicated in the presence of cardiac tamponade.
	Diagnostic pericardiocentesis should be considered in all patients with suspected tuberculous pericarditis, and the following tests performed on the pericardial fluid:
	Direct inoculation of the pericardial fluid into double strength liquid Kirchner culture medium (or equivalent medium) at the bedside, and culture for *M. tuberculosis*.
	Biochemical tests to distinguish between an exudate and a transudate (fluid and serum protein; fluid and serum LDH).
	White cell analysis and count, and cytology: a lymphocytic exudate favours TB pericarditis.
	Indirect tests for tuberculous infection: adenosine deaminase (ADA), interferon-gamma (IFN-γ) or lysozyme assay.
Stage 3: Pericardial biopsy	*"Therapeutic" biopsy*: as part of surgical drainage in patients with severe tamponade relapsing after pericardiocentesis or requiring open drainage of pericardial fluid for whatever reason.
	Diagnostic biopsy: in areas where TB is endemic, a diagnostic biopsy is not required prior to commencing empiric antituberculosis treatment. In areas where TB is not endemic, a diagnostic biopsy is recommended in patients with >3 weeks of illness and without etiologic diagnosis having been reached by other tests.
Stage 4: Empiric antituberculosis chemotherapy	*Tuberculosis endemic in the population*: trial of empiric antituberculosis chemotherapy is recommended for exudative pericardial effusion, after excluding other causes such as malignancy, uremia, and trauma.
	Tuberculosis not endemic in the population: when systematic investigation fails to yield a diagnosis of tuberculous pericarditis, there is no justification for starting antituberculosis treatment empirically.

longer gives no better results, but has the disadvantages of increased cost and poor compliance.[95] Short-course chemotherapy is also highly effective in curing tuberculosis in HIV-infected patients[96] (**Class I, Level A**).

The role of routine pericardiotomy at the outset has been studied in a trial of 122 consenting participants randomized to complete open drainage by substernal pericardiotomy and biopsy under general anesthesia on admission or percutaneous pericardiocentesis as required to control symptoms and signs.[75] Complete open drainage abolished the need for repeat pericardiocentesis (relative risk (RR) 0.04; 95% CI 0.00–0.64, P = 0.02) but did not significantly influence the need for pericardiectomy for subsequent constriction (RR 0.39; 95% CI, 0.08–1.91; P = 0.20) or the risk of death as a result of pericarditis (RR 1.29; 95% CI 0.30–5.49; P = 0.70).[97] Therefore, routine open drainage by substernal pericardiotomy is not recommended (**Class III, Level B**).

Preliminary reports have identified two interventions that may reduce the incidence of constriction in tuberculous pericarditis. First, extended pericardial drainage with an indwelling pigtail catheter has been reported to be safe and associated with a low rate of constrictive pericarditis at two years (1.7 %) in a series of 118 patients with tuber-

culous pericardial effusion in Africa, a significant proportion of whom were HIV positive.[98] Second, a small controlled study of intrapericardial urokinase in 60 patients with tuberculous pericarditis and 34 with purulent pericarditis reported a 67% reduction in the risk of constriction in the total group of patients with infectious pericarditis (P < 0.001).[69] Intrapericardial hemorrhage was seen in 13% of the treatment group but no deaths were associated with the intervention. The effectiveness of extended intrapericardial drainage and intrapericardial urokinase in reducing the risk of constriction in tuberculous pericarditis requires further evaluation in randomized controlled studies (**Class IIb, Level C2**).

Tuberculous pericardial constriction

Prior to the introduction of effective tuberculosis chemotherapy, up to 50% of patients with effusive tuberculous pericarditis progressed to the constrictive stage of the disease.[99] The introduction of rifampicin-based antituberculosis treatment in the 1970s resulted in reduction of the incidence of constriction to 17–40% in patients with effusive tuberculous pericarditis.[81,85]

Constriction generally develops within six months of presentation with effusive pericarditis.[100,101] The presentation is highly variable, ranging from asymptomatic to severe constriction. The diagnosis is often missed on cursory clinical examination (see Table 53.2). The diastolic lift (pericardial knock) which coincides with a high-pitched early diastolic sound and sudden inspiratory splitting of the second heart sound are subtle but specific physical signs, which are found in 21–45% of patients.

Diagnosis

Most patients with constrictive pericarditis in South Africa have the subacute variety, in which a thick fibrinous exudate fills the pericardial sac, compressing the heart and causing a circulatory disturbance. As a result, calcification of the pericardium is absent in the majority and 75% have increased cardiothoracic ratio.[76] It is uncommon to find concomitant pulmonary tuberculosis. Non-specific but generalized T-wave changes are seen in most cases, while low-voltage complexes occur in about 30% of cases. Atrial fibrillation occurs in less than 5% of cases, is persistent, and usually occurs with a calcified pericardium. As with tuberculous pericardial effusion, the electrocardiogram is useful only in drawing attention to the presence of a cardiac abnormality. Echocardiography is particularly valuable in confirming the diagnosis of subacute constrictive pericarditis. Typically, a thick fibrinous exudate is seen in the pericardial sac and is associated with diminished movements of the surface of the heart, normal-sized chambers, absence of valvular heart disease, and absence of myocardial hypertrophy.[76] In time, the pericardial exudate condenses into a thick skin surrounding the heart, which usually, but not always, can be distinguished from myocardium. CT and MRI of the heart offer the advantage of better imaging of the pericardium with more accurate measurement of pericardial thickening.[102] This is important as tuberculous pericardial constriction is almost always associated with pericardial thickening; reports of constriction in the face of normal pericardial thickness have not included tuberculosis as a cause.[103] Contrast MRI has the added advantage of identifying ongoing pericardial and myocardial inflammation. Cardiac catheterization usually confirms the diagnosis.

Management

In a prospective study of 143 patients in Africa with clinical signs of pericardial constriction treated with antituberculosis therapy, only 25% required pericardiectomy for persistent or worsening constriction during the follow-up of two years.[76] These benefits were maintained up to 10 years.[104] The treatment of tuberculous pericardial constriction therefore involves the use of standard antituberculosis drugs for six months (**Class I, Level C1**). Pericardiectomy is recommended if the patient's condition is static hemodynamically or deteriorates after 4–8 weeks of antituberculosis therapy (**Class I, Level C2**). If, however, the disease is associated with pericardial calcification, a marker of chronic disease, surgery should be undertaken earlier under antituberculosis drug cover. Perioperative mortality ranges from 7% to 11%[105–107] (**Class I, Level C2**).

Effusive constrictive tuberculous pericarditis

Effusive constrictive pericarditis is a common presentation in Southern Africa; preliminary studies suggest that it can be demonstrated in 50% of patients with suspected tuberculous pericardial effusion when right atrial pressure is monitored during pericardiocentesis.[108] Conventional assessment is less sensitive but in addition to physical signs of pericardial effusion, a diastolic knock may be detected on palpation and an early third heart sound on auscultation, while echocardiography may show a pericardial effusion between thickened pericardial membranes, with fibrinous pericardial bands apparently causing loculation of the effusion.[13]

The treatment of effusive constrictive pericarditis is problematic because pericardiocentesis does not relieve the impaired filling of the heart and surgical removal of the fibrinous exudate coating the visceral pericardium is not possible. Antituberculosis drugs should be given and the patient monitored clinically and by echocardiography for development of constrictive pericarditis (**Class I, Level C2**).

Steroids

The role of adjunctive corticosteroids in the management of tuberculous pericarditis has been reviewed systematically by Mayosi and others.[97,109] Four randomized controlled trials with a total of 469 participants have assessed the impact of oral steroids on mortality in tuberculous pericarditis.[75,76,99,110] Three of the trials (including 411 participants) tested adjunctive oral steroid use in participants with suspected tuberculous pericarditis in the pre-HIV era.[75,76,99] Fewer participants died in the intervention group, but the potentially large reduction in mortality was not statistically significant (RR 0.65, 95% CI 0.36–1.16, $P = 0.14$). A similarly promising but non-significant trend was found for other important clinical outcomes including the need for pericardiectomy for constriction (RR 0.85, 95% CI 0.51–1.42) and the need for repeat pericardiocentesis for cardiac tamponade (RR 0.45, 95% CI 0.20–1.05, $P = 0.07$). When a combined end-point of death or persisting symptoms and signs of pericardial disease at two years follow-up was considered, participants on steroids for pericardial effusion were significantly more likely to be cured at 24 months (i.e. alive and symptom free) than participants on placebo (RR

0.48, 95% CI 0.29–0.80, $P = 0.04$). This promising effect was not statistically significant in a sensitivity analysis of the worst case scenario in which all participants lost to follow-up in each group were assumed to have died (12/105 lost in treatment group, 7/116 in placebo group; sensitivity analysis assuming all died: RR 0.78, 95% CI 0.52–1.118, $P = 0.1$).

One trial with 58 HIV-infected individuals,[110] which was analyzed separately from the non-HIV studies, also showed a potentially large reduction in mortality of 50%, but this was not statistically significant (RR 0.50, 95% CI 0.19–1.28, $P = 0.15$).[97,111] There was no increase in opportunistic infections or malignancy associated with adjunctive steroid use in this small study with 18 months of follow-up.

It is clear from the meta-analysis that adjunctive oral steroids could potentially have large beneficial effects on the major clinically significant outcomes in tuberculous pericarditis (i.e. death, constriction, cardiac tamponade), but the published trials are too small to be conclusive (**Class IIa, Level B**). The effectiveness of intrapericardial instillation of corticosteroids was also examined in a randomized trial of 57 patients with tuberculous pericarditis.[109] There was no significant effect found on major clinical outcomes in this small study which was probably underpowered for major clinical events such as mortality (**Class IIb, Level B**).

Neoplastic pericarditis

Epidemiology

In developed countries, neoplastic pericarditis accounts for 5–7% of presentations with acute pericardial disease[2,4,5] and 30–60% of patients undergoing drainage of pericardial effusions.[112,113] Metastases are 40 times more common than primary cardiac tumors; mesothelioma, the most common of the primary tumors, is almost always incurable.[10] The common malignancies giving rise to symptomatic neoplastic effusions are bronchogenic (51%), hematologic (24%), gastrointestinal (9%), breast (8%) cancer, and melanoma (11%);[39,113] lymphoma and Kaposi's sarcoma are the predominant forms of neoplastic effusions in patients with AIDS.[111] Pericardial involvement may be the first manifestation of malignancy in 22–55% of cases of neoplastic pericardial effusion with or without cardiac tamponade.[114,115] Survival is principally determined by the underlying malignancy with median survival times ranging from 22 days for adenocarcinoma of unknown origin, 3.0–3.6 months for bronchogenic carcinoma, 3.2 months for Kaposi's sarcoma, 3.7–16.4 months for other solid malignancies, 4.9–17 months for hematologic malignancies, 6.2 months for primary effusion lymphoma, and 8.8–14.5 months for breast carcinoma.[116–120]

Diagnosis

Demonstration of neoplastic pericarditis requires sampling of pericardial fluid for cytologic examination and/or pericardial tissue for histology. Cytology has a high specificity (100%) but variable sensitivity (67–92%) which is higher with adenocarcinoma and lower with mesothelioma and lymphoma.[121–123] Cytologic analysis can be supplemented with immunocytochemistry which offers the added advantage of identifying cellular lineage, though is dependent on the markers used;[124,125] in one study the origins of 85% of metastatic carcinomas were correctly identified using a sequential panel of six antibodies.[125] Similarly, techniques such as flow cytometry and telomerase repeat amplification protocol (TRAP) in situ have yet to be proven in neoplastic pericardial disease per se.[126,127]

Histologic analysis of pericardial tissue in adjunction to cytologic analysis increases sensitivity. Studies delineating the stages leading up to targeted biopsy under pericardioscopy have reported incremental sensitivities from 54–65% with cytology alone, 71–75% with subxiphoid biopsy and cytology, to 92–97% with addition of pericardioscopic epicardial biopsy.[128,129] Increasing the number of targeted epicardial biopsies increases yield.[130] In contrast, blind pericardial biopsy has a lower sensitivity to cytology alone (45–55%).[113,122]

In the majority, clinical presentation, chest radiography, electrocardiography and echocardiography indicate only the presence of significant pericardial disease.[122] CT and MR imaging may be useful in providing evidence of malignancy elsewhere and further detail on pericardial and myocardial involvement.[131] The diagnosis of neoplastic pericarditis therefore rests on adequate sampling of pericardial fluid or tissue for pathologic examination. However, only 40–55% of malignancy-related effusions are shown to be secondary to neoplastic pericardial spread when investigated invasively.[122,129] Other causes include radiation pericarditis in 3–18% and idiopathic pericardial effusions in 30%.

Management

Treatment of neoplastic pericardial effusion is directed at the relief of immediate symptoms of pericarditis or tamponade, preventing reaccumulation, and diagnosis and management of the underlying cancer.[132] Pericardiocentesis is recommended for diagnosis in suspected neoplastic pericardial effusion, and as a therapeutic intervention in the presence of cardiac tamponade (**Class I, Level C2**). The great challenge is to prevent recurrence of malignant pericardial effusion. There are three strategies that have been used: (1) intrapericardial instillation of cytostatic/sclerosing agents (Table 52.4), (2) intrapericardial or external radiation therapy, and (3) mechanical drainage by pericardiocentesis with indwelling catheter, subxiphoid pericardiotomy or

Table 52.4 Recent prospective experience of intrapericardial therapy in preventing recurrent neoplastic effusion (limited to those distinguishing outcome of pericardial disease)

pleuropericardiotomy with drainage of malignant pericardial effusion into the pleural space. Vaitkus and colleagues report a statistically superior effect of indwelling pericardial catheters, intrapericardial sclerosis, subxiphoid or percutaneous balloon pericardiotomy and pericardiectomy over pericardiocentesis alone (**Class IIb, Level C2**).[132] In the treatment of lung cancer-associated moderate to large pericardial effusions, intrapericardial instillation of bleomycin following pericardial drainage was not demonstrated to be superior to drainage alone in a randomised trial of 80 patients. Survival at two months free of effusion was 29% in the bleomycin group compared to 46% in controls (one-sided $P = 0.086$). There was no difference in symptom palliation, survival was equally low at 6 months (27% vs 31%), and rates of repeat pericardiocentesis were not reported.[132a]

In choosing the appropriate strategy for the management of the patient with neoplastic pericardial effusion, it is important to note, first, that the treatment of neoplastic pericardial effusion is palliative as the prognosis is ultimately determined by the underlying disease. Second, there are no good randomized studies to guide the management strategy in this field. Finally, the management of the patient must be individualized and will depend on the experience and available therapeutic options in a particular center, and the preferences of the patient and relatives.

Specific cardiovascular disorders: valvular heart disease

Bernard J Gersh, Editor

53 Rheumatic heart disease: prevention and acute treatment

Bongani M Mayosi and Patrick J Commerford
Division of Cardiology, Department of Medicine, Groote Schuur Hospital and University of Cape Town, Cape Town, South Africa

Introduction

Rheumatic fever is the most important cause of acquired heart disease in children and young adults worldwide. Initiated by an oropharyngeal infection with group A beta-hemolytic streptococci (GAS) and following a latent period of approximately 3 weeks, the illness is characterized by an inflammatory process primarily involving the heart, joints, and central nervous system. Pathologically, the inflammatory process causes damage to collagen fibrils and connective tissue ground substance (fibrinoid degeneration) and thus rheumatic fever is classified as a connective tissue or collagen vascular disease. It is the destructive effect on the heart valves that leads to the important effects of the disease, with serious hemodynamic disturbances causing cardiac failure or embolic phenomena resulting in significant morbidity and mortality at a young age.

A number of recent systematic reviews have summarized the effectiveness of primary and secondary prevention of rheumatic fever and the treatment of the acute attack.[1–3] The evidence from randomized controlled clinical trials, while dated, is in favor of the effectiveness of antibiotics in the primary (or the treatment of pharyngitis caused by group A streptococci) and secondary prevention of rheumatic fever.[1,2] In the treatment of the acute attack, most publications have been observational studies with only a small minority of poorly designed randomized trials.[3]

Epidemiology

In the developed countries of the world, the incidence of rheumatic fever has fallen markedly during the last century. For example, in the USA the incidence per 100 000 was 100 at the start of the last century, 45–65 between 1935 and 1960, and is currently estimated to be approximately 10 cases per 100 000.[4] This decrease in rheumatic fever incidence preceded the introduction of antibiotics and is a reflection of improved socio-economic standards, less overcrowded housing and improved access to medical care. The current prevalence of rheumatic heart disease in the USA and Japan, 0.6–0.7 per 1000 population, contrasts sharply with that in the developing countries of Africa and Asia where rates as high as 30 per 1000 have been reported.[5] As GAS pharyngitis and rheumatic fever are causally related, both diseases share similar epidemiologic features.[4] The age of first infection is commonly between 6 and 15 years. Also, the risk for developing rheumatic fever is highest in situations where GAS is more common, for example where people live in crowded conditions.[6]

Pathogenesis

Clinical, epidemiologic, and immunologic observations tend to strongly support the causative role of untreated GAS pharyngitis in rheumatic fever.[6,7] Beyond this, however, the pathogenesis of acute rheumatic fever (ARF) and clinical heart disease remains unclear and several important and unexplained observations render the management of this important disease extremely difficult. These are:
• individual variability of susceptibility to GAS pharyngitis
• individual variability of development of symptomatic GAS pharyngitis
• individual variability of development of acute rheumatic fever after an episode of GAS pharyngitis
• individual variation in the development of carditis and chronic rheumatic heart disease after an attack of acute rheumatic fever
• the development of chronic rheumatic heart disease (RHD) in patients who have no definite history of acute rheumatic fever.

Streptococcal skin infection (impetigo) is considered not to cause rheumatic fever. However, a report of acute rheumatic fever following streptococcal wound infection[8] and the high prevalence of pyoderma with relative paucity of streptococcal pharyngitis in some communities with a high incidence of rheumatic fever has raised questions about the link between streptococcal skin infection and rheumatic fever.[9] While effective antibiotic treatment virtually abolishes the risk of rheumatic fever, in situations of untreated epidemic GAS pharyngitis up to 3% of patients develop it.[1,7] Worryingly, as many as a third of patients who develop rheumatic fever do so after virtually asymptomatic GAS and in more recent outbreaks, 58% denied preceding symptoms.[10] This does not augur well for the primary prevention of rheumatic fever where prompt diagnosis of GAS pharyngitis and treatment are essential.

The virulence of the streptococcal infection is dependent on the organisms' M protein serotype which determines the antigenic epitopes which are shared with human heart tissue, especially sarcolemmal membrane proteins and cardiac myosin.[11] It is these variations in virulence, as a result of M protein variation, which are thought to explain the occasional outbreaks of rheumatic fever in areas of previously low incidence.[12] Other factors influencing the risk for rheumatic fever are the magnitude of the immune response and the persistence of the organism during the convalescent phase of the illness.[7]

Evidence suggests that host factors play a role in the risk for rheumatic fever. In patients who have suffered an attack of rheumatic fever, the incidence of a repeat attack is approximately 50%. A specific B-cell alloantigen has been found to be present in 99% of patients with rheumatic fever versus 14% of controls.[13] Certain HLA antigens appear to be associated with increased risk for rheumatic fever. Approximately 60–70% of patients worldwide are positive for HLA-DR3, DR4, DR7, DRW53 or DQW2.[14] Such genetic markers for rheumatic fever risk may be useful to identify those in need of GAS prophylaxis. However, in view of the frequency with which these markers occur, they are unlikely to be of practical benefit in the short term.

Clinical features

While there is no specific clinical, laboratory or other test to confirm conclusively a diagnosis of rheumatic fever, the diagnosis is usually made using the clinical criteria first formulated in 1944 by Duckett Jones[15] and recently modified by the World Health Organization (WHO).[16] The diagnosis is suggested if, in the presence of preceding GAS infection, two major criteria (carditis, chorea, polyarthritis, erythema marginatum, and subcutaneous nodules) or one major and two minor criteria (fever, arthralgia, elevated erythrocyte sedimentation rate, elevated C-reactive protein

or a prolonged PR interval on ECG) are present. Evidence of preceding GAS infection, essential for the diagnosis, may be obtained from throat swab culture (only positive in approximately 11% of patients at the time of diagnosis of acute rheumatic fever[3]) or by demonstrating a rising titer of antistreptococcal antibodies, either antistreptolysin O (ASO) or antideoxyribonuclease B (anti-DNase B).

There has been concern that strict application of the Jones criteria may result in underdiagnosis of rheumatic fever in endemic areas. particularly in the case of recurrent episodes.[17] During recurrence of rheumatic activity in a patient with pre-existing RHD, the carditis may precipitate heart failure but may not be possible to diagnose because of lack of information on previous cardiac findings or because valve replacement surgery has been performed. The new WHO criteria thus recommend that a diagnosis of a recurrence of ARF in a patient with pre-existing RHD is possible on the basis of minor manifestations and evidence of recent streptococcal infection.[16] Doctors should recognize that the published criteria are guidelines, and are particularly useful in epidemiologic investigations where diagnostic rigor is essential. It is appropriate for clinical judgment to be applied and to supersede guidelines particularly in parts of the world where ARF remains common.[17]

Prevention

The most recent recommendations on the prevention of rheumatic fever have been published by the WHO.[16]

Prevention of rheumatic fever may be considered to be either prevention of the initial attack (primary prevention) or prevention of recurrent attacks (secondary prevention). *True primary prevention* of rheumatic fever depends more on socio-economic than medical factors. Upgrading housing and other aspects of poverty eradication will do more to eradicate the disease than antibiotic prophylaxis.

Primary prevention

Prevention of the initial attack of rheumatic fever depends on the prompt recognition of GAS pharyngitis and its effective treatment. While it has been demonstrated that therapy initiated as long as 9 days after the onset of GAS pharyngitis can prevent an attack of rheumatic fever,[18] early treatment reduces both the morbidity and the period of infectivity.

The first report of the use of penicillin for the treatment of GAS pharyngitis and prevention of most attacks of rheumatic fever was published in 1950.[18] Over the following 40 years, attention focused on accurate diagnosis and treatment of GAS pharyngitis. A single dose of intramuscular benzathine penicillin G became the most common mode of treatment and avoided problems of non-compliance. Sub-

sequently, as a result of the pain and possibility of allergic reaction associated with benzathine penicillin G, oral penicillin became the treatment of choice[19] and remains so today[20] (**Class I, Level A**). In situations where compliance with a 10-day course of oral penicillin would be unreliable, a single dose of intramuscular benzathine penicillin G would be preferred (dosage 1.2 million u if >27 kg, otherwise 600 000 u).[21]

Early studies established a 10-day course of oral penicillin as optimal[22,23] and this has been supported in more recent studies.[24,25] Shorter treatment periods are associated with significant decreases in bacteriologic cure while longer courses of treatment do not increase cure rate. Current recommendations[26] for oral penicillin therapy in children cite a dose of 250 mg two or three times daily. These recommendations are based on trials (Table 53.1) of 250 mg given two, three or four times daily resulting in equivalent cure rates[27–30] (**Class I, Level A**). A dose of 750 mg penicillin once a day yielded significantly worse results than 250 mg three times daily when compared in a randomized study.[31] There is no evidence available for optimal doses of penicillin in adults but 500 mg two to three times daily is currently recommended.[26]

Over the past decade, many trials have been published comparing penicillin VK to a variety of other antimicrobial agents, most commonly cephalosporins and macrolides. This has been prompted by the reported increase in treatment failures with penicillin. It has been suggested that treatment failure rates of up to 38% are possible. This contention, however, has been thoroughly investigated in a study by Markowitz et al[32] in which treatment failure rates of penicillin were compared between two time periods, 1953–1979 and 1980–1993. Of the almost 2800 patients with GAS serotyping, treatment failures ranged between 10.5% and 17%, with no significant difference between each time period. It was thus concluded that the overreporting of

treatment failures was due to problems with the design of the individual studies.

An increased bacteriologic cure rate for streptococcal pharyngitis by cephalosporins was demonstrated in a meta-analysis of 19 randomized comparisons of a variety of cephalosporins with 10 days of oral penicillin therapy.[33] Throat swab cultures were used to determine the presence of GAS and clearance after treatment. The results showed a statistically significant advantage of cephalosporins for which a bacteriologic cure rate of 92% was reported versus 84% for penicillin. The corresponding clinical cure rates were 95% and 89% respectively. It is suggested that the resistance of cephalosporins to penicillinase-producing anaerobes and staphylococci present in the pharyngeal flora may explain these findings. This difference in efficacy would mean that 12–13 patients would require cephalosporin treatment to potentially prevent one penicillin bacteriologic treatment failure (**Class II, Level A**). More recently, a multicenter comparison of 10-day therapy with cefibuten oral suspension (9 mg/kg/d in one dose) and penicillin V (25 mg/kg/d in three divided doses)[34] revealed a bacteriologic cure rate of 91% versus 80% respectively (corresponding clinical cure rates were 97% v 89%). Shorter courses of selected cephalosporins[35] (4 or 5 days) have been shown to be effective but current recommendations[26] suggest that further study of these regimens is required before their adoption.

The cephalosporins offer statistically significant advantages over penicillin in controlled clinical trials. It remains to be demonstrated, however, whether this statistical benefit can be translated into clinical or epidemiologic benefit in regions where the disease is endemic. Given the financial constraints on healthcare resources of developing nations and the considerable cost difference, it would seem that this is unlikely in the foreseeable future. Greater benefit is likely to be achieved by concerted efforts to identify, treat, and ensure compliance in large numbers of patients with the established, albeit inferior, penicillin schedules[1,21] (**Class II, Level A**).

In patients allergic to penicillin, erythromycin has been shown to have an equivalent cure rate.[36] The recommended dosage for erythromycin estolate is 20–40 mg/kg/d in 2–4 divided doses and for erythromycin ethylsuccinate, it is 40 mg/kg/d in 2–4 divided doses, both for 10 days[37] (**Class I, Level A**). The efficacy of erythromycin estolate is superior to that of erythromycin ethylsuccinate and is associated with fewer gastrointestinal tract side effects.[38] GAS strains resistant to erythromycin have been reported in some parts of the world.[39]

Thus, penicillin V remains the treatment of choice in non-penicillin allergic patients as it has a long record of efficacy and is probably the most cost-effective option.[1]

Appropriate antibiotic therapy in children with streptococcal pharyngitis should result in a clinical response

Table 53.1 Cure rates for various penicillin dosage schedules used in treatment of streptococcal pharyngitis

Reference	Agent/dose	Bacteriologic cure rate (%)
Gerber et al[30]	Pen V 250 mg 2× daily ×10 days	82
	Pen V 250 mg 3× daily ×10 days	71.5
Gerber et al[31]	Pen V 750 mg once daily ×10 days	78
	Pen V 250 mg 3× daily ×10 days	92
Vann & Harris[28]	Potassium Pen G 80 000 u 2× daily ×10 days	88
Spitzer & Harris[29]	Pen V 500 mg 2× daily ×10 days	83
	Pen V 250 mg 3× daily ×10 days	84

within 24 hours – most children will become culture negative within the first or second day of treatment.[40] After completion of therapy, only patients who have persistent or recurring symptoms or those at an increased risk for recurrence require repeat throat swab culture. If symptomatic patients are still harboring GAS in the oropharynx, a second course of antibiotics, preferably with another agent (amoxicillin clavulanate, cephalosporins, clindamycin or penicillin and rifampicin), is recommended.[26] Failure to eradicate GAS occurs more frequently following the administration of oral penicillin than intramuscular benzathine penicillin G.[41] Further treatment of asymptomatic patients, who are frequently chronic GAS carriers, is only indicated for those with previous rheumatic fever or their family members.

Secondary prevention

Following an initial attack of rheumatic fever, there is a high risk of recurrent attacks which increase the likelihood of cardiac damage and continuous antibiotic therapy is required[42] (**Class I, Level A**). This is especially important as GAS infections need not be symptomatic to trigger a recurrence of rheumatic fever nor does optimal GAS treatment preclude a recurrence. It is recommended that patients who have suffered either proven attacks of rheumatic fever or Sydenham's chorea be given long-term prophylaxis following the initial treatment to eradicate the pharyngeal GAS organisms. Recommendations regarding the duration of such prophylaxis are largely empiric and based on observational studies.

The duration of prophylaxis should be individualized and take into account the socio-economic conditions and risk of exposure to GAS for that patient. Individuals who have suffered carditis, with or without valvular involvement, are at higher risk for recurrent attacks[43,44] and should receive prophylaxis well into adulthood and perhaps for life. If valvular heart disease persists then prophylaxis should be lifelong.[16] Those patients who have not suffered rheumatic carditis can receive prophylaxis until 21 years of age or 5 years after the last attack.[45]

The choice of prophylactic agent has to be made with due regard for the likelihood of compliance with a regimen over a period of many years. Therefore, despite associated pain, which can be ameliorated by using lidocaine as a diluent,[46] intramuscular injection of benzathine penicillin G is the method of choice in most situations.[2,42] The recommended dose is 1.2 million u every 3–4 weeks. A comparison of 3-weekly ($n = 90$) versus 4-weekly ($n = 63$) benzathine penicillin prophylaxis[47] demonstrated the superiority of the 3-weekly dosage. The only prophylaxis failure in the 3-weekly dosage group was due to partial compliance, versus five true failures in the 4-weekly dosage group. A long-term follow-up study[48] for a mean period of 6.4 years

(range 1–12 years) in 249 consecutively randomized patients to 3- or 4-weekly regimens further supported the former schedule (0.25% versus 1.29% prophylaxis failures respectively) (**Class II, Level A**). Assays for penicillin levels in blood have also shown that 4-weekly dosage did not provide adequate drug levels throughout the intervening period between doses.[49] Therefore, only those considered at low risk should receive a 4-weekly dose.

Oral prophylaxis has been shown to be less effective than intramuscular penicillin G prophylaxis, even when compliance is optimal.[1,42,43] Penicillin V 250 mg twice daily for adults and children is the recommended dose. No published data exist on other penicillins, macrolides or cephalosporins for secondary prophylaxis of rheumatic fever. However, erythromycin, at a dose of 250 mg twice daily, is usually recommended for those allergic to penicillin.

Patients who have either had mechanical prosthetic valves inserted and/or who are in atrial fibrillation require warfarin anticoagulation. This is a situation which may necessitate the use of an oral prophylaxis regimen. In such patients intramuscular injections of penicillin may carry the risk of hematoma formation, especially in patients rendered asthenic as a consequence of their underlying illness. This important circumstance is, as far as we are aware, not addressed in the literature.

Acute management

The aim of the acute treatment of a proven attack of rheumatic fever is to suppress the inflammatory response and so minimize the effects on the heart and joints, to eradicate the GAS from the pharynx, and provide symptomatic relief.

The long-standing recommendation of bedrest would appear to be appropriate, mainly in order to lessen joint pain. The duration of bedrest should be individually determined but ambulation can usually be started once the fever has subsided and acute phase reactants are returning towards normal. Strenuous exertion should be avoided, especially for those with carditis (**Level C**).

Even though throat swabs taken during the acute attack of rheumatic fever are rarely positive for GAS, it is advisable for patients to receive a 10-day course of penicillin V (or erythromycin if penicillin allergic). Although conventional, this strategy is untested. Thereafter, secondary prophylaxis should commence as described in the previous section[21] (**Level C**).

The choice of anti-inflammatory agent is between salicylates and corticosteroids. A meta-analysis of trials comparing these two agents was published in 1995.[50] In this review, a total of 130 publications from 1949 onwards were assessed. While 11 studies had been randomized, only five[51–55] (Table 53.2) fulfilled the meta-analysis criteria of:

Table 53.2 Randomized trials of acute rheumatic fever treatment

Reference	Number of patients analyzed	Agent/dose	Apical murmur present at 1 year (%)
Combined Rheumatic Fever Study Group[51]	57	Prednisone 60 mg/d ×21 d then taper vs ASA 50 mg/lb/d ×9 wk, then taper	Steroids 57.1% vs ASA 37%
Combined Rheumatic Fever Study Group[52]	73	Prednisone 3 mg/lb/d ×7 d then taper vs ASA 50 mg/lb/d ×6 wk	Steroids 25.3% vs ASA 32.1%
Dorfman et al[53]	129	Hydrocortisone 250 mg then taper and/or ASA to 20–30 mg%	Steroids 12.5% vs ASA 34.4%
Rheumatic Fever Working Party[54]	497	ACTH 80–120 u and taper vs cortisone 300 mg and taper vs ASA 60 mg/lb/d and taper	Steroids 48.6% vs ASA 44%
Stolzer et al[55]	128	ASA 30–60 mg/lb/d ×6 wk vs cortisone 50–300 mg/d vs ACTH 20–120 mg/d	Steroids 26.3% vs ASA 34.6%

- adequate case definition by the Jones criteria
- proper randomization to either salicylates or some form of corticosteroid
- non-overlap of subjects between studies
- follow-up for at least a year for assessment of the presence of an apical systolic murmur suggesting structural cardiac damage as a result of carditis.

The trials varied in the use of steroid agent used –cortisone, ACTH or prednisone. The largest study of the five selected for the meta-analysis was that of the Rheumatic Fever Working Party where ACTH, cortisone, and aspirin were compared in a trial involving 505 children in the USA and United Kingdom.[54] This study found no long-term advantage to be associated with either therapy. While apical systolic murmurs disappeared more rapidly in the steroid-treated groups, the prevalence of a cardiac murmur at 1-year follow-up was the same as for the salicylate-treated group. The erythrocyte sedimentation rate was found to normalize and nodules resolved faster in the steroid group.

When the five studies were examined in the meta-analysis, it was found that the advantage of corticosteroids over salicylates, in preventing the development of a pathologic apical systolic murmur after 1 year of treatment, was not statistically significant (estimated odds ratio 0.88; 95% confidence interval (CI) 0.53–1.46). A more recent systematic review of the effectiveness of anti-inflammatory agents (steroids, aspirin or immunoglobulins) for preventing or reducing further heart valve damage in patients with acute rheumatic fever came to a similar conclusion[56] (**Class II, Level B**).

All these trials may be criticized on two important points. First, the method used to assess cardiac involvement was clinical with the development or persistence of an apical systolic murmur the usual criterion. It could be argued that observer error and interobserver variability of clinical methodology could invalidate the results and that the question should be re-examined using modern non-invasive techniques. It has, however, been shown that, at least during the acute phase of the illness, transthoracic two-dimensional echocardiography with color flow imaging does not add significantly to the clinical evaluation of the degree of cardiac involvement.[57] The second point relates to the duration of follow-up. Lack of clinical evidence of cardiac involvement at 1 or 2 years following the initial attack of acute rheumatic fever is no guarantee that the important sequelae of valvular incompetence or stenosis will not develop in the ensuing decades.

Appropriate dosages of anti-inflammatory agents are aspirin 100 mg/kg/d in four or five divided doses or prednisone 1–2 mg/kg/d. Patients with severe cardiac involvement appear to respond more promptly to corticosteroids.[58]

The duration of therapy must be gauged from the severity of the attack, the presence of carditis, and the rate of response to treatment. Milder attacks with little or no carditis may be treated with salicylates for approximately a month or until inflammation has subsided, as assessed by clinical and laboratory evidence. More severe cases may require 2–3 months of steroid therapy before this can be gradually weaned. Up to 5% of patients may still have rheumatic activity despite treatment at 6 months. Occasionally a "rebound" of inflammatory activity can occur when anti-inflammatory therapy is reduced and may require salicylate treatment.

Alternative non-steroidal anti-inflammatory agents have not been adequately assessed in trials and would only be of benefit in individuals allergic to or intolerant of aspirin.

A prospective randomized controlled trial demonstrated no benefit for intravenous immunoglobulin over placebo when administered during the first episode of rheumatic fever.[56,59] In patients whose initial attack of rheumatic fever is inadequately treated, there is a high risk that the rheumatic activity will continue and result in valvular incompetence, most commonly of the mitral valve. The end result of an ongoing rheumatic process with deteriorating valvu-

Table 53.3 Randomized trials of acute rheumatic fever treatment

Agent	Dose	Route	Duration
Primary prevention			
Benzathine penicillin G	600 000 u if ≤27 kg, 1200 000 u if >27 kg	Intramuscular injection	Once
Penicillin V	Children 250 mg, 2–3× daily	Oral	10 days
	Adults 500 mg 2–3× daily		
Erythromycin estolate	20–40 mg/kg/d 2–4× daily (max 1 g/d)	Oral	10 days
Secondary prevention (prevention of recurrent attacks)[a]			
Benzathine penicillin G	1200 000 u every 3 weeks (low risk, every 4 weeks)	Intramuscular injection	
Penicillin V	250 mg 2× daily	Oral	
Erythromycin	250 mg 2× daily	Oral	

Treatment of the acute attack of rheumatic fever
- Bedrest
- Salicylates 100 mg/kg/d in 4–5 doses (in severe attacks with cardiac involvement, prednisone 1–2 mg/kg/d)
- Valve repair/replacement surgery for severe valve dysfunction

lar function is heart failure. Experience has shown that in such cases prompt surgical management[60] is the sole option and can result in the survival of up to 90% of patients.[61,62] It has been suggested that the reduction in cardiac workload following valve surgery results in a settling of the rheumatic process – akin to the beneficial effect observed for bedrest (**Class II, Level C**).

Conclusion

While questions regarding the pathogenesis of rheumatic fever remain, sufficient evidence is available to offer guidance on the appropriate prevention and acute treatment of this common illness (Table 53.3).[1,2] It must be remembered that as most sufferers of this disease are in poor socioeconomic environments and in countries where resources are scarce, the regimens used must be cost-effective and chosen with a view to maximizing patient compliance. A study of the effect of a 10-year education program on the reduction of rheumatic fever incidence[64] demonstrated what can be achieved by a structured approach to community education, patient identification, and effective diagnosis and treatment. This intervention resulted in a 78% reduction in the incidence of rheumatic fever within 10 years. Much could be achieved through the establishment of similar programs where rheumatic fever is rife.[64]

54 Mitral valve disease: indications for surgery

Blase A Carabello
Baylor College of Medicine, Houston, TX, USA

Introduction

In mitral valve disease, symptomatic status, ventricular functional status, and the kind of operation which will ultimately be performed all affect the indication for valve surgery. This chapter will integrate these aspects into a strategy for surgical correction. It should be noted that in surgery for valve disease there are few large controlled trials of therapy. Indeed, in the most recent (2006) AHA/ACC Guidelines for the Management of Patients with Valvular Heart Disease no recommendation is based on a level of evidence "A."[1] Most knowledge of the response of valve disease to surgery accrues from reports of surgical outcome in both selected and unselected patients.

Mitral regurgitation

Surgical objectives

Like all valvular lesions, mitral regurgitation imposes a hemodynamic overload on the heart. Ultimately, this overload can only be corrected by surgically restoring valve competence. For valve surgery in general, the timing of surgery has two opposing tenets. First, since surgery has an operative risk and, if a prosthesis is inserted, imposes the risks inherent to valve prosthesis, surgery should be delayed for as long as possible. Second, surgery which is delayed until the hemodynamic overload has caused irreversible left ventricular dysfunction will result in a suboptimal outcome. In some patients, far advanced left ventricular dysfunction may militate against operating at all.

The timing of valve surgery is made even more complex in mitral regurgitation since frequently valve repair rather than valve replacement can be effected. Because valve repair does not involve the use of a valvular prosthesis and because it also helps to preserve left ventricular function, it is applicable at the two ends of the spectrum of mitral regurgitation. Repair might be considered in asymptomatic patients with normal left ventricular function because the disease could be cured then without the need for intense follow-up and without the use of a valve prosthesis.[2] At the other end of the spectrum, patients with severe impairment of left ventricular function who might not be candidates for mitral valve replacement with chordal disruption might have a good result from mitral valve repair.[3] However, for most patients, mitral valve surgery is performed for the relief of symptoms or for prevention of worsening of asymptomatic left ventricular dysfunction.

Etiology

The mitral valve apparatus consists of the mitral valve annulus, the valve leaflets, the chorda tendineae, and the papillary muscles. Abnormalities of any of these structures may cause mitral regurgitation. The common causes of mitral regurgitation include infective endocarditis, the mitral valve prolapse syndrome with myxomatous degeneration of the valve, spontaneous chordal rupture, rheumatic heart disease, collagen disease such as Marfan's syndrome and coronary artery disease leading to papillary muscle ischemia or necrosis. These etiologies of mitral regurgitation are important especially with regard to surgical correction. For instance, the spontaneous rupture of a posterior chorda tendinea leads to mitral valve repair in almost 100% of cases. On the other hand, severe rheumatic deformity of the valve which has led to mitral regurgitation may be irreparable, necessitating mitral valve replacement.

Pathophysiology

Hemodynamic phases of mitral regurgitation

Figure 54.1 depicts the pathophysiologic phases of mitral regurgitation.[4] In the acute phase, such as might occur with spontaneous chordal rupture, there is sudden volume overload on both the left ventricle and left atrium. The regurgitant volume, together with the venous return from the pulmonary veins, distends both chambers. Distension of the left ventricle increases use of the Frank–Starling mechanism by which increased sarcomere stretch increases end-diastolic volume modestly and also increases left ventricular stroke work. The new orifice for left ventricular ejection (the regurgitant pathway) facilitates left ventricular emptying and end-systolic volume decreases. Acting in concert, these two effects increase ejection fraction and total stroke volume. However, as shown in Figure 54.1, panel A, if only 50% of the total stroke volume is ejected into the aorta there is a net loss of 30% of the initial forward stroke volume. At the same time, volume overload on the left atrium increases left atrial pressure. At this point, the patient suffers from low output and pulmonary congestion and appears to be in left ventricular failure although left ventricular muscle function is either normal or even augmented by sympathetic reflexes. Acute severe mitral regurgitation may lead to shock and pulmonary edema, requiring intra-aortic balloon counterpulsation and urgent mitral valve repair or replacement. However, if the patient can be maintained in a relatively stable condition, he or she may then enter the chronic compensated phase (Fig. 54.1, panel B) within 3–6 months.

In the chronic compensated phase of mitral regurgitation, eccentric cardiac hypertrophy, in which sarcomeres are laid down in series, allows enlargement of the left ventricle, enhancing its total volume pumping capacity. Total stroke volume is increased, allowing normalization of forward stroke volume. Enlargement of the left atrium accommodates the volume overload at a lower pressure, eliminating pulmonary congestion. In this phase the patient may be remarkably asymptomatic, able to perform normal daily activities, and can even engage in sporting events of modest physical demands.[5]

The patient may remain in the compensated phase for months or years. However, eventually the persistent volume overload leads to a decline in left ventricular function (Fig. 54.1, panel C). A loss of myofibrils or an insensitivity to cyclic AMP may be responsible, at least in part, for loss of left ventricular contractility.[6,7] In this phase, left ventricular end-systolic volume increases because reduced force of contraction results in poor left ventricular emptying, forward stroke volume falls, and left ventricular dilation may worsen the mitral regurgitation. At this time there is re-elevation of the left atrial pressure, resulting again in pulmonary congestion. Of note, the still favorable
Figure 54.1 (a) Normal hemodynamic state compared to acute mitral regurgitation (AMR). In AMR, total stroke volume and ejection performance increase as preload is increased and afterload is reduced. However, forward stroke volume is reduced and left atrial pressure is increased. (b) AMR compared to chronic compensated mitral regurgitation (CCMR). In CCMR, increased end-diastolic volume permitted by eccentric hypertrophy increases both total and forward stroke volume. Enlargement of atrium and ventricle allows increased volume to be accommodated at lower filling pressure. Increase in afterload toward normal in this state of compensation reduces ejection performance slightly. (c) Chronic decompensated mitral regurgitation (CDMR) compared with CCMR contractile function is reduced and afterload is increased in CDMR. Both reduce ejection performance and forward cardiac output. There is further cardiac dilation in CDMR, leading to worsening mitral regurgitation, further compromising pump function by reducing forward stroke volume and increasing filling pressure. CF, contractile function; EDV, end-diastolic volume; EF, ejection fraction; ESS, end-systolic stress; ESV, end-systolic volume; FSV, forward stroke volume; LA, left atrial pressure; N, normal hemodynamic state; RF, regurgitant fraction; SL, sarcomere length. (Reproduced with permission from Carabello.[4])

loading conditions of mitral regurgitation (increased preload and normal afterload) permit a "normal" ejection fraction even though left ventricular dysfunction has developed.

Importance of the mitral valve apparatus

Although the contribution of the mitral valve apparatus to left ventricular function was noted by Rushmer and Lillehei decades ago,[8,9] its physiologic significance and impact on patient care have only recently received widespread appreciation. It is quite clear that the mitral valve apparatus has a wider role than to simply prevent mitral regurgitation. Rather, the apparatus is an integral part of the left ventricular internal skeleton. In early systole, tugging on

the apparatus by the chorda tendineae may shorten the major axis while lengthening the minor axis, in turn augmenting preload there during ejection systole. In addition, the apparatus helps to maintain the normal and efficient ellipsoid shape of the left ventricle.

Transsection of the chordae causes an immediate fall in left ventricular function.[10] Until the importance of chordal preservation during mitral valve surgery was recognized, ejection fraction almost always fell following surgery. This fall was attributed to increased afterload from surgical closure of the low-impedance pathway which preoperatively had facilitated ejection into the left atrium. However, it is now clear that closure of the same low-impedance pathway in which chordal integrity is maintained results in no fall in ejection fraction or only a modest decline, suggesting that the increased postoperative load theory is not the sole mechanism for why ejection fraction falls.[3] In fact, chordal preservation can actually effect a lowering of systolic wall stress (afterload) instead of an increase as left ventricular radius decreases following surgery (stress = pressure × radius/2× thickness).[11] Thus, chordal integrity should be maintained whenever possible[12–14]; in fact, a randomized study demonstrated that maintenance of just the posterior apparatus lowers mortality and leads to superior postoperative function compared to posterior and anterior chordal transection.[15]

Apart from the benefits on left ventricular function, if mitral valve repair instead of a replacement can be performed, operative mortality is lower (Fig. 54.2), postoperative survival is better and the need for anticoagulation is removed while thromboembolism remains low.[13,16–18] Long-term outcome is excellent and repairs are durable. In one study only seven of 162 patients required reoperation a mean of 17 years after repair.[19] Even if the mitral valve is so badly damaged that a mitral valve prosthesis must be inserted, chordal preservation, especially of the posterior chords, can usually be performed resulting in better ventricular function than if all the chords were removed.[12]
Figure 54.2 Postoperative survival following mitral valve repair is compared to that of mitral valve replacement.

Unfortunately, despite recognition of the importance of the mitral valve apparatus, mitral repair is only performed in about 50% of all operations for mitral regurgitation, varying from 0% in some institutions to 90% in others.

Indications for surgery

Severity of mitral regurgitation

Under most circumstances only severe mitral regurgitation is corrected surgically. Mild to moderate regurgitation (regurgitant fraction <40%) neither causes symptoms nor leads to left ventricular dysfunction even over a protracted period of time in the absence of other cardiac disease. Severity is difficult to ascertain by physical examination alone, especially in acute mitral regurgitation. As noted above, in acute mitral regurgitation there has been no time for cardiac dilation to occur. Thus, palpation of the precordium does not reveal a hyperdynamic left ventricular impulse. Although the murmur of mitral regurgitation is present, severity cannot be gauged from its intensity. In most cases of severe mitral regurgitation an S3 should be present. This finding does not necessarily indicate heart failure but may simply be the result of a large regurgitant volume filling the left ventricle under a higher than usual left atrial pressure. In chronic mitral regurgitation there should be evidence on physical examination of an enlarged hyperdynamic left ventricle unless the patient's size or habitus makes physical examination difficult. Failure to find evidence of an enlarged heart suggests that the mitral regurgitation is neither severe enough or chronic enough to cause left ventricular enlargement.

In chronic severe mitral regurgitation, the chest radiograph should also show cardiac enlargement and the electrocardiogram is likely to demonstrate left atrial abnormality and left ventricular hypertrophy.

In most cases, quantitation of regurgitant severity is estimated during echocardiography with Doppler interrogation of the mitral valve. In acute mitral regurgitation, transthoracic echocardiography may underestimate regurgitant severity.[20] In such cases, transesophageal echocardiography is helpful. It should be noted that Doppler flow studies visually demonstrate blood flow velocity across the mitral valve and not true flow. Because of this, both under- and overestimation of regurgitant severity is possible. Flow mapping, which expresses the regurgitant jet in terms relative to left atrial size, has been used extensively. However, limitations of this method are well known and the technique is semiquantitative at best.[20,21] Other methods, such as the proximal isovelocity surface area, have been employed experimentally and in clinical investigation.[23–25] In using proximal isovelocity surface area to estimate regurgitation flow, the area of convergence of the regurgitant jet on the ventricular side of the mitral valve is measured at the point of aliasing. By multiplying proximal

isovelocity surface area by the known aliasing velocity, actual flow is obtained, which should be a better indication of regurgitant severity and even outcome. Indeed, in one prospective study a regurgitant orifice area of $>0.4\,cm^2$ predicted a poorer prognosis than when orifice area was smaller.[26] However, the convergence pattern is often difficult to pinpoint clinically and is not applicable in many cases. As with mitral valve repair, practice varies from center to center with some centers routinely accurately quantifying the severity of disease[27] while others rely upon a visual estimation.

When regurgitation severity is in doubt because of discordance between left ventricular size and the regurgitant signal, i.e. a small left ventricle and left atrium suggesting mild disease and a Doppler signal suggesting severe disease, the issue often can be resolved at cardiac catheterization. During cardiac catheterization, hemodynamics and a left ventriculogram give additional although also imperfect information about the degree of mitral regurgitation. The left ventriculogram, unlike the Doppler study, visualizes actual flow of contrast media from the left ventricle into the left atrium. Care must be taken to inject enough contrast agent (at least $60\,mL$) to opacify both the enlarged left ventricle and left atrium of mitral regurgitation. Coronary arteriography is also performed at cardiac catheterization if there is any suspicion of an ischemic etiology for mitral regurgitation or when risk factors for coronary disease co-exist.

Acute mitral regurgitation

In almost all cases of severe acute mitral regurgitation, the patient is symptomatic. The acute hemodynamic changes noted above cause decreased forward output and sudden left atrial hypertension, resulting in pulmonary congestion, reduced forward flow, and the symptoms of dyspnea, orthopnea, exercise intolerance, and fatigue. Vasodilator therapy may be successful in alleviating symptoms by preferentially increasing forward flow while simultaneously decreasing left ventricular size, partially restoring mitral valve competence.[28] If vasodilators fail or if the patient is so severely decompensated that hypotension contraindicates the use of vasodilators, intra-aortic balloon counterpulsation is necessary. In such cases surgery should follow soon after. This is especially true for the patient with ischemic mitral regurgitation. Such patients may have a volatile course with initially mild heart failure which progresses unpredictably in severity. These patients require close follow-up.[29,30] In milder cases where symptoms can be relieved by medical therapy, patients should be given a trial of medical therapy during which they may enter the compensated chronic phase. In such cases, patients may then become asymptomatic for months or years. However, one study suggests that such patients are at risk for sudden death.[31] If confirmed, this would indicate that relief of symptoms with medical therapy might be masking hemodynamic or electrical instability and thus be dangerous.

Chronic mitral regurgitation

Symptomatic disease The onset of symptoms of congestive heart failure or a more subtle decrease in exercise tolerance is usually indicative of a change in physiologic status which usually has important clinical significance. The onset of new atrial fibrillation is also probably indicative of a significant change in disease status. Further, atrial fibrillation by itself leads to increased morbidity and decreased cardiac output. In most cases, the onset of symptoms or persistent atrial fibrillation is an indication for mitral valve surgery even when objective indicators of left ventricular function do not show advancement to dysfunction. Early surgery in the mildly symptomatic patient is especially indicated when there is a high probability that mitral valve repair can be effected. In this circumstance there is no need to delay longer, waiting for more severe symptoms or the onset of more apparent left ventricular dysfunction. A valve repair will allow improvement in lifestyle while at the same time avoiding the risks of a prosthesis. Early surgery may be especially important when mitral regurgitation is due to a flail leaflet because this condition may be associated with a modest increase in the risk of sudden death.[32] If preoperative evaluation indicates repair is unlikely, close follow-up of the patient is indicated. If symptoms continue to worsen or if left ventricular dysfunction develops, mitral competence should be restored.

In the patient with mild symptoms and normal left ventricular function, transesophageal echocardiography to determine valve anatomy is crucial. This procedure is the best preoperative test to define whether or not repair can be performed or if replacement will be necessary.

Assessment of left ventricular function A major goal in the management of the patient with mitral regurgitation is to correct the lesion prior to the development of irreversible left ventricular contractile dysfunction. Unfortunately, contractility is difficult to measure clinically. Standard ejection phase indices such as ejection fraction, which are used to gauge left ventricular function in most cardiac diseases, are confounded by the abnormal loading conditions present in mitral regurgitation, necessitating alterations in the way these indexes are used.[33] Because ejection fraction is augmented by increased preload in mitral regurgitation,[34] the value for ejection fraction should be supernormal in the face of normal contractility. A "normal" ejection fraction for the patient with mitral regurgitation is probably 0.65–0.75. Indeed, Enriquez-Sarano and colleagues have demonstrated that once the ejection fraction falls to less than 0.60 in patients with mitral regurgitation, long-term mortality is increased, suggesting that left ventricular dysfunction has already developed at that threshold for ejection fraction.[35]

End-systolic dimension, which is less dependent upon preload, has also been developed as an important indicator of left ventricular dysfunction in this disease. Wisenbaugh *et al* noted that when end-systolic dimension exceeded 45 mm, outcome following surgery was compromised.[36] This figure or its angiographic equivalent has been found to be predictive in other studies.[37,38] However, more recent studies have suggested that for ejection fraction to be predictably normal following surgery, end-systolic dimension should not exceed 40 mm, now the new ACC/AHA guideline for operation.[39] Careful evaluation of the patient with mitral regurgitation with history and physical examination augmented with serial echocardiograms should avoid the situation in which unrecognized left ventricular dysfunction develops. Yearly follow-up is probably adequate as long as the ejection fraction exceeds 0.65 and the end-systolic dimension is less than 35 mm. If the ejection fraction is lower or the end-systolic dimension is higher, more frequent follow-up is indicated. When the ejection fraction approaches 0.60 or when the end-systolic dimension approaches 40 mm, surgery should be contemplated.

Indications for surgery in the asymptomatic patient with mitral regurgitation

Patients with normal left ventricular function At first glance, the asymptomatic patient with mitral regurgitation who has normal left ventricular function would not seem to require surgery. In this patient, surgery will neither improve lifestyle nor prevent reversible left ventricular dysfunction from developing imminently. However, patients with flail leaflet may become symptomatic within the next year[32] and may be at some increased risk for sudden death. In other cases where it is apparent that the severity of mitral regurgitation will eventually necessitate surgery, it could be argued that if mitral valve repair could be performed, little is to be gained by waiting. This circumstance is much like atrial septal defect where at low operative mortality (less than 1%) the defect can be repaired without the use of a prosthesis before unwanted sequelae develop (in the case of atrial septal defect, persistent atrial arrhythmias and pulmonary hypertension; in the case of mitral regurgitation, left ventricular dysfunction). If this approach is taken it must be clear that repair rather than replacement can be effected. If the asymptomatic patient with normal ventricular function is ultimately treated with a prosthesis when a repair had been anticipated, it should be considered a complication of surgery since the unwanted risks of a prosthesis could have been at least temporarily avoided.

Asymptomatic patients with left ventricular dysfunction It is the asymptomatic patient with left ventricular dysfunction at whom serial follow-up is aimed. If left ventricular dysfunction has developed (ejection fraction <0.6, end-systolic dimension >40 mm), surgery should be performed to prevent further irreversible left ventricular dysfunction even if surgery entails a prosthetic valve. Since left ventricular dysfunction has already been indicated by noninvasive testing in such patients, every effort should be made to spare at least part of the mitral valve apparatus to prevent a further decline in left ventricular function postoperatively. Indeed, a recent prospective but nonrandomized study demonstrated that when patients undergo corrective surgery either at the onset of symptoms or when left ventricular dysfunction occurs using these points of demarcation, the outcome is excellent.[40]

Asymptomatic elderly patients Patients with mitral regurgitation over the age of 75 are at increased risk for operative death and a poor outcome. This is especially true if mitral valve replacement instead of repair is performed or if concomitant coronary disease, a consequence of aging, is present.[13,41] However, recent reports indicate improved results in octogenarians undergoing mitral valve surgery, especially when preoperative left ventricular function has been avoided and when mitral valve repair has been employed.[42,43] A summary of indications for surgery is shown in Table 54.1.

Establishment of symptom status

Because of the insidious nature of mitral valve disease, patients may subtly alter their lifestyle to maintain their asymptomatic status. Thus, history alone may fail to identify this gradual decline in exercise tolerance. Therefore, in patients with mitral valve disease, formal exercise testing is useful to objectively quantify changes in exercise tolerance over the time of follow-up and to separate truly asymptomatic patients from those who avoid situations which produce symptoms.

Far advanced disease

Occasionally patients reach the first attention of the physician in severe congestive heart failure with far advanced

Table 54.1 Indications for mitral surgery in asymptomatic patients with severe non-ischemic mitral regurgitation

Repair likely	Repair unlikely
Patient with flail leaflet	–
Patient with persistent atrial fibrillation	–
Patient with EF < 0.60 or ESD > 40 mm	Patient with EF < 0.60 or ESD > 40 mm

ESD, end-systolic minor axis dimension; EF, ejection fraction.

left ventricular dysfunction. Many patients in this category may benefit from surgery because correction of mitral regurgitation will lower left atrial pressure and perhaps increase forward output. However, in such cases postoperative left ventricular function will remain depressed and lifespan is likely to be shortened. It is often difficult to decide whether left ventricular dysfunction is so far advanced that surgery should not be performed. The answer to this question is predicated upon what kind of operation is contemplated. If repair with sparing of most chordal structures can be performed, patients with an ejection fraction as low as 30% can survive surgery with postoperative ejection performance maintained at this relatively low level.[3] However, for patients with an ejection fraction <40% in whom only mitral valve replacement can be performed, operative mortality might be prohibitive. Wisenbaugh has further suggested that if the end-systolic dimension exceeds 50 mm in patients with rheumatic mitral regurgitation, postoperative risk is extremely high whether repair can be effected or not.[36]

Ischemic and cardiomyopathic (functional) mitral regurgitation

In primary mitral regurgitation as discussed above, valve pathology causes regurgitation, inducing a volume overload that damages the left ventricle, i.e. "the valve makes the heart sick." However, in functional mitral regurgitation, either from ischemic ventricular damage from coronary disease or from dilated cardiomyopathy, wall motion abnormalities and annular dilation lead to papillary muscle displacement, causing a normal valve to leak, i.e. "the heart makes the valve sick." Because there are already other serious cardiac abnormalities present, the outcome of surgical correction for functional mitral regurgitation is worse than with primary mitral regurgitation[44,45] and guidelines for surgery are not well developed. As noted above, there is no obligatory fall in ejection fraction after mitral valve repair so even patients with very low ejection fraction may benefit from surgery.[46] However, while some have found good results with surgery in this group of patients,[47] there is no proof that such surgery prolongs life and even studies of quality of life have been disappointing.[48,49] Common sense indicates that surgery should be performed when ischemic mitral regurgitation has caused shock or intractable pulmonary congestion.

Medical therapy

Apart from the use of prophylactic antibiotics against infective endocarditis in very specific patients, there is no proven medical therapy for chronic mitral regurgitation. While vasodilators are effective in treating the acute disease, no large long-term trials have been performed to examine their effect in chronic disease. The trials which have been performed differ regarding benefit from this therapy.[50,51] Further, since afterload is not typically elevated in chronic mitral regurgitation, the physiologic underpinnings for vasodilators used for afterload reduction are less clear.

Summary

Patients with acute mitral regurgitation with severe hemodynamic instability require surgical correction. In less severe situations, medical therapy may allow the patient to enter the chronic compensated phase in which surgery can be delayed.

When symptoms develop in chronic mitral regurgitation, they are usually an indication for valve surgery. This is especially true if left ventricular dysfunction is developing or if it is certain that a mitral valve repair can be performed. In asymptomatic patients with normal ventricular function, surgery should only be contemplated when there is certainty of repair. On the other hand, if left ventricular dysfunction is developing, surgery should be performed to prevent further deterioration whether or not a repair can be effected.

Mitral stenosis

Etiology and pathophysiology

Most mitral stenosis in adults is acquired through rheumatic heart disease. In developed countries it typically appears in women in their fourth or fifth decades. In developing nations, where the rheumatic process appears to be more aggressive, stenosis may develop in adolescence or early adulthood.

As mitral stenosis worsens, a gradient develops between the left atrium and left ventricle during diastole. At the same time the stenotic valve impairs left ventricular filling, limiting cardiac output. The combination of pulmonary congestion caused by left atrial hypertension and diminished forward cardiac output caused by inflow obstruction mimics the hemodynamics of left ventricular failure even though the left ventricle itself is usually spared from the rheumatic process, especially in developed countries.[52] However, in approximately one-third of patients, left ventricular ejection performance is reduced despite no impairment in contractility.[53] Reduced ejection fraction is caused by reduced preload from the impairment of left ventricular filling and from increased left ventricular afterload secondary to reflex systemic vasoconstriction in the face of decreased cardiac output. Ejection performance may return to normal shortly after mitral stenosis is relieved.[54]

Although the left ventricle is usually spared from direct involvement in this disease, the right ventricle experiences

pressure overload because it supplies the hemodynamic force propelling blood across the stenotic mitral valve. Thus, as left atrial pressure rises, pulmonary pressure and right ventricular pressure also must increase, placing a pressure overload on the right ventricle. For unclear reasons, as the disease progresses, reversible pulmonary vasoconstriction develops, leading to a worsening of pulmonary hypertension and eventually to right ventricular failure.

Indications for surgery

In most cases, mitral stenosis can be relieved by balloon valvotomy which offers results comparable to open commissurotomy, as shown in a randomized trial.[55] Surgery is reserved for those cases in which valve anatomy is unfavorable for balloon valvotomy or in which balloon valvotomy has been attempted and failed. Although in some instances open surgical commissurotomy can be successful even though balloon valvotomy was predicted to be unsuccessful, the unfavorable anatomy for balloon valvotomy will also be unfavorable for commissurotomy, necessitating valve replacement. Thus when surgery is anticipated, the risks and complications of a prosthesis should also be anticipated.

The timing of surgery for mitral stenosis can largely be predicated on symptomatic status as shown in Figure 54.3.[56] Once more than New York Heart Association

(NYHA) class II symptoms develop, mortality increases abruptly and surgery should be performed before class III symptoms appear. Additionally, some studies indicate that the presence of pulmonary hypertension substantially increases operative risk[38,57] and thus surgery should be contemplated in patients who develop asymptomatic pulmonary hypertension (pulmonary artery systolic pressure >50 mmHg). When surgery precedes severe pulmonary hypertension, operative mortality, even with the insertion of a prosthesis, is 1–3%.

The most difficult situation for timing surgery arises in the young woman who wishes to bear children. In such patients in whom balloon valvotomy has already been ruled out because of unfavorable valve anatomy, the choice of prosthetic valve becomes quite difficult. If a mechanical valve is placed, it will require anticoagulation which is problematic during pregnancy. Administration of warfarin causes a particularly high incidence of fetal malformation, especially when used during the first trimester. It can be substituted by daily injections of heparin but serious thrombotic complications have occurred in such circumstances, suggesting that this therapy is inadequate at least in some cases.[58] On the other hand, if a bioprosthesis is placed in a young woman it is likely to degenerate within a decade or sooner, forcing the patient to have a reoperation attended by increased surgical risk. There is no correct solution to this dilemma and the prosthesis which is eventually inserted is chosen after lengthy consultation between both the patient and surgeon.

Summary

In most cases, mitral stenosis can be treated successfully with balloon valvotomy. However, if this procedure is unfeasible, open commissurotomy or valve replacement is indicated for greater than NYHA class II symptoms or for the development of pulmonary hypertension.
Figure 54.3 Comparison of surgically treated patients with medically treated patients with mitral stenosis. Groups II, III, and IV equivalent to NYHA classifications II, III, and IV are approximately similar to the groups represented by letters B, C, and D, respectively. Class IV patients had better improved survival when treated surgically than did class D patients who were treated medically. Class II and III patients also had better survival when treated surgically than did the patients in groups B and C, although the difference is not as dramatic. 55 Surgical indications in aortic valve disease

Sunil Mankad,[1] Heidi M Connolly[1] and Shahbudin H Rahimtoola[2]

[1] Mayo Clinic, Rochester, MN, USA

Introduction

Evidence-based management of patients with aortic valve disease is limited by the absence of prospective randomized trials of surgery versus medical therapy. Furthermore, the small number of prospective, randomized trials of medical treatment in aortic valve disease have provided conflicting results. However, retrospective studies provide extremely useful data which are important in the management of patients. Sir Thomas Lewis pointed out over 80 years ago the inadequacy of knowledge of prognosis in patients with heart disease and proposed a system for prospective follow-up of patients, which we now call "databases" or "registries". The latter are, of course, the major evidence used in this chapter to delineate the indications for surgery and also influenced the recently updated American College of Cardiology (ACC) and American Heart Association (AHA) *Guidelines for the Management of Patients with Valvular Heart Disease*,[1] and the European Society of Cardiology (ESC) *Guidelines on the Management of Patients with Valvular Heart Disease*[2] which provide a framework upon which clinical decisions can be based. However, the guidelines must be put in perspective. The ACC/AHA guidelines had 124 pages and 1066 references. Of their 324 recommendations, only one (0.3%) was based on level of evidence A and 242 (74.7%) were based on level of evidence C. The ESC guidelines had 32 pages and 232 references. Of the 64 recommendations, none (0%) had level of evidence A and 58 (90.6%) were based on level of evidence C.

Aortic valve stenosis

Etiology

A wide variety of disorders may produce aortic valve obstruction.[3] However, those that result in severe stenosis in adults are:
- congenital
- acquired
- calcific (degenerative)
- autoimmune
- rheumatic.

The most common cause of aortic stenosis (AS) in younger adults is a congenital bicuspid valve, which is found in approximately 1% of the general population. In most patients aged 40–64 years, the severely stenotic aortic valve is bicuspid. In patients aged ≥65 years, 90% of severely stenotic valves are tricuspid. Non-rheumatic calcified valves are thought to be "degenerative" but recent data suggest that calcification and obstruction may be the result of an autoimmune reaction to antigens present in the valve,[4] and that the initial process may be an atherosclerotic lesion.[5,6] Early lesions are similar to atherosclerosis, with prominent accumulation of "atherogenic" lipoprotein, including low-density lipoprotein (LDL) and lipoprotein(a), evidence of LDL oxidation, an inflammatory cell infiltrate, and microscopic calcification. In late lesions, there are more prominent accumulation of lipid cells and extracellular matrix.[7] Rheumatic heart disease is still common in developing countries.

Grading the degree of stenosis

The natural history of AS is variable depending on the degree of stenosis and the rate at which it progresses. Cardiac catheterization and echocardiographic–Doppler ultrasound studies indicate the systolic pressure gradient increases on an average by 10–15 mmHg per year. The

10–15 mmHg increase is not linear but a stepwise function with periods of steady state interspersed by an increase in gradient. The range of progression is also wide. Data suggest that the progression of AS may be related to cardiovascular risk factors[8] and the rate of progression may be more rapid if marked leaflet calcification is noted by echocardiography.[9] However, even some patients with only modest calcification may progress very rapidly, making careful follow-up essential.

The systolic gradient across the stenotic aortic valve is dependent on the following:
• the stroke volume (not the cardiac output because the gradient and valve area are a per beat, and not a per minute, function)
• the systolic ejection period
• the systolic pressure in the ascending aorta.

The stenotic valve area is inversely related to the square root of the mean systolic gradient. Thus, measurement of valve area is an important part of the assessment of the severity of AS. The valve area may decrease by as much as $0.12 \pm 0.19\,cm^2$ per year.[10]

Valve area is related to body surface area and is larger in bigger individuals, probably because of the need for a larger stroke volume and cardiac output. The normal aortic valve area ranges from 3 to $4\,cm^2$. It is reduced to half its size before a systolic gradient occurs.[11] The orifice area has to be reduced to one-third of its size before significant hemodynamic changes are seen;[12] gradients increase precipitously after that. The obvious clinical problem is that in an individual patient with AS, one usually does not know the valve area prior to the onset of disease.

Cardiac magnetic resonance imaging (MRI) and computed tomography (CT) are emerging tools in assessment of patients with AS.[13,14] However, echocardiography remains the primary diagnostic tool and initial procedure used to confirm the presence and determine the severity of AS.[15] In an experienced center the severity of AS determined by Doppler echocardiography correlates well with the severity determined by cardiac catheterization.[16] A comprehensive echocardiographic-Doppler examination in AS should include assessment of the aortic valve peak and mean gradient as well as aortic valve area.[17] When the clinical picture does not correlate with the hemodynamic data obtained by Doppler echocardiography, re-evaluation by cardiac catheterization is indicated.

Several series suggest B-type natriuretic peptide (BNP) is useful in assessing severity of aortic stenosis and identifying patients at high risk for cardiovascular events. It has been found that BNP is regulated by systolic and diastolic load, suggesting that myocardial stretch modulates BNP.[18]

The outcome of patients with severe AS was described by Ross and Braunwald[19] after review of seven autopsy studies published before 1955, and also by Horstkotte and Loogen[20] reporting on 55 patients (10 of whom were

Table 55.1 Survival, according to symptoms, of patients with "severe" aortic stenosis

Symptoms	Average survival	
	Autopsy data[a] (years)	Post cardiac catheterization[b] (months)
Overall	3	23
Angina[c]	5	45
Syncope	3	27
Heart failure	<2	11

[c] Angina in patients with AS occurs even in those without associated obstructive CAD.

asymptomatic) with aortic valve area of $<0.8\,cm^2$ by cardiac catheterization who refused surgery. The findings are shown in Table 55.1. The mortality of symptomatic patients with "severe" AS from eight studies[21] is given in Table 55.2.

Mild aortic stenosis

AS is best considered a disease continuum with resulting overlap of specific cut-off values. Nevertheless, a defined classification template is useful clinically. The ACC/AHA valve guidelines revised severity criteria[1] are shown in Table 55.3. This document defines mild AS as an aortic valve area $>1.5\,cm^2$, peak aortic valve jet velocity by Doppler echocardiography $<3.0\,m/sec$, and mean gradient $<25\,mmHg$. In two studies, patients with aortic valve area $>1.5\,cm^2$ by catheterization had no mortality on follow-up. At the end of 10 years, in one study 8% had severe stenosis, and in the other 15% had a cardiac event. At the end of 20 years, AS had become severe in only 20% and continued to be mild in 63%.[20,21]

Moderate aortic stenosis

Moderate AS is defined as a valve area of $>1.0–1.5\,cm^2$, peak aortic valve jet velocity by Doppler echocardiography 3.0–4.0 m/sec, and mean gradient 25–40 mmHg. In one study in which patients were followed after cardiac catheterization, the one-year and 10-year mortality was 3% and 15%, respectively, and at 10 years 65% of patients had had a cardiac event.[21]

Severe aortic stenosis

Several criteria have been used to define severe AS. The guidelines provided by the ACC and AHA Committee on Valvular Heart Disease[1] describe severe AS as an aortic

Table 55.2 Mortality of symptomatic patients with "severe" aortic stenosis[21]

Authors	Year of publication	Patients (n)	Mortality follow-up time (years)					
			1	2	3	5	10	11
Frank et al[29]	1973	15			36%	52%	90%

Horstkotte et al[20]	1988	35			82%			

Table 55.3 ACC/AHA recommendations for classification of aortic stenosis[1]

Parameter	Mild	Moderate	Severe
Jet velocity (m/sec)	<3.0	3.0–4.0	>4.0
Mean gradient (mmHg)	<25	25–40	>40
Valve area (cm^2)	>1.5	1.0–1.5	<1.0
Valve area index (cm^2 per m^2)			<0.6

valve area $\leq 1.0\,cm^2$ and a mean aortic pressure gradient, in the setting of normal cardiac output, of >40 mmHg. Although controversial, this definition was supported by data from a large multicenter database (492 patients) which suggested that the one-year mortality of those with aortic valve areas after catheter balloon valvuloplasty for calcific AS of $\leq 0.7\,cm^2$ versus that of those with valve areas >0.7 cm^2 was 37% versus 42%, respectively.[22] Kennedy and co-workers[23] reported on 66 patients with aortic valve areas of 0.7–1.2 cm^2 (0.92 ± 0.15 cm^2), normal left ventricular volumes and ejection fraction, whose average age was 67 years. In an average follow-up of 35 months, 21% died and 32% had valve replacement; at four years, the actuarial incidence of death or valve replacement was 41%.[23] Thus, these studies show that patients with aortic valve areas of 0.7–1.0 cm^2 have an outcome without valve replacement that is not benign, and is not consonant with moderate stenosis; these patients should be considered as having severe AS.

Natural history

The duration of the asymptomatic period after the development of severe AS is variable. Pellikka et al recently added to their previous work and reported the long term (5.4 ± 4.0 years) follow-up of 622 patients (aged 72 ± 11 years) with asymptomatic, hemodynamically significant AS (peak jet

velocity 4 m/sec by Doppler echocardiography).[24] They found that most patients developed symptoms related to AS with the probability of remaining symptom-free at one, two and five years being 82%, 67%, and 33%, respectively. Furthermore, the one-, two- and five-year probabilities of remaining free of aortic valve surgery or cardiac death were 80%, 63%, and 25%, respectively with the risk of sudden death of approximately 1%/year. Patients having a peak velocity of ≥4.5 m/sec had a higher likelihood of developing symptoms (relative risk, 1.34) or having aortic valve surgery or cardiac death (relative risk, 1.48). In another study of 123 asymptomatic adults with varying grades of severity of AS (aged 63 ± 16 years),[10] the actuarial probability of death or aortic valve surgery was 7 ± 5% at one year, 38 ± 8% at three years and 74 ± 10% at five years. The event rate at two years for aortic jet velocity by Doppler ultrasound of >4.0 m/s (peak gradient by Doppler ultrasound >64 mmHg) was 79 ± 18%, for a velocity of 3.0–4.0 m/s (peak gradient 36–64 mmHg) was 66 ± 13%, and for a velocity of <3.0 m/s (peak gradient of <36 mmHg) was 16 ± 16%.[10] Thus, the duration of the asymptomatic period, particularly in those aged ≥60 years, is probably very short and the course of these patients is not benign.[25,26] However, it should be remembered that it can be difficult to ascribe with certainty a cardiac cause of death if the patients died in their own communities far from the referral center.

Paul Dudley White in 1951[27] credited the first recorded occurrence of sudden death from AS to T. Bonet in 1679.[28] In the past 70 years the reported incidence of sudden death in AS from eight series has ranged from 1% to 21%. Ross and Braunwald,[19] after reviewing seven autopsy series published before 1955, concluded the incidence was 3–5%. The data reported by Pellikka et al[24] suggest the risk of sudden death in asymptomatic patients with AS is approximately 1%/year. The incidence of sudden death in symptomatic adult patients has been 33% (one in three) in one series[29] and 30% (three of ten) in another series.[20] The development of symptoms of angina, syncope or heart failure

changes the prognosis of the patient with AS. Average survival after the onset of symptoms is <2–3 years and careful clinical monitoring for the development of symptoms and progressive disease is paramount.

Management

Medical management

For many years, the standard of care has been to provide antibiotic prophylaxis against infective endocarditis in patients with significant AS.[1] However, recently published AHA guidelines for the prevention of infective endocarditis have created significant controversy and no longer recommend antibiotic prophylaxis for AS based on lack of proven efficacy, risk of adverse reactions and poor cost-effectiveness unless the patient has had prior endocarditis, has a prosthetic valve, or has additional complex cardiac lesions that are high risk for the development of endocarditis.[30] Patients who have had rheumatic fever should still receive antibiotic prophylaxis against recurrences of rheumatic fever[1,31] (**Class I, Level B**; recommendation classes and levels of evidence are as noted in Box 55.1).

Unfortunately, there are no medical treatments proven to delay the progression of AS. AS shares similar atherosclerotic risk factors with coronary artery disease (CAD). Retrospective, observational studies have suggested that both statin therapy and possibly angiotensin-converting enzyme inhibition (ACEI) are effective in slowing progression of AS.[32–35] However, no prospective trials assessing the efficacy of ACEI in AS exist and the two largest

---

BOX 55.1 Recommendation classes and levels of evidence

Class I: Conditions for which there is evidence and/or general agreement that a given procedure or treatment is useful and effective.

Class II: Conditions for which there is conflicting evidence and/or a divergence of opinion about the usefulness/efficacy of a procedure or treatment.

Class IIa: Weight of evidence or opinion is in favor of usefulness/efficacy.

Class IIb: Usefulness/efficacy is less well established by evidence/opinion.

Class III: Conditions for which there is evidence and/or general agreement that the procedure/treatment is not useful, and in some cases, may be harmful.

Level of Evidence A: Data derived from multiple randomized clinical trials or meta-analyses

Level of Evidence B: Data derived from a single randomized clinical trial or large non-randomized studies

Level of Evidence C: Consensus of opinion of the experts and/or small studies, retrospective studies, registries

---

prospective, randomized trials looking at statin therapy in this setting have yielded conflicting results.[36,37] Thus, further prospective trials with longer follow-up and assessment of these treatment strategies in mild or moderate AS are needed. Evaluation and modification of cardiovascular risk factors to prevent concurrent CAD as recommended by current guidelines is the best approach for now.

Surgical management

Surgery is recommended for severe symptomatic AS and is the only specific and direct therapy for most adults with severe AS. Rarely, in young patients, the aortic valve is suitable for balloon or surgical valvotomy. Recently, the results of transcatheter implantation of a balloon-expandable stent valve using a femoral arterial approach in 50 patients with severe AS at high risk for conventional open heart surgery have been published.[38] The procedure was successful in 86% of patients and 30-day mortality was 12% in this high-risk cohort. With further refinement, percutaneous valve replacement may become an alternative to conventional open heart surgery in selected high-risk patients with severe symptomatic AS but in most adults, surgery for AS means aortic valve replacement (AVR).[31,39] AVR is indicated for symptomatic patients with severe AS (**Class I, Level B**), although there are no prospective randomized trials of surgery versus no surgery in severe symptomatic AS, and there are unlikely to be any in the future.

In severe symptomatic AS, AVR results in an improvement of survival even with normal preoperative left ventricular function.[20,40] Schwartz *et al*[39] compared the results of AVR with medical treatment during the same time period in patients with severe symptomatic AS and normal LV systolic function at a single center. They demonstrated significant survival benefit with AVR (Fig. 55.1). Horskotte and Loogen further demonstrated the poor prognosis of medical treatment in severe symptomatic AS with a mean survival of only 23 ± 5 months and a five-year probability of survival of only 18 ± 7% in patients who refused AVR.[20] In patients who refused surgery, mean survival after the occurrence of angina pectoris was 45 ± 13 months, after syncope 27 ± 15 months, and after first occurrence of left heart failure 11 ± 10 months.[20] These differences in survival between those treated medically and surgically are so large that there is a great deal of confidence that AVR significantly improves the survival of those with severe, symptomatic AS (**Class I, Level B**).

The operative mortality of valve replacement is ≤5%.[39,41,42] Data from the Euro Heart Survey demonstrate that operative mortality rates have dropped to 2.7% and 4.3%, for AVR and AVR+ coronary bypass surgery, respectively.[43] Furthermore, in patients without other co-morbid conditions, the risk of AVR is ≤2% in experienced and skilled

Figure 55.1 Aortic valve replacement is associated with a survival benefit in patients with severe symptomatic aortic stenosis. (From Schwarz et al[40] with permission.) Open circles, unoperated; closed circles, operated.

centers.[44] The operative mortality in those ≥70 years is increased, averaging 8% for AVR and 13% for those undergoing AVR and associated coronary bypass surgery;[39] however, operative mortality is also dependent on co-morbidities.[45] Patients with associated CAD should have coronary artery bypass grafting at the same time as AVR, because it results in a lower operative mortality (4.0% vs 9.4%) and better 10-year survival (49% vs 36%).[44] This was in spite of the fact that those who underwent coronary bypass surgery had more CAD (34% had three-vessel disease, 11% had left main artery disease, and 38% had single-vessel disease) than those who did not undergo coronary bypass surgery (13% had three-vessel disease, 1% had left main disease, and 65% had single-vessel disease).[44] Although this approach to CAD is generally approved, there are no randomized trials to support these recommendations. The presence of CAD, its site and severity can be estimated best by selective coronary angiography, which should be performed in all patients 35 years of age or older who are being considered for aortic valve surgery, and in those aged <35 years if they have left ventricular dysfunction, symptoms or signs suggesting CAD, or they have two or more risk factors for premature CAD (excluding gender).[39] The incidence of associated CAD will vary con-

siderably depending on the prevalence of CAD in the population;[21,39] in general, in persons 50 years of age or older it is about 50%.[39] Normal preoperative left ventricular function remains normal postoperatively if perioperative myocardial damage has not occurred.[46] Left ventricular hypertrophy regresses toward normal;[46,47] after two years, the regression continues at a slower rate up to 10 years after AVR.[47] In patients with excessive preoperative left ventricular hypertrophy,[48] the hypertrophy may regress slowly or not at all. Preoperatively, these patients have a small left ventricular cavity, severe increase in wall thickness, and "supernormal" ejection fraction; this occurs in 42% of women and 14% of men aged ≥60 years.[48] After AVR their clinical picture often resembles that of hypertrophic cardiomyopathy without outflow obstruction, which is a difficult clinical condition to treat, both in the early postoperative period and after hospital discharge;[48] therefore, surgery should be performed prior to development of excessive hypertrophy. Surviving patients are functionally improved.[39]

After AVR, the 10-year survival is ≥60% and 15-year survival is about 45%.[39,49] One half or more of the late deaths are not related to the prosthesis but to associated cardiac abnormalities and other co-morbid conditions.[49] Thus, the late survival will vary in different subgroups of patients. The older patients (≥60 years) have a 12-year actuarial survival of ≥60%.[50] Data from the Karolinska Institute in Sweden have provided an interesting perspective on the long-term survival after AVR in patients with AS aged ≥65 years. They compared the relative survival of the patient who has undergone AVR with another age- and sex-matched person in the same population. Relative survival refers to survival of patients compared to age- and gender-matched people in the population. Patients under the age of 65 had a relative survival of 81% which is significantly lower than 100%, and is also lower than that of those aged ≥65 years. On the other hand, patients who underwent AVR at age ≥65 had a relative survival of 94% at the end of 10 years and this was not significantly different from 100% (Fig. 55.2). These data indicate that survival following AVR for AS in patients aged ≥65 is not significantly different from age- and sex-matched individuals in the population without AS; and the late relative survival of patients aged ≥65 years is much better than that of patients aged <65. Thus, surgery should not be denied to those ≥60–65 years old and should be performed early.[50–52]

Patients who present with heart failure related to AS should undergo surgery as soon as possible. Medical treatment in hospital prior to surgery is reasonable to improve the perioperative risk, but ACE inhibitors should be used with great caution and in such a dosage that hypotension is avoided. Selected critically ill patients with left ventricular systolic dysfunction and severe AS may benefit from cautious administration of sodium nitroprusside therapy.[53]
Figure 55.2 Relative survival rates for patients operated on for pure AS. Patients are stratified according to age: <65 years old (dashed line) or ≥65 years old (solid line) with vertical bars indicating 95% confidence limits. Patients aged ≥65 who underwent AVR for AS obtained a normalized survival pattern after operation. POST-OP, postoperatively; AS, aortic stenosis; AVR, aortic valve replacement. (From Lindblom et al[51] with permission.)

BOX 55.2 Results of valve replacement in patients with severe aortic valve stenosis

- Improved symptoms and survival in symptomatic patients, especially in those with left ventricular systolic dysfunction, clinical heart failure, and in those aged ≤65 years
- Improvement in left ventricular systolic dysfunction, which normalizes in two thirds of patients
- Regression of left ventricular hypertrophy
- Improvement in functional class, more marked in those with severe symptoms preoperatively

BOX 55.3 Factors predictive of a less favorable outcome

- Extent and severity of associated co-morbid conditions
- Presence and severity of clinical heart failure preoperatively
- Severe associated coronary artery disease
- Severity of depression of preoperative left ventricular ejection fraction
- Duration of preoperative left ventricular systolic dysfunction
- Extent of preoperative irreversible myocardial damage
- Skill and experience of operating and other associated professional teams
- Extent of perioperative myocardial damage
- Complications of a prosthetic heart valve

However, this study is problematic. The goal was to study cardiac output by the Fick principle after 24 hours, but O_2 consumption was not measured but obtained from a nomogram that has no data on O_2 consumption in heart failure before and after treatment. The patients were made hypotensive and the one-month mortality was 25%. We strongly discourage the use of nitroprusside unless the patient is very hypertensive and needs intravenous therapy for control of hypertension and with the caveat that hypotension must be avoided. If heart failure does not respond satisfactorily and rapidly to medical therapy, surgery becomes a matter of considerable urgency.[39] Catheter balloon valvuloplasty has a very limited role in adults with calcific AS and carries a mortality risk of >10%. In addition, restenosis and clinical deterioration occur within 6–12 months. In adults with AS, balloon valvuloplasty is not a substitute for AVR but can be a bridge procedure in selected patients.[54] It may improve hemodynamics and make them better candidates for AVR. The results of valve replacement in patients with severe AS and preoperative left ventricular systolic dysfunction and the factors predictive of reduced postoperative survival, persistent left ventricular systolic dysfunction, and persistence of symptoms are summarized in Boxes 55.2 and 55.3.[21,39,40,45–47,49–51,55–57]

Surgical mortality for AS patients with heart failure has declined: 25 years ago the operative mortality was <20%[57] but in the current era it is ≤10%.[55] Although this is higher than in patients without heart failure, late outcome in those who survive the operation is excellent and is far superior to that which can be expected with medical therapy. Patients who survive operation have an 84% seven-year survival.[56] Survival in those without associated CAD is greater than in those with CAD (69% vs 39% five-year survival, $P = 0.02$).[55] Left ventricular function improves in most patients after AVR, and becomes normal in two-thirds of the patients, unless there was irreversible preoperative myocardial damage (Fig. 55.3).[55,57] In addition, operative survivors are functionally much improved, and left ventricular hypertrophy and left ventricular dilation, if present preoperatively, regress toward normal.[57] Despite the excellent results of AVR in patients with severe AS who are in heart failure, these results are not as good as for those who are not in heart failure; therefore, it is important to recognize that surgery should not be delayed until heart failure develops (**Class I, Level B**).

Six percent of older patients with AS present in cardiogenic shock.[54] The hospital mortality in such patients is near 50%. The subsequent mortality is also very high if the patients have not had their AS relieved.[54] Thus, these patients need to be managed aggressively by medical therapy[53] and emergency surgery with or without catheter balloon valvuloplasty as a "bridge" procedure.[54]
Figure 55.3 Change in LV EF for each individual patient with severe AS and LV systolic dysfunction. After AVR the LV EF improved from 0.34 to 0.63. All but one patient showed an improvement in LV EF; the only patient who showed deterioration in EF suffered a perioperative MI and had a complete heart block; and the only patient who showed only a relatively small increase in EF had had a MI prior to AVR. Note that LV EF normalized in two-thirds of the patients and in the two patients with the lowest ejection fraction (0.18 and 0.19), LV EF normalized in both. These data indicate that there is probably no lower limit of EF at which time patients with AS become inoperable. This also indicates that the lower the EF, the more urgent the need for AVR. AS, aortic stenosis; LV, left ventriclular; EF, ejection fraction; AVR, aortic valve replacement; MI, myocardial infarction. (From Smith et al[67] with permission.)

Low gradient aortic stenosis

Patients with severe left ventricular systolic dysfunction, low aortic valve gradient, and small calculated aortic valve area represent a difficult clinical problem. There is controversy regarding the best management of these patients, in part related to the difficulty differentiating patients with true severe AS from patients with moderate AS and severe left ventricular dysfunction. A small gradient across the valve may be associated with a small calculated aortic valve area that would be in a range indicating severe AS. There are at least two possible causes for this clinical circumstance. First, there is a small or reduced stroke volume and a normal or near normal systolic ejection time; thus, the gradient is small and the calculated aortic valve area correctly indicates severe AS. The second consideration is that the stroke volume is reduced, and thus the valve needs to open only to a small extent to allow the left ventricle to eject the small stroke volume. The calculated aortic valve area accurately reflects the extent to which the valve has opened but overestimates the severity of AS. Use of a provocative test using an inotropic agent, such as dobutamine,[58–60] may allow one to make the correct differentiation between the two. Dobutamine increases systolic flow per second owing to increases in stroke volume or shortening of ejection time or both. In the first circumstance described above, dobutamine will result in an increase in gradient but the calculated valve area remains more or less unchanged. On the other hand, in the second circumstance described above, the gradient may or may not increase with dobutamine but the calculated valve area increases significantly, indicating that the stenosis is not severe. When the dobutamine test is used in the catheterization laboratory, it is important to measure cardiac output and simultaneous left ventricular and aortic pressures both before and during dobutamine infusion. Alternatively, the gradient and valve area may be assessed by echocardiography/Doppler during dobutamine infusion; however, one needs to be certain that cardiac output has increased significantly with dobutamine (**Class IIa, Level B**).

Differentiating these two patient groups with AS may impact management decision and affects the operative outcome.[59] A multicenter study reported that the surgical mortality is related to contractile reserve, which was determined during echocardiographic-Doppler investigation and described as an increase in stroke volume ≥20%.[61] The presence of contractile reserve in this high-risk AS subset impacts surgical outcome.[62] The absence of LV contractile reserve in patients with low-gradient AS identifies a group of patients who have a higher AVR mortality compared to those with contractile reserve[59] (Fig. 55.4). However, if these patients survive surgery, their left ventricular ejection fraction increases in the majority of cases and the concept that surgery should be contraindicated in the absence of contractile reserve with dobutamine stimulation is incorrect.[63] BNP has been demonstrated to be significantly higher in patients with truly severe low-gradient AS compared to patients with pseudosevere low-gradient AS. BNP was also demonstrated to predict survival of the whole cohort and in patients undergoing AVR.[64]

Aortic valve replacement in asymptomatic AS

In view of the dismal natural history of symptomatic patients with severe AS, the excellent outcome after

Patient Survival (%)
Figure 55.4 Importance of contractile reserve in low-gradient, low-EF severe aortic stenosis. Kaplan–Meier survival estimates by group are shown; improvement in three-year survival with AVR was significant in group I but not significant in group II; survival duration under medical therapy was not different between groups. According to Cox proportional hazard analysis, two parameters were independently associated with long-term survival: AVR (hazard ratio 0.30; 95% CI 0.17–0.53; $P = 0.001$) and LV contractile reserve (hazard ratio 0.40; 95% CI 0.23–0.69; $P = 0.001$). Group I patients *did* and Group II patients *did not* demonstrate contractile reserve with dobutamine on echo/Doppler evaluation. EF, ejection fraction; AVR, aortic valve replacement. (From Monin *et al*[61] with permission.)

surgery, and the uncertain natural history of the asymptomatic patient, it is reasonable to recommend AVR in select asymptomatic patients in centers with the appropriate skill and experience. Recently, a large retrospective review of 622 asymptomatic patients with hemodynamically significant AS followed for over five years was published by Pellikka *et al*[24] which demonstrated that most patients with asymptomatic, hemodynamically significant AS will develop symptoms within five years and that sudden death occurred in ≈1%/year. They found that age, chronic renal failure, inactivity, and aortic valve velocity by Doppler echocardiography independently were predictive of all-cause mortality. The combined risk of surgery and late complications of AVR must be weighed against the risk of sudden death. There is no consensus about AVR in the truly asymptomatic patient. Clearly, if the patient has left ventricular dysfunction, obstructive CAD or other valve disease that needs surgery, and has severe AS, then AVR should be performed. Some would recommend AVR in all asymptomatic patients with severe AS, while others would recommend it in all those with aortic valve area of ≤0.70 cm² and in selected patients only with aortic valve area of 0.71–1.0 cm².

Exercise testing should be avoided in symptomatic patients with AS but it may have a role in risk-stratifying asymptomatic AS patients.[25] In a small series, Amato and colleagues reported no serious exercise-related complications.[25] All patients in this series had documented no coro-

nary artery disease by angiography prior to performing the exercise test. During follow-up, 6% of the asymptomatic patients (4/66) experienced sudden death; all had a positive exercise test and an aortic valve area of ≤0.6 cm². The exercise test was considered positive if there was a horizontal or down-sloping ST segment depression of ≥1 mm in men or ≥2 mm in women, or an up-sloping ST segment depression of ≥3 mm in men, measured 0.08 seconds after the J point. The exercise test was also considered positive if precordial chest pain or near syncope occurred, if the ECG showed a complex ventricular arrhythmia or if systolic blood pressure failed to rise by ≥20 mmHg during exercise compared with baseline.

Lancellotti *et al* evaluated the prognostic importance of quantitative Doppler exercise supine bicycle echocardiography in a group of patients (n = 69) with severe asymptomatic AS.[65] In multivariate Cox regression analysis, an increase in the mean transaortic pressure gradient by ≥18 mmHg during exercise, an abnormal exercise test (defined as having ≥1 of the following: angina, dyspnea, 2 mm ST depression 0.08 sec after the J point, fall or small (<20 mmHg) rise in systolic blood pressure, or significant arrhythmias), and an aortic valve area <0.75 cm² were independent predictors of cardiac events in follow-up (15 ± 7 months).

It must be emphasized that this is a controversial issue. Some cardiologists advise against exercise testing in any patient with severe AS, especially when the extent of coronary artery disease is not known. The recommendations of the ACC/AHA[1] and European Society of Cardiology Guidelines[2] for AVR in severe AS are shown in Tables 55.4 and 55.5.

Chronic aortic valve regurgitation

Etiology

The causes of chronic aortic regurgitation (AR) are:[66,67]
- aortic root/annular dilation
- congenital bicuspid valve
- previous infective endocarditis
- rheumatic
- in association with other diseases – aortitis, drug-related valve disease and others.

In developed countries, aortic root/annular dilation and congenital bicuspid valve are the commonest causes of severe chronic AR.

Natural history

Chronic aortic valve regurgitation is a condition of combined volume and pressure overload. With progression of the disease, compensatory hypertrophy and recruitment of

Table 55.4 ACC/AHA recommendations for AVR in aortic stenosis[1]

	Class	Level of evidence
AVR is indicated for symptomatic patients with severe AS	I	B
AVR is inidicated for patients with severe AS undergoing CABG, surgery on the aorta or other heart valves	I	C
AVR is recommended for patients with severe AS and LV systolic dysfunction (EF < 0.50)	I	C
AVR is reasonable for patients with moderate AS undergoing CABG or surgery on the aorta or other heart valves	IIa	B
AVR may be considered for asymptomatic patients with severe AS and abnormal response to exercise (e.g. development of symptoms or asymptomatic hypotension)	IIb	C
AVR may be considered for adults with severe asymptomatic AS if there is a high likelihood of rapid progression (age, calcification, and CAD) or if surgery might be delayed at the time of symptom onset	IIb	C
AVR may be considered in patients undergoing CABG who have mild AS when there is evidence, such as moderate to severe valve calcification, that progression may be rapid	IIb	C
AVR may be considered for asymptomatic patients with extremely severe AS (aortic valve area less than $0.6\,cm^2$, mean gradient greater than 60 mmHg, and jet velocity greater than 5.0 m per second) when the patient's expected operative mortality is 1.0% or less	IIb	C
AVR is not useful for the prevention of sudden death in asymptomatic patients with AS who have none of the findings listed under the Class IIa/IIb recommendations	III	B

Table 55.5 European Society of Cardiology Recommendations for AVR in severe aortic stenosis[65]

	Class of recommendation	Level of evidence
Patients with severe AS and any symptoms	I	B
Patients with severe AS undergoing coronary artery bypass surgery, surgery of the ascending aorta, or on another valve	I	C
Asymptomatic patients with severe AS and abnormal exercise test showing symptoms on exercise	I	C
Asymptomatic patients with severe AS and abnormal exercise test showing fall in blood pressure below baseline	IIa	C
Asymptomatic patients with severe AS and moderate-to-severe valve calcification, and a rate of peak velocity progression ≥ 0.3m/sec/year	IIa	C
AS with low gradient (<40 mmHg) and LV dysfunction with contractile reserve	IIa	C
Asymptomatic patients with severe AS and abnormal exercise test showing complex ventricular arrhythmias	IIb	C
Asymptomatic patients with severe AS and excessive LV hypertrophy (≥15 mm) unless this is due to hypertension	IIb	C
AS with low gradient (<40 mmHg) and LV dysfunction without contractile reserve	IIb	C

preload reserve permit the left ventricle to maintain normal global LV systolic pump function despite the elevated afterload. The majority of patients remain asymptomatic throughout the compensated phase, which may last decades. The natural history of chronic aortic valve regurgitation can be divided into three different eras: the era of syphilis, the era of rheumatic fever/carditis, and the current era of non-invasive quantification of left ventricular function.

Era of syphilis
Prior to availability of antibiotics, the duration from syphilis infection to death was 20 years.[68] The duration of the asymptomatic AR was five years in 60% of patients and the

five-year survival was 95%. Once symptoms had developed, the 10-year survival ranged from 40% to 60%. Heart failure was associated with a one-year survival of 30–50%, and 10-year survival of 6%. In a study of 161 patients reported in 1935, the 10-year survival after the onset of heart failure had developed was 34% but was 66% in those treated with arsenic.[68] Syphilis still occurs, but current therapy is cheap and efficacious if diagnosed early. Syphilitic AR is uncommon.

Era of rheumatic fever/carditis
Although the incidence of rheumatic valve disease is low in developed countries, rheumatic heart disease remains

Table 55.6 Outcomes of patients with severe aortic regurgitation

Outcome	Incidence
Asymptomatic patients with normal left venticrular systolic function[69–75,101]	
Progression to symptoms and/or left ventricular systolic dysfunction	2.4–5.7% per year (average 3.8% per year)
Progression to asymptomatic left ventricular dysfunction	
– follow-up at 12-month intervals[c(69)]	0.9% per year
– follow-up at 6-month intervals[c(73)]	3.4% per year
sudden death	0.1% per year
Asymptomatic patients with left ventricular systolic dysfunction[102,103]	
Progression to cardiac symptoms	>25% per year
Symptomatic patients[66,96,104,105]	
Mortality rate	Average >10% per year
Angina	>10% per year
Heart failure	>20% per year

Table 55.7 Likelihood of symptoms of left ventricular dysfunction or death

Left ventricular end-diastolic dimension	
≥70 mm	10% per year
<70 mm	2% per year
Left ventricular end-systolic dimension	
≥50 mm	19% per year
End-systolic dimension >25 mm/m^2	8% per year
40–49 mm	6% per year
<40 mm	0% per year

the most common form of valve disease in many parts of the world. Moreover, some people now domiciled in the developed world have had their initial attack(s) of acute rheumatic fever whilst living in developing countries.

Following the episode of acute rheumatic fever, a murmur is characteristically detected after approximately 10 years.[68] The average interval from detection of a murmur to development of symptoms is 10 years and the percentage of patients remaining symptom free 10 years after detection of the murmur is 50%.[68] Rheumatic AR most commonly occurs in conjunction with mitral valve disease.

Current era

In the current era, patients with AR are followed clinically, with non-invasive tests including echocardiography/ Doppler, and radionuclide angiogram to assess left ventricular ejection fraction (EF) or after invasive studies such as cardiac catheterization with angiography. Reported outcomes are shown in Table 55.6. As outlined in Table 56.6,[66,69–75] the natural history of patients with chronic AR depends on the presence or absence of symptoms and on the status of the left ventricle. In asymptomatic patients with normal left ventricular function, data would suggest the progression to symptoms and/or left ventricular systolic dysfunction in approximately 4% per year. Sudden death occurs very rarely, 0.1% per year, and asymptomatic left ventricular dysfunction occurs at a rate of 1–3% per year, depending on the frequency of follow-up.

There are limited data on asymptomatic patients with AR and reduced left ventricular systolic function. Available data would suggest that most of these patients will

develop symptoms warranting surgery within 2–3 years, at an average rate of >25% per year. Similarly, limited data are available on the natural history of symptomatic patients with severe AR. These patients have a poor prognosis despite medical therapy, with reported mortality rates of 10% and 20% per year in patients with angina and heart failure, respectively.

Important limitations of some of the studies in the literature must be kept in mind. For example, the "natural history" group in one study was composed of several subsets of patients[74] and 36% of this group was on medication for symptoms. Another concern is the true rate of the development of asymptomatic left ventricular dysfunction.[69] At least 25% of patients who develop left ventricular systolic dysfunction do so before they have symptoms, thus emphasizing the need for regular quantitative assessment of left ventricular systolic function at follow-up in asymptomatic patients with severe AR and previously normal left ventricular systolic function. More recent studies indicate a poor outcome of symptomatic patients with medical therapy, even among those with preserved systolic function (Table 55.7).[70,76]

Sir William Broadbent stated 100 years ago that "The *age* of the patient at the time when the lesion is acquired is the most important consideration in prognosis …".[77] In asymptomatic patients with normal left ventricular systolic function, the independent predictors of symptoms, left ventricular systolic dysfunction, and death by multivariate analysis were: older age, decreasing resting left ventricular EF at rest, and left ventricular dimension on M-mode echocardiography.[69] Importantly, most of these dimensions were obtained in the United States, and American women have smaller body surface area and thus smaller left ventricular dimensions than men, in the absence of valve disease, or in the presence of AR, even when they become symptomatic.[78] Thus, recommendations for intervention based on left ventricular dimension alone will not be applicable to most women and almost certainly will not be applicable to populations of smaller body size. The left ventricular dimension should be corrected to body surface area.[79] Patients also develop symptoms and/or left ven-

tricular systolic dysfunction at a faster rate if their initial left ventricular end-diastolic volume is ≥150 mL/m² when compared to those with volumes <150 mL/m².[74] Older age also appears to increase the annual mortality.[79]

Management

This chapter discusses indications for intervention in patients with chronic severe AR. It should be mentioned that acute severe AR usually causes sudden severe symptoms of heart failure or cardiogenic shock. The sudden large regurgitant volume load is imposed on a normal size left ventricle causing marked elevation in left ventricular end-diastolic pressure and left atrial pressure. Echocardiography is invaluable in determining the severity and etiology of aortic valve regurgitation.[15] The etiology of acute aortic valve regurgitation may have an important impact on the treatment, which is usually emergency surgery.

Medical management

Angina is a recognized symptom in patients with severe AR and is a result of a relative reduction of myocardial blood flow because of an increased demand and/or associated obstructive CAD.[39] The treatment options are to reduce the degree of AR, reduce the myocardial demand or revascularize the myocardium. Clinical heart failure is treated with traditional therapy, including digitalis, diuretics, and ACEI. Parenteral inotropic and vasodilator therapy may be needed for those in severe heart failure.[80] Ultimately the only direct method to reduce the amount of AR is with AVR or valve repair.

Arterial dilators

The role of arterial dilators in chronic, severe, asymptomatic AR is controversial, partly because some of the patients in several of the studies that demonstrated benefit were symptomatic and/or had associated systemic hypertension. Therapy with vasodilating agents should improve forward stroke volume and reduce regurgitant volume and these effects might then translate into reductions in left ventricular end-diastolic volume, wall stress, and afterload, resulting in preservation of left ventricular systolic function and reduction in left ventricular mass. These effects have been observed in small numbers of patients receiving hydralazine.[81] In a trial of 80 patients treated with digitalis, diuretics, and hydralazine over two years, medical therapy produced very minor improvements in left ventricular size and function.[82] Side effects associated with long-term use of hydralazine seriously impaired compliance and only 46% of the patients completed the trial. Hydralazine is rarely used currently.

Inconsistent results have been reported with ACEI, depending on the degree of reduction in arterial pressure

and end-diastolic volume. In an acute study in the catheterization laboratory, 20 patients with severe AR were randomized to either oral nifedipine or oral captopril.[83] Nifedipine produced a reduction of regurgitant fraction but captopril did not. Nifedipine produced a greater increase of forward stroke volume and cardiac output and a greater fall of systemic vascular resistance. This study showed that, acutely, nifedipine was superior to an ACEI. A subsequent six-month randomized trial of a small number of patients showed that the results with captopril were similar to placebo, demonstrating no significant changes in left ventricular dimensions.[84]

The role of long-acting nifedipine on *patient outcome* was evaluated by Scognamiglio *et al* in a prospective, randomized trial of 143 asymptomatic patients with chronic severe AR, and normal left ventricular systolic function; 69 patients were randomized to long-acting nifedipine and 74 patients to digoxin. The patients underwent clinical and echocardiographic evaluation at six-month intervals. At six years, the need for AVR was 34 ± 6% in the digoxin-treated group and 15 ± 3% in the nifedipine-group, *P* < 0.001 (see Fig. 55.4).[73] Thus, for every 100 patients treated with nifedipine, 19 fewer AVRs were needed at the end of six years (see Fig. 56.4). Compared to the digoxin group, the nifedipine-treated group demonstrated a reduction in left ventricular volume and mass. Ejection fraction, left ventricular volumes and mass all increased during follow-up in the digoxin arm of the trial. Normal left ventricular EF was noted after AVR in 12 of 16 patients (75%) in the digoxin group and all six patients in the nifedipine group who had an abnormal left ventricular EF before surgery. This randomized trial demonstrates that arteriolar dilator therapy with long-acting nifedipine delays the need for AVR in asymptomatic patients with severe AR and normal left ventricular systolic function. The same group has more recently reported a favorable recovery of left ventricular systolic function following AVR in patients with reduced left ventricular EF from chronic severe AR treated with nifedipine.[85]

Evangelista and colleagues studied 95 patients with asymptomatic severe AR and normal left ventricular systolic function who were randomly assigned to open label nifedipine (20 mg every 12 hours), enalapril (20 mg per day) or no treatment.[86] In contrast to the findings of Scognamiglio *et al*,[71,73] they found that neither nifedipine nor enalapril reduced or delayed the need for AVR in patients with asymptomatic severe AR and normal left ventricular systolic function. In this study vasodilator therapy was not found to reduce the aortic regurgitant volume, decrease the size of the left ventricle, or improve left ventricular systolic function. This study has major flaws with respect to methodology (many patients did not have severe AR), very small numbers of patients (32 in the nifedipine arm of whom seven were lost to follow-up within a few months),

Table 55.8 ACC/AHA recommendations for vasodilator treatment in severe AR[1]

	Class of recommendation	Level of evidence
Vasodilator therapy is indicated for chronic therapy in patients with severe aortic regurgitation who have symptoms or LV dysfunction whn surgery is not recommended because of additional cardiac or non cardiac factors	I	B
Vasodilator therapy is reasonable for short-term therapy to improve the hemodynamic profile of patients with severe heart failure symptoms and severe LV systolic dysfunction before proceeding with AVR	IIa	C
Vasodilator therapy may be considered for long-term therapy in asymptomatic patients with severe aortic regurgitation who have LV dilation but have normal LV systolic function	IIb	C
Vasodilator therapy is not indicated for long-term therapy in asymptomatic patients with mild-moderate aortic regurgitation and normal LV systolic function	III	B
Vasodilator therapy is not indicated for long-term therapy in asymptomatic patients with LV systolic dysfunction who are otherwise candidates for AVR	III	C
Vasodilator therapy is not indicated for long-term therapy in symptomatic either normal LV function or mild-moderate LV systolic dysfunciton who are otherwise candidates for AVR	III	C

and the type as well as dosing of nifedipine used. Nevertheless, there is now less confidence about the role of arterial vasodilators in chronic severe AR and the current ACC/AHA (Table 55.8) and ESC guidelines have downplayed the use of arterial vasodilators.

Surgical management

Surgery for primary AR should only be considered when the degree of regurgitation is severe. However, the presence of severe AR does not mandate surgery. The critical issue is to choose the best time for surgical intervention. Aortic valve repair or AVR should be performed in symptomatic patients irrespective of left ventricular function. Postoperative survival is better after AVR in symptomatic patients with normal or mildly impaired left ventricular systolic function than in those with greater impairment of left ventricular systolic function.[87]

Recently, an important study has documented the long-term outcome of surgically treated AR.[88] One hundred and seventy patients with severe isolated chronic AR had AVR between 1982 and 2002 according to predefined protocol. Patients were divided into two groups depending on their preoperative clinical status: Group A ("early" surgery) included asymptomatic patients and those in NYHA functional class II with "moderate degrees" of LV dysfunction (EF 45–50% and/or end-systolic diameters 50–55 mm) and Group B ("too late" surgery) included patients with either severe symptoms (NYHA functional classes III and IV) or in NYHA functional class I/II with an left ventricular EF <45% or a left ventricular end-systolic diameter >55 mm. Follow-up was 10 ± 6 years (1–22 years). Survival up to 22 years was significantly better in Group A patients. Both groups showed significant increases in left ventricular EF,

reductions in left ventricular end-diastolic diameter and left ventricular end-systolic diameter and improvement in NYHA functional class (Table 55.9). The authors concluded: "Early operation as defined in the guidelines improves long-term survival in patients with chronic AR".

Extreme left ventricular dilation (end-diastolic dimension >80 mm) associated with AR occurs primarily in men and is often associated with left ventricular dysfunction. Extreme left ventricular dilation, however, is not a marker of irreversible left ventricular dysfunction. Operative risk and late postoperative survival are acceptable in these patients.[89]

Chaliki *et al* reconfirmed the excess mortality rates of AVR in patients with severe AR and markedly reduced left ventricular EF.[90] Importantly, they demonstrated that EF increases significantly and that most patients have improved survival without recurrence of heart failure after AVR. Bhudia *et al* have demonstrated a dramatic reduction in operative mortality in this group of patients over the last 30 years.[91] Thus, even in patients with severe left ventricular systolic dysfunction, the risk of surgery and postoperative medical therapy for heart failure are usually less than the risk of long-term medical management.

After AVR, patients with normal preoperative left ventricular systolic function have reduction in left ventricular volumes and hypertrophy.[88] In the majority of patients with normal preoperative left ventricular systolic function, there is an eventual increase in EF after AVR, presumably because of a reduction of myocardial stress.[88] Left ventricular hypertrophy continues to decline for up to 5–8 years in those with normal preoperative left ventricular systolic function, but at a slower rate after 18–24 months.[46,92] Most patients are symptomatically improved and are in NYHA class I (Boxes 55.4, 55.5).[39]

Table 55.9 Long-term outcome after aortic valve replacement for aortic regurgitation

	Group A ("Early" Surgery)	Group B ("Too Late" Surgery)	P value

*Best-case scenario: 2 patients lost to follow-up considered to be alive. Data from Tornos et al.[88]

BOX 55.4 Results of valve replacement in patients with severe chronic aortic valve regurgitation

- Improved survival in those with mild to moderate impairment of left ventricular systolic function and in those with severe left ventricular enlargement irrespective of their symptomatic status
- Improvement in left ventricular systolic dysfunction; function normalizes if the dysfunction is of ≤12 months' duration preoperatively
- Regression of left ventricular hypertrophy
- Improvement in functional class, particularly in those with preoperative mild to moderate impairment and in those with preoperative left ventricular dysfunction

BOX 55.5 Factors predictive of a less favorable outcome after AVR for AR

- Extent and severity of associated co-morbid conditions
- Severe obstructive coronary artery disease
- Presence and severity of clinical heart failure preoperatively
- Severity of depression of preoperative LVEF
- Duration of preoperative left ventricular systolic dysfunction
- Extent of preoperative irreversible myocardial damage
- Severity of increase in left ventricular end-diastolic and end-systolic size (left ventricular end-diastolic and end-systolic volumes of ≥210 and ≥110 ml/m², respectively, or end-diastolic and end-systolic dimensions of ≥80 mm and ≥60 mm, respectively)
- Skill and experience of operating and associated professional teams, for example, anesthetists
- Extent of perioperative myocardial damage
- Complications of a prosthetic heart valve

After AVR in those with abnormal preoperative left ventricular systolic function (EF 0.25–0.49), there is a reduction of heart size and left ventricular end-diastolic pressure, end-diastolic and end-systolic volumes and hypertrophy.[88] Generally, left ventricular EF improves or normalizes only if the EF was abnormal for ≤12 months prior to surgery.[92] Early after AVR, there may be a reduction in EF. The left ventricular end-diastolic volume has not yet decreased but the regurgitant volume has been eliminated; this causes a decline in EF. An early decrease in left ventricular end-diastolic dimension is a good indicator of functional success of AVR as the magnitude of reduction in end-diastolic dimension after operation correlates with the magnitude of late increase in EF.[1] Moreover, unless there is a perioperative complication, most patients are symptomatically improved and are in NYHA class I or II after AVR for chronic AR.[39] In those with severe symptoms and severe reduction of EF or severe left ventricular dilation preoperatively, the operative mortality can still be relatively low although survival as well as the beneficial effects on left ventricular function and functional class are less marked.[93,94]

The current status of aortic valve repair prevents recommending this as an early prophylactic procedure. It is difficult to determine which aortic valves will be amenable to repair and repair is feasible only in a minority of cases even at experienced and skilled centers. The rate of recurrent AR requiring reoperation is at a level that decreases the enthusiasm for this procedure in asymptomatic patients with minimal left ventricular enlargement.[95]

Aortic valve replacement in asymptomatic AR

Aortic valve surgery for asymptomatic patients with AR is controversial. AVR is indicated in the setting of left ventricular dysfunction with an EF ≤0.50[92] and in the setting of severe left ventricular dilation (end-diastolic dimension >70 mm, end-systolic dimension >50 mm, or left ventricular systolic dimension/body surface area ≥0.25 mm/m^2), even if the EF is normal. Ideally, the threshold values of end-diastolic and end-systolic dimension recommended for AVR in asymptomatic patients should be adjusted to body surface area. It has been demonstrated that a left ventricular end-systolic dimension corrected for body surface area (left ventricular systolic dimension/body surface area) of ≥25 mm/m^2 is associated with increased mortality when followed conservatively.[1,79,89] Aortic valve surgery for asymptomatic patients with severe AR is also recommended for when these patients are being referred for cardiac surgery for associated conditions such as CAD, thoracic aortic aneurysmal disease, or another valve lesion. Asymptomatic patients who do not have severe left ventricular dilation and those who do not have left ventricular dysfunction at rest or exercise should not have surgery for chronic AR, and can be safely followed. The current ACC/AHA and European guidelines for AVR in patients with AR are shown in Tables 55.10 and 55.11.

Table 55.10 ACC/AHA guidelines for AVR in AR[1]

	Class of recommendation	Level of evidence
AVR is indicated for symptomatic patients with severe aortic regurgitation irrespective of LV systolic function	I	B
AVR is indicated for asymptomatic patients with chronic severe aortic regurgitation and LV systolic dysfunction (EF ≤50% at rest)	I	B
AVR is indicated for patiens with chronic severe AR while undergoing CABG or surgery on the aorta or other valves	I	C
AVR is reasonable for asymptomatic patients with severe aortic regurgition with normal LV systolic function (EF >50%) but with severe dilation of the LV (end-diastolic dimension >75 mm or end-systolic dimension >55 mm)	IIa	B
AVR may be considered in patients with moderate AR while undergoing surgery on the ascending aorta or CABG	IIb	C
AVR may be considered in asymptomatic patients with severe aortic regurgitation and normal LV systolic function (EF >50%) when the degree of LV dilation exceeds an end-diastolic dimension of 70 mm or end-systolic dimension of 50 mm, when there is evidence of progressive LV dilation, declining exercise tolerance, or abnormal hemodynamic responses to exercise	IIb	C
AVR is not indicated for asymptomatic patients with mild, moderate, or severe AR and normal LV systolic function at rest (EF >50%) when the degree of dilation is not moderate or severe (end-diastolic dimension <70 mm or end-systolic dimension <50 mm)	III	B

Table 55.11 European Society of Cardiology recommendations for surgery in severe aortic regurgitation[65]

	Class of recommendation	Level of evidence
Symptomatic patients (dyspnea, NYHA class II, III, IV or angina)	I	B
Asymptomatic patients with resting LVEF ≤50%	I	B
Patients undergoing CABG or surgery of ascending aorta, or on another valve	I	C
Asymptomatic patients with resting LVEF >50% with severe LV dilation: end-diastolic dimension >70 mm or end-systolic dimension >50 mm (or >25 mm/m² BSA)	IIa	C

Conclusion

The timing of AVR in aortic valve disease remains one of the more important decisions in cardiology. Although operative mortality has diminished with improvement in surgical techniques, the risk of AVR and the presence of an aortic valve prosthesis still outweigh the benefits in most patients without symptoms or evidence of LV remodeling/dysfunction. The regular use of imaging techniques, especially echocardiography, plays an important role not only in quantifying the severity of the valve lesion but also in assessing LV geometry and function. A careful evaluation of evidence based on good studies and data from excellent databases is paramount in making decisions about surgical intervention in patients with aortic valve disease.

Non-surgical aortic valve therapy: balloon valvuloplasty and transcatheter aortic valve replacement

Robert H Boone and John G Webb

St Paul's Hospital, University of British Columbia, Vancouver, British Columbia, Canada

Surgical valve replacement is the current standard of care for many patients with degenerative valve disease. In appropriate candidates outcomes are excellent and benefit is durable. Nevertheless, surgical valve replacement may not be ideal for all patients and the search for less invasive options has been aggressively pursued.

There was initial enthusiasm for balloon aortic valvuloplasty as a palliative alternative for patients with severe aortic stenosis who were at high operative risk. However, multiple series have shown that although valvuloplasty can be completed with acceptable risk, it provides only short-term symptomatic benefit without improved survival. Nevertheless, valvuloplasty may have a role in temporary palliation or as a bridge to, or component of, a more definitive therapy.

Transcatheter aortic valve replacement is a new therapy which is progressing rapidly, and preliminary experience suggests it may be a viable alternative to conventional surgical valve replacement while avoiding the need for median sternotomy and cardiopulmonary bypass. In selected high-risk patients mortality and morbidity may be superior to outcomes anticipated with conventional surgery. However, current information is primarily from relatively small, single-center registries. Larger, multicenter and randomized evaluations are needed.

Introduction

There are three primary causes of aortic stenosis (AS): congenitally bicuspid valves with superimposed calcification, rheumatic valve disease, and calcific disease of a trileaflet valve. Calcific AS is the most frequent expression of valvu-

lar heart disease in the Western world, is the leading indication for valve replacement, and its prevalence increases with increasing age. Community data document the prevalence of moderate or severe AS at 0.6%, 1.4% and up to 4.6% in patients aged 55–64, 65–74, and ≥75 years, respectively.[1] Surgical aortic valve replacement (AVR) is the preferred treatment strategy for symptomatic patients, but has limitations in the presence of co-morbidities, including advanced age, which increase the operative risk.

Pathophysiology and natural history

The early valve lesions of AS show features similar to atherosclerosis with lipid accumulation and accompanying inflammatory cells and calcification. Myofibroblasts play a central role in the process, and it is believed these cells differentiate into an osteoblast-like cell phenotype which in turn promotes formation of the calcified nodules and bone.[2] The calcification process occurs over decades and causes reduced leaflet mobility, which leads to increased transvalvular pressure gradients, left ventricular outflow obstruction, and systolic pressure overload. The left ventricular wall thickens to maintain chamber size, wall stress and ejection fraction,[3] which is both beneficial and detrimental. Hypertrophied myocardium has less coronary flow per gram and less vasodilator reserve which makes it vulnerable to ischemia, even in the absence of epicardial coronary disease.[4-6] Ischemic stress can be greater in the hypertrophied heart, which must be considered during transcatheter aortic valve replacement (TAVR) where transient left ventricular outflow obstruction and rapid pacing are procedurally required.

The natural history of adult AS consists of a prolonged latent period during which morbidity and mortality are very low. As the calcification process continues, the transvalvular gradient increases and eventually the cardinal symptoms of AS are experienced: angina, syncope and

heart failure. The outlook changes dramatically once symptoms are present, and average survival is 2–3 years.[7–9] Progression from mild AS to severe AS is variable, but once moderate stenosis is present the average rate of progression is a decrease in aortic valve area (AVA) of 0.1cm^2/ year.[10] Once symptoms are present the risk of sudden death is high and AVR must be considered.[11]

Aortic valve replacement indications and risk

Surgical AVR may offer survival and symptom benefit, and can be performed at low risk with excellent and durable results in most patient groups. The current American College of Cardiology (ACC)/American Heart Association (AHA) valvular heart disease guideline recommendations for AVR are provided in Table 56.1 and, simply stated, give a Class I recommendation to surgical aortic valve replace-

ment for patients with severe AS in combination with symptoms, left ventricular ejection fraction (LVEF) <50%, or concomitant coronary bypass, aortic or heart valve surgery. In the developing arena of transcatheter aortic valve replacement (TAVR), such guidelines do not exist, and the understanding of surgical risk is fundamental to the process of patient selection.

Among those centers reporting within the Society of Thoracic Surgeons (STS) database (1998–2005) the average perioperative mortality was 3–4% for isolated AVR, and 5–7% for AVR plus coronary artery bypass grafts (CABG).[12] In patients ≥70 years of age, other large series report a 5–15% operative mortality for isolated AVR, and rates are higher in the presence of co-morbidities or the need for additional cardiac procedures.[13–20]

Beyond mortality, morbidity is a significant risk with surgical AVR. For very elderly patients, postoperative stay is more than tw weeks, most are discharged to nursing care or rehabilitation facilities, and rehospitalization within one

---

Table 56.1 ACC/AHA recommended indications for AVR in patients with AS[37]

Indication	Class[1]	Level of evidence[2]
Severe AS[3] and symptoms	I	B
Severe AS, undergoing CABG	I	C
Severe AS, undergoing aortic or other valve surgery	I	C
Severe AS and EF <50%	I	C
Moderate AS,[4] undergoing CABG, aortic or other valve surgery	IIa	B
Asymptomatic, severe AS, and abnormal exercise response[5]	IIb	C
Asymptomatic, severe AS, and features suggesting rapid progression[6] or potential delay of surgery at the time of symptom onset	IIb	C
Mild AS, undergoing CABG, and features suggesting rapid progression[6]	IIb	C
Asymptomatic, extremely severe AS[7], and expected operative mortality <1%	IIb	C
Asymptomatic, no findings listed above	III	B

ACC, American College of Cardiology; AHA, American Heart Association; AVR, aortic valve replacement; AS, aortic stenosis; CABG, coronary artery bypass grafting; EF, ejection fraction; AVA, aortic valve area.

[1] Definitions for recommendation:

    Class I: Conditions for which there is evidence and/or general agreement that the procedure or treatment is beneficial, useful, and effective.

    Class II: Conditions for which there is conflicting evidence and/or a divergence of opinion about the usefulness/efficacy of a procedure or treatment: IIA Weight of evidence/opinion is in favor of usefulness/efficacy; IIB Usefulness/efficacy is less well established by evidence/opinion.

    Class III: Conditions for which there is evidence and/or general agreement that the procedure/treatment is not useful/effective and in some cases may be harmful.

[2] Definitions for level of evidence:

    A: Data derived from multiple randomized clinical trials.

    B: Data derived from a single randomized trial or non-randomized studies.

    C: Only consensus opinion of experts, case studies or standard of care.

[3] Severe AS: AVA <1cm^2, AVA index <0.6cm^2/m^2, mean gradient >40mmHg, and/or jet velocity >4m/s.[37]

[4] Moderate AS: AVA 1.5–1cm^2, mean gradient 25–40mmHg, and/or jet velocity 3–4m/s.[37]

[5] Development of symptoms or asymptomatic hypotension.

[6] Age, calcification, and CAD.

[7] AVA <0.6cm^2, mean gradient >60mmHg, and jet velocity >5m/s.

month is required for >20%.[21,22] Nevertheless, some series show excellent outcomes.[23]

The increased risk of morbidity and mortality may lead patients, or their physicians, to hesitate when considering surgical options. Iung *et al*[24] performed a cross-sectional survey of patients with valvular heart disease presenting to 92 European hospitals or clinics over a three-month period in 2001, and found that 9.8% of those with aortic stenosis who had guideline indications for surgery were not offered intervention. Subsequently they looked at elderly patients with AS (age >75 yrs), and found that 33% of those with indications for surgery were not offered intervention.[25] Others found that 40–60% of elderly patients with severe symptomatic AS were not offered intervention.[26,27] Patient refusal of surgery has been a consistent reason for conservative management despite the one-, five- and 10-year survivals of 60%, 32%, and 18% respectively of medical therapy.[28]

The growing series of successful TAVR procedures have been performed in an elderly cohort of "high-risk" or non-surgical candidates. This classification has been based on the clinical opinion of senior surgeons in high-volume centers and the use of objective risk calculators as defined by the European System for Cardiac Operative Risk Evaluation (EuroSCORE)[29,30] and/or the Society of Thoracic Surgeons (STS) database.[31] Both EuroSCORE and STS provide an estimate of mortality at 30 days or hospital discharge for patients undergoing CABG and/or valve surgery.

The EuroSCORE model considers 17 clinical risk factors, and was developed in a 13 302 patient cohort with validation in a 1479 patient cohort. It was subsequently tested in a North American cohort of 401 684 patients where the predicted mortality was almost identical to the observed mortality (predicted 3.994%, observed 3.992%). The STS model was developed from the STS National Adult Cardiac Surgery Database which collects information on cardiac surgery morbidity and mortality from 497 participating member sites throughout the United States.[31] The 11 STS models predict both 30-day mortality and major morbidity, are updated and reported annually, and allow comparisons between the observed and predicted outcomes in an effort to improve quality of care. An alternative risk model for patients undergoing valve surgery has been published by Ambler *et al*.[32] It was developed and validated using the database of the Society of Cardiothoracic Surgeons of Great Britain and Ireland, but remains less well utilized. All groups have facilitated risk calculations by providing on-line calculators: 66.89.112.110/STSWebRiskCalc/, euroscore.org/calc.html and www.ucl.ac.uk/stats/research/riskmodel/.

An objective assessment of individual risk has been commonly used to define TAVR eligibility.[33] Published case series have seen average logistic EuroSCOREs >20.[34,35] Furthermore, the inclusion criteria for upcoming randomized

trials will likely have an objective risk measurement, with possible thresholds being in the range of logistic EuroSCORE >20 or STS score >10.

Balloon valvuloplasty

Percutaneous balloon aortic valvuloplasty (PBAV) was first performed by Cribier in 1985, with the first three patient series published in 1986.[36] Subsequently there have been many reports of the effectiveness and durability of PBAV, and in reviewing the literature for this chapter we collected 50 publications documenting results from over 2400 patients. Most procedures were performed in elderly patients with calcific AS who were considered either non-operative candidates or of high operative risk. All reports are case series (**Level C1**), and PBAV has never been subjected to a large-scale randomized trial. The discussion below is not a formal systematic review, but is based on a comprehensive and representative sample of English-language publications. We will not discuss the evidence for PBAV in young patients with congenital AS where it remains a Class I therapeutic option.[37]

The 27-center Mansfield Investigational Device Exemption Protocol employed standardized protocols with definite inclusion and exclusion criteria to study aortic valvuloplasty.[38] Patient recruitment occurred from December 1986 through November 1987. The data collected from 492 patients undergoing PBAV were pooled to create the Mansfield Scientific Balloon Aortic Valvuloplasty Registry.[38–45] Subsequently, the NHLBI Balloon Valvuloplasty Registry was organized, and enrolled 674 patients from 24 centers between 1987 and 1989, generating reports on early and late procedure results.[46,47] The Cribier group in France[48–52] and the Duke University Medical Center group[53–55] have also contributed significant numbers of patients to this literature.

To support PBAV as a therapeutic option, we must consider the ability of the procedure to do what it claims: reduce the transaortic pressure gradient. Table 56.2 outlines the changes in AVA and mean transaortic gradient (MG) reported in a variety of series. Most reports show the AVA increases to between 0.8 and 1 cm^2, and the largest series found AVA increased <0.4 cm^2 in 77% of patients.[47] However, in 13% of this cohort there was either no change or <0.1 cm^2 improvement in AVA. Similarly, 13% of the Mansfield group had an unsuccessful procedure (procedural/in-hospital death, AVR within seven days, or <40% change in AVA).[42] It is clear that PBAV is successful in reducing the transaortic gradient in most, but not all patients with critical AS secondary to calcific disease.

Another measure of procedural success is symptom status, and all series report significant initial improvement. We present a representative sample of the available data in

Table 56.2 Summary of hemodynamic effectiveness and procedural complications of percutaneous aortic balloon valvuloplasty

Reference	Number of patients	Average age (yrs)	Hemodynamic outcomes				Complication rate (excluding in-hospital mortality)				In-hospital mortality

AVA, aortic valve area; MG, mean transaortic gradient.

Table 56.3. The NHLBI registry found symptom improvement in 75% of survivors at 30-days, and 60–85% of survivors report symptom improvement at follow-up out to 24 months. Davidson *et al* [56] report LVEF was the only independent predictor of overall symptom improvement at 3 months, and found less than 50% of those with an ejection fraction (EF) <45% had symptom improvement. Taken in aggregate, the data suggests the majority of survivors have some initial symptom improvement.

However, the result is not durable, and most patients will see symptom recurrence with time. Agarwal *et al* [57] report that the mean duration of symptom relief after

Table 56.3 Summary of studies reporting symptom response to percutaneous aortic balloon valvuloplasty, sorted by duration of follow-up

Reference	Number of patients	Age (yrs)	Follow-up duration (months)	Symptom response
NHLBI Registry[47]	674	78 ± 9	30 days	75% of survivors (86%) improved 1 NYHA class (or remained class I) 53% experienced at least a quartile improvement in functional status score
Davidson[56]	81		3	65.4% of patients had sustained symptom improvement LVEF was the only independent predictor of overall status at 3 months: • EF >45% : 84% improvement in symptoms • EF <45% : <50% had symptom improvement

NYHA, New York Heart Association; AVR, aortic valve replacement; LVEF, left ventricular ejection fraction; LV, left ventricle; PBAV, percutaneous balloon aortic valvuloplasty; PG, peak gradient.

PBAV was 18 ± 3 months. Upon repeat investigation, most patients with recurrent symptoms are found to have restenosis (defined as ≥50% loss in the AVA gained by PBAV), and this is assumed to be the cause of recurrent symptoms. The rate of restenosis has been reported to vary between 25% and 47% at six months[58–60] and up to 80% at 15 months.[61] Postprocedure AVA can be influenced by a variety of procedural modifications[42,47] and although initially thought to alter prognosis,[57–60] these techniques have not been found to change rates of restenosis or survival in larger series.[39]

Reported periprocedural complication rates range from 9% to 25% (see Table 57.2). The nature of periprocedural complications as reported in the NHLBI Registry can be found in Table 57.4. Procedural morbidity and in-hospital mortality decreases with increased procedural experience and equipment refinements.[50,62] Interestingly, the two most recent PBAV series report periprocedural complication rates of 22% and 18%.[57,63] Although Klein et al[63] do report a trend toward a decrease in procedural complications over time, these complication rates are not significantly less than that reported in the Mansfield Registry. Periprocedural stroke and aortic insufficiency are uncommon complications (see Table 56.2).

The final analysis of PBAV must consider its effectiveness in altering the natural history of the disease. Mortality rates address this question directly, and are presented in Table 56.5. One- and two-year survival ranged from 75% to 38% (average 65%) and 28% to 60% (average 35%), respectively. These rates are not significantly different from the one- and two-year survival of elderly patients with untreated AS (60% and 40%, respectively)[9,28] and suggest PBAV alone does not alter the natural history of AS for most patients.

Many authors employed multivariate techniques to identify clinical, historical and/or hemodynamic factors that might be significantly associated with PBAV outcome. These results are presented in Table 56.5 and consistently show older age, low EF, and worse baseline NYHA class are all associated with a poor prognosis. In the largest series, Otto et al defined a "lower risk" subgroup (normal LVEF and mild functional limitation) who had a three-year survival of 36% as opposed to 17% in the rest of the group.[46]

Table 56.4 Comparison of periprocedural complications between PBAV and TAVR procedures

Complications[1]	NHLBI BAV Registry[47]* % (n)	Core valve[34]† % (n)	Edwards Lifesciences[35]* % (n)

AVR, aortic valve replacement; PBAV, percutaneous balloon aortic valvuloplasty; NR, not reported; m, month; y, year; LV, left ventricle; EF, ejection fraction; NYHA, New York Heart Association; CO, cardiac output; CHF, congestive heart failure.

Given the early benefit but limited durability of PBAV, some investigators proposed that patients with restenosis be considered for repeat valvuloplasty. Table 56.5 provides details on the incidence of such treatment (roughly 5–20%), but the outcomes were most carefully considered in the three separate series.[40,49,57] Each series has shown a second procedure is efficacious in reducing AVA and symptoms, but none was able to find factors that would point to an increased durability of a second procedure. Although patients who underwent repeat procedures had higher three-year survival rates than those with a single procedure,[54,57] there was a decrease in the duration of symptom relief with each subsequent dilation.[57] Several reports have highlighted the success of PBAV followed by AVR where two-year survival can be as high as 92%.[54] This is an attractive strategy but has limited applicability as it is unclear how delaying definitive treatment would improve operative risk for the majority of patients. In fact, the AHA/ACC guidelines give a Class III recommendation to the concept of PBAV as an alternative to AVR.[37]

Despite the problems with PBAV, the current AHA/ACC guidelines recognize the possibility that it may have a limited therapeutic role, and the following situations are given Class IIB recommendations.

1 Aortic balloon valvotomy might be reasonable as a bridge to surgery in hemodynamically unstable adult patients with AS who are at high risk for AVR.

2 Aortic balloon valvotomy might be reasonable for palliation in adult patients with AS in whom AVR cannot be performed because of serious co-morbid conditions.[37]

Additionally, several groups have reported that PBAV can be used to successfully treat patients with cardiogenic shock secondary to severe AS.[64,65] Similarly, PBAV can be used to reduce the risk of non-cardiac surgery when a stepwise approach using AVR is not possible.[66,67]

In an attempt to address the significant problem of limited durability with PBAV, newer studies have focused on the mechanisms of restenosis. PBAV improves leaflet mobility by fracturing calcified nodules and creating cleavage planes within collagenous stroma.[68,69] Feldman et al[70] suggest that the process of restenosis following PBAV is histologically distinct from that of calcified valves not having undergone PBAV. They found granulation tissue, fibrosis, and ossification present within the leaflets of valves treated with PBAV, suggesting an active process of osteoblast-mediated calcification. This lead Pedersen et al to perform a 20-patient pilot study of external beam radiation applied 3–5 days following PBAV in elderly patients with calcific AS (the RADAR pilot trial).[71] They found one-year restenosis rates of 21–30% in a dose-responsive manner. This is substantially less than the 15-month 80% restenosis rates found by Letac et al[61] and offers an interesting option for the future of PBAV techniques.

In summary, PBAV is successful in reducing left ventricular outflow obstruction in most patients with severe calcific AS. However, the results are not durable, and the long-term survival resembles that of the natural history of critical AS. We conclude that PBAV currently has a limited role in palliation of some patients with critical AS, and surgical AVR remains the treatment of choice. However, new therapies targeting post-PBAV restenosis offer promise and may lead to expanded indications in the elderly population. Furthermore, the future role of PBAV may be influenced by the development of TAVR as discussed below.

Transcatheter heart valve

Andersen et al pioneered the development of a balloon-expandable aortic valve, reporting experience with a porcine model in 1992.[72] Subsequently, others demonstrated the feasibility of percutaneous prosthetic valve delivery.[73–77] In 2000, Bonhoeffer et al described the first-in-man experience of a successfully implanted catheter-based stent valve in a pulmonary conduit.[78] In 2002, Cribier et al demonstrated the feasibility of aortic valve implantation in man using an antegrade approach via the femoral vein and transseptal puncture,[79] following which we described the development of a retrograde approach via the femoral artery.[80] Subsequently, the experience and technology for transcatheter aortic valve replacement (TAVR) have evolved rapidly, and will be discussed below. Like the PBAV literature, the evidence for these procedures is limited to case series (**Level C1**), but randomized trials are under way.

Balloon-expandable aortic valve

The currently available SAPIEN™ valve (Edwards Lifesciences LLC, Irvine, CA) consists of three bovine pericardial leaflets hand-sewn to a stainless steel, tubular, slotted, balloon expandable stent (Fig. 56.1). There is a fabric sealing cuff that covers the bottom portion of the stent and is intended to form a seal against the aortic annulus. Currently the valve is available in 20, 23 and 26 mm diameter sizes. The SAPIEN™ valve replaces the Cribier–Edwards equine valve that was used for the majority of the published experience with balloon-expandable valves described below. As of late October 2007, 494 patients have been treated with this prosthesis.

The procedure for TAVR with balloon-expandable stents utilizes three approaches: transvenous, transarterial and transapical.

Transvenous procedure

Following the first successful human TAVR by Cribier in 2002, a formal European registry was initiated (I-REVIVE

(a)   (b)
Figure 56.1 (a) The SAPIEN™ balloon-expandable aortic valve. (b) Aortogram showing the implanted valve.

or Initial Registry of EndoVascular Implantation of Valves in Europe) for patients with critical AS and no surgical options. A single-center registry was also established by the group in Rouen for high-risk patients who had been refused surgery (RECAST or Registry of Endovascular Critical Aortic Stenosis Treatment). The results of the initial 36 patients enrolled in these registries by Cribier were reported in 2006.[81] The majority of patients (79%) had a transvenous antegrade approach. Stent placement was successful in 75%, with failures secondary to embolization of the stent valve, hemodynamic instability, and inability to cross the native aortic valve. Postprocedure hemodynamics showed a significant decrease in MG (from 37 to 9 mmHg), increase in AVA (from 0.6 to 1.7 cm^2), and paravalvular aortic insufficiency was graded moderate to severe in 63% of patients. There was a high rate of procedure-related in-hospital complications (26%), and an additional 10 patients died in the subsequent six months. Nevertheless, extended follow-up demonstrated sustained normal bioprosthetic valve function for over three years. This experience provided proof that TAVR could be performed with a durable result, but it became clear that the transvenous antegrade approach was technically complex and unpredictable.[82]

Transarterial procedure

The early attempts with the transarterial retrograde approach encountered a number of difficulties which included: arterial access issues related to the need for large sheaths and catheters, passage of large-diameter prosthesis around the aortic arch, difficulty crossing the stenotic aortic valve from the retrograde direction, and the use of standard valvuloplasty balloons for stent deployment which was only sporadically successful.[83] An important advance was the 2006 publication by Webb *et al* of an 18-patient series of high-risk elderly patients (logistic EuroSCORE 26%) in whom a reproducible transarterial approach had been developed.[80] Procedural advancements included the development of arterial access equipment and techniques and a steerable guiding catheter used to actively direct the prosthesis through the tortuous aorta and retrograde through the aortic valve. Transarterial TAVR was successful in 14 of 18 patients, and there were no intraprocedural deaths. Thirty-day mortality was 11.1% with two early deaths related to procedural complications: one due to iliac artery perforation, and the other likely due to inadvertent obstruction of the left main coronary ostium by a displaced native aortic valve leaflet excrescence.

Recently Webb *et al* have published a 50-patient series which confirmed the success of the transarterial approach.[35] Valve implantation was successful in 86% of patients with an intraprocedural mortality of 2%. Mortality at 30 days was 12%, which compared favorably to a logistic EuroSCORE estimate of 28%. With experience, procedural success increased from 76% in the first 25 patients to 96% in the second half of this experience, and 30-day mortality fell from 16% to 8%. There were significant improvements in AVA, left ventricular ejection fraction, mitral regurgitation and functional class, and all were maintained at one year (Fig. 56.2). An 85-patient series by our group confirm and
Figure 56.2 Hemodynamic results before and after transcatheter aortic valve replacement with the SAPIEN™ valve. (a) Preprocedure simultaneous left ventricular and femoral artery peak to peak gradient was 108 mmHg and mean gradient was 108; calculated aortic valve area was 0.43 cm^2 using the Gorlin formula. (b) Postprocedure peak to peak gradient was 3 mmHg.

improve the above findings.[84] Importantly, procedural success increased to 91%, and 30-day mortality was 11% in the group with a mean logistic EuroSCORE of 31%. None of the patients had moderate or severe aortic insufficiency, and although mild paravalvular aortic regurgitation was common, it remained stable with no clinical consequences at one year. Furthermore, at a median follow-up of 359 days there was no structural valve deterioration, endocarditis or late valve embolization. Survival at one, six and 12 months was 89%, 84% and 77% respectively. Our largest series of combined transfemoral (n = 113) and transapical (n = 55) procedures was recently published.[85] Thirty-day mortality mortality was further reduced: transfemoral 8% vs transapical 18.2% (P = 0.07, overall 30-day mortality of 11.3%), and evidence of a learning curve continued with mortality falling from 14.3% to 8.3% between the first and second half of the series. (From 12.3% to 3.6% (P = 0.16) in transfemoral patients and from 25% to 11.1% (P = 0.30) in transapical patients.) Functional class improved over the year following the procedure (P < 0.001). Survival at 1 year was 74%, with the bulk of late re-admissions and mortality occurring as a function of co-morbidities rather than procedure or valve-related events. The 1-year survival of 74% compares favourably with the reported 1-year survivals of 51% and 66% in elderly patients with aortic stenosis who were not considered to be surgical candidates or who declined surgery (respectively).[86]

Edwards Lifesciences (unpublished data) has maintained a worldwide registry of patients treated with TAVR. In September 2007, the SAPIEN™ valve received CE mark in the European community and as of May, 2009 there have been over 2500 SAPIEN™ implants world wide. The SOURCE registry contains data on over 1000 implants. These data confirm the structural and hemodynamic integ-

rity of the valve with follow-up to one year, and the transfemoral (n = 459 patients) 30-day mortality was 6.3% with 93.3% of the cohort having a logistic EuroScore of >20% (mean 33.3%). One-year survival was approximately 75%.

The demonstrated safety and feasibility of the transarterial approach has lead to the development of a randomized clinical trial: the PARTNER (Placement of AoRTic TraNscathetER Valves) Trial. This prospective, randomized, controlled, multicenter pivotal trial will evaluate the safety and effectiveness of the SAPIEN™ Transcatheter Heart Valve in a stratified population of 600 patients with symptomatic severe aortic stenosis. One cohort will consist of high-risk surgery patients (operative mortality estimated at >15% and STS ≥10) randomized to either transarterial aortic valve implantation or surgical aortic valve replacement. The second cohort will consist of inoperable patients (cardiologist and two cardiovascular surgeons agree that the probability of death or serious, irreversible morbidity should exceed 50%) randomized to medical therapy or TAVR. The primary outcome is one-year mortality, and enrolment began in 2007.

Transapical approach

Some patients are poorly suited to the transarterial procedure due to femoral, iliac or aortic size, tortuousity or atheroma. Direct balloon catheter implantation of experimental prostheses through the left ventricular apex was used by our group in early studies of percutaneous valve implantation,[77] and was subsequently trialed extensively in animals.[87] The first human applications utilized a median sternotomy with cardiopulmonary bypass[88] but this has been supplanted by the current approach of intercostal thoracotomy without cardiopulmonary bypass.[89–90] The procedure is performed by a combined team of interventional cardiologists and cardiac surgeons in an operating room or catheterization laboratory using fluoroscopy and echocardiographic guidance with the patient under general anesthesia.[88,91–93]

The transapical approach avoids problems related to arterial access, and the short distance from the LV apex to the aortic valve may facilitate antegrade crossing and prosthesis positioning. However, disadvantages include the need for a thoracotomy, chest tube, apical repair, and the possibility of injury to the mitral apparatus. Experience with this procedure is limited. As of October 2007, 193 procedures had been performed in seven centers in Canada, Europe and the United States with a 30-day mortality of 18% in a high-risk cohort (source: Edwards Lifesciences LLC, unpublished data). The largest experience from four centers in Europe and North America was recently published and highlights the success of this approach. Fifty-nine patients with average logistic EuroSCORE of 26.8 ± 13.5% underwent transapical TAVR. Thirty-day mortality was 13.6%, and actuarial survival 75.7 ± 5.9% at a follow-up interval of 110 ± 77 days (range 1–255 days).[91]

A slightly larger series of 61 patients showed six- and 12-month survival of 74.4 ± 6.6% and 70.5 ± 7.3%, respectively.[94] This procedural success was recently replicated by Walther *et al.*[95] where procedural success was 92.8% in a cohort of 168 patients. Thirty-day and 6-month mortality was 16% and 30% respectively.

Self-expanding aortic valve

The CoreValve ReValving™ System (CoreValve Inc, Irvine, CA) is delivered using a transcatheter procedure, but the prosthesis is self-expanding rather than balloon expandable. When the restraining sheath is retracted the nitinol stent alloy expands to its predetermined shape, forming a tubular rigid frame with a trileaflet pericardial tissue valve attached with PTFE sutures. It measures 50 mm in axial length and incorporates three distinct areas of radial force. The lower portion has a high radial force and implants within the subannular region. The middle portion contains the valve leaflets and is tapered so as to be unopposed to the aorta and coronary sinuses, thereby allowing normal flow and access to the coronary ostia through the stent struts. The upper portion is flared and anchors the prosthesis against the ascending aorta with low radial force while providing longitudinal stability.[96] The valve is currently available in two sizes depending on the diameter of the ascending aorta (<35 mm or <45 mm) with one aortic annular diameter (23 mm). Initially the delivery system was 24Fr, but subsequently evolved to 21Fr with a more recent 18Fr iteration.[34,96] Following PBAV, the CoreValve ReValving™ System is correctly positioned in a transaortic position and the over-riding sheath slowly withdrawn. Initially, valve implantation required femoral–femoral cardiopulmonary support due to obstruction of transvalvular flow during valve release, but recent cases have been performed without this support.

As of early 2007, over 168 CoreValve procedures had been performed.[34] Initial procedures were performed in India with procedural success but poor clinical outcomes. The first case report from Germany was published in 2005[97] and the first series of 25 elderly patients (mean age 80.3 ± 5.4) was published in 2006.[96] Valve implantation was successful in 88% patients. Mean transvalvular gradients were significantly reduced (44 to 12 mmHg), and postprocedure aortic regurgitation grade was unchanged. However, major in-hospital adverse events occurred in 32%, and in-hospital mortality was 20% in this high-risk group with a median logistic EuroSCORE of 11%.

A more recent report describes 86 cases performed using the newer 21Fr and 18Fr systems.[34] The group had a mean age of 81.3 ± 5.2 (21Fr) and 83.4 ± 6.7 years (18Fr), and a mean logistic EuroSCORE of 23.4 ± 13.5% (21Fr) and 19.1 ± 11.1% (18Fr). The valve was successfully implanted in 88% of patients, with a marked reduction in mean trans-

valvular gradient (44 to 9 mmHg) and no change in aortic regurgitation. Periprocedural major adverse cardiovascular and cerebral events were reported in 26% of patients within the first 48 hours after device implantation, primarily driven by stroke (10%) and tamponade (7%). Procedural mortality was 6%, and overall 30-day mortality was 12% which was a significant improvement over the earlier case series. The most recent series of 1243 patients shows 30-day mortality has decreased to 6.7% (Logistic EUROscore 22.9 ± 4.1%), and post-procedure pacemaker implant was required in 12%.[98] Importantly, the 18Fr system has allowed transition to a percutaneous approach under local anaesthesia without hemodynamic support.[34]

Evidence around procedural issues

Paravalvular insufficiency

Mild paravalvular aortic regurgitation (PVAR) is commonly found with the current transcatheter valves, but for the most part does not appear to have major clinical consequences.[35,80] Severe leaks are uncommon but can occur. Accurate aortic annulus sizing has played a key role in minimizing paravalvular leak. Complicating sizing is variability in annular measurements obtained with the available imaging modalities and the apparent demonstration by multislice cardiac computed tomography that at least a portion of patients have an aortic annulus that is oval rather than round.[99]

PVAR can sometimes be reduced with redilation. Our center found 31 of 124 (26%) balloon-expandable valves were redilated for significant PVAR at the time of the initial procedure.[100] It appeared that cautious redilation appeared safe (no embolizations or persistent worsening of valvular insufficiency) and effective at reducing PVAR, and that oversizing the valve and using less compliant balloons may prove to be useful in reducing PVAR.

Learning curve

Transcatheter aortic valve implantation is a relatively complex procedure in which technical errors are not well tolerated and mortality may ensue. Like the previously outlined experience for PBAV, TAVR outcomes clearly improve with improvements in equipment, techniques and experience.[34,35] Consequently, cautious dissemination appears prudent. Formal educational programs, virtual simulators and proctoring have been utilized and appear helpful. Regional centers of expertise may be desirable to optimize outcomes.

Long-term follow-up

Early experience demonstrated an acute improvement in left ventricular systolic function.[101] Unlike the experience with PBAV, longer term follow-up has confirmed that this is sustained and associated with a sustained improvement

Table 56.6 Comparison of outcomes between PBAV and TAVR procedures

	NHLBI BAV Registry[46,47]	CoreValve[34]	Edwards Lifesciences[35]
Demographics			
Number of patients	674	86	50
Age (years)	78 ± 9	82 ± 6	82 ± 7
Follow-up (days)	3 years	30	359
Mortality:			
Logistic EuroSCORE	NR	21.7 ± 12.6%	28%
Mortality (30 days)	14%	12%	12%
Survival (1 year)	55%	n/a	81%
Survival (2 year)	35%	n/a	70%[1]
Hemodynamic:

[1] 2-year survival data taken from Pasupati *et al.*[102]

[2] Only 157 of 674 completed 6-month echocardiographic follow-up.

[3] VALUES are estimated from figure in paper, exact valves not provided in text.

[4] 30-day follow-up, 6-month data not available.

[5] Only 214 of 674 completed 1-year follow-up.

Table 56.7 Screening for transcatheter valve replacement

Questions to be answered	Evaluation	Comments
Should the patient have conventional AVR?	Surgical consult	Estimated operative mortality <20% Acceptable morbidity
What is the annulus diameter?	Echocardiogram	Valves are specific to a range of diameters Transesophageal echocardiogram if transthoracic parasternal long axis dimensions are borderline
Is percutaneous access adequate?	Iliofemoral angiogram with calibrated measurement catheter, CT or MR	Assess lumen diameter, tortuousity and calcification
Is the aortic root adequate?	Aortic root angiogram with calibrated measurement catheter, CT or MR	Assess abnormal root, potential for coronary obstruction
Is the ascending aorta diameter suitable?	CT or MR	Relevant to the CoreValve device
Is there LV dysfunction?	Echocardiogram or left ventricular angiogram	Increases risk of myocardial ischemia during implantation
Is there the potential for ischemia?	Coronary angiogram	Is there increased risk of ischemia during implantation. Is revascularization required?
Is there anemia or a clotting disorder?	Hemoglobin concentration, platelet count, partial thromboplastin time, prothrombin time	There is a risk of blood loss from access sites
Is there renal dysfunction?	Serum creatinine, glomerular filtration rate	Contrast nephropathy and transient hypotension can occur
Are there anesthetic concerns?	Anesthetic consult	Intubation and ventilation may be utilized
Are expectations realistic?	History, family support, co-morbidities	Do co-morbidities permit a reasonable quality and duration of life?

CT, computed tomography; MR, magnetic resonance.

in mitral insufficiency and functional class.[35,102] *In vitro* valve testing of currently available devices anticipates durability in excess of 10 years and structural valve deterioration has not been reported. However, only one report has documented late survival beyond one year in a significant number of patients, and follow-up beyond three years has only been reported in a few patients to date.[35,81] Zajarias and Cribier (REF) recently published a review of over 4000 transcatheter valve replacement procedures highlighting the lack of re-stenosis or prosthetic valve dysfunction over mid-term follow-up. Futhermore, a small series by Ussia *et al.* have shown a striking improvements in physical and physical and mental quality of life scores 5 months following transcatheter aortic valve replacement.[103]

Non-surgical aortic valve therapy compared

TAVR procedures are technically complex and evolving rapidly. Table 56.6 provides a comparison of the outcomes from PBAV and the two currently available TAVR devices.

Recommendations

- Surgical aortic valve replacement is currently the treatment of choice for patients with symptomatic critical aortic stenosis (**Class I, Level B**).
- In symptomatic patients with critical aortic stenosis who are felt to be of high surgical risk (EuroSCORE >15, STS >10), TAVR may be a reasonable alternative (**Class IIa, Level C1**).
- Current prosthesis size limits the procedure to patients whose annulus is appropriate (≥18 mm or ≤26 mm diameter).
- Patients with excessively bulky native valve leaflets in close proximity to a coronary ostium may be at risk of coronary occlusion.
- Selection between transarterial or transapical access should take into account local expertise, current more favorable outcomes with the transfemoral approach and the advantages of transapical access in the presence of arterial and aortic access limitations.
- A variety of patient factors may increase procedural risk and should be considered individually: obstructive coronary artery disease, reduced ejection fraction, chronic renal insufficiency, immobility.
- Percutaneous balloon aortic valvuloplasty may be a reasonable therapeutic alternative for patients with symptomatic critical AS in the following settings if they are NOT CANDIDATES for either transcatheter or surgical aortic valve replacement:
  - bridge to surgical AVR or TAVR in hemodynamically unstable patients (**Class IIa, Level C1**)
  - anticipated survival of <3 years (**Class IIb, Level C1**)
  - severe and/or disabling conditions that would limit the ability to undergo postoperative rehabilitation (**Class IIb, Level C1**).

Procedural complications have been compared previously and can be reviewed in Table 56.4. These comparisons form the basis for the recommendations below, but patient selection needs to be individualized. Table 56.7 is provided for reference and outlines some of the issues to be addressed for individualization.

Conclusion

Critical AS is a common problem and patients are often elderly and not well suited to surgery. For those with multiple co-morbidities and at high risk for morbidity and mortality from open heart surgery with cardiopulmonary bypass, therapeutic options are limited. Medical therapy provides no survival advantage and has limited efficacy for symptom control. PBAV can be performed with some periprocedural morbidity and modest symptom control, but is limited in durability and does not alter the natural history of the disease process. It is early in the development of TAVR technology, but in a relatively short period of time it has become clear that the procedure can reduce symptoms and potentially improve longevity with a periprocedural morbidity and mortality rate that continues to improve. This technology offers a viable therapeutic alternative to patients at high risk for traditional surgical AVR. A potential role in routine management of lower risk aortic stenosis remains speculative and restraint remains desirable.

57 Balloon valvuloplasty: mitral valve

Zoltan G Turi

Division of Cardiology, Cooper University Hospital, Camden, NJ, USA

Introduction and historical perspective

Percutaneous balloon mitral valvuloplasty (PBMV) represents part of an evolution from early, primitive cardiac surgical techniques to the modern era of percutaneous valve interventions. This evolution began with Elliot Cutler advancing a knife retrograde through the apex of the left ventricle of a beating heart in 1923.[1] Neither he nor Henry Suttar, who performed what today would be considered an antegrade fingertip commissurotomy in England 2 years later,[2] received the expected accolades. In part this reflected disagreement over the role of mitral valve obstruction in defining the spectrum of mitral stenosis (MS). Sir Thomas Lewis' statement that valvotomy was based on an "erroneous idea, namely that the valve is the chief source of the trouble"[3] has few proponents in the modern era. Nevertheless, because of the broad spectrum of cardiac and non-mitral valvular involvement resulting from rheumatic carditis and valvulitis,[4] relieving mitral valve obstruction largely palliates rather than cures patients with MS.

Some 20 years after the initial attempts to relieve mitral obstruction, the surgical experience in World War II battlefield hospitals with closed heart procedures led to the application of newly learned techniques to civilian use. Although early results were confounded by significant morbidity and mortality, closed mitral valvotomy became a routine procedure for severe MS by the 1950s and 1960s, and is still performed in many parts of the world where the disease is endemic and medical facilities are limited. Large series[5,6] have claimed good long-term results, but lack of systematic follow-up or comprehensive objective data obscures the actual restenosis rate and survival. In a

Mayo Clinic retrospective analysis[7] there was a 79% 10-year and a 55% 20-year survival rate with reoperation in 34% by 10 years; however, nearly a quarter of patients were lost to follow-up and severity of disease at baseline could only be estimated. A more recent evaluation of a 36-year experience included a 44% rate of repeat surgery by 12 years.[8] Open commissurotomy, with the potential advantages of direct vision, has supplanted closed procedures in industrial nations.[9] Controversy remains as to its superiority,[10–12] with the advantages of direct vision favoring cases where thrombus is present. The relative role of open commissurotomy versus mitral valve replacement with or without chordal preservation has been explored with somewhat equivocal results.[13] Mitral valve replacement has higher periprocedural and postoperative event rates including mortality, but superior freedom from repeat mitral valve intervention; when the chordae to at least one leaflet are preserved, the outcomes of mitral valve replacement are superior (**Level C**).

The percutaneous approach

Following the initial percutaneous structural heart disease interventions of Rashkind with balloon atrial septostomy,[14] a device designed by Inoue to inflate sequentially across the septum (Fig. 57.1) was instead adapted for PBMV.[15] After initially demonstrating its ability to split fused commissures in the operating room,[16] the first percutaneous PBMV was performed in 1982.[17] After several small series demonstrated feasibility,[18,19] a number of alternative techniques were developed, including large single balloons,[18] two cylindrical balloons used in parallel over two guidewires[20] through a single or two transseptal punctures,[21] a monorail technique for using two balloons,[22] a retrograde technique that avoided the transseptal approach[23] and a percutaneous metal commissurotome.[24] The initial technique and device developed by Inoue, with scant
Figure 57.1 Deployment of the Inoue balloon via the transseptal approach. The catheter has been advanced across the interatrial septum from the right atrium (RA) into the left atrium (LA) and then into the left ventricle (LV) across the stenotic mitral valve. The balloon is designed to inflate distally first (left frame), then to be pulled back against the mitral valve after which the proximal portion inflates (center frame), centering the balloon across the valve. As additional volume is injected into the balloon, full inflation occurs, ideally causing splitting of the commissures (right frame).

modification, remains the predominant (and only US FDA approved) approach.

PBMV typically results in a doubling of the mitral valve area (on average from $1.0\,cm^2$ to $2.0\,cm^2$) with a 50% reduction in gradient and an 80–95% success rate, the latter defined as the mitral valve area increasing to >$1.5\,cm^2$ and left atrial pressure decreasing to <18 mmHg without major complications.[25] Overall, the results are highly operator dependent with a steep learning curve.[26,27] As a result, the ACC/AHA guidelines[25] emphasize that the decision to proceed to PBMV must take into consideration the experience of the operators involved (**Class I, Level B**).

Mechanism of balloon commissurotomy and Pathophysiology

In general, balloon valvuloplasty, regardless of the valve being dilated, has three possible mechanisms for relief of obstruction: stretching of the valve orifice, splitting of fused commissures, and cracking of valvular calcifications. In the case of PBMV, the mechanisms[28] responsible for the benefits seen arise from the substantial radial force[29] exerted by the enlarging balloon. This stretches the mitral annulus, has the capacity to split fused commissures, and occasionally results in cracking of calcifications. The stretching mechanism has been described in the intraoperative setting.[30] The splitting of commissures[31] and cracking of calcification[32] have been demonstrated by direct observation in excised valves. The largely successful nature of PBMV is derived virtually exclusively from commissural splitting of rheumatically fused leaflets.[33] Balloon dilation procedures dependent on the other two mechanisms, such as balloon valvuloplasty for calcific aortic stenosis[34] or bio-

prosthetic valves,[35] have poor short- and long-term results. Thus non-rheumatic MS secondary to calcification of the mitral annulus, leaflets or subvalvular apparatus, such as seen with elevated hyperparathyroid levels (e.g. patients on dialysis), lends itself poorly to balloon dilation (**Level C**).

Successful splitting of the commissures results in decreased gradient and improved mitral valve area, and typically leads to significant clinical and hemodynamic improvement. This occurs progressively, with reduction in gradient, left atrial pressure and pulmonary artery pressures continuing over a 3-year period.[36] It is important to consider that relief of mitral valve obstruction will typically increase left ventricular volume loading secondary to facilitated left atrial emptying. In the relatively underfilled ventricle seen with "pure" MS this is typically well tolerated, although some degree of left ventricular dysfunction in patients with rheumatic heart disease may be present even without concomitant valvular regurgitation. In patients with concomitant mitral or aortic insufficiency, the left ventricle may become volume loaded after PBMV. Thus, although the gradient may be substantially reduced, left heart filling pressures may rise and be accompanied by failure of clinical improvement or actual deterioration.

Indications

Balloon valvuloplasty is primarily indicated for moderate to severe MS (Table 57.1) and is the procedure of choice for symptomatic patients if the valve anatomy is suitable and there is neither left atrial thrombus nor greater than mild mitral insufficiency (**Class I, Level A**). The guidelines incorporate evidence that PBMV is beneficial for patients with MS and pulmonary hypertension (**Class I**) or atrial

fibrillation (AF) (**Class II, Level B**). The guidelines have been expanded to include mild MS under limited circumstances (**Class II, Level C**).

Preprocedure evaluation and prediction of outcomes

A variety of anatomic and physiologic factors determine suitability for PBMV. Anatomic features that correlate with procedural success as well as long-term outcomes have been described since the early development of PBMV.[37] These include characteristics of the valve leaflets, annulus and subvalvular apparatus. Although there are major limitations, the most commonly used has been a scoring system described by Wilkins and colleagues[38] that incorporates thickening, mobility and calcification of the valve leaflets as well as disease of the subvalvular apparatus (Table 57.2). This, the so-called MGH (Massachusetts General Hospital) scoring system, assigns up to four points for the most severe disease for each characteristic, with a maximum of 16 points. Ideal valves have a score of eight or less, and echo scores >12 have been predictive of poor short- and long-term outcomes[39] (Fig. 57.2) (**Level B**).

Intermediate and long-term event-free survival has correlated well with the echo score, as well as the immediate postprocedure hemodynamics[39–42] (see Fig. 57.2). Five-year event-free survival is negligible in patients with echo scores of 12 or greater, but approximately two-thirds in those with favorable valve morphology (**Level B**).

While the correlation between the echo score and initial as well as long-term outcomes has been good, the MGH scoring system has been criticized because it is semiquantitative, does not include important anatomic elements

such as the nature of commissural fusion, and because one element of the score, leaflet mobility, correlates more strongly with outcome (r value = 0.67) than the complete score. Valve calcification alone predicts a fourfold increase in cardiac complications and a 26% increase in 6-year mortality.[43] Anatomic features such as a funnel-shaped subvalvular apparatus and eccentric commissural fusion[44] are not included in the score, nor is severe fusion and calcification

Table 57.1 Indications for percutaneous balloon mitral valvuloplasty, incorporating modifications from the 2006 ACC/AHA guidelines.[25] Note that the presence of pulmonary hypertension in asymptomatic patients is now a Class I indication. The effect of exercise has been incorporated. Pulmonary hypertension is assumed to be secondary to mitral stenosis. Where the guidelines specify valve morphology favorable for PBMV, the table lists an echo score ≤8 using the MGH scoring system. It should be noted that a boundary effect likely exists, and the scoring system has significant limitations so the guidelines do not specify either a specific scoring system or an absolute threshold. AF, atrial fibrillation: LA, left atrium; MR, mitral insufficiency; MVA, mitral valve area; PA, pulmonary artery systolic pressure.

Symptoms	MVA	Score	Other	Class
+	≤1.5 cm²	≤8		I
−	≤1.5 cm²	≤8	PA > 50 mmHg or 60 ex	I
II	≤1.5 cm²	>8	PA > 60 mmHg	IIa
III–IV	≤1.5 cm²	>8	High risk for surgery	IIa
−	≤1.5 cm²	≤8	New onset AF	IIb
+	>1.5 cm²	≤8	PA > 60, PAW > 25, MVG > 15 EX	IIb
III–IV	≤1.5 cm²	>8	Low risk for surgery	IIb
			LA thrombus, severe MR	III

Table 57.2 The Wilkins–Weyman echocardiographic scoring system of mitral valve characteristics

Grade	Mobility	Subvalvar thickening	Thickening	Calcification
1	Highly mobile valve with only leaflet tips restricted	Minimal thickening just below the mitral leaflets	Leaflets near normal in thickness (4–5 mm)	A single area of increased echo brightness
2	Leaflet mid and base portions have normal mobility	Thickening of chordal structures extending up to one third of the chordal length	Midleaflets normal, considerable thickening of margins (5–8 mm)	Scattered areas of brightness confined to leaflet margins
3	Valve continues to move forward in diastole, mainly from the base	Thickening extending to the distal third of the chords	Thickening extending through the entire leaflet (5–8 mm)	Brightness extending into the midportion of the leaflets
4	No or minimal forward movement of the leaflets in diastole	Extensive thickening and shortening of all chordal structures extending down to the papillary muscles	Considerable thickening of all leaflet tissue (>8–10 mm)	Extensive brightness throughout much of the leaflet tissue

The total echocardiographic score was derived from an analysis of mitral leaflet mobility, valar and subvalvar thickening, and calcification which were graded form 0 to 4 according to the above criteria. The total possible score ranges from 0 to 16.
(Reprinted by kind permission of the BMJ Publishing Group from reference.)[38]
Figure 57.2 Survival free of repeat balloon dilation or mitral valve replacement in 879 patients undergoing percutaneous balloon mitral valvuloplasty with echo scores of ≤8, 9–11, and ≥12. (Reproduced from Palacios[39] with permission of the American Heart Association, Inc.)

of the commissures[45]; all are strong negative predictors of outcome.[46] In the case of calcification, valve area varied inversely in 223 patients: $0.9\,cm^2$ in those with no calcification versus 0.8, 0.7 and $0.6\,cm^2$ respectively in those with grade 1, 2 and 3 calcium ($P < 0.05$).[47] A number of other scoring systems have been proposed, some of which appear to have a strong correlation with outcomes,[48] including an echocardiographic system assessing characteristics of leaflets and the subvalvular apparatus that correlates with PBMV-induced mitral regurgitation.[49] Perhaps the most compelling reason for routinely deriving the MGH echo score is to allow for comparison with known data: most PBMV trials have incorporated this system to define baseline severity of disease. As such, an echo score ≤8 is commonly interpreted as representing the ideal valve anatomy for PBMV described in the ACC/AHA guidelines[25] (see Table 57.1).

Besides anatomic features, a number of other factors appear to predict acute and longer term results. The presence of AF is an independent risk factor for adverse outcomes in several datasets.[50] A recent analysis of a 531-patient cohort with long-term follow-up demonstrated inferior acute results ($1.87\,v\,2.0\,cm^2$ mitral valve area (MVA) and higher restenosis rates (33% v 23% at 10 years, 66% v 54% at 15 years)[51] in patients with AF. Age[39,52] and severity of stenosis as defined by hemodynamics and functional class[53] correlate with outcomes based on multivariate analyses (**Level C**).

Physiologic determinants of outcome may include the presence of left ventricular volume loading or dysfunction with or without concomitant valvular or myocardial disease. PBMV in the setting of more than mild mitral insufficiency

is an independent predictor of adverse events at long-term follow-up.[39] Increase of mitral regurgitation by one grade is common after PBMV, occurring in some 33% of patients; an additional 13% increased by two grades or more.[54] Superimposed on pre-existing mitral insufficiency, developing post-procedure mitral regurgitation of 3+ or greater is therefore a significant risk, the latter being an independent predictor of adverse outcomes as well.[39] In contrast, PBMV in the setting of mild to moderate aortic insufficiency (AI) is usually well tolerated. Comparing outcomes in 315 patients with mild or moderate AI versus 361 patients without AI, the only significant difference in outcomes was a higher rate of aortic valve replacement in patients with moderate AI, albeit at a mean of 4.1 years after PBMV[55] (**Level C**).

Transesophageal echocardiography

Routine preprocedure transesophageal echocardiography (TEE) has become the standard of care and has been raised to a **Class I, Level C** indication. Essential is the increased sensitivity for detection of left atrial thrombus,[56] as well as aspects of mitral valve morphology and regurgitation; however, the subvalvular apparatus is better interrogated with transthoracic echo. It should be noted that left atrial thrombus occurs outside the appendage in 43% of patients with rheumatic heart disease.[57] Although left atrial thrombus is primarily seen in patients in AF, it has been reported in approximately 2% of severe MS patients in sinus rhythm.[58] Based on a study of 100 patients referred for PBMV, there is a significant increased risk of left atrial thrombus in the presence of spontaneous echo contrast.[59] However, with successful resolution of the gradient, and perhaps with the detergent effect of any periprocedural mitral insufficiency, resolution of spontaneous echo contrast corresponds with relief of mitral obstruction.[60] An increasing body of evidence has also demonstrated increased coagulability in patients with mitral valve stenosis.[61] Finally, other structural abnormalities such as the presence of vegetations or ruptured chordae can be detected by TEE with much higher sensitivity than surface echo.

Cardiac catheterization

Cardiac catheterization to assess hemodynamics is indicated only if the non-invasive evaluation is equivocal in assessing valve anatomy and physiology, ventricular function and pulmonary hypertension (**Level C**). Patients with angina, objective evidence of ischemia or known coronary artery disease should have coronary angiography before PBMV; coronary angiography for risk factors alone is not required (**Level C**). A new element in the guidelines is a **Class IIb** indication for so-called "drive-by" coronary angi-

ography regardless of whether patients meet these criteria if they do require a hemodynamic study because of equivocal non-invasive data; there is no evidence base for this recommendation, however (**Level C**).

The severity of MS can be determined by multiple methods including gradient, valve area as derived from multiple techniques, and finally the pulmonary artery pressure. It is important to consider that each technique is fraught with significant potential for inaccuracy. Importantly, the gradient is highly flow dependent, and is thus a poor proxy for severity of disease. It is particularly likely to lead to overestimation of severity of MS in the setting of poor heart rate control. Patients with new onset of AF are highly prone to having the extent of MS judged severe when it is mild or moderate, since these patients usually have poor initial rate control combined with loss of the contribution of atrial contraction to atrial emptying. Because tachycardia disproportionately shortens the diastolic filling period, they also have disproportionately high gradients and far worse symptoms than their MS would otherwise warrant. Inappropriate intervention in these patients, when heart rate control or cardioversion would suffice, is a classic error in management of MS. In contrast, excessive bradycardia or dehydration (such as occurs when a patient is maintained without fluids pending catheterization for an extensive period of time) can lead to gross underestimation of severity of MS. The use of pulmonary artery wedge pressures as proxy for left atrial pressure leads to overestimation of the gradient and underestimation of the mitral valve area because of the delayed decompression of wedge pressure across the high resistance of the pulmonary vascular bed.[62]

Contraindications

The ACC/AHA guidelines specifically cite left atrial thrombus and greater than mild mitral regurgitation as absolute contraindications and suggest that severe calcification and severe subvalvular disease are relative contraindications.

Left atrial thrombus

Several studies have explored chronic oral anticoagulation followed by repeat TEE to assess for thrombus resolution prior to PBMV. The rate of resorption is highly variable; the ACC/AHA guidelines recommend anticoagulation for 3 months. However, a prospective survey found resorption at 6 months in only one-quarter of 219 candidates for PBMV[63]; resorption was predicted by absence of spontaneous echo contrast, small thrombus size, and anticoagulation to an INR of 2.5 or greater. If clot remains present, we generally would avoid PBMV in favor of surgery since

avoiding the left atrial appendage with guidewires and balloons, while usually feasible, takes significant additional skill, and even in the best of hands cannot be guaranteed. Nevertheless, Chen and colleagues[64] have described a large series of patients with apparent organized left atrial appendage clot who underwent uncomplicated PBMV despite documented left atrial appendage thrombus. We believe that clot elsewhere in the left atrium remains an absolute contraindication, although novel algorithms such as placing distal protection devices in both internal carotid arteries have been described[65] (**Level C**).

Mitral regurgitation

A comparison of 25 patients with moderate mitral regurgitation and 25 age- and gender-matched patients with mild or no regurgitation demonstrated an increased incidence of severe insufficiency post procedure in the former.[66] However, these patients had much higher echo scores and twice as frequently had severe calcification. While 20% of those with initially moderate mitral regurgitation developed severe regurgitation, hemodynamic improvement overall was similar, as was the incidence of postprocedure mitral valve replacement. Even patients with mild mitral regurgitation tend to have less favorable anatomy at baseline and lower event-free survival but a similar success rate[67] (**Level C**).

Severe calcification

Balloon dilation of a symmetric fused and severely calcified and essentially immobile mitral apparatus as well as attempted dilation of a severely calcified mitral annulus are largely futile. Thus patients with symmetric severely fused commissures may not respond at all.[45,68] In contrast, those with asymmetric calcification are prone to leaflet tearing or rupture due to asymmetric application of force to the less diseased commissure or leaflet.[69] While high echo score alone does not predict the occurrence of severe post-PBMV mitral regurgitation,[70] one component, severe calcification, does.[71] In general, greater degree of calcification predicts less successful improvement in valve area, higher periprocedural complications, and lower event-free survival.[43] Nevertheless, when the risk of surgery is prohibitive, growing experience with predominantly elderly patients with high echo scores and poor overall morphology has shown moderate improvement in hemodynamics and palliation of symptoms at the cost of high morbidity and mortality[72] (**Level C**).

Procedure

Except for a small cohort of patients, virtually all PBMV has been performed via the antegrade transseptal route.

The retrograde approach avoids the need for transseptal puncture, an advantage that is offset by the need to introduce relatively large hardware into the arterial circulation and to advance a balloon retrograde across the submitral apparatus over a guidewire, potentially causing entrapment in the subvalvular apparatus. Nevertheless, the success rates and intermediate term follow-up of retrograde PBMV have been comparable to the antegrade approach (88% success in a 441-patient cohort) with the usual finding of outcomes correlating with the MGH echo score.[73] A small, 72-patient, single-site non-randomized comparison found no significant difference in outcomes between the antegrade Inoue technique and retrograde approaches except for increase in mitral insufficiency with the latter, but the study was underpowered to assess trends in postprocedure adverse events.[74]

The Inoue technique is virtually unchanged since the mid-1980s. In a review of 19 series reporting results in a total of 7091 patients, the overall success rate was 93%.[75] Success was variably defined, and in some studies the definition included patients with severe iatrogenic mitral insufficiency, atrial septal defect or embolic events, but typically included a doubling of valve area. The principal features of the Inoue device are a balloon with a stretchable distal shaft to facilitate transseptal passage, a nylon mesh over a latex balloon that allows for variable inflation of the distal and proximal portions to promote straddling of the mitral valve (see Fig. 57.1), and a compliance curve that allows the balloon to dilate predictably over at least a 4 mm range of sizes. The device lends itself to a stepwise dilation technique, with repetitive inflations at progressively increasing balloon sizes.[76] After each inflation, residual gradient, hemodynamics including blood pressure and left atrial pressure, and echocardiographic data are assessed; if residual MS is still substantial and mitral insufficiency has not increased, repeat inflation with the balloon inflated to a larger size is performed. No formal evidence base exists comparing this stepwise technique to a single inflation at the calculated optimal balloon size based on patient height and body surface area. The compliance curve of the Inoue balloon results in an exponential rise in radial force within a mm of its maximal size and is a risk factor for post-PBMV mitral insufficiency[77] (**Level C**).

PBMV is typically performed with continuous TEE or, more recently, intracardiac echocardiographic guidance.[78] The benefits include continuous monitoring for periprocedural mitral insufficiency, tamponade, and spontaneous echo contrast.[79] TEE is useful as an aid to optimize transseptal puncture[80] with decreased procedure time, mitral insufficiency, and residual atrial septal defects described in a randomized study of fluoroscopy plus TEE versus fluoroscopy without echo during PBMV.[81] The evidence base provided by these studies is not compelling, with the latter study including a 60% rate of major complications in the non-TEE group, suggesting limited experience on the part of the operators. Surface two-dimensional echo is sensitive enough to detect increasing mitral regurgitation during PBMV in most patients, and is an excellent tool for early appreciation of tamponade. A randomized prospective study comparing TEE with intracardiac echo guidance found equal utility to facilitate transseptal puncture, but otherwise superior imaging with TEE[82] (**Level B**).

Alternative techniques

Cylindrical balloons

The first alternative technique to the Inoue device was a single large cylindrical balloon[18] but this gave way early to two parallel cylindrical balloons[20] with the rationale that two balloons better distributed lateral pressure along the planes of the commissures. Anecdotal results comparing single cylindrical (non-Inoue) versus double balloon inflations demonstrated superior acute gradient reduction with two balloons deployed in parallel.[19] More formal but non-randomized comparison also suggested superior results with the double balloon technique.[27,83,84] Additional confirmation came from an *in vitro* study of operatively excised fused mitral valves that demonstrated superior splitting and increase in valve area.[33]

Relatively few operators still perform cylindrical balloon valvuloplasty of the mitral valve. Disadvantages have included the need to dilate the septum to accommodate the bulk of hardware when two balloons are used, as well as risk of adverse events including "harpooning" of a balloon through the apex of the ventricle, in part due to a "water melon seed" effect with balloon inflation. Nevertheless, cylindrical balloon series have had relatively good results, including an extraordinary 4832 patient experience in 120 centers across China claiming a 99.3% success rate with virtually no complications, and a low 5.2% restenosis rate at a mean 32 months follow-up, likely suggesting significant problems with data collection.[85] Nevertheless, PBMV studies using cylindrical balloons have been generally good when the anatomy was favorable.[86] This is particularly true with a monorail system that simplifies the double balloon technique and has potential cost advantages as well.[22] Regardless of technology used, the results are dependent on anatomic suitability. Thus, a 145-patient cylindrical balloon trial by Cohen *et al*[53] revealed only 51% 5-year freedom from mitral valve replacement, redilation or death in a setting where patients had unfavorable anatomic features. Many of the cylindrical balloon studies occurred early in the development of PBMV and suffered from incomplete follow-up, non-overlapping endpoints, and lack of serial hemodynamic measurements for assessing hemodynamic results and restenosis.

Inoue versus cylindrical balloons

A large number of studies have compared the Inoue technique to double balloons.[87] Generally, the former has greater simplicity, resulting in shorter procedure times. The Inoue balloon, unlike cylindrical balloons, is self-centering across the mitral valve (see Fig. 57.1) and does not predispose to the occasional catastrophic left ventricular apex perforations seen with cylindrical devices.[88] Because of its low-profile passage over a specially designed stainless steel guidewire across the septum, avoiding the need for balloon dilation of the septum itself, the rate of iatrogenic atrial septal defect with the Inoue balloon is substantially lower[89] (≤2.5% v approximately 10% for the double balloon technique[27]) (**Level B**). Several randomized trials have compared Inoue and double balloon techniques[90,91] and demonstrated similar outcomes. It is likely that an easier procedure with lower complication rates (the Inoue technique) is a trade-off for slightly greater mitral regurgitation,[92,93] possibly because the distal portion of the balloon is oversized and may traumatize the subvalvular apparatus. There are also suggestive data that the double balloon technique, by virtue of the lateralization of forces, is advantageous in less favorable anatomy. One example is the result of dilation of asymmetrically fused commissures: where the Inoue technique has been used, this led to significant risk of mitral regurgitation[69] whereas with double balloon use this has been less common.[94] Other findings, primarily from non-randomized or historical comparisons, reflect inferiority of the double balloon technique compared to Inoue, including longer procedure times, higher risk of left ventricular perforation[95–98] and higher complication rates[91,97] although the latter may reflect operator learning curves with this more complex procedure (**Level C**).

A percutaneous metallic mitral valvulotome, designed to mimic the Tubbs dilator used by surgeons for closed commissurotomy but delivered percutaneously via a transseptal route, was highly effective.[24] Its theoretic advantages included the ability to resterilize most of the valvulotome assembly, a potentially important cost benefit in developing countries. The technique was challenging and had a significant complication rate. Randomized comparisons[99] suggested a somewhat lower success rate and higher complication rate, though this device had the steepest learning curve of the PBMV technologies and is no longer available (**Level B**).

Balloon Versus Open and Closed Surgical Commissurotomy

Randomized trials comparing balloon and surgical commissurotomy began early in the development phase of the percutaneous technique. Because blind dilation of the valve with blunt instruments, typically via the retrograde approach through the left ventricular apex with instruments like the Tubbs dilator, was the standard procedure in countries where MS was prevalent, the early randomized trials compared balloon and closed commissurotomy. In these trials, surgeons were typically highly experienced while the operators performing PBMV were in their learning curve. In 1988 we randomized 40 patients with relatively ideal anatomy and severe MS[100]; these patients were followed with serial invasive and non-invasive testing. There were similar hemodynamic improvements in both groups through 7 years (Fig. 57.3), with one cardiovascular death and a 25% clinical restenosis rate.[101] The actual 3-year restenosis rate (26% in the balloon group and 35% in the surgical group), as defined by a 50% loss of the gain and a valve area <1.5 cm², is significantly higher than the repeat intervention rate because restenosis and functional class do not correlate strongly. Thus it is likely that restenosis rates in trials that have not done formal follow-up hemodynamics or non-invasive testing underestimate the true severity of disease during follow-up.

Two other studies compared balloon and closed commissurotomy with shorter non-invasive follow-up only; these demonstrated PBMV to be superior[102] or similar to closed commissurotomy.[103] These studies had relatively unaggressive dilation, with relatively small postprocedure mitral valve areas. A 90-patient three-arm study by Ben Farhat and colleagues compared PBMV with closed and open commissurotomy and demonstrated superior acute results for PBMV (2.2 ± 0.4 cm²) than for closed commissurotomy (1.6 ± 0.4 cm²) and a 7-year actuarial restenosis rate of 7% v 37%.[104] Thus, PBMV is at least equal and probably superior to closed mitral commissurotomy (**Level A**).

The hypothesis that open commissurotomy would be superior to PBMV and closed commissurotomy was based on the potential benefits of direct vision, including surgical splitting and remodeling of the subvalvular apparatus, neither of which is a feature of closed commissurotomy or PBMV. A prospective series of 100 open mitral commissurotomy patients had data analyzed specifically to compare to the then reported results of PBMV and concluded that the latter was inferior to the 2.9 cm² they reported for open commissurotomy.[105] While these exceptional results were laudable, they likely were impacted by measurement technique as well, and exceed the results reported by others.[10] In our randomized prospective comparison of 60 patients with balloon or open commissurotomy, patients undergoing PBMV had superior mitral valve areas at 3 years,[36] findings that were sustained through 7-year follow-up (see Fig. 57.3).[106] A possible explanation for the superior results of PBMV is the benefit of hemodynamic and echocardiographic feedback to the operator in the catheterization laboratory during stepwise dilation that allows for optimizing inflations, feedback that is less avail-
Figure 57.3 Mitral valve area at baseline, 1 week, 6 months, 3 and 7 years after balloon dilation, closed (CMC) or open (OMC) mitral commissurotomy, in prospective randomized trials conducted in Hyderabad, India.[36,100]

able to the surgeon. Ben Farhat and colleagues, in the three-arm trial referred to earlier, found similar results through 7 years for both PBMV and open commissurotomy, in contrast to the inferior results for closed commissurotomy. Thus, PBMV is equal or superior to closed or open commissurotomy, acutely and at long-term follow-up (**Class I, Level A**).

Restenosis

Early mitral restenosis is likely secondary to a suboptimal result[107] although the possibility of a repeat bout of rheumatic fever and carditis should be considered, particularly in endemic areas.[108] Progressive thickening and calcification of the leaflets and subvalvular apparatus are considered the likely mechanisms of longer term restenosis, with pathologic evidence not supporting commissural refusion.[109] Similar to the results of repeat valve surgery,[110] balloon dilation for mitral valve restenosis after surgical commissurotomy has had inferior results.[111] Thus, patients have had less symptomatic improvement,[112] lower success rate (with only 51% having valve area >1.5 cm²),[113] a higher incidence of subsequent mitral valve replacement (20% by 4 years)[113] and a twofold[114] to 10-fold[115] increase in restenosis rates at 5 years for patients with prior surgical commissurotomy. Similarly, patients with restenosis after PBMV have had lower success rates and less improvement in mitral valve area.[116] However, the poorer outcomes appear to be related to a deterioration in valve morphology at the time of redilation, with results similar to those predictable by the echo scores of patients undergoing *de novo* dilation.[113,117,118] Thus PBMV is appropriate first-line therapy in restenosis patients with suitable anatomy (**Class II, Level C**).

Pulmonary hypertension

The improvement in hemodynamics after PBMV includes not only gradient reduction and improvement in mitral valve area, but also a progressive decrease in pulmonary artery pressure and pulmonary vascular resistance.[119] Even in patients with severe pulmonary hypertension, a marker for overall MS severity, there is parallel postprocedure improvement in hemodynamics,[120] a phenomenon that continues through 3 years of follow-up[36] (**Class II, Level B**).

Pregnancy

A number of studies have reported successful PBMV in pregnant women with initial results identical to the superior valve areas seen in non-pregnant patients in the same age groups.[121,122] In order to avoid the radiation exposure to the fetus, the procedure has been done with echo guidance only, although appropriate shielding of the fetus is adequate in most instances[123] (**Class II, Level C**).

Tricuspid insufficiency

Song and colleagues compared PBMV to mitral valve surgery and tricuspid valve repair for 92 patients with severe MS and severe functional tricuspid insufficiency.[124] The 7-year event-free survival was 77% in the PBMV-only group versus 95% for the operated group (**Class II, Level C**).

Bioprosthesis

A number of case reports have described balloon dilation of bioprosthetic mitral valves,[125–127] although the acute hemodynamic benefits, potential for complications, and long-term outcomes are questionable. Histologically, bioprosthetic valves resemble calcific native aortic stenosis and balloon dilation is of limited effectiveness.[128] Intraoperative balloon dilation, examining the morphology of severely stenosed bioprosthetic valves before and after balloon dilation, appeared "completely ineffectual" with leaflet tearing and cuspal perforation.[129]

Complications

The rate of complications is inversely proportional to operator experience with a steep learning curve associated with the procedure.[26,27] The NHLBI reported substantially lower rates of all major complications except acute mitral insufficiency at centers performing more than 25 cases and in the second year that sites enrolled patients; a willingness to attempt PBMV in higher risk subsets in the second year may explain the mitral insufficiency. The ACC/AHA guidelines emphasize that the decision to proceed to PBMV must take into consideration the experience of the operators involved (**Level B**).

Overall mortality has been approximately 1%, most commonly related to tamponade from transseptal catheterization[130] but also from fenestration of the left ventricular apex. Tamponade has been reported in a range of <1–4% of PBMVs, the latter level reported in both a 146-patient series from the Beth Israel Hospital in Boston[53] and the 738-patient NHLBI Mitral Valvuloplasty Registry.[27] Besides transseptal puncture and balloon "harpooning," catheter manipulation in the left atrium has also been implicated. In an analysis of 10 cases of tamponade in a 903-patient PBMV series,[88] Joseph *et al* demonstrated the following etiologies: perforation during transseptal puncture (2), harpooning of the left ventricular apex (3), perforation by an apical guidewire (2), stitch perforation caused by low transseptal puncture of the posterior wall of the right atrium (2), and temporary pacing-induced perforation of the right ventricle (1). There was an inverse relationship between frequency of tamponade and operator experience.

Other complications include severe mitral insufficiency (1–6%) and cerebrovascular accident and thromboembolism (up to 4%). Disturbingly, magnetic resonance imaging detected new hyperintensity foci suggestive of periprocedural cerebral infarcts in 18 of 63 post-PBMV patients[131] although only one had relegatable symptoms. Clot in the left atrium had not been detected on TEE in these patients. Thus, embolization may be common even if not clinically apparent. The probable sources, besides intracavitary clot, are catheter-induced thrombus formation and showers of calcium; the latter has been associated with rare but catastrophic coronary artery occlusion.[132]

Atrial septal defects were a significant source of complications early in the development of technologies for PBMV, in part arising from tearing of the septum during balloon dilation to allow catheter passage, inadvertent proximal deployment of cylindrical balloons or withdrawal of winged balloons retrograde through the septum. Residual left to right flow is seen in >90% of patients[133] though the majority resolve within 3 months. Persistent left to right shunting is likely related to size of the hole and the residual gradient across the mitral valve. Because the Inoue balloon does not require balloon dilation of the septum and proximal inflation is unlikely given its self-centering method, a comparison of Inoue and double or bifoil balloon techniques demonstrated substantial reduction in residual shunt with the former.[134] The presence of a residual atrial septal defect does decompress the left atrium after PBMV and leads to overestimation of the mitral valve area because of lowering of the mitral valve gradient by left to right transseptal flow.[135]

Postprocedure management

Oral anticoagulation is indicated in MS patients in AF, known clot in the left atrium or a history of prior embolic disease (**Class I, Level A**). When the left atrium is enlarged at 55 mm or greater, or in the presence of spontaneous echo contrast,[59] the guidelines suggest that anticoagulation be considered in the setting of severe MS (**Class II, Level B**). However, there is little evidence base regarding continuation of anticoagulation in the latter patients after PBMV.

Patients with successful PBMV and therefore decompression of the left atrium have been shown to have some involution of left atrial size[136] with about a one-third reduction in left atrial volume, although this phenomenon is less pronounced in patients with AF. Cardioversion after PBMV has been recommended predicated on successful maintenance of sinus rhythm in patients operated for MS routinely shocked during recovery from cardioplegic arrest.[137] Successful post-PBMV cardioversion has correlated strongly with duration of pre-PBMV AF.[138] In a recent study using an inclusion threshold of left atrial size <60 mm, two-thirds of patients undergoing cardioversion remained in sinus rhythm 12 months after PBMV[139] (**Class II, Level C**).

Conclusion

Percutaneous balloon mitral valvuloplasty is both safe and effective. Short-term results in ideal patients include a

doubling of the mitral valve area and a relatively low complication rate, with freedom from reintervention at 7–10 years of >50% (**Level A**). Less favorable outcomes are seen in patients with significant thickening and calcification of the leaflets and subvalvular apparatus, as well as older patients and those in AF (**Level C**). The procedure has a steep learning curve and success and complication rates are directly related to operator experience (**Level B**). Based on a sizable evidence base of randomized controlled trials, PBMV is the treatment of choice for patients with rheumatic MS and suitable valve anatomy who require intervention (**Class I, Level A**).

58 Valve repair and choice of valve

Shafie S Fazel and Tirone E David

Peter Munk Cardiac Center, Toronto General Hospital, University of Toronto, Toronto, Canada

Introduction

The ideal replacement cardiac valve is yet to be developed. The ideal valve would be easy to implant, would be non-thrombogenic, would last the patient's lifetime, and in children it would grow with the child. Currently available mechanical and biologic heart valves are imperfect and heart valve repair should always be considered prior to replacement.

This chapter reviews the information on the surgical management of heart valve disease excluding transcatheter therapies. The heterogeneity of heart valve disease and the variability of outcome of complex procedures make the design and execution of randomized clinical trials difficult. The majority of the present evidence is derived from single-center reports. Our recommendations reflect the position of the American College of Cardiology and American Heart Association (ACC/AHA) 2006 Practice Guidelines.[1]

Nomenclature and definitions

Since the publication of the *Guidelines for Reporting Morbidity and Mortality After Cardiac Valvular Operations* approved by the Society of Thoracic Surgeons and the American Association for Thoracic Surgery in 1988, and revised in 1996,[2] surgical journals require that authors conform to those guidelines, which are presented in Box 58.1.

Natural history and indications for surgery

The ACC/AHA 2006 guidelines contain a comprehensive review of the natural history of heart valve disease and the

indications for surgery.[1] This information is also covered in Chapters 53–55, and 81.

Valve repair

Aortic valve repair

The morphologic characteristics and function of the aortic valve are interrelated to the aortic root and are best described as a single functional unit. The aortic root is the anatomic segment that connects the left ventricle with the ascending aorta and has four components: aortoventricular junction or aortic annulus, aortic cusps, aortic sinuses or sinuses of Valsalva, and sinotubular junction. Although the aortic cusps are the most important component of the aortic valve, aortic insufficiency (AI) can occur in patients with normal aortic cusps that have dilation of the sinotubular junction and/or aortic annulus.

Congenital aortic stenosis used to be managed by means of open surgical valvotomy but this procedure has been largely replaced by transcatheter valvotomy (see Chapter 56). Acquired aortic stenosis is not suitable for aortic valve repair.

Patients with AI are potential candidates for aortic valve repair and the aortic cusps are the most important determinant of reparability.[3,4] If the cusps are thin and mobile and have smooth free margins, the feasibility of aortic valve repair is high. Calcified, fibrotic or excessively overstretched cusps preclude aortic valve repair. Aortic insufficiency caused by prolapse of a single cusp in patients with tricuspid aortic valves is uncommon but repairable. Prolapse of one cusp in patients with bicuspid aortic valve is common and is also suitable for repair.[5] Aortic valve repair frequently is needed in combination with aortic valve-sparing operations.[6] However, isolated repair of the aortic valve is not routinely carried out given the durability of contemporary mechanical and bioprosthetic valves (**Class I, Level C**).

BOX 58.1 Guidelines for reporting morbidity and mortality after cardiac valvular operations

Operative mortality

This is defined as death within the index hospitalization or within 30 days of the operation.

Structural valve deterioration

This is defined as any change in function (including a decrease in New York Heart Association functional class) of an operated valve resulting from an intrinsic abnormality of the valve that causes either stenosis or regurgitation. This definition, however, does not include deterioration because of infection or thrombosis of the valve as determined by reoperation, autopsy or clinical investigations. The term includes changes that are intrinsic to the valve such as wear, fracture, poppet escape, calcification, leaflet tear, stent creep, and suture line disruption of components of an operated valve.

Non-structural dysfunction

This is defined as any abnormality resulting in stenosis or regurgitation at the operated valve that is not intrinsic to the valve itself. Again, this term is exclusive of thrombosis and/or infection but includes entrapment by pannus, tissue or suture; paravalvular leak; inappropriate sizing or positioning; residual leak or obstruction; and clinically important hemolytic anemia.

Valve thrombosis

This includes any thrombosis, in the absence of infection, attached to or near an operated valve that occludes part of the blood flow path or that interferes with the function of the valve.

Embolism

This is any embolic event that occurs in the absence of infection after the immediate perioperative period (when anesthesia-induced unconsciousness is completely reversed). Importantly, a neurologic event includes any new, temporary or permanent focal or global neurologic deficit, but does not include psychomotor deficits elicited by specialized testing. Patients who do not awaken or who awaken after operation with a new stroke are excluded from tabulations of valve-related morbidity. A peripheral embolic event is also tabulated under this definition.

Bleeding event (formerly anticoagulant hemorrhage)

This is any episode of major internal or external bleeding that causes death, hospitalization or permanent injury or that requires blood transfusion. Notably, this definition applies also to patients who are not taking anticoagulants or antiplatelet agents.

Operated valvular endocarditis

This is defined as an infection involving an operated valve. It is based on the traditional criteria including an appropriate combination of positive blood cultures, clinical signs, and/or autopsy or operative findings. Importantly, morbidity associated with endocarditis, such as valve thrombosis, thrombotic embolus, bleeding event or paravalvular leak, is included under this category and is not included in other categories of morbidity.

Note added in proof: these guidelines have recently been updated. See Atkins CW *et al. J Thorac Cardiovasc Surg* 2008;**135**(4):732–8.

Patients with aortic root aneurysm often have normal or minimally stretched aortic cusps and reconstruction of the aortic root with preservation of the native aortic cusps is feasible. Most patients with aortic root aneurysms have normally functioning aortic valve or mild AI. If the AI is severe, the cusps may be thinned and overstretched, or have stress fenestrations along the commissural areas. These valves are not suitable for repair. Patients with ascending aortic aneurysm and AI often have dilated sinotubular junction and normal or minimally altered aortic cusps. The AI is central and caused by outward displacement of the commissures of the aortic valve.

Aortic valve-sparing operations are usually feasible in patients with aortic root aneurysms without AI or with AI and fairly normal aortic cusps as well as in patients with ascending aortic aneurysm and AI due to dilated sinotubular junction. These operations can be classified into three types[7,8]:

• replacement of the ascending aorta with downsizing of the sinotubular junction

• replacement of diseased aortic sinuses (one, two or all three sinuses – in the latter group the procedure is

also referred to as a root remodeling or Yacoub procedure)[9]

• full root replacement with reimplantation of the aortic valve in a tube graft (David procedure).[10]

Aortic valve-sparing operations are technically demanding. They can be applied to aortic dissection that extends into the root,[11] Marfan's syndrome patients with aortic root aneurysms,[9,10] in patients with bicuspid aortic valves[5,12] and in patients with aortic root aneurysms of unknown etiology. The competing options for dealing with aortic root and ascending aortic aneurysms are the composite valve graft (mechanical or bioprosthetic valve in a Dacron graft or a biologic valve conduit such as aortic valve homograft or xenograft)[13,14] and aortic valve replacement and supracoronary replacement of the ascending aorta.[15,16]

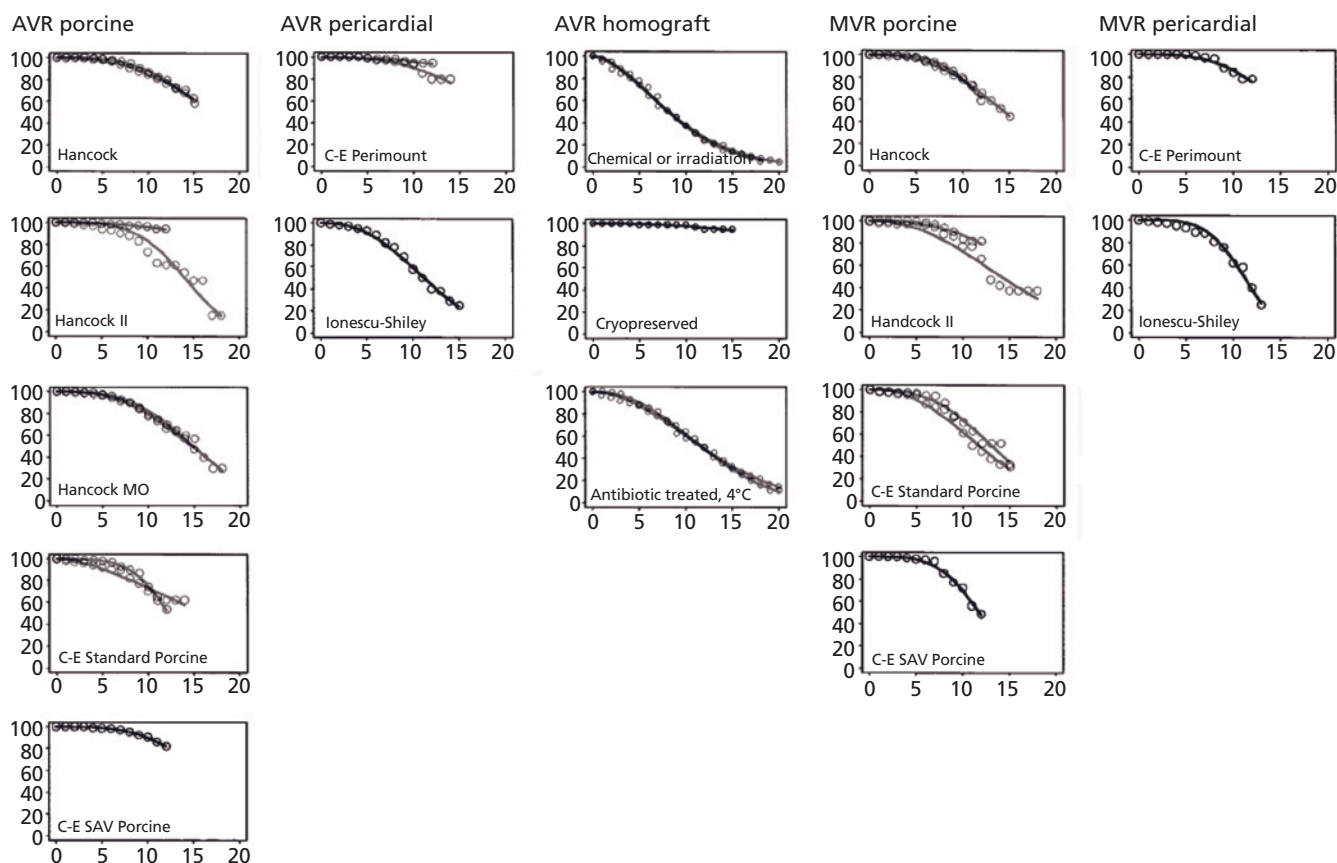
The long-term outcomes of aortic valve-sparing operations in patients with ascending aortic aneurysms are excellent.[17] Reoperation rate at 10 years after replacement of the ascending aorta with reduction of the diameter of the sinotubular junction is only 3%, which is better than the results of valve replacement (Fig. 58.1). However, if the surgeon is not familiar with aortic cusp repair, presence of an eccen-


Figure 58.1 Freedom from structural valve deterioration. If data from more than two reports were available, only data from the two largest reports were included. (Modified from Grunkemeier *et al.*[110])

tric AI jet at preoperative echocardiography should alert him or her to other concomitant aortic valve pathology and the need for more complex surgery.

Aneurysm of the sinuses of Valsalva requires either a remodeling or a reimplantation procedure. Long-term results indicate a reoperation rate of about 10% at 10 years for progressive AI[18] with the remodeling technique. In our own experience, return of moderate to severe AI occurred in 15% of patients at 10 years.[6] This rate is suboptimal in young patients but may be acceptable in an older patient population.[5] In patients with dilated aortic annuli, further strategies to stabilize the annulus should be employed.[19] Otherwise, these patients, and patients with connective tissue disorders such as Marfan's syndrome, will have progressive annular dilation, which would cause AI again.[6,20] The reimplantation technique allows stabilization of the annulus within the cylindrical graft and avoids moderate to severe AI in 94% of patients at 10 years.[21,22] Some question the appropriateness of preserving the aortic valve in patients with Marfan's syndrome, but valve repair is safe and durable in this patient population.[6,23] Composite valve graft replacement of the valve and aortic root remains the gold standard across most centers given the reproducibility of the procedure (**Class I, Level C**).

Mitral valve repair

The mitral valve, which includes the annulus, leaflets, chorda tendineae, papillary muscles, and left ventricular wall, may become dysfunctional for a variety of reasons.[24] Rheumatic heart disease causes fibrosis of all components of the mitral valve with resulting mitral stenosis (MS) and/or regurgitation (MR) (see Chapter 53). Myxomatous mitral valve disease typically causes MR because of elongated/ruptured chordae and redundant and prolapsing leaflets. Ischemic functional MR is caused by infarction of the left ventricular wall that tethers the mitral leaflets. This causes an increase in the septolateral dimension of the annulus toward the posteromedial commissure or may result in leaflet prolapse due to papillary muscle rupture and/or fibrosis and elongation. Non-ischemic functional MR is caused by global left ventricular and mitral annular dilation.

Rheumatic mitral valve disease

Mitral balloon valvotomy, in the MS patient without MR and with low echocardiographic calcium scores, is the first line of intervention (see Chapter 57). Patients with moderate distortion of mitral valvular anatomy, but in whom the

anterior leaflet and chordae tendineae still appear to be pliable, may be candidates for open mitral commissurotomy and repair. However, in patients in whom there is severe distortion of the valve apparatus preoperatively, mitral valve replacement is more appropriate. Repair of rheumatic MR has been relatively successful but may be attempted by experienced surgeons only if the mitral apparatus is not significantly damaged (**Class IIa, Level C**).

The failure of mitral valve repair in patients with rheumatic disease is related to progressive primary valve disease, leaflet fibrosis and retraction.[25] Valve repair in this population is not as durable as valve repair in patients with non-rheumatic disease. Freedom from reoperation is approximately 70–85% at 5–10 years of follow-up.[26–29] A recent meta-analysis, however, demonstrated superior survival of patients with repair as compared to replacement.[30] If a patient has an indication for anticoagulation, serious consideration should be given to mechanical mitral valve replacement (**Class IIa, Level C**). In this context, we emphasize the critical importance of preserving the chordae tendineae[31–35] (**Class I, Level C**).

Myxomatous or degenerative mitral valve disease

The two major subcategories as initially defined by Carpentier are: myxomatous degeneration where typically the valve leaflets are redundant with elongated chordae, and fibroelastic deficiency which occurs in the older patient with minimal thickening of the leaflet.[36] In the extreme form of myxomatous degeneration, the so-called "Barlow's disease" of the mitral valve, there is also atrialization of the posterior mitral annulus that may have bearing on the technique of repair.[37] Valve repair for these patients involves resection of the prolapsing segment,[38] replacement and/or transposition of the chorda if necessary, and mitral valve annuloplasty.[39,40] Mitral valve repair for degenerative mitral disease may be possible in greater than 90% of cases in experienced hands with excellent results and is recommended (**Class I, Level C**).

Several groups have reported long-term survival outcomes of mitral valve repair in comparison with mitral valve replacement.[41–44] In broad terms, repair provides better survival and clinical outcomes than replacement, but more often than not, patients who undergo mitral valve replacement are sicker. The longest follow-up on mitral valve repair to date shows a freedom from reoperation of 92% at 20 years.[45] At our center, freedom from reoperation ranged from 88% to 96% at 10 years depending on the prolapsing leaflet. Anterior leaflet prolapse or bileaflet prolapse portends worse outcome.[46,47] Results of the edge-to-edge repair in a somewhat younger but similar patient population (with an incomplete follow-up) documented a freedom from reoperation of 96% at 10 years.[48] The superior results obtained in the repair of the mitral valve in myxomatous disease,[46] given the natural history of asymp-

tomatic but severe MR,[49] argues for early surgical intervention (**Class IIa, Level C**). Caution and judgement, however, must be exercised when the mitral valve is affected by rheumatic disease, if MR is caused by complex valvular abnormalities that include anterior leaflet prolapse, or if the surgical team has inadequate experience with valve repair.

Endocarditis

Mitral valve replacement had been the standard surgical therapy for patients with mitral valve endocarditis but repair is feasible depending on the degree of tissue destruction.[50–52] A recent pooled analysis of the reported series demonstrated low rates of early and late repeat mitral valve surgery after mitral valve repair for endocarditis.[53] The principles of mitral valve repair in endocarditis are to remove all infected tissue and to avoid implantation of foreign material. Autologous pericardium, which may be fixed with glutaraldehyde, or bovine pericardium can be used in place of prosthetic annuloplasty rings.

Ischemic mitral regurtitation (IMR)

The role of mitral valve replacement versus repair in chronic IMR is controversial.[54] Mitral replacement is typically reserved for patients with higher preoperative risk factors and co-morbidity at experienced centers.[55–57] Although the results of mitral valve repair appear to be superior to mitral valve replacements in early follow-up, these differences disappear and possibly reverse in longer follow-up.[55–57] This suggests that mitral valve replacement may be the procedure of choice at centers that have limited experience with mitral valve repair (**Class IIa, Level C**).

The most common technique of mitral valve repair for IMR is undersized annuloplasty. Considering the asymmetric alteration in the mitral valve annulus, some advocate the use of a rigid and geometric ring that reduces the septal-lateral annular dimension in particular in the posteromedial segment.[58] Clinical outcomes do not support the use of a complete over a partial ring[59] but given that the intertrigonal region dilates over time, it is reasonable to suggest that complete rings are likely to provide better long-term durability.[60,61] Most support the use of a rigid ring,[62] although concerns that rigid ring annuloplasty may adversely affect LV function remain.[63,64] The long-term result of mitral repair for IMR is poor with return of significant MR in nearly 30% of patients.[59] Perhaps an undersized annuloplasty does not fully address the multifaceted alterations in the mitral apparatus of a patient with IMR.[24] We have clinically introduced Levine's concept of severing secondary chordae tendineae.[65,66] Our initial results are encouraging.[65]

Non-ischemic mitral regurgitation

The principal repair techniques are undersized annuloplasty and the edge-to-edge repair. Correction of severe

MR in end-stage heart failure is safe.[67,68] In spite of symptomatic benefit, no survival benefit is currently apparent.[69,70] Importantly, the Acorn clinical trial confirmed the impact of MR repair alone on patient symptoms and also documented progressive decline in left ventricular volume in a randomized trial setting[71] (**Class IIa, Level B**). The results of the edge-to-edge technique in patients with LV dysfunction have been somewhat mixed.[72,73]

Tricuspid valve repair

Commonly, tricuspid regurgitation (TR) occurs as a result of left heart pathology. In these instances, the tricuspid apparatus is normal, but dilation of the tricuspid annulus results in significant regurgitation. Organic tricuspid valve disease is less common. Functional TR may be repaired by suture annuloplasty (De Vega procedure) or by ring annuloplasty. Ring annuloplasty provides superior long-term outcomes[74–76] (**Class IIa, Level C**). Plication of the posterior leaflet (bicuspidalization) is now rarely performed.[77]

Valve replacement

Types of heart valves

The two main categories of valves are mechanical and tissue valves. Within the former category, three principal valve types are available: caged-ball valves, single tilting disc valves, and bileaflet valves. Tissue valves may also be divided in to three major subtypes: xenografts, homografts, and pulmonary autograft. Xenograft valves are either porcine aortic valves or constructed pericardial valves. Xenograft valves can also be subdivided into stented and stentless.

Randomized clinical trials: mechanical versus biologic

Two randomized clinical trials have compared the outcome of aortic and mitral valve replacement. The Edinburgh Heart Valve Trial[78–80] enrolled patients between 1975 and 1979 and the Department of Veterans Affairs Trial[81–83] enrolled patients between 1977 and 1982. Both of these trials compared the Bjork–Shiley tilting disk valve to the first-generation Hancock or Carpentier–Edwards porcine valve. Although these valves are no longer used in North America, certain principles of valve behavior may be distilled from these two trials.

Edinburgh Heart Valve Trial
In this study, a total of 541 men and women undergoing either aortic or mitral valve replacement were included. The major finding of this trial was the lack of survival

benefit for a particular valve type at 20 years. Porcine valves had a substantially higher structural valve deterioration and reoperation rate. Bioprosthesis had structural valve deterioration 12–14 years after implantation in the aortic position and 8–10 years after implantation in the mitral position. The bleeding rates were substantially higher with the mechanical valves, implanted in the aortic but not in the mitral position.

Department of Veterans Affairs Trial
This multicenter trial enrolled a total of 575 men only. It showed that patients randomized to receive a mechanical valve had improved survival after aortic valve replacement (AVR) but not after mitral valve replacement (MVR). Importantly, differences in mortality started to diverge after 10 years. As with the Edinburgh trial, porcine valves had substantially higher primary valve failure. The outcome in the two groups at 15 years is summarized in Table 58.1.

Differences between the trials
In the Edinburgh trial, the linearized rates of major hemorrhage requiring hospital admission and/or blood transfusions were 1.5% per year in the porcine group and 2% per year in the mechanical valve group. In the VA trial the linearized bleeding rates were 2.5% per year in the porcine group and 4.3% in the mechanical group. Higher intensity of anticoagulation in the USA likely accounts for this difference.[84] In the contemporary data from the Stroke Prevention in Atrial Fibrillation III[85] trial with international normalized ratio (INR) of 2.0–3.0, the incidence of bleeding was 1.5% per year. The linearized rates of thromboembolism were not different between the two types of valve.

New developments in valve prostheses

Since the above two trials were concluded, other single-center or multi-center but non-randomized studies have been published documenting the performance of newer biologic and mechanical prostheses in terms of structural valve deterioration[86–98] (Fig. 58.1) and patient survival.[90,99–109] These are reviewed in Table 58.2 and Table 58.3. Most biologic valves are now treated with anticalcification agents, undergo zero-pressure fixation, have a lower profile, and are hemodynamically superior to the older valves. These advances have generally meant longer durability of the bioprosthetic valves. At the same time, new mechanical valve designs such as the bileaflet design have improved the hemodynamic performance. By and large, the majority of the valves that have received FDA approval based on 800 patient-years of experience are similar in terms of valve function and valve durability (see Fig. 58.1) and risk of complications (Fig. 58.2). Leaders in the field have generalized the comparison of the various valves by

Table 58.1 Probability of an outcome event at 15 years after valve replacement

	Aortic valve replacement		P-value	Mitral valve replacement		P-value

concluding that patient-related factors are more important than valve-related factors.[110,111]

Stentless xenograft valves

Conventional porcine and bovine pericardial valves, which are mounted on a stent, cause some degree of obstruction with persistent gradients that may be clinically important.[112] Stentless xenograft valves were developed to provide superior hemodynamics[113] which may not necessarily be evident at rest.[114] Stentless valve implantation appears to be associated with greater left ventricular mass regression and improved survival.[115,116] Long-term follow-up on the Toronto SPV bioprostheis, however, has demonstrated suboptimal durability with a freedom from reoperation of 69% at 12 years.[117]

Aortic homograft

Aortic valve homograft has been used with satisfactory results since 1962.[118–121] Cryopreservation is the preferred technique of valve preservation during storage[122–124] (see Fig. 58.1). Freedom from reoperation for structural valve deterioration at 15 years of follow-up is age dependent (0–20 years of age, 47%; 21–60 years of age, 80%; >60 years

of age, 94%).[121] Aortic valve homograft is an excellent choice for patients with active valve endocarditis, particularly with aortic root abscess.[121,125–127] Aortic valve homograft may be used as a full root replacement, as a root inclusion or in the subcoronary position. When the homograft is used as a full root replacement, better long-term durability and valve function are obtained, but neo-root dilation may occur in patients with annuloaortic ectasia.[128,129] The recreation of normal aortic root anatomy may be difficult with the subcoronary technique, and emphasizes the importance of surgical expertise.[124] Reoperation on homografts is technically difficult because of extensive calcification.[130]

Pulmonary autograft

Aortic valve homograft has high failure rates in the younger patient. The Ross procedure was developed to overcome this limitation in 1967.[131,132] In the pioneer series, the mean age at time of operation was 32 years and the majority of the patients received the autograft in the subcoronary position and not as a root inclusion or root replacement. Twenty years after operation, survival was 61%, freedom from autograft replacement was 75%, and freedom from replace-

ment of homograft in the pulmonary position was 80%.[133] Others have also reported excellent outcome with this operation.[134–137] A subset of patients developed AI, likely because of technical difficulties of placing the valve in the subcoronary position, as with the experience with aortic valve homograft.[133] Surgeons adopted the root inclusion or the root replacement, because the technique was more reproducible.[138] Stabilization of the aortic annulus and downsizing of the sinotubular junction provide improved results.[138]

Given the superior performance of today's bioprostheses, the lifespan of the patient has to be judged to be greater than 20 years for the patient to derive benefit from the Ross procedure. Relative contraindications to this procedure have been proposed:
- multiple valve disease
- Marfan's syndrome
- variety of autoimmune diseases such as systemic lupus erythematosus, rheumatoid arthritis, acute rheumatic fever, ankylosing spondylysis, Reiter's syndrome, Libman–Sachs endocarditis
- dilated aortic root and/or annulus.[139–141]

ACC/AHA guidelines

The use of biologic prostheses is increasing. The ACC/AHA guidelines documented five principal reasons for this observation:

1 current bioprostheses have longer durability

2 the risk of reoperation has continued to decrease with time

3 patients receiving AVR are now more likely to be older than in the previous era

4 young patients are more reluctant to accept the risks of anticoagulation and the restraints that the therapy places on lifestyle

5 recent non-randomized trials have now suggested an apparent survival benefit for patients receiving bioprosthesis.

The most recent guidelines regarding prosthesis choice for aortic valve replacement (Table 58.4), mitral valve repair (Table 58.5) and mitral valve replacement (Table 58.6) are summarized.

Conclusion

Valve repair, when feasible, remains the best option only in experienced hands. Valve replacement remains quite reproducible from center to center with excellent long-term results and should be, in most instances, the procedure of choice. The currently available biologic valves have very good durability. As a result, there will most likely be a decrease in the age cut-off at which patients are recom-

Table 58.4 Major criteria for valve selection in aortic valve replacement (AVR)

Class of recommendation	Level of evidence
Class I	
A mechanical prosthesis is recommended for AVR in patients with a mechanical valve in the mitral or tricuspid position	C
A bioprosthesis is recommended for AVR in patients of any age who will not take warfarin or who have major medical contraindications to warfarin therapy	C
Class IIa	
Patient preferences is a reasonable consideration in the selection of aortic valve operation and valve prosthesis. A mechanical prosthesis is reasonable for AVR in patients under 65 years of age. A bioprosthesis is reasonable for AVR in patients under 65 years of age who elect to receive this valve for lifestyle considerations after detailed discussion of the risks of anticoagulation versus the likelihood that a second AVR may be necessary in the future	C
A bioprosthesis is reasonable for AVR in patients aged 65 years or older without risk factors for thromboembolism	C
Aortic valve replacement with a homograft is reasonable for patients with active prosthetic valve endocarditis	C
Class IIb	
A bioprosthetic might be considered for AVR in a woman of child-bearing age	C

Table 58.5 Major criteria for mitral valve (MV) repair

Class of recommendation	Level of evidence
Class I	
Degenerative mitral valve disease: MV repair is recommended when anatomically possible for patients who fulfill clinical indications, only by surgeons who are experts in mitral valve repair	C
Rheumatic mitral valve disease: percutaneous or surgical commissurotomy is indicated when anatomically possible for treatment of severe mitral valve stenosis, when clinically indicated	C
Class IIa	
Functional mitral valve regurgitation: MV repair is recommended in patients who fulfill clinical indications, only by surgeons who are experts in mitral valve repair, and only in patients who are clinically stable	C

Table 58.6 Major criteria for mitral valve (MV) replacement

Class of recommendation	Level of evidence
Class I	
A bioprosthesis is indicated for MV replacement in a patient who will not take warfarin, or has a clear contraindication to warfarin therapy	C
Class IIa	
A mechanical prosthesis is reasonable for MV replacement in patients under 65 years of age with long-standing atrial fibrillation	C
A bioprosthesis is reasonable for MV replacement in patients 65 years of age or older	C
A bioprosthesis is reasonable for MV replacement in patients under 65 years of age in sinus rhythm who elect to receive this valve for lifestyle considerations after detailed discussions of the risks of anticoagulation versus the likelihood that a second MV replacement may be necessary in the future	C

mended to have a biologic valve substitute. The pulmonary autograft and the homograft will continue to occupy a specialized niche, but will not become routine given the inherent complexity of the procedures. Stentless valves and biologic aortic roots are increasingly used, but the long-term data on their durability remain to be seen. Valve surgery is rapidly evolving and new technologies now allow implantation of a bioprosthetic valve in a stent using catheter-based techniques or transapical approach. Simplified mitral valve repair with percutaneous edge-to-edge techniques or annular cinching is under clinical trials. There is no evidence to allow proper evaluation of these new techniques. Although these procedures may be widely used in the future, they have not been discussed here. Advances in tissue-engineering techniques may finally allow the manufacture of the perfect living valve prosthesis.

59 Infective endocarditis

Zainab Samad and Andrew Wang
Duke University Medical Center, Durham, NC, USA

Introduction and historical perspective

Infective endocarditis (IE) is a non-contagious, microbial infection of the valves and endocardium of the heart. The disease was first described by a French physician, Jean Francois Fernel, in his book *Medicina* in 1554.[1] Almost 300 years later, in 1885, Sir William Osler gave a comprehensive account of endocarditis in three Gulstonian lectures.[2] Osler astutely noted the host factors which predisposed to developing endocarditis, describing it "*as a primary disease of the lining membrane of the heart or its valves, either attacking persons in previous good health or more often attacking the debilitated and dissipated and those with old valve lesions.*"

Nomenclature

Initially known as bacterial endocarditis, infective endocarditis (IE) is the current nomenclature used since fungi are recognized as potential causative organisms.[3] Infection of arteriovenous shunts, arterio-arterial shunts (such as patent ductus arteriosus), and coarctation of the aorta, although known as infectious endarteritis, are clinically and pathologically similar to infective endocarditis. Endocarditis is classified as acute or subacute based on the rapidity of progression and presentation of the illness prior to diagnosis, factors related to both the virulence of the causative organism and host immune response. Acute endocarditis develops over days to weeks with marked toxicity and a course involving valvular destruction, extracardiac complications and, if untreated, death. In contrast, subacute endocarditis follows an indolent course, progressing slowly over weeks to months, causing less severe valvular destruction and rarely metastatic infection or extracardiac complications.[4] Native valve endocarditis involves any of the four native cardiac valves, whereas prosthetic valve endocarditis involves a biologic or mechanical valve replacement or prosthetic repair material (e.g. annuloplasty ring). Prosthetic valve endocarditis is further classified into early (within 12 months of valve replacement) and late (greater than 12 months after implantation). Nosocomial endocarditis is defined as developing in a patient hospitalized for more than 48 hours before the onset of signs or symptoms consistent with endocarditis. Cardiac device infection refers to an infection of an intracardiac device such as a permanent pacemaker or implantable cardioverter-defibrillator, the infection of which may also be associated with IE.

Incidence and epidemiology

The incidence of IE varies regionally from 2.6/100 000 population reported in France[5] to 11.6/100 000 population in Philadelphia.[6] This range of incidence has been attributed to differences in predisposing cardiac conditions or risk factors, such as injection drug use. The incidence of native valve endocarditis increases with age and exceeds 14.5–30/100 000 after 30 years of age. The average age of the patient with endocarditis has increased over time, likely related to the decreased prevalence of rheumatic heart disease (the major predisposing cardiac condition in Oslerian times)[7] and increased prevalence of degenerative valvular disease in the aging population. IE is more commonly diagnosed in men, with studies showing male-to-female ratios of 1.7:1.[8]

In earlier eras, streptococcal species were the predominant cause of native valve IE. However, changes in the delivery of healthcare, with increasing exposure to invasive procedures and devices, and the changing demo-
Plate 38.1 Typical lesion set used to perform pulmonary vein isolation. The figure shows an ESI/NavX reconstruct of the left atrium in two views. On the left is an anteroposterior view; on the right is a posteroanterior view. The RF lesion points are represented by the red dots. It can be appreciated that ablation is performed encircling the right- and left-sided veins as two separate units. The ablation points are distant from the ostia of the pulmonary veins, thereby minimizing the risk of pulmonary vein stenosis. The above representation is the usual minimal ablation set in most electrophysiology laboratories; additional ablation may be performed along the posterior LA wall, LA roof, mitral isthmus (from the left inferior pulmonary vein to the mitral valve), along the interatrial septum and also in areas where complex fractionated atrial electrograms are observed.
Plate 38.2 Atypical flutter in a patient following previous RF ablation for atrial fibrillation. An ESI/NavX electroanatomic activation map of the tachycardia in the same patient. This demonstrates activation breaking through the roof of the left atrium, where a region of slow conduction was observed. Ablation at this point terminated the tachycardia.
Plate 38.3 Atypical flutter in a patient following previous RF ablation for atrial fibrillation. Carto electroanatomic activation map of the tachycardia in the same patient. This demonstrates a gap between the right superior PV and a septal scar in gray. Such gaps between an area of scar and an anatomical boundary can facilitate atypical atrial flutter in patients following left atrial ablation.

graphics of patients and their risk factors for endocarditis have led to major changes in the microbiologic causation of endocardits.[9] In the contemporary, multinational study, the International Collaboration on Endocarditis or ICE registry (n = 1179 patients with definite native or prosthetic endocarditis), 32% cases were attributable to *S. aureus*, 18% viridans streptococci, 11% enterococci, 11% coagulase-negative staphylococci, 5% other streptococcal species, 2% non-HACEK gram-negative bacteria, 2% fungi, and 2% HACEK group.[10] Among those with *S. aureus* endocarditis, healthcare-associated infection accounted for 39% of cases.[10]

Similarly, the microbiology of prosthetic valve endocarditis (PVE) has changed. Whereas coagulase-negative staphylococcal infection (such as *S. epidermidis*) was previously the most common causative species, a recent, large study of 556 cases of definite PVE found that *S. aureus* (23.0%) was the predominant cause of infection, with coagulase-negative staphylococci accounting for 16.9%.[11]

Pathogenesis

A pre-existing valvular or endocardial condition, such as mitral valve prolapse with regurgitation, degenerative aortic valve disease (including bicuspid aortic valve) and congenital heart disease, is a major host factor related to development of IE. Endothelial damage and denudation of the endothelium exposes the underlying basement membrane and fosters platelet and fibrin deposition, a process that occurs spontaneously in individuals with valvular heart disease. These deposits are called non-bacterial thrombotic endocarditis and form the nidus for vegetations in the setting of bacteremia. The ability of micro-organisms to adhere to denuded endothelium is another factor related to development of IE. The classic lesion of endocarditis, the vegetation, is thus made up of fibrin, platelets, inflammatory cells and micro-organisms, adherent to the endothelium of the heart (Plate 59.1).

Diagnosis

The diagnosis of endocarditis is dependent on findings of bacteremia with an organism associated with endocarditis and evidence of endocardial involvement. Because these objective findings may not be sought unless the possibility of endocarditis is considered, careful attention to the patient's history and physical examination is critical to the eventual diagnosis. The clinical presentation of IE is highly variable, and can range from chronic fatigue with low-grade fever to acute heart failure due to new, severe valvular regurgitation. While the virulence of the organism can influence acuity of presentation, the onset of infection

in most cases is quickly followed by the onset of symptoms. Most patients with endocarditis develop symptoms within two weeks of bacteremia.[12] In general, four processes contribute to the clinical presentation of endocarditis: (1) infection on the valve, including the local intracardiac complications; (2) septic or aseptic embolization to distant organs; (3) continuous bacteremia, often with metastatic foci of infection; and (4) circulating immune complexes and other immunopathologic factors.[8]

Approximately 85% patients present with fever, although this finding may not be present in immunosuppressed states and in patients who have previously been on antibiotic therapy. Non-specific symptoms such as chills (42–75%), sweats (25%), anorexia (25–55%), weight loss (25–35%), malaise (25–40%), dyspnea (20–40%), and cough (25%) are common. In addition, predisposing conditions or risk factors for the development of endocarditis, including a history of structural heart disease, injection drug use or recent invasive procedure, should be sought in the patient's history.

Evidence of a *new or changing* regurgitant murmur in the presence of fever of undetermined origin should prompt further, objective evaluation for possible endocarditis. Embolic phenomena, a common extracardiac complication of endocarditis, may present with localizing symptoms.[8] The patient should be carefully examined for any peripheral stigmata of endocarditis such as petechiae, splinter hemorrhages, Janeway lesions (10%), Osler nodes (10–25%) and Roth spots. Many of these findings are immune mediated. Although Janeway lesions, Osler nodes, and Roth spots are more specific abnormalities for endocarditis, they may occur in other conditions and their low frequency in cases of proven endocarditis limits their diagnostic utility for this condition.

Laboratory testing

Blood cultures

Blood cultures remain the definitive microbiologic procedure for the diagnosis of IE. Continuous and low-grade bacteremia makes it unnecessary to await fever spikes or chills to obtain blood cultures and the first two blood cultures yield an etiologic agent in 90% of cases.[13] In antibiotic-naïve patients, it is recommended that at least three blood culture sets from separate venepunctures should be obtained over the first 24 hours, which will increase the yield to more than 95% in cases of untreated endocarditis with continuous bacteremia (**Class I, Level A**). Finally, each culture media bottle should be inoculated with at least 10 mL of blood to increase the number of colony-forming units per culture (**Class I, Level B**). The results of blood cultures should be interpreted based on the specific micro-organisms identified as well as the recognized, constant nature of bacteremia in endocarditis.

Other laboratory data, although useful clues, are not diagnostic due to their lack of specificity. Hematologic parameters are often abnormal. A normocytic, normochromic anemia (70–90%), thrombocytopenia (5–15%) and leukocytosis (30%) dominate the peripheral blood picture. The differential cell count is usually normal, but there may be a neutrophil predominance. The erythrocyte sedimentation rate (ESR) and C-reactive protein concentrations are usually elevated.[13] Rheumatoid factor assay is positive in up to half of the cases, especially if the illness is protracted.[14] Urinalysis may demonstrate microscopic hematuria and mild proteinuria. Red blood cell casts and heavy proteinuria can be seen in patients with immune complex glomerulonephritis.[8,13]

Electrocardiography

Although the electrocardiogram lacks sufficient sensitivity and specificity for the diagnosis of endocarditis, electrocardiographic abnormalities commonly occur in patients with endocarditis (26% in one cohort) and are associated with invasive infection and increased in-hospital mortality. The presence of atrioventricular heart block in a patient with IE is diagnostic of the presence of a ring abscess, typically of the aortic valve with invasion posteriorly toward the atrioventricular conduction system. Meine *et al* found that 53% of patients with invasive infection had EKG changes and about a third of the patients with EKG conduction abnormalities died during hospitalization in their cohort of 137 patients with definite endocarditis.[15]

Diagnostic criteria for IE

Diagnostic criteria developed by Petersdorf and Pellitier in 1977[13] and subsequently by Von Reyn in 1981[16] have been replaced by the Duke Criteria, first proposed in 1994,[17] which incorporated echocardiographic findings and isolation of "typical" micro-organisms into the case definitions. Several comparative studies of the Von Reyn and Duke Criteria in various cohorts established the superior sensitivity of the Duke criteria.[18–25] Recent modifications of the Duke criteria have added more specificity to the schema[26] (Table 59.1). In addition to their diagnostic utility in clinical

Table 59.1 The modified Duke Criteria and case definitions of infective endocarditis

Modified Duke Criteria	Case definitions

Major Criteria
Blood culture positive for IE
Typical microbes consistent with IE from 2 separate blood cultures: viridans streptococci, *Strep bovis*, HACEK group, *Staph aureus*, community-acquired enterococci in absence of another focus; or
 	
Micro-organisms consistent with IE from persistently positive blood cultures defined as follows: at least 2 blood cultures drawn >12 h apart or all of three or majority of >4 separate blood cultures
 	
Single positive blood culture for *Coxiella burnetti* or antiphase IgG antibody titer >1:800
 	
Evidence of endocardial involvement
 	
Echo positive for IE defined as follows:
  Oscillating intracardiac mass on valve or supporting structure
  Abscess
  New partial dehiscence of prosthetic valve
 	
New valvular regurgitation
 	
Minor criteria
 	
Predisposition; predisposing heart condition or injection drug use
 	
Fever, temperature > 38 °C
 	
Vascular phenomena, major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhage, and Janeway lesions
 	
Immunologic phenomena; glomerulonephritis, Osler's nodes, Roth's spots, rheumatoid factor
 	
Microbiologic evidence: positive blood cultures but does not meet a major criterion as noted above, or serologic evidence of active infection with organism consistent with causing IE
	Definitive Infective Endocarditis
	Pathologic criteria
	1. Micro-organisms demonstrated by culture or histologic examination of a vegetation, a vegetation that has embolized or an intracardiac abscess specimen; or
	2. Pathologic lesions; vegetation or intracardiac abscess confirmed by histologic examination showing active endocarditis
	
	Clinical criteria
	1. 2 major criteria; or
	2. 1 major and 3 minor criteria; or
	3. 5 minor criteria
	
	Possible Infective Endocarditis
	1. 1 major criterion and 1 minor criterion; or
	2. 3 minor criteria
	
	Rejected
	1. Firm alternative diagnosis explaining evidence of infective endocarditis; or
	2. Resolution of infective endocarditis syndrome with antibiotic therapy for ≤4 days; or
	3. No pathologic evidence of infective endocarditis at surgery or autopsy, with antibiotic therapy for < 4 days; or
	4. Does not meet criteria for possible infective endocarditis, as above

Adapted from Li[8].

care, these criteria provide a common case definition for studies of this condition.

Echocardiography and other cardiac imaging modalities

Echocardiography provides not only non-invasive evidence of endocardial infection that, as described above, is among the major diagnostic criteria for endocarditis, but also important hemodynamic information regarding the presence and severity of valvular regurgitation. It is of fundamental importance in detecting vegetations, visualized as "echogenic distinct masses" from the adjacent valve with "independent motion", from the valve itself (Fig. 59.1).

The diagnostic utility of transthoracic echocardiography (TTE) for suspected IE is highest in patients with intermediate to high likelihood of this disease[27] (e.g. a patient with a new or changed heart murmur and bacteremia). Hence, TTE should be performed in all patients with suspected IE (**Class I, Level A**). However, the diagnostic sensitivity of TTE for the visualization of an intracardiac vegetation or abscess is limited, ranging from 40% to 80%, and thus the diagnosis of endocarditis cannot be "ruled out" on the basis of a negative study.

Transesophageal echocardiography (TEE) has greater spatial resolution than TTE and thus is more sensitive than TTE for the detection of intracardiac vegetations As a result, TEE should be performed in patients with a high likelihood of IE and a negative TTE[28,29] (**Class I, Level A**) (Plate 59.2). Although TTE and TEE have been found to have concordant results in approximately half of patients with suspected endocarditis, TEE results in additional diagnostic information in a high percentage, particularly those with prosthetic valves.[30] Specific subsets of patients

Figure 59.1 TTE parasternal long axis view demonstrating a large vegetation on the ventricular aspect of the anterior mitral valve leaflet extending into the left ventricular outflow tract.

in which TEE should be performed, even as the primary imaging modality (without TTE) include those with prosthetic heart valves and suspected endocarditis (**Class I, Level B**) and those with persistent staphylococcal bacteremia without known source (**Class IIa, Level B**) or nosocomial staphylococcal bacteremia (**Class IIb, Level C**). For instance, TEE has been shown to be a cost-effective method for determining the duration of antibiotic therapy (two weeks vs four weeks) compared to empiric duration in patients with intravascular catheter associated *S. aureus* bacteremia.[31] TEE has a high sensitivity and specificity (87% and 95%, respectively) and therefore should be performed in patients with endocarditis when perivalvular abscess is suspected (**Class I, Level A**).[32]

Cardiac magnetic resonance imaging with contrast appears promising for the detection of perivalvular abscesses, thrombus associated with vegetations, valvular complications and aortocameral fistulas, although temporal resolution may limit its use for detection of vegetation (**Level C**). Cardiac computed tomography has also been used to detect aortic root abscess. However, clinical experience with these techniques in IE patients is limited and their operating characteristics (sensitivity and specificity) in comparison to echocardiography are not well defined.[33–35]

Routine coronary angiography is recommended in patients over age 55 prior to surgery for IE or in those at high risk for coronary artery disease.

Treatment

The management of IE has evolved over the last few decades with improvements in diagnostic capabilities and therapy.[17,32] Rapid diagnosis, early risk stratification, institution of appropriate bactericidal therapy, and prompt recognition and treatment of complications are key elements in a good outcome. Central to the care of these complex patients is the involvement and close collaboration of multiple interdisciplinary teams including the general medicine team, infectious diseases specialists, cardiologists, and cardiothoracic surgeons.

Antibiotic therapy

Antibiotic therapy has improved survival in IE by 70–80%, and has been shown to reduce the incidence of complications of endocarditis. Although the choice of antimicrobial therapy is mainly guided by the infecting organism and its antibiotic susceptibilities, there are three basic tenets of treatment that are aimed at eradicating the infecting organism from vegetations.

First, a prolonged course of antibiotic treatment (4–6ix weeks) is necessary to eradicate infection because bacterial concentration within vegetations is as high as 10^9 to

10^{11}CFU/gram of tissue and organisms deep within vegetations are inaccessible to phagocytic cells[36,37] (**Class I, Level A**). Consensus dictates that the counting of days for recommended duration of treatment should begin on the first day of negative blood cultures in cases where blood cultures had been positive previously (**Class IIa, Level B**). For patients who undergo valve replacement for endocarditis, the postoperative course of antibiotics should be similar to that prescribed for PVE rather than native valve endocarditis. If the excised native valve tissue is culture negative, then the recommended duration of treatment for PVE should be given after subtracting the duration of antibiotics administered prior to valve replacement surgery (**Class IIa, Level C**).[38]

Second, parenteral administration of antibiotic therapy is necessary to achieve adequate drug levels required to eradicate infection (**Class I, Level A**). Parenteral therapy is typically initiated in the hospital setting, and the patient may be transitioned to outpatient parenteral antibiotic therapy for the remaining duration after an initial period of observation to assess for clinical response to therapy (e.g. clearance of bacteremia, absence of complications). Oral therapy for endocarditis has been described in certain situations but is not recommended, particularly for left-sided endocarditis[39,40] (**Class IIb, Level B**).

Third, because of rising antimicrobial resistance amongst organisms, combination therapy typically involving a beta-lactam and aminoglycoside antibiotic is recommended. Combination therapy has been shown to reduce the duration of bacteremia in *S. aureus* endocarditis[41] although this more rapid resolution of bacteremia was not associated with an improved clinical response or outcome. While administering combination therapy, both antibiotics should be given temporally close together so that maximum synergistic killing effect is obtained.[38] In addition, careful monitoring of the dosage and renal function should be performed, as combination therapy has been associated with a higher rate of renal dysfunction.[41]

Initial choice of therapy should be guided by clinical findings and microbiologic evidence. Antibiotic therapy should only be administered after obtaining at least three sets of blood cultures, since a high percentage of "culture-negative" endocarditis may be attributable to prior antibiotic therapy. In uncomplicated cases with a subacute course, treatment can be delayed up to 48 hours till the results of the initial blood cultures are available. In cases complicated by sepsis, valvular dysfunction, conduction disturbances or embolic phenomena, empiric antimicrobial therapy should be initiated after obtaining blood cultures.[42] Clinical efficacy studies support the use of antibiotics regimens described in the American Heart Association (AHA) and European Society of Cardiology (ESC) scientific statements. Specific recommendations of the AHA and ESC for antimicrobial treatment of native and prosthetic valve endocarditis, based on common causative micro-organisms, are shown in Tables 59.2–59.7.[38,42]

Surgical treatment: indications and outcome

Surgical intervention for endocarditis may be performed in either the acute or active phase of infection or after the eradication of infection. Surgery during the active phase is generally considered for those patients in whom the likelihood of cure with antibiotic therapy alone is low or in whom severe complications of endocarditis have occurred or will likely occur. Surgery after eradication of infection is predominantly performed for adverse hemodynamic effects of valvular regurgitation that results from valve damage. In native valve endocarditis, heart failure due to valvular regurgitation, which often develops and progresses rapidly due to ongoing valvular damage and the lack of ventricular adaptation in the acute setting, is a primary indication for urgent surgical intervention (**Class I, Level B**). In the absence of overt heart failure symptoms, hemodynamic evidence of severe regurgitation (such as premature closure of the mitral valve in severe aortic regurgitation or pulmonary hypertension in severe mitral regurgitation) should also prompt surgical intervention since valvular regurgitation, or rarely stenosis, is a mechanical or structural complication of endocarditis that will not improve with antimicrobial therapy alone. For mitral valve regurgitation, surgical repair of the native valve without replacement of the valve with a prosthesis has been reported in a number of case series.[43,44] However, the role of repair has not been evaluated in controlled studies and its feasibility will be limited by the extent of infection and valvular damage as well as the experience of the surgeon. Because embolic complications often involve the central nervous system and may worsen neurologic function after cardiopulmonary bypass, the timing of surgery after a cerebral embolic infarct is controversial. One recent study found that neurologic deterioration did not occur among patients with IE who experienced transient ischemic attacks or asymptomatic emboli, even if surgery was performed acutely (median 9 days after cerebrovascular complication) (**Class IIb, Level C**). Overall mortality as well as neurologic death were independently associated with lower Glasgow Coma Scale, and valve surgery had a survival benefit.[45] Regarding persistent bacteremia as an indication for surgery, it is important to recognize that certain micro-organisms, particularly *S. aureus*, may be associated with prolonged bacteremia (up to 10 days) after initiation of antibiotic therapy. Because of possible difficulty in eradicating infection from prosthetic materials, all cases of prosthetic valve endocarditis should receive surgical consultation. Other indications for surgery are described in Box 59.1.

With valve conservation and improved surgical techniques, the surgical mortality rates have declined over time with recent reported rates in the range of 7–14%.[46,47] The

optimal timing of surgery in the setting of active endocarditis has not been well evaluated. In patients with serious, life-threatening complications of endocarditis, surgery should be performed urgently. A number of case series have shown that surgery in the active phase of endocarditis can be performed with acceptable risk and without an obvious risk of prosthetic valve infection.[48]

An understanding of outcomes with surgical treatment of endocarditis is influenced by the inherent selection bias

---

BOX 59.1 Surgical indications in native valve infective endocarditis

Class I recommendation
- Heart failure (**Level B**)
- Aortic regurgitation or mitral regurgitation with evidence of elevated left ventricular end-diastolic or left atrial pressure (**Level B**)
- Fungal endocarditis or highly resistant organism (left-sided IE with *S. marcescens* and *Pseudomonas* species, persistent infection with blood cultures positive despite 1 week of antibiotic therapy, or 1 or more embolic event during first 2 weeks of therapy (**Level B**)
- Echocardiographic evidence of valve dehiscence, perforation, rupture, fistula or large perivalvular abscess (**Level B**)

Class IIa recommendation
- Recurrent emboli and persistent vegetations despite appropriate antibiotic treatment (**Level B**)

Class IIb recommendation
- Mobile, large(>10 mm) vegetation with or without emboli (**Level C**)

Adapted from Bonow et al.[29]

---

in observational cohorts and the lack of randomized, controlled trials for this therapy. One recent, retrospective study of 513 cases of complicated, left-sided endocarditis found that valve surgery was independently associated with reduced six-month mortality (hazard ratio (HR) 0.40; 95% confidence interval (CI) 0.18–0.91; $P = 0.03$) in propensity-matched subgroups. Patients with moderate to severe heart failure appeared to derive the greatest benefit from surgery, whereas surgical treatment had a neutral effect on mortality for patients without heart failure[49] (Fig. 59.2). Other factors which have been related to a survival benefit from surgery include patients with aortic valve disease and prosthetic endocarditis.[50]

This differential effect of surgery on outcome depending on the presence or absence of complications may simply reflect that surgery confers the greatest clinical benefit or absolute risk reduction for patients at highest risk, but demonstrating a benefit for patients at lower risk is more challenging. Along these lines, when propensity score adjustment is used to assess the effect of surgery on outcome of endocarditis as compared to medical therapy alone, studies have shown differing results, including survival benefit,[49] neutral effect,[51] and poorer survival[52] associated with surgery. These contrasting results likely reflect significant differences in the study cohorts, the clinical variables collected and included in the analyses, statistical methodologies, and the time points for the survival endpoint.

Complications and outcome

In the absence of appropriate therapy, endocarditis typically progresses to the development of various intra- and
Figure 59.2 Kaplan-Meir survival curve relating the effect of congestive heart failure to time to death among propensity-matched patients receiving medical therapy or surgery. (From Vikram *et al*[49] with permission.)

No. at Risk

Medical Therapy	41	24	24	21	21	20	19

extracardiac complications. Heart failure or pulmonary edema is probably the most common complication, occurring in about a third to one half of patients with IE, as well as the most frequent indication for urgent surgery. Heart failure occurs as a result of valvular destruction and ensuing insufficiency or, in rare cases of large vegetations, as a result of valvular stenosis. Heart failure complicates aortic valve endocarditis more frequently than mitral or tricuspid endocarditis and may result in the setting of moderate, rather than severe, regurgitation, particularly in case of involvement of the aortic valve,[53] since the left ventricle is unable to compensate for the acute increase in preload and afterload in this condition.

Medical therapy alone is generally insufficient in managing endocarditis complicated by heart failure, particularly in the setting of severe or progressive valvular regurgitation. Surgery should be prompt and unnecessary delays avoided (**Class III, Level C**).[42]

Paravalvular abscess complicates 30–40% cases of IE[32] and is a result of invasive infection that spreads generally along contiguous tissue planes, particularly with aortic valve infection. In the International Collaboration on Endocarditis (ICE) cohort, 22% cases of definite aortic valve endocarditis were complicated by a periannular abscess. These patients were more likely to have prosthetic valves and coagulase-negative staphylococcal infection. Transesophageal echocardiography is the diagnostic test of choice when an abscess is suspected clinically. An abscess is diagnosed by TEE as the visualization of a "thickened area" or "mass with a heterogeneous echogenic or echolucent appearance".[32] Rarely, antibiotic therapy may be used to treat an intracardiac abscess, though this treatment alone is generally reserved for patients who are poor surgical candidates. The vast majority of patients with an intracardiac abscess require cardiac surgery for debridement (**Class I, Level C**) as evidenced in a recent large study in which 86% of patients with periannular abscess underwent surgery.[54] In addition, surgery represents the gold standard for the diagnosis of abscess.

In rare cases, due to high intravascular pressures and progressive burrowing infection, these perivalvular cavities can form fistulous connections (aorto-atrial or aorto-ventricular), and even myocardial perforation (Plate 59.2). Fistula formation complicated endocarditis in 1.6% cases of native valve endocarditis and 3.5% cases of PVE in a cohort of 4681 cases of IE. These occurred with similar frequency in the three sinuses of Valsalva and among all the cardiac chambers. Despite surgical intervention (87%), the mortality rate in this group of patients was 41%.[54] The development of cavitary fistulas thus heralds a poor outcome and must prompt surgical intervention.

Embolic phenomena frequently complicate the clinical course in endocarditis. Although clinical signs of embolization manifest in approximately one-third of patients with

IE,[55] atleast another third of patients have silent embolism.[56] In the majority of cases, embolic events occur before the initiation of antibiotic therapy, whereas only 7% of events occur after treatment has begun.[57] In a subset of 66 patients with embolic complications among 178 patients with endocarditis, the most frequent sites of embolic events were central nervous system (41%), lungs (18%), spleen (21%), peripheral artery (14%), and kidney (12%).[58]

Factors including vegetation size, mobility, and location as well as the causative organism have been associated with the likelihood of embolic event. Vegetations larger than 10 mm in greatest diameter pose an increased risk of embolization.[57,59] Causative organisms such as *S. aureus* and *Strep. bovis* confer an independent risk of embolization.[60] Also, there is a 2–3 times higher frequency of embolism in endocarditis caused by enterococci, *Abiotrophia* spp, fastidious gram-negative organisms (HACEK) and fungi as compared to streptococci.[61,62] In addition to causing infarction of distal vascular beds, embolic events may result in metastatic sites of infection.

Cerebral embolization occurs in 10–35% and is at times complicated by meningitis, brain abscess or intracerebral hemorrhage. In the ICE cohort, stroke complicated endocarditis in 15% of patients.[63] The risk of stroke dramatically decreases with initiation of antibiotic therapy. Findings from the ICE merged database suggested a 65% reduction in stroke incidence by week two of initiating antimicrobial therapy.[63] Given the low incidence of embolic events after initiation of antibiotic therapy, routine screening for emboli in patients with IE is not recommended (**Class IIb, Level C**). However, patients with persistent fever or bacteremia or localizing symptoms of possible infarction should undergo computed tomographic imaging with radiographic contrast for the diagnosis of embolic complications.

Embolic events have been found to be an independent predictor of in-hospital death in endocarditis.[64] In patients who experience recurrent embolic events, particularly if occurring after initiation of antibiotic therapy, surgical treatment is indicated (**Class IIa, Level C**). For the prevention of embolic events, surgery may be considered for patients with endocarditis who have large (greater than 10 mm), mobile vegetations, especially with involvement of left-sided heart valves (**Class IIb, Level C**).

The issue of anticoagulation in patients with endocarditis remains controversial. There is no demonstrable benefit of anticoagulation in native valve endocarditis. In patients with PVE, continuation of oral anticoagulation or switching to intravenous heparin has been advocated by some experts, while others have recommended discontinuation of all anticoagulation in patients with *S. aureus* endocarditis and recent stroke until completion of two weeks of antibiotic therapy,[65] presumably to avoid hemorrhagic transformation.[66] Regarding antiplatelet therapy with aspirin, no

beneficial effect on outcome has been found, and aspirin therapy has been associated with a higher risk of bleeding complications in IE (**Class III, Level A**).[67,68]

Mortality in native valve endocarditis

The six-month mortality estimate from various reports is approximately 27%.[69,70] Such unacceptably high mortality rates despite therapeutic and diagnostic advances have lead many investigators to risk stratify patients with endocarditis. Amongst host factors, age, female sex, presence of diabetes mellitus, APACHE II score, elevated white blood cell count, serum creatinine level >2 mg/dL, and lower serum albumin have been associated with poor outcomes. Moderate to severe congestive heart failure, periannular abscess formation, vegetation length >10 mm, absence of surgical therapy, and infection with virulent organisms, particularly *S. aureus*, are disease factors related to embolic events and death.[57,64,69,71,72]

Mortality in prosthetic valve endocarditis

Medical progress has similarly allowed the in-hospital mortality rates of PVE to fall from 50–60% in earlier series[73] to approximately 23% as reported in a recent large, multi-national study.[11] Studies have found that long-term survival after the active phase of infection is similar for early and late PVE (74% and 82% survival at four-year follow-up).[74]

Heart failure severity was the only predictor of death among 66 patients with PVE, in the Veterans Affairs Co-operative Study on Valvular Heart Disease.[75] More recently, results of the International Collaboration on Endocarditis-Prospective Cohort Study (ICE-PCS) confirmed that complications of heart failure, persistent bacteremia, abscess, and stroke are important, independent prognostic factors in PVE. In addition, older age, healthcare-associated infection and *S. aureus* infection were factors associated with a higher mortality.[11] Recent guidelines support the use of surgery for PVE associated with these complications.[29]

Prevention

Over the past few decades, the efficacy of antimicrobial prophylaxis in preventing IE has been questioned. Recently, after an extensive review of all available literature and consensus of experts, the American Heart Association published updated guidelines for IE prophylaxis.[76] These guidelines have concluded that endocarditis was more likely to result from bacteremia associated with daily activities than with a dental procedure. Antibiotic prophylaxis, even if 100% effective, is estimated to prevent only an extremely small number of cases of endocarditis. These

---

> **BOX 59.2** Conditions warranting antimicrobial prophylaxis
>
> - Prosthetic cardiac valve or prosthetic device used for valve repair
> - History of endocarditis
> - Unrepaired cyanotic CHD, including palliative shunts and conduits
> - Repaired CHD with prosthetic materiel (whether placed surgically or catheter based) in the first six months following the procedure
> - Repaired CHD with residual defect at the site or adjacent to site of prosthetic material
> - Cardiac transplant recipients who develop valvulopathy
>
> Adapted from Wilson *et al.*[76]

recommendations surmised that antibiotic prophylaxis should not be prescribed solely on the basis of an increased life-time risk of endocarditis but on the basis of cardiac conditions associated with highest risk of an adverse outcome from endocarditis.[76]

Conditions that warrant IE prophylaxis prior to dental procedures, and procedures on respiratory tract, skin and musculoskeletal structures are listed in Box 59.2 (**Class I, Level C**). The American Heart Association no longer recommends prophylaxis before gastrointestinal or genitourinary procedures solely for the prevention of IE.[76]

60 Antithrombotic therapy after heart valve replacement

Jack C J Sun and John W Eikelboom
McMaster University, Hamilton, Ontario, Canada

Introduction and historical perspective

Valvular heart disease affects more than 100 million patients worldwide and is a growing problem because of the increasing survival of patients with rheumatic heart disease in the developing world and the growing burden of degenerative valve disease in the aging population.[1–2] Prosthetic valve replacement is the only definitive treatment for valvular heart disease and is performed in about 100 000 patients each year in North America.[3] Thromboembolism is one of the most important complications of prosthetic heart valves and although the thrombogenicity of newer valves is less than with older valves, all patients undergoing valve replacement surgery require antithrombotic therapy.

This chapter reviews the evidence for antithrombotic therapy in patients with prosthetic heart valves and makes treatment recommendations based on the strength and quality of the evidence. The class of evidence reflects opinion about the usefulness of the treatment, and balances the positive effects of treatment against the negative effects on patient-important outcomes. Class I recommendations are strong and indicate that the benefits of the treatment outweigh the risks. Class II recommendations are weak and suggest that there are differences between patients in the balance of the benefits and risks of treatment. Class III recommendations indicate that the treatment does not have any benefits or that the risks outweigh the benefits. The level of evidence reflects the quality of the evidence. Level A is high-quality evidence from well-conducted randomized controlled trials or meta-analyses of well-conducted randomized trials with clear results. Level B is evidence from randomized trials or overviews of randomized trials that have significant limitations. Level C1 is evidence from high-quality and persuasive cohort studies, case–control studies or case series while Level C2 is lower quality evidence from non-randomized studies or opinions of experts.

Nomenclature and definitions

Mechanical valves

Mechanical heart valves comprise three major components: an occluder (closure mechanism), housing and sewing ring.[4] There are three main types of mechanical valves: caged ball, single leaflet/tilting disk and bileaflet valves (Figure 60.1). All mechanical valves have some degree of regurgitant flow that acts as a "washing jet" to prevent thrombus formation on the surfaces of the valve.

Caged-ball valves
The first prosthetic heart valve was the Starr–Edwards caged-ball valve introduced in 1960.[5] The original version of the Starr–Edwards valve had a silicone rubber (Silastic) ball or poppet that freely moved within the confines of a three-strut alloy cage (Fig. 60.1a). Subsequent models had a metal ball and a four-strut cage. The free ball design theoretically prevents thrombus growth from the sewing ring onto the occluder[6] but the ball generates a large wake of stagnant flow that may account for the high risk of thromboembolism associated with caged-ball valves.[7] The Starr–Edwards valve was the "gold standard" against which new mechanical valves were compared for more than 20 years.[8]

Single leaflet/tilting disk valves
Single leaflet/tilting disk valves consist of a major orifice and a minor orifice. The single tilting disk enables central

(d) St Jude Medical bileaflet (courtesy of Sorin Group of Canada Inc.).

flow of blood, which may reduce the risk of thromboembolism compared to the circumferential blood flow of caged-ball valves. Single tilting disk valves appear to be associated with a slightly higher risk of thromboembolism than bileaflet mechanical valves, possibly because they have a region of stagnant blood flow located adjacent to the wall immediately downstream from the minor orifice and because the regurgitant washing jet volume is lower than for bileaflet valves.[7]

The first successful tilting disk valve was the Bjork–Shiley valve introduced in 1969.[9] This valve consists of a single leaflet of pyrolytic carbon held in place by large inflow and small outflow alloy struts encircled by a Teflon sewing ring[6] (Fig. 60.1b). The Bjork–Shiley convexoconcave valve was withdrawn in 1986 because of several cases of strut fracture and embolization of the disk.[6] Figure 60.1c displays the Medtronic Hall single leaflet/tilting disk valve. Table 60.1 lists other models of single leaflet/tilting disk valves.

Bileaflet valves

The St Jude Medical valve introduced in 1977[10] was the first bileaflet valve and is the single most commonly implanted mechanical valve. Made of pyrolytic carbon coated with graphite, it consists of two leaflets hinged on a ring (Fig 60.1d). Encircling this structure is a sewing ring. The bileaflet valves listed in Table 60.1 have a similar design. Bileaflet valves provide symmetric, relatively non-turbulent, central blood flow.[6]

Bioprosthetic valves

Most bioprosthetic valves are porcine or made from bovine pericardium that is fashioned into valve leaflets. The valves are preserved in glutaraldehyde and mounted on a frame or stent made of metal or plastic covered with fabric that acts as the sewing ring.[11] Bioprosthetic valves mimic native heart valves more closely than mechanical valves because they have unobstructed central flow which provides excel-

lent hemodynamics. The surfaces of bioprosthetic valves also are less thrombogenic than mechanical valves and do not require lifelong anticoagulant therapy. Porcine and pericardial (bovine) valves do not differ importantly in thrombogenicity.

Porcine bioprosthetic valves

Porcine valves are the most widely used bioprosthetic valves.[8] The first commercial porcine valve was the Hancock

valve introduced in 1970. Figure 60.2a displays the Medtronic valve and Figure 60.2b displays a freestyle model consisting of a porcine valve housed within its native aorta. Table 60.1 lists other types of porcine valves.

Bovine pericardial bioprosthetic valves

Bovine pericardial valves have several theoretic advantages over porcine valves. The valve leaflets are larger, which accommodates shrinkage over the life of the valve; leaflet opening is more complete and symmetric, which improves valve hemodynamics; and the collagen content of the valves is higher, which improves valve durability. The Carpentier–Edwards Perimount valve (Fig. 60.2c) is the only pericardial valve presently available in North America. It is unclear whether the theoretic advantages of pericardial over porcine valves translate into improved outcomes for patients. Bovine valves appear to be at least as durable as contemporary porcine valves.[12,13]

Oral anticoagulants

Vitamin K antagonists (VKAs) are the only oral anticoagulants available for clinical use and warfarin is the most widely used VKA in North America. Other VKAs commonly used in Europe include acenocoumarol and phenprocoumon. VKAs are challenging to use in clinical practice because they have a slow onset and offset, narrow therapeutic window, and variable dose response and are subject to numerous food and drug interactions.[14] Thus close laboratory monitoring of the anticoagulant effect of VKAs is required. The international normalized ratio (INR) is a standardized method of reporting the intensity of anticoagulant therapy with VKAs adopted in 1982.[15,16] Studies completed prior to 1982 often reported anticoagulant intensity based on the ratio of the patient's plasma value to that of plasma from a healthy control and it is difficult to compare these results with subsequent studies that reported anticoagulant intensity based on the INR.

Starting dose of VKA for patients requiring oral anticoagulant therapy

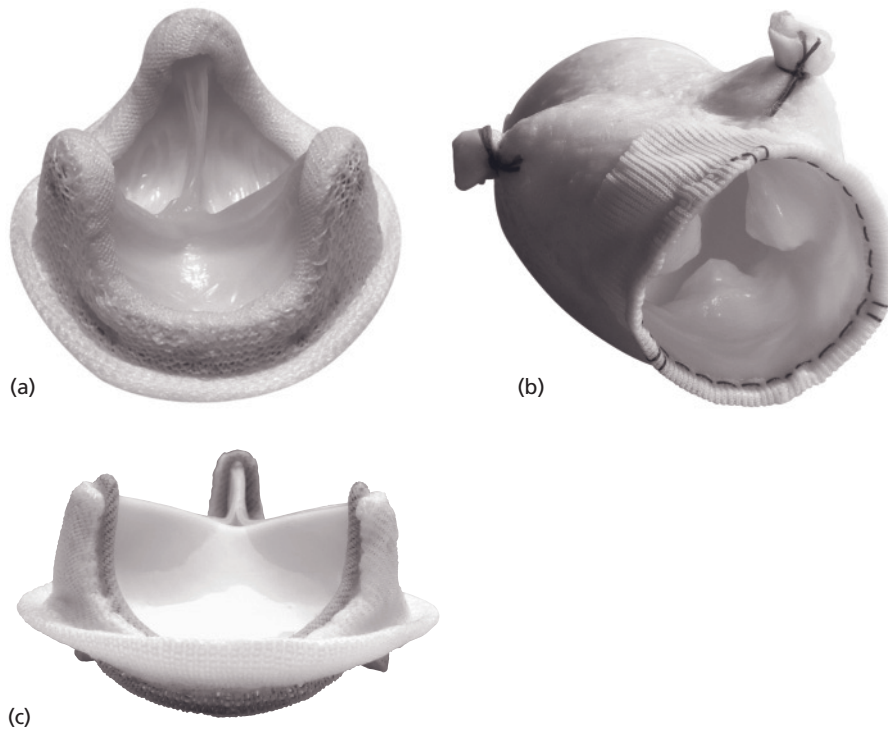
One randomized trial has studied the optimal starting dose of VKA for patients who have undergone valve replacement. Ageno *et al* randomized, in an open-label fashion, 197 patients after heart valve replacement to an initial 2.5 mg (n = 84) versus 5 mg dose of warfarin (n = 113).[17] The INR was measured daily and the dose of warfarin was adjusted according to the result of the INR in the 5 mg starting dose group. The dose of warfarin was not modified in the 2.5 mg group until day 3 and then only if the INR was less than 1.5 or greater than 3.0. The primary outcome of the study was the proportion of patients with an INR of >2.6 within 6 days of surgery. A greater percentage of patients in the 5 mg than the 2.5 mg group had an INR level


Figure 60.2 Different models of bioprosthetic valves. (a) Medtronic HK II Ultra porcine. (b) Medtronic Freestyle porcine (©Medtronic Inc. Printed with permission.). (c) Carpentier–Edwards Perimount bovine pericardial (courtesy of Edwards Lifesciences LLC, Irvine, California).

>2.6 within 6 days of surgery (42% v 26%, $P < 0.05$). There was no difference in the rate of bleeding between the two groups although the study was not powered for clinical outcomes (Level A).

Incidence, natural history and prognosis

Thromboembolism after mechanical valve replacement without antithrombotic therapy

Information concerning the risk of thromboembolism after mechanical valve replacement in patients not treated with anticoagulants primarily comes from small case series of patients who had a contraindication to VKAs. Cannegieter and colleagues performed a systematic review in which they examined the risk of thromboembolism and bleeding in patients with mechanical heart valves.[18] Included in the review were seven studies involving 460 patients who did not receive oral anticoagulant therapy. During 1225 patient-years of follow-up the rates of thromboembolism per 100 patient-years were (95% confidence intervals (CI) in parentheses): valve thrombosis 1.8 (0.9–3.0), major embolism 4.0 (2.9–5.2), total embolism 8.6 (7.0–10.4). The risk thromboembolism was reduced by more than 75% in a parallel group of patients who received VKA therapy (**Level C1**).

Thromboembolism after bioprosthetic valve replacement

The largest study of thromboembolism risk after bioprosthetic valve replacement is by Heras and colleagues who followed 816 patients with aortic, mitral or combined aortic and mitral bioprosthetic valves for a median of 8.6 years.[19] The rate of thromboembolism during the first 10 days among patients who did not receive any antithrombotic therapy was approximately 50% for aortic valves and 60% for mitral valves. Patients who were commenced immediately postoperatively on VKA therapy had higher rates of thromboembolism during the first 10 days (aortic 41%, mitral 55%) compared with between day 11 and 30 (aortic 3.6%, mitral 10%) and after day 30 (aortic 1.9% per year, mitral 2.4% per year) (**Level C2**). The unexpectedly high rate of early thromboembolism in the study by Heras and colleagues is unexplained and is inconsistent with other reports. Multiple small cases series of patients with bioprosthetic valves have reported thromboembolism rates of between 0.7% and 2.8% per patient-year during long-term follow-up ranging from 18 months to 6 years.[20–21,22,23,24,25,26] Most patients in the latter studies received oral anticoagulants, antiplatelet therapy or a combination of anticoagulants and antiplatelet therapy for 2–3 months after surgery (**Level C2**).

Pathophysiology

Factors that contribute to the thrombogenicity of prosthetic heart valves include altered blood flow and hemostatic activation caused by endothelial injury during surgery or exposure of artificial surfaces (sutures, sewing ring, occluder and valve housing) to the circulating blood.[27] Because almost all prosthetic valves are stented, they have a smaller effective orifice area than the native valve that results in a transvalvular flow gradient. Stagnant flow may also result from growth of endocardial tissue (pannus) into the leaflets or valve mechanism. Endothelialization of foreign surfaces occurs over a period of about 3 months after which the risk of thrombosis decreases.[21]

Antithrombotic therapy

In this section, we review the evidence for the benefits and risks of antithrombotic therapy in patients with prosthetic heart valves and make recommendations based on the usefulness of the treatment and the quality of the evidence. We focus on the results of high-quality studies (randomized controlled trials and meta-analyses of randomized controlled trials) whenever available and consider lower quality studies only when there are no high-quality studies.

Mechanical valves

Acute

Possible approaches to antithrombotic therapy immediately after mechanical heart valve replacement include aspirin, oral VKA therapy with or without initial "bridging" unfractionated heparin (UFH) or low molecular weight heparin (LMWH) therapy, or aspirin in combination with oral VKA therapy.

Oral VKA therapy There are no randomized trials comparing oral anticoagulation to placebo (or no anticoagulation) in the immediate postoperative period. A systematic review by Kulik *et al* of primarily observational studies comparing different initial anticoagulation strategies involving 3056 patients who received VKA therapy immediately after surgery[28] revealed an absolute rate of thromboembolism of 0.9% and a bleeding rate of 3.3% during the first 30 days (**Level C1**).

Oral VKA + LMWH There are no randomized trials comparing VKA plus LMWH to VKA alone in patients with a mechanical heart valve. A prospective observational "before-and-after" study by Talwar and colleagues compared initial LMWH plus oral VKA therapy to VKA therapy alone in 538 patients.[29] Group A (n = 245) consisted of con-

secutive patients undergoing mechanical valve replacement over a 2-year period who were started on VKAs on postoperative day 1. Group B (n = 293) consisted of consecutive patients undergoing mechanical valve replacement over a subsequent 2-year period who received enoxaparin 1 mg/kg started 6 hours after surgery, repeated every 12 hours, in combination with VKA therapy (started day one) and continued until the INR was therapeutic. The target INR was 2.5 (range 2.5–3.5) for patients with a mitral valve replacement (MVR) or multiple mechanical valves and 2.0 (range 2.0–3.0) for patients with an aortic valve replacement (AVR). All patients received aspirin 150 mg daily and were followed for 6 months. The incidence of prosthetic valve thrombosis (PVT) was significantly lower in patients who received enoxaparin compared with those who did not receive enoxaparin (6.1% v 2.0%, *P* = 0.01) and there was no significant difference in bleeding (**Level C1**).

Three observational studies reviewed by Kulik and colleagues involving a total of 168 patients who received oral anticoagulation in combination with LMWH showed a rate of thromboembolism of 0.6% and bleeding 4.8% during the first 30 days after surgery[30] (**Level C2**).

Oral VKA therapy + UFH There have been no randomized trials comparing the combination of VKA therapy and UFH with VKA therapy alone in patients with a mechanical heart valve. Kulik *et al* reviewed seven observational studies involving 2535 patients who received oral anticoagulation and intravenous UFH postoperatively and reported thromboembolism rates of 1.1% and bleeding 7.2% during the first 30 days.[30] Bleeding data were available from only two studies (n = 261) (**Level C2**).

Oral VKA therapy + UFH versus oral VKA therapy + LMWH There have been no randomized comparisons between UFH and LMWH for immediate postoperative anticoagulation in patients with mechanical heart valves receiving VKA therapy but UFH and LMWH have been compared in observational studies.

Montalescot and colleagues studied 208 consecutive patients undergoing mechanical heart valve replacement.[30] The first 106 patients were treated with intravenous UFH as soon as postoperative chest tube drainage had decreased to acceptable levels (approximately 2 days after surgery) and were switched from intravenous to subcutaneous UFH three times daily in conjunction with oral VKAs starting on postoperative day 6. The target activated partial thromboplastin time (APTT) was 1.5–2.5 times control for both intravenous and subcutaneous heparin therapies. The next 102 patients were treated with LMWH (enoxaparin or nadroparin) immediately after surgery and were started on oral VKAs on postoperative day 6. LMWH doses were titrated according to anti-Xa levels (target 0.5–1.0 IU/mL). In both groups, intravenous or subcutaneous anticoagula-

tion was discontinued once the INR was therapeutic. One patient treated with UFH suffered a TIA while there were no thromboembolic events in the LMWH group. There were two major bleeds in each treatment group (**Level C2**).

Fanikos and colleagues compared 29 patients receiving postoperative LMWH to 34 retrospectively matched patients who had received UFH.[31] In both groups treatment was continued until the INR was therapeutic. One patient in the LMWH group and four in the UFH group died within 90 days of discharge. There were two (6%) thromboembolic events in the UFH group and none in the LMWH group. Three patients in each group experienced major bleeding (**Level C2**).

Long-term
Possible approaches to long-term antithrombotic therapy after mechanical heart valve replacement include antiplatelet therapy alone, oral VKA therapy alone or antiplatelet therapy in combination with oral VKA therapy.

Oral VKA alone There have been no randomized studies comparing the VKA therapy with placebo or no VKA therapy in patients with mechanical prosthetic heart valves. However, there is a widespread belief that lifelong anticoagulation is necessary, based on the inherent thrombogenicity of mechanical valves and the results of studies of the natural history of thromboembolism in patients with mechanical valves who did not receive anticoagulation (see Incidence, natural history and prognosis above) (**Level C2**).

Oral VKA versus antiplatelet therapy Only one randomized trial has compared oral VKA therapy to antiplatelet therapy for the long-term management of patients with mechanical heart valves. Mok *et al*[32] treated patients with either Starr–Edwards or Bjork–Shiley valves with warfarin (target INR range 1.8–2.5) for the first 6 months after surgery. After 6 months, patients were randomized to continue warfarin (n = 97) or to switch to dipyridamole-aspirin (dipyridamole 75 mg twice daily and aspirin 650 mg once daily) (n = 81) or pentoxifylline-aspirin (pentoxifylline 400 mg twice daily and aspirin 650 mg daily) (n = 76). Follow-up was continued for a mean of 24 months in the warfarin group and approximately 18 months in each of the antiplatelet groups.

The incidence of thromboembolism was significantly lower in the warfarin group compared to the dipyridamole-aspirin and pentoxifylline-aspirin groups (4.1% v 13.6% v 10.5% respectively, *P* < 0.05). Rates of bleeding were higher in the warfarin group compared to the dipyridamole-aspirin and pentoxifylline-aspirin groups (5.2% v 0% v 1.3% respectively) (**Level B**).

Optimal intensity of anticoagulation In 1995 Cannegieter and colleagues published the results of a cohort study in which they examined the relationship between thromboembo-

lism, bleeding, anticoagulant intensity and type of mechanical valve.[33] The study included retrospective and prospective data on 1608 patients with mechanical prosthetic valves treated with oral VKA therapy who were monitored by regional anticoagulation clinics. The target INR was 3.6–4.8 and patients were followed for up to 6 years. The number of thromboembolic events and major bleeding episodes were recorded as well as the most recent INR prior to the event (to a maximum of 8 days before). The study included patients with mechanical aortic (59.8%), mitral (30.2%), and combined aortic and mitral (9.8%) valves. Valve types included tilting disk (76.7%), bileaflet (19.6%), and caged-ball or caged-disk valves (3.0%). Follow-up was 6475 patient-years and 123 254 INR measurements. INRs were within the target range 61% of the time, below therapeutic range 31% of the time, and above therapeutic range 8% of the time.

The lowest rates of bleeding and thromboembolism occurred when the INR was between 2.5 and 4.9 (2 per 100 patient-years). The incidence of thromboembolic events increased significantly when the INR was below 2.5 and bleeding increased sharply when the INR was greater than 4.9. The rates of thromboembolism were higher for valves in the mitral compared to the aortic position (0.9 and 0.5 per 100 patient-years respectively), and were still higher in patients with two mechanical valves (1.2 per 100 patient-years). Caged-ball and caged-disk valves were the most thrombogenic (2.5 per 100 patient-years), followed by tilting disk valves (0.7 per 100 patient-years) and bileaflet valves (0.5 per 100 patient-years). *P*-values were not reported for the comparisons of thromboembolism rates between valve in the aortic compared with the mitral position or between different valve types (**Level C1**).

Two open-label randomized controlled trials have tested the hypothesis that a lower target INR level is safe and effective for patients with a bileaflet mechanical valve in the aortic position. The AREVA trial[34] randomized 380 patients with a St Jude bileaflet mechanical valve (81%) or Omniscience single leaflet/tilting disk valve (19%) to receive VKA therapy with a target INR range of 2.0–3.0 (n = 188) or 3.0–4.5 (n = 192). Patients were followed for an average of 2.2 years and the majority (96%) had a mechanical aortic valve replacement. Rates of thromboembolism were similar in both groups (5.3% v 4.7%, *P* = 0.78) but those with a lower intensity target INR group had fewer non-major hemorrhages (12.2% v 22.9%, *P* < 0.01) and a non-significant reduction in major hemorrhages (6.9% v 9.9%, *P* = 0.29) (**Level B**).

The GELIA trial[35] randomized 2735 patients 3 months after surgery for a St Jude bileaflet mechanical valve replacement to one of three target INR ranges: 2.0–3.5, 2.5–4.0 or 3.0–4.5. Most patients had a mechanical aortic valve (74%) and there were 6801 patient-years of follow-up. Rates of thromboembolic events and clinically important

bleeding were not significantly different in the three groups. The overall incidence of thromboembolic events for patients with an AVR was 0.53 per patient-year of follow-up and for patients with a MVR was 1.64 per patient-year of follow-up (**Level A**).

A meta-analysis of 35 (mostly observational) studies reported the incidence of thromboembolic and hemorrhagic events in 23 145 patients with mechanical valves and found that patients had significantly fewer thromboembolic events when the target INR was at least 3.0 compared to less than 3.0.[36] Among patients with a mechanical aortic valve, those targeted with higher-intensity VKA therapy had an incidence of valve thrombosis of 0.87 compared with 1.16 per 1000 patient-years in the low-intensity group (relative risk (RR) 0.75, 95% CI 0.50–1.13, $P = 0.13$). The incidence of thromboembolism was 9.83 per 1000 patient-years versus 13.09 per 1000 patient-years favoring the higher intensity therapy (RR 0.75, 95% CI 0.70–0.81, $P < 0.01$) but at the cost of more bleeding (14.89 versus 12.06 per 1000 patient-years, RR 1.23, 95% CI 1.16–1.31, $P < 0.01$). Among patients with a mechanical mitral valve the incidence of adverse events (thromboembolism or bleeding) was 29.76 per 1000 patient-years in the high-intensity group compared with 35.33 per 1000 patient-years in the lower intensity group (RR 0.84, 95% CI 0.79–0.89, $P < 0.001$) (**Level C1**).

Self-monitoring of oral anticoagulation The Early Self-Controlled Anticoagulation Trial (ESCAT I) randomized 600 patients with mechanical heart valves to self-management (n = 305) or conventional management (n = 295) of anticoagulation.[37] The target INR range for all patients was 2.5–4.5. After a mean follow-up period of 38 months, the conventional monitoring group had mean INRs consistently around 2.0 and anticoagulation was frequently subtherapeutic. The self-monitoring group tended to be subtherapeutic for the first 6–8 weeks, but was consistently within the therapeutic range thereafter. Complications leading to hospital admission during the study were significantly lower in the self-monitoring group compared with conventionally monitored patients (9.5% v 15.3%, $P = 0.03$) (**Level B**).

The ESCAT II study randomized 2673 patients with mechanical heart valves to self-monitoring of the INR, targeting a range of 2.5–4.5 (n = 1346) versus 1.8–2.8 for aortic valves or 2.5–3.5 for mitral and combined aortic and mitral valves (n = 1327).[38,39] The majority of the valves were St Jude Medical (49%) or Medtronic Hall (47%) valves and 81% were in the aortic position. Patients were followed for 24 months. The proportion of patients requiring hospital admission was similar between the low- and high-intensity groups (0.19% v 0.37% per patient-year, $P =$ NS) as was the rate of bleeding (1.42% v 1.52% per patient-year, $P =$ NS) (**Level A**).

Oral VKA therapy combined with antiplatelet therapy The results of the three largest randomized studies and a meta-analysis of randomized controlled trials comparing oral VKA therapy versus oral VKA in combination with antiplatelet therapy are summarized below.

Turpie and colleagues randomized 370 patients with a mechanical (76%) or tissue (24%) valve treated with warfarin (target INR range 3.0–4.5) to receive low-dose aspirin (100 mg daily) or placebo for a median of 2.5 years.[40] Patients receiving both aspirin and warfarin experienced less major systemic embolism or death from vascular causes (1.9% v 8.5% per year, relative risk reduction (RRR) 77%, $P < 0.001$) and less all-cause death (2.8% v 7.4%, RRR 63%, $P = 0.01$). There were more bleeding events in the dual therapy group (35% v 22%, relative risk increase (RRI) 55%, $P = 0.02$) but major bleeding was not significantly increased (12.9% v 10.3%, RRI 27%, $P = 0.43$) (**Level A**).

Meschengieser and colleagues randomized 503 patients with a mechanical heart valve to receive low-dose aspirin (100 mg per day) plus low-intensity warfarin (target INR 2.5–3.5) (n = 258) or high-intensity warfarin alone (target INR 3.5–4.5) (n = 245) using an open-label design.[41] Types of valves included single leaflet tilting disk (65%), Starr–Edwards caged ball (26%) and St Jude bileaflet (5%) with the remaining types unknown. During a median follow-up of 23 months, median INRs for both groups were within the respective target INR ranges. Rates of thromboembolism were similar: 2.7% in the combined aspirin and warfarin group and 2.8% in the high-intensity warfarin group ($P = 0.7$). There was an excess of major bleeding in patients receiving combined anticoagulant and antiplatelet therapy (4.5% v 2.3%, $P = 0.11$) but the difference was not statistically significant (**Level B**).

Laffort and colleagues[42] randomized 229 patients with a mechanical St Jude bileaflet valve in the mitral position to receive oral anticoagulation (target INR 2.5–3.5) plus aspirin (200 mg per day) (n = 109) or oral anticoagulation alone (target INR 2.5–3.5) (n = 120) using an open-label design. Transesophageal echocardiogram was performed at 9 days, 5 months, and 1 year. The group receiving combined therapy had significantly fewer thromboembolic events (9% v 25%, $P = 0.004$) and fewer valvular thrombi seen on echocardiogram (5% v 13%, $P = 0.03$), but more major hemorrhage (19.2% v 8.3%, $P = 0.02$) due to an excess number of gastrointestinal bleeds (7% v 0%, $P = 0.003$) (**Level B**).

The Cochrane Collaboration published a systematic review and meta-analysis of 11 studies involving 2428 patients comparing oral anticoagulation plus antiplatelet therapy with anticoagulation alone in patients with prosthetic heart valves in 2003.[43] Studies were eligible for inclusion if they were randomized, followed patients for at least 1 year, and reported thromboembolism, death and major bleeding. The addition of antiplatelet therapy to oral anti-

coagulation reduced thromboembolism (3.8% v 9.0%, odds ratio (OR) 0.39, 95% CI 0.28–0.56, $P < 0.01$) and death (5.2% v 9.0%, OR 0.55, 95% CI 0.40–0.77, $P < 0.01$) but increased major bleeding (8.6% v 5.4%, OR 1.66, 95% CI 1.18–2.34, $P < 0.01$). A subgroup analysis suggested that the mortality benefits of adding aspirin to oral anticoagulation were also evident when the dose of aspirin was lowered to 100 mg daily but that bleeding was not increased with low-dose aspirin[42,43] (**Level A**).

Recommendations

For all patients with a mechanical heart valve we recommend oral anticoagulation with a VKA (**Class I, Level C1**). Oral VKAs should be started immediately after surgery and continued lifelong (**Class I, Level C2**). It is reasonable to "bridge" patients with UFH or LMWH in the immediate postoperative period until INR level reaches the target therapeutic range (**Class IIa, Level C1**). For patients with a mechanical valve in the aortic position we recommend a target INR of 2.5 (range 2.0–3.0) (**Class I, Level A**). For patients with a caged-ball or single leaflet/tilting disk valve in the aortic position it is reasonable to target an INR of 3.0 (range 2.5–3.5) instead of 2.5 (range 2.0–3.0) (**Class IIa, Level C1**). For patients with a mechanical valve in the mitral position we recommend a target INR of 3.0 (range 2.5–3.5) (**Class I, Level B**). We recommend that all patients with a mechanical heart valve receive low-dose aspirin (≤100 mg daily) in combination with a VKA (**Class I, Level A**).

Bioprosthetic valves

Acute

Possible approaches to immediate antithrombotic therapy after bioprosthetic heart valve replacement include aspirin, oral VKA with or without initial "bridging" UFH or LMWH therapy, or aspirin in combination with oral VKA.

Oral VKA There are no randomized studies comparing immediate oral VKA with placebo in patients who have received a bioprosthetic valve.

Blair *et al* performed a retrospective study comparing patients with Carpentier–Edwards Perimount aortic or mitral valve replacements who received either warfarin starting on day 3 or 4 after surgery (n = 103), aspirin alone started on day 1 after surgery (n = 509) or no antithrombotic therapy (n = 136).[44] During a mean follow-up of 7 years the rates of thromboembolism were not significantly different between the warfarin, aspirin, and no therapy groups but rates of bleeding were significantly greater with warfarin (16.7% per patient-year) compared with aspirin or no antithrombotic therapy (3.4% and 3.1% per patient-year respectively)($P = 0.03$). The data on VKA therapy in this study are difficult to interpret because laboratory measure-

ment of the intensity of anticoagulation was not standardized (**Level C2**).

Moinuddeen and colleagues retrospectively studied a cohort of bioprosthetic AVR patients who received immediate postoperative with warfarin (in combination with UFH) (n = 109) or no anticoagulant therapy (n = 76).[45] Warfarin was continued for 3 months. There was no significant difference in death, embolism or bleeding between the two groups (**Level C2**).

Optimal intensity of VKA Turpie and colleagues have performed the only randomized controlled trial comparing different intensities of VKA therapy for patients with bioprosthetic heart valves.[46] Two hundred and ten patients with bioprosthetic valves were randomized to receive warfarin at a target INR range of 2.5–4.0 (n = 108) or 2.0–2.25 (n = 102) using an open-label design. Patients started warfarin after surgery as soon as they were able to tolerate oral medications. The rates of major and minor embolism during 3 months of follow-up were similar in both groups (1.9% v 2.0% for major embolism and 10.2% v 10.8% for minor embolism, *P*-value not reported). There were significantly more bleeds in patients treated with high- compared with low-intensity VKA therapy (13.9% v 5.9%, $P = 0.04$). Different laboratory methods were used to monitor the intensity of VKA therapy in the two groups and it is unclear whether this impacted the results (**Level B**).

Oral VKAs versus antiplatelet therapy Whether patients with bioprosthetic valves should receive initial oral anticoagulation with a VKA or antiplatelet therapy is controversial.[47–48 49] One randomized trial has compared antiplatelet therapy with VKA for the initial antithrombotic management of patients with bioprosthetic heart valves. Aramendi *et al*[50] randomized 191 patients to either antiplatelet therapy with triflusal 600 mg/d (an antiplatelet agent similar to aspirin that irreversibly inhibits cyclo-oxygenase) or acenocoumarol (target INR range 2.0–3.0) using an open-label design. The study included patients with aortic (93.8%) and mitral (5.2%) bioprosthetic valves. Study treatments were started within 48 hours of surgery and were continued for 3 months with follow-up to 180 days. The primary outcome was the composite of thromboembolism, hemorrhage, and valve-related death. There was no significant difference between the treatment groups in the rates of the primary efficacy outcome (hazard ratio (HR) 1.07, $P = 0.57$) or treatment-related bleeding (three versus six events, $P = 0.33$) (**Level B**).

Three prospective observational studies have compared antiplatelet therapy with VKA in patients undergoing bioprosthetic valve replacement. Most patients included in these studies received a bioprosthetic valve in the aortic position and the results may not be generalizable to patients with a bioprosthetic valve in the mitral position.

Aramendi et al[51] treated 162 patients with bioprosthetic valves (34% AVR, 33% MVR), annuloplasty rings (28%), or homografts (3%) with ticlopidine (250 mg twice daily) (n = 122) or warfarin (target INR 2.0–3.0) (n = 40) for 3 months after surgery. After a mean follow-up of 3.2 years, the incidence of thromboembolism was 0.5% per patient-year in the ticlopidine group and 3% per patient-year in the warfarin group (P < 0.01). There was no difference in the incidence of bleeding or overall survival at 5 years. This study had significant limitations and methodologic weaknesses. Patients in the warfarin group had a significantly higher prevalence of preoperative atrial fibrillation (50% v 30%), and 15 patients originally started on ticlopidine therapy were excluded from the study due to intolerance of the drug (**Level C2**).

Gherli et al[52] treated 249 patients undergoing bioprosthetic aortic valve replacement with or without coronary artery bypass grafting (CABG) with aspirin 100 mg daily started on day 2 after surgery (n = 141) or with LMWH started day 1 after surgery and with oral anticoagulation started on day 2 (n = 108). There were no differences in the rates of death, stroke or major bleeding between the two groups (**Level C2**).

Di Marco et al[53] treated 200 patients receiving aortic bioprosthetic valves with aspirin (100 mg daily) (n = 100) or warfarin (target INR 2.0–3.0) (n = 100). An additional 50 patients were randomized to one of the two treatment groups. There was no difference in death, thromboembolism or bleeding between the two treatment groups (**Level C2**).

The results of the above studies are consistent with the findings of multiple small retrospective observational studies and case series suggesting either no benefit of postoperative oral anticoagulation over antiplatelet therapy after bioprosthetic aortic valve replacement[54–55,56] or that antiplatelet therapy is adequate[22,57] (**Level C2**).

Oral VKA therapy + UFH or LMWH There are no studies comparing oral VKA therapy in combination with UFH or LMWH and VKA therapy alone in the immediate postoperative period after bioprosthetic valve replacement surgery.

Long-term

Oral VKA therapy There are no studies comparing short-term with lifelong VKA therapy for patients with bioprosthetic valves. However, observational studies suggest that the risk of thrombosis is low after 3 months[22–28] and its is likely therefore that the risk of bleeding associated with continued VKA therapy will outweigh any benefit (**Level C2**).

Antiplatelet therapy There are no randomized studies comparing long-term antiplatelet versus no antithrombotic therapy after the initial 3-month period following surgery. The only observational study addressing this question was performed by David et al[20] who followed 215 patients with a porcine aortic valve replacement treated with warfarin for the first 3 months. After 3 months, patients either received aspirin at a dose of either 325 mg or 650 mg daily (n = 80) or no antithrombotic therapy at all (n = 135) based on the preference of the attending cardiologist. Patients were followed for a mean of 36 months. Multivariate analysis found that not being on aspirin therapy was significantly associated with an increased risk of thromboembolism (P < 0.01). The incidence of transient ischemic attacks and strokes was lower in the aspirin group compared to the control group (1.3% v 5.2% per patient-year, P < 0.02). Bleeding rates were not reported (**Level C2**).

Recommendations

For all patients with a bioprosthetic heart valve we recommend antithrombotic therapy for the first 3 months after surgery (**Class I, Level C2**). For patients with a bioprosthetic valve in the aortic position it is reasonable to treat with low-dose aspirin (≤100 mg daily) instead of VKA therapy for the first 3 months (**Class IIb, Level C2**). For patients with a bioprosthetic mitral valve replacement we recommend VKA therapy over aspirin (**Class IIa, Level C2**). For patients in whom a decision has been made to treat with oral anticoagulants who have a bioprosthetic valve in the aortic position we recommend a target INR of 2.5 (range 2.0–3.0) and for patients who have a bioprosthetic valve in the mitral position we recommend a target INR of 3.0 (range 2.5–3.5) (**Class IIa, Level C2**). It is reasonable to bridge patients with UFH or LMWH in the immediate postoperative period until INR level reaches the target therapeutic range (**Class IIb, Level C2**). We recommend against continuing oral VKA therapy after the first 3 months unless patients have another indication for anticoagulation (e.g. atrial fibrillation) (**Class III, Level C1**). It is reasonable for patients with bioprosthetic valves to continue life-long aspirin (≤100 mg daily) after the first 3 months (**Class IIb, Level C2**).

Conclusion

Prosthetic heart valves have been in use for almost 50 years and have transformed the management of patients with advanced valvular heart disease. Mechanical and bioprosthetic valves differ in their durability and thrombogenicity: mechanical valves are more durable than bioprosthetic valves but are associated with a higher risk of thromboembolism. Caged-ball valves are more thrombogenic than other types of mechanical valves, valves in the mitral position are associated with higher risk of thromboembolism than valves in the aortic position and the risk of thrombo-

embolism is highest during the first 3 months after prosthetic valve replacement surgery.

Management of acute ischemic stroke

Brian H Buck, Ashfaq Shuaib

Introduction

Epidemiology

Worldwide, stroke is the second most common cause of death after coronary heart disease (CHD)[1] and accounts for 4.38 million deaths annually, with almost three million of those in developing countries. Most strokes are not fatal[2] and consequently mortality data underestimate the true global burden of stroke which is chronic disability.[3] Stroke is the sixth most common cause of disability-adjusted life years (DALYs).[4] More than 80% of strokes occur in the 14% of the population aged 65 and older[5] and 20–25% of individuals will have a stroke if they live until 85 years.[6] Consequently the incidence of stroke and socioeconomic burden is expected to increase globally and particularly in Western countries, where there is expected to be a shift in the age distribution of the population towards older ages. By 2030 stroke is projected to be the fourth most common cause of reduced DALYs.[7]

Estimates of the incidence of stroke come from a number of population-based epidemiologic studies. One of the largest studies to examine the incidence of vascular disease including stroke is the Oxford Vascular Study (OXVASC) in which >91 000 individuals were followed over a three-year period in Oxfordshire, United Kingdom (UK). The rate per 1000 population per year of first-ever incident cerebrovascular events was 2.27 (95% confidence interval

(CI) 2.09–2.45) which was higher than event rates in the coronary and peripheral vascular beds[5] (Table 61.1). Event rates rose steeply with age with 80% of strokes occurring in the 14% of the study population aged 65 and older. Long-term trends in stroke incidence have been reported over a 20-year period in Oxfordshire. The age-specific incidence of stroke has fallen by 40% largely due to increased use of preventive medications and risk factor modifications.[8]

Nomenclature, definitions

Stroke is divided broadly into either ischemic or hemorrhagic types with ischemic strokes accounting for the majority of stroke (>80%).[9] The treatment of these stroke subtypes is dramatically different and as a result, one of the first steps in managing stroke patients is to evaluate them for the presence of hemorrhage. Clinical features of hemorrhagic and ischemic stroke overlap and as a result, the distinction is often made with hyperacute computed tomography (CT) imaging. Specialized magnetic resonance imaging (MRI) sequences are more sensitive than CT to acute and chronic hemorrhage and better at detecting early ischemia and are becoming more commonly used for the early diagnosis of stroke.[10]

Ischemic strokes can be further classified based on clinical findings and the results of investigations into subtypes. The value of identifying stroke subtype is that identifying the most likely mechanism of vessel occlusion helps guide early treatment and subsequent investigations. The Trial of Org 10172 in Acute Stroke Treatment (TOAST) criteria is one of the most widely employed classification systems for ischemic stroke.[11] Ischemic stroke, based on the presumed pathophysiologic mechanism of occlusion, is subdivided into small vessel occlusion ("lacunes"), large artery atherosclerosis (embolus or thrombosis) and cardioembolic. The TOAST criteria also recognize that a proportion of ischemic stroke will remain cryptogenic in etiology or will result

Table 61.1 Incidence of first and recurrent stroke compared to ischemic heart disease and peripheral vascular disease in Oxford Vascular Study population[5]

		Total number*	Rate† (95% CI)
Cerebrovascular events	Ischemic stroke	550	2.01 (1.85–2.19)
	Intracerebral hemorrhage	41	0.15 (0.11–0.20)
	Subarachnoid hemorrhage	27	0.10 (0.07–0.14)
	Transient ischemic attack	300	1.10 (0.98–1.23)
	All events	918	3.36 (3.14–3.58)
Coronary vascular events	Sudden cardiac death	163	0.60 (0.51–0.7)
	STEMI	159	0.58 (0.49–0.68)
	NSTEMI	316	1.16 (1.03–1.29)
	Unstable angina	218	0.80 (0.70–0.91)
	All coronary events	856	3.13 (2.93–3.35)
Peripheral vascular events	All events	188	0.69 (0.59–0.79)

Table 61.2 Acute stroke management strategies of proven benefit (**Level A**)

Intervention	Outcome	RRR	ARR	NNT	Reference
Stroke unit	Death or dependency	9% (4–14%)	5.6%	18	96
Thrombolysis with 3 hours of symptom onset (IV tPA)	Minimal or no disability at 3 months	30%	11–13%	7–9	46
ASA	Recurrent stroke	24%	0.5%	200	74
Decompressive hemicraniectomy for malignant MCA infarct (within 48 hours)	Survival with favorable outcome	68%	51%	2	91

RRR, relative risk reduction; ARR, absolute risk reduction; NNT, numbers needed to treated; IV tPA, intravenous tissue plasminogen activator; ASA, acetylsalicylic acid; MCA, middle cerebral artery.

from some combination of mechanisms or other causes such as dissection or a vasculitis.

There are two subtypes of hemorrhagic stroke: intracerebral hemorrhage (ICH) and subarachnoid hemorrhage (SAH). Primary ICH is more common (about 8% of total strokes) and is most often caused by hypertensive small vessel disease which causes the rupture of small lipohyalinotic aneurysms.[12] SAH accounts for about 5% of strokes and is usually caused by the rupture of saccular aneurysms within the subarachnoid space. The acute management of ICH frequently involves admission to an intensive care unit and management of increased intracranial pressure, a discussion of which is beyond the scope of the current chapter (see American Heart Association guidelines for detailed review[13]). With the exception of a recently reported negative Phase III trial of hemostasis with recombinant activated factor VII,[14] treatments for ICH have not been subjected to large randomized trials. There are no therapies for ICH with Level A evidence and in general, the evidence guiding therapy for ICH is less established. Acute ischemic

stroke treatments with Level A evidence are summarized in Table 61.2.

Acute stroke management

Prehospital management

The treatment of acute ischemic stroke (AIS) is exquisitely time sensitive and the speed and accuracy of evaluating and managing patients are important in optimizing patient outcomes. Based on data extrapolated from experimental studies of ischemic stroke, with each minute that passes there is a loss of 1.9 million neurons.[15] Accordingly, timely reperfusion of ischemic brain is the primary goal of most acute stroke therapies.

The narrow time window for the delivery of reperfusion therapies such as intravenous (IV) recombinant tissue plasminogen activator (tPA) necessitates the development of stroke-specific prehospital algorithms to ensure the timely

transport of patients to hospitals capable of providing acute stroke care. The most time-efficient means for stroke patients to seek medical care is by activating Emergency Medical Services (EMS) by calling 911 or the equivalent "immediate" EMS response phone service. Compared to patients who contact their primary physician or hospital directly, stroke patients who call EMS are more likely to arrive within the three-hour time window.[16] Currently only about half of patients with signs and symptoms of acute stroke will use EMS to first access medical care.[17] The decision to call 911 either by patients or other bystanders is influenced by the knowledge that stroke is a serious and treatable disease.[18] There is evidence that patients transported to hospitals through the activation of emergency stroke pathways receive neurologic attention sooner, more frequently are treated with tPA, and have better outcomes[19] (**Level C1**).

Early recognition of stroke by EMS paramedics helps ensure that patients are provided with appropriate initial stabilization and therapy, and advance notice is provided to the receiving emergency department. Diagnosis of stroke in the prehospital setting can be facilitated by the use of validated prehospital screening tools (**Class I, Level B**) such as the Los Angeles Prehospital Stroke Screen[20] and the Cincinnati Prehospital Stroke Scale.[21] Once a diagnosis of stroke is made, patients with acute symptoms that may eligible for fibrinolytic therapy can then be transported to the closest facility that provides emergency stroke care. In rural areas where long distances prevent timely transport of patients to specialized stroke centers, telestroke systems can facilitate the safe delivery of intravenous tPA administration[22–24] (**Class IIa, Level B**).

Emergency management

The initial management of acute stroke patients most often occurs in the emergency department (ED) of hospitals. A number of conditions can mimic stroke including seizures, tumors, infection, hypoglycemia and other metabolic abnormalities. Stroke mimics are common and 13–31% of patients initially diagnosed with acute stroke in the emergency room have other conditions.[25,26] Early brain imaging of stroke patients is required to help make decisions about the emergency management. A non-contrast enhanced CT (NCCT) scan is recommended to exclude non-vascular causes of neurologic symptoms and identify brain hemorrhage (**Class I, Level A**). NCCT will often show early signs of brain ischemia and identify arterial occlusion; however, the interobserver agreement for these early infarction signs on NCCT is general poor (κ statistic range 0.14–0.78).[27] NCCT (performed within 14 hours of symptom onset) will reveal brain parenchymal abnormalities in up to 94% of ischemic stroke patients[28]; however, the sensitivity decreases at earlier time points. In the first six hours the

sensitivity of NCCT is 66% (range, 20–87%) with a specificity of 87% (range, 56–100%).[27] At under three hours, which is the time window for treatment with intravenous fibrinolytics, the diagnostic sensitivity of NCCT has been reported as low as 7% (range 3–14%).[10]

The sensitivity of MRI with diffusion-weighted susceptibility images (DWI) is greater than NCCT for the detection of acute stroke (83% vs 26%).[10] DWI MRI sequences measure the degree of free diffusion of water molecules. With cerebral ischemia and subsequent cytotoxic edema, water diffusion becomes restricted and will result in abnormal DWI signal[29] that can be seen within minutes of stroke onset.[30] Case–control studies have suggested that the use of MRI with DWI may improve the safety and efficacy outcomes of fibrinolytic therapy[31]; however, at present there is insufficient evidence to recommend the routine use of MRI for the initial management of acute stroke (**Class II, Level C**).

Early infarction signs such as extent of brain parenchymal hypoattenuation, hyperattenuation within the intracranial artery, and swelling in the affected hemisphere increase the risk of poor functional outcome (overall odds ratio (OR) 3.11; 95% CI 2.77–3.49) but do predict response to fibrinolytic therapy.[27] Other than the identification of intracerebral hemorrhage, no finding on NCCT should preclude treatment of AIS patients with tPA within three hours of symptom onset (Class IIb, Level A).

General supportive care

There are few data from clinical trials to guide initial medical care of acute stroke patients. It is generally agreed that ventilatory assistance should be provided to patients with decreased level of consciousness or bulbar dysfunction compromising the airway. Supplemental oxygen should be provided to prevent hypoxia but in general most stroke patients do not need or benefit from routine oxygen supplementation.[32] Furthermore, increasing brain tissue oxygenation with hyperbaric oxygen therapy has been the focus of a Cochrane review and the authors concluded that there was no evidence of clinical benefit.[33]

Fever in the setting of acute stroke has been consistently associated with stroke severity, infarct size and poor neurologic outcomes[34,35] and should be treated with antipyretics such as acetaminophen (**Class I, Level C**). In experimental studies, small elevations in ischemic brain temperature have a large impact on the extent of ischemic neuronal injury.[36] A few small trials have examined whether prophylactic antipyretic use improves clinical outcomes. These studies have shown a small mean decrease in body temperature in treated patients but without any clear benefit on clinical outcomes. There is both experimental and clinical evidence to suggest that more aggressive lowering of body temperature (induced hypothermia) can protect the

brain after cardiac arrest.[37] The value of induced hypothermia in stroke is not yet established but is the focus of ongoing investigations.

Hyperglycemia is commonly detected in acute stroke patients[38] and has been associated with poor outcomes and increased odds of symptomatic intracerebral hemorrhage (OR 1.75 per 100 mg/dL increase in admission glucose, 95% CI 0.61–0.95), independent of fibrinolytic treatment.[39] Hyperglycemia is thought to increase hemorrhage by provoking anaerobic metabolism, lactic acidosis, and free radical production, resulting in membrane lipid peroxidation and cell lysis in ischemic brain tissue.[40] A randomized clinical trial (GIST-UK) of aggressive treatment of hyperglycemia in acute stroke with glucose-potassium-insulin infusions found lower blood pressures and blood glucose in treated patients but no differences in stroke outcomes[41] (**Level A**). In all stroke patients, monitoring of blood glucose is recommended and persistent extreme hyperglycemia should be treated with insulin (**Class II, Level C**). Hypoglycemia can result in brain injury and mimic stroke symptoms and should be corrected as part of the emergency management of stroke patients (**Class I, Level C**).

Acute management of blood pressure

The goal of blood pressure (BP) management in acute stroke is to maximize perfusion to the ischemic penumbra while minimizing the risk of hemorrhagic transformation. Both high and low blood pressures are associated with poor outcomes.[42] Data from the IST trial showed that early death increased by 17.9% for every 10 mm Hg of systolic blood pressure (SBP) below 150 mm Hg and by 3.8% for every 10 mm Hg SBP above 150 mm Hg, suggesting a "U shaped" curve.[43] The optimal blood pressure in the setting of acute stroke remains poorly defined with little clinical trial evidence to guide decisions about blood pressure thresholds. Current guidelines for blood pressure management are largely empirically derived.[44]

BP elevation is often seen in the first minutes to hours after the onset of focal cerebral ischemia[45] and represents a compensatory reaction to vascular occlusion. Targets for the treatment of hypertension depend on whether the patient is a potential candidate for fibrinolytic therapy. A systolic blood pressure >185 mm Hg or a diastolic blood pressure >110 mm Hg is a contraindication to intravenous administration of tPA, which is based on the criteria for the NINDS trial[46] rather than experimental data. Patients with blood pressures above this level should be treated prior to starting lytic therapy (**Class I, Level B**).

There is a theoretic basis for not being overly aggressive with BP lowering in the hyperacute phase of ischemic stroke. Cerebral autoregulation is disrupted by acute ischemia and subsequent tissue acidosis and in turn leads to maximal vasodilation.[47] As a result, with vascular occlusion, overly aggressive treatment of blood pressure could reduce cerebral blood flow (CBF) through stenotic and collateral vessels[48] and cause tissue in the ischemic penumbra to progress to infarction. As a result, AIS patients not receiving tPA therapy should be treated with antihypertensive medications only when blood pressure exceeds 220/120 mm Hg.[44] This blood pressure upper limit corresponds to a mean arterial pressure of around 150 mm Hg, which is the normal upper limit of cerebral autoregulation (**Class II, Level C**).

In acute stroke, tolerating elevated blood pressures in order to maintain CBF ("permissive hypertension") needs to be balanced with the potentially harmful effects of severe hypertension. Acute blood pressure elevation in stroke may increase the risk of ICH and worsen cerebral edema. However, the benefits of early BP reduction have yet to be confirmed in large clinical trials. Only five trials and a total of 218 patients were identified in a recent systematic review of blood pressure alterations in acute stroke and the conclusion was that data were too limited to assess the effect of BP modulation on clinical outcomes.[49]

Intravenous thrombolysis

Within the first hours after the onset of stroke symptoms, most patients with persistent arterial occlusion will have brain tissue that is hypoperfused and functionally inactive.[50] Hypoperfused brain tissue that has not been irreversibly damaged is termed ischemic penumbra. Penumbral tissue is present in almost all stroke patients at under three hours but after three hours the number of patients with salvable penumbra rapidly diminishes.[51]

Early vessel recanalization and cerebral reperfusion is goal of most acute stroke therapies and it is the most effective means to salvage penumbral tissue and improve clinical outcomes. A meta-analysis of pooled data from 53 studies of acute stroke therapies that reported recanalization rates found that good functional outcomes at three months were more frequent in recanalized than in non-recanalized patients (OR 0.24, 95% CI 0.16–0.35) with no difference in symptomatic hemorrhage[52] (**Level B**).

Currently the only approved and recommended reperfusion therapy for AIS is thrombolysis with intravenous tPA administered within three hours of symptom onset (**Class I, Level A**). Intravenous tPA was approved for use in AIS by the US Food and Drug Administration in 1996 based partly on the National Institute of Neurologic Disease and Stroke (NINDS) tPA Stroke Study.[46] In the study, 624 patients with ischemic stroke were treated with placebo or tPA (0.9 mg/kg IV, maximum 90 mg; 10% given as a bolus with the remainder given over one hour) within three hours of symptom onset and almost half of patients were treated within 90 minutes. The NINDS study was conducted in two parts. The primary endpoint in part I was

neurologic improvement in 24 hours as indexed by an improvement of ≥4 points on the National Institutes of Health Stroke Scale (NIHSS) (Table 61.3) or complete neurologic recovery. Part II of the study used a global test statistic to assess clinical outcome at three months, with favorable outcome defined as a complete or nearly complete neurologic recovery. The trial showed no group difference in percentages of patients with neurologic improvement at 24 hours. At three months, however, tPA treatment resulted in a 32% relative (12% absolute) increase in the proportion of patients with minimal or no disability.[46] The major risk of treatment with tPA is symptomatic hemorrhage, which in the NINDS trial occurred in 6.4% of treated patients compared to 0.6% in the placebo group. Despite the increased hemorrhage risk, there was no difference in the three-month mortality between the tPA-treated and placebo groups (17% vs 20%, respectively). Recently a large prospective, open-label, observational study of 6438 patients from 14 countries confirmed that tPA is safe, with hemorrhage rates comparable to clinical trials, when used within three hours of stroke onset following protocols, even in centers with little prior experience in treating acute stroke patients.[53]

In addition to the NINDS trial, there have been a number of other trials of intravenous fibrinolytic agents in stroke. These trials all had important differences from the NINDS trial, including the use of higher doses of tPA,[54] the randomization of patients beyond three hours,[54–57] and treatment with other fibrinolytics such as streptokinase along with antithrombotic drugs.[58–60] Streptokinase trials were halted prematurely due to high hemorrhage rates and its use is not recommended (**Class III, Level A**). Intention to treat analysis of data pooled from randomized trials of tPA in stroke patients treated up to six hours (NINDS, ECASS-I, ECASS-II and ATLANTIS) has highlighted the important relationship between time to initiate treatment and clinical outcomes.[54–57] Combined data from 2775 stroke patients treated in more than 300 hospitals in 18 countries was used to analyze the relationship between tPA benefit and time to treatment.[61] This study showed that the odds ratio for favorable outcome at three months and adjusted for baseline clinical features decreases as time to treatment increases (Fig. 61.1). The odds of a favorable outcome was greatest in the 0–90 minute interval (1.2, 95% CI 1.8–4.5). The beneficial effect of tPA extended beyond three hours to 270 minutes at which point the lower confidence interval for the odds ratio crosses unity (see Fig. 61.1).

The recently completed ECASS-3 trial provides new data on the tPA treatment in an extended time window.[61a] The trial randomized ischemic stroke patients (n = 821) between 3 and 4.5 hours after symptom onset to treatment with IV tPA or standard medical care. The tPA dosing regimen and enrollment criteria were similar to the current guidelines for treating stroke patients within 3 hours. More patients

Table 61.3 National Institutes of Health Stroke Scale (NIHSS) used to measure the severity of stroke deficit. Total NIHSS score is calculated by adding scores on the 11 items

Tested item	Title	Responses and scores
1A	Level of consciousness	0 – alert 1 – drowsy 2 – obtunded 3 – coma/unresponsive
1B	Orientation questions (2)	0 – answers both correctly 1 – answers one correctly 2 – answers neither correctly

8	Sensory	0 – no sensory loss 1 – mild sensory loss 2 – severe sensory loss
9	Language	0 – normal 1 – mild aphasia 2 – severe aphasia 3 – mute or global aphasia
10	Articulation	0 – normal 1 – mild dysarthria 2 – severe dysarthria
11	Extinction or inattention	0 – absent 1 – mild (loss 1 sensory modality) 2 – severe (loss 2 modalities)
Figure 61.1 Model estimating odds ratio for favorable outcome at 3 months in rt-PA treated patients compared with controls by OTT. Adjusted for age, baseline glucose concentration, baseline NIHSS measurement, baseline diastolic blood pressure, previous hypertension, and interaction between age and baseline NIHSS measurement. (From Hack *et al.* [61] with permission).

treated with tPA had good outcomes (no or minimal disability) than with placebo (52.4% vs 45.2%; odds ratio, 1.34; 95% CI, 1.02 to 1.76; *P* = 0.04) although the degree of benefit was less than that of patient enrolled from 0 to 3 hours in the NINDS study. The tPA treated group had higher rates of symptomatic intracranial hemorrhage (2.4% vs 0.2%) but this did not result in any increase in mortality. ECASS-3 provides further evidence that although the benefits of tPA are attenuated at later time points, IV tPA therapy can be administered safely from 3 to 4.5 hours in select patients and improves clinical outcomes (**Class I, Level B**).[61b]

Recent studies have examined whether specialized stroke MRI sequences that include DWI and images of brain perfusion can identify ischemic stroke patients with penumbral tissue who may benefit from perfusion with IV tPA beyond three hours.[62,63] These studies show that patients with large regions of hypoperfusion and relatively small areas of tissue infarction (i.e. large amounts of penumbral tissue) may safely be given tPA beyond three hours. The subset of patients with large amounts of penumbral tissue and early reperfusion shows the greatest improvement in clinical outcomes.[63] The value of MRI selection of stroke patients for IV tPA therapy beyond three hours has yet to be replicated in larger Phase III trials.

Other reperfusion therapies that are currently being evaluated in clinical trials include alternative fibrinolytic agents such as reteplase, desmoteplase, and tenecteplase, and augmenting IV tPA with transcranial Doppler.[64] At present, there are insufficient data to support the use of any of these reperfusion approaches (**Class III, Level C**).

Intra-arterial thrombolysis

Endovascular methods of achieving vessel recanalization in AIS include mechanical and pharmacologic approaches.[65] Intra-arterial (IA) delivery of fibrinolytic agents offers the potential advantage of more rapid removal of thrombus compared to intravenous approaches as agents are infused at high concentration in close proximity to sites of occlusion with a microcatheter system. IA therapies, at least in theory, may expand the time window for reperfusion therapy by reducing or eliminating systemic exposure to fibrinolytic agents.

The only randomized trial to assess the efficacy and safety of IA fibrinolytic therapy was the Prolyse in Acute Cerebral Thromboembolism Trial (PROACT-II).[66] In PROACT-II, 180 patients with acute stroke of less than six hours and angiographically confirmed occlusion of the middle cerebral artery (MCA) were randomized to receive IA recombinant prourokinase (r-proUK) plus heparin or heparin alone. The primary outcome was the proportion of patients with mild or no neurologic disability at 90 days. Based on an intention to treat analysis, 40% of r-proUK treated patients had good outcomes, which was significantly better than the 25% of control patients. Rates of partial or full recanalization were also markedly higher in the r-proUK group than controls (66% versus 18%). Mortality rates were around 25% for both groups. Symptomatic hemorrhage rates were, however, higher in the r-proUK patients compared to controls (10% vs 2% respectively).

The only other randomized data of IA fibrinolytics come from the recently published MELT trial.[67] In this study, conducted in Japan prior to the availability of IV tPA, ischemic stroke patients presenting within six hours were randomized to IA UK or placebo. The trial was halted prematurely largely over ethical concerns about the randomization once IV tPA was approved for use in Japan. The incomplete MELT dataset, however, when pooled with other trials of r-proUK, further supports a benefit of IA fibrinolytics in AIS.[68]

In addition to pharmacologic approaches to recanalization, there have been a number of endovascular approaches to treat intracranial or extracranial occlusions that do not involve the delivery of fibrinolytics (see Molina and Saver[65] for review). At present, the only devices approved by the FDA for the revascularization of patients with AIS are the Merci Retriever device (Concentric Medical) and the Penumbra System (Penumbra Inc.) aspiration catheter. While these devices can achieve high rates of vessel recanalization when used in AIS,[69,70] they lack any evidence of improved clinical outcomes from randomized controlled trials.

The treatment of acute stroke with endovascular therapies suffers a number of important limitations that prevent their widespread adoption. Endovascular procedures require substantially more infrastructure support, there are insufficient numbers of neurointerventionalists, treatment is limited to more proximal vessel occlusions, and time to initiate therapy is longer than IV fibrinolysis. Current guidelines recognize the value of IA fibrinolysis as a treatment option for patients with major anterior circulation stroke within six hours of symptom onset and up to 24

hours for vertebrobasilar occlusion (**Class I, Level B**). IA therapies should not take precedence over the administration of IV tPA to eligible patients.

Anticoagulants

There is no evidence that urgent anticoagulation with either unfractionated or low molecular weight heparin (LMWH) reduces the rate of recurrent stroke, improves neurologic outcomes or can be used either along with or in place of IV tPA (**Class III, Level A**). The largest study of anticoagulation in AIS was the International Stroke Trial (IST).[71] This was a randomized, open-label trial, which compared the safety and efficacy of acetylsalicylic acid (ASA) and subcutaneous heparin (5000 or 12500 IU) in 19 435 patients. Neither heparin regimen offered any clinical advantage over ASA. The higher dose of heparin was associated with an excess of morbidity and mortality. *Post hoc* analysis of the IST data examined stroke patients with atrial fibrillation and presumed cardiac embolism. Even in this subgroup of patients, the absolute risk of recurrent stroke in the first 14 days was relatively low (3.9%) and there was no net benefit to use of heparin.[72] Other trials have similarly found no benefit of emergency anticoagulation for AIS behond prevention of deep vein thrombosis and pulmonary embolism.[73]

Antiplatelet agents

ASA has been evaluated for the treatment of AIS in two large randomized controlled trials (CAST and IST) and one smaller trial (MAST).[58,71,74] In the CAST trial (n = 21 106), patients with acute ischemic stroke were randomized within 48 hours to ASA or placebo. There was a small but significant reduction in mortality amongst ASA-allocated patients (relative risk reduction (RRR) 14%, absolute risk reduction (ARR) 0.6%) and patients treated with ASA had significantly fewer recurrent strokes than patients in the placebo arm (1.6% vs 2.1%, respectively). ASA was associated with slightly more (0.2%) recurrent hemorrhagic strokes but this did not affect overall mortality, as ASA patients were less likely to be dead or dependent at discharge (11.4 fewer per 1000).

Meta-analysis of nine trials (n = 41 399) confirmed that acute ASA treatment was associated with a significant decrease in death or dependency at the end of follow-up (OR 0.94; 95% CI 0.91–0.98) and increased odds of making a complete recovery from the stroke (OR 1.06; 95% CI 1.01–1.11).[75] For every 1000 ischemic stroke patients treated with ASA within 48 hours, there were 13 more patients alive and independent at follow-up and 10 additional patients made a complete recovery. In addition, per 1000 ASA treated patients there was reduction of seven recurrent ischemic strokes and one pulmonary embolus but at a cost of two excess symptomatic intracranial hemorrhages. Based on these data, ASA

is recommended for all ischemic stroke patients within 48 hours of stroke onset provided there are no strong contraindications, and hemorrhagic stroke has been excluded (**Class I, Level A**). In patients treated with fibrinolytic therapy, ASA should not be given in the first 24 hours.

Neuroprotection

The development of neuroprotective therapies that attenuate the cascade of pathophysiologic events that occur with ischemia in acute stroke has been disappointing. A large number of neuroprotective agents have been developed based on animal models of focal ischemia but all have failed in translation to clinical practice.[76] Most recently, the results of a large trial using NXY-059 was reported. The initial NXY-059 trial suggested the drug was safe and effective in improving stroke outcomes[77] but a subsequent Phase III trial found no evidence of efficacy.[78] The failure to develop neuroprotective agents using current paradigms has led researchers to explore different strategies such as prehospital delivery of neuroprotective drugs.[79] Currently, no neuroprotective therapy is recommended for treating stroke (**Class III, Level A**).

Preventing early complications

Stroke care units

The intervention that has the greatest potential to improve outcomes of stroke patients is the establishment of specialized stroke care units (SCU). A recent Cochrane analysis pooled data from 31 trials and a total of 6936 patients examining the benefits of routine management of stroke patients in SCUs.[80] Stroke patients who received organized care in a SCU had significantly lower odds of being dead or dependent at follow-up (OR 0.82; 95% CI 0.73–0.92; $P = 0.001$) than patients receiving care on general medical wards. Subgroup analyses showed that stroke patients benefit regardless of sex, age or stroke severity. Based on data extrapolated from a community-based epidemiologic study, it is estimated that the establishment of SCUs has the potential to prevent death and disability for 50 patients per 1000 strokes compared to six per 1000 for tPA treatment and four per 1000 with ASA therapy.[81]

The precise components of an SCU that account for the benefit in functional outcomes are not well delineated. It is established that SCUs that occupy a separate physical space are associated with better outcomes than care provided by mobile stroke teams in general wards.[82] Likely interventions that are important for improved outcomes include early mobilization, better blood pressure control, and prevention of complications such as deep venous thrombosis through closer adherence to current evidence-based guidelines. All stroke patients should be admitted to

SCUs (**Class I, Level A**). Stroke units ideally should be geographically distinct, with well-defined protocols that address common problems such as early mobilization, screening for dysphagia, treatment of infections with antibiotics, and subcutaneous administration of anticoagulants for deep vein thrombosis (DVT) prophylaxis.

Venous thromboembolism

Venous thromboembolism is an important cause of morbidity in stroke patients. The risk of venous thromboembolism in patients with AIS approaches that of surgical patients and without thromboprophylaxis, about 20% of patients will develop pulmonary embolus (PE) and 1–2% of stroke patients will have a fatal PE. Unfractionated heparin is associated with an 81% reduction in deep vein thrombosis and 58% reduction in PE with a small increased risk of hemorrhagic transformation of the infarct.[83] The recently completed PREVAIL trial showed that thromboprophylaxis with LMWH may further reduce the risk of venous thromboembolism by 43% compared to unfractionated heparin; however, most (95%) of the DVT detected in the trial were asymptomatic.[84] Current guidelines recommend thromboprophylaxis for all ischemic stroke patients with anticoagulants (**Class I, Level A**) although there is still controversy about whether LMWH or unfractionated heparin is superior.

Acute neurologic complications

Many patients with ischemic stroke will worsen during the first 24–48 hours after stroke onset. The main neurologic causes of early worsening are the development of intracerebral hemorrhage and space-occupying cerebral edema and, less commonly, seizures. The risk of hemorrhagic transformation of ischemic stroke is increased with fibrinolytic drugs, anticoagulation or antiplatelet agents. Hemorrhage after ischemic stroke can be petechial, which is often asymptomatic, or result in hematoma formation that increases intracranial pressure and results in neurologic decline. There are currently no proven therapies for the treatment of hemorrhagic transformation. Seizures occur in about 3% of stroke patients within the first 24 hours.[85] Prophylactic anticonvulsant therapy is not recommended (**Class III, Level C**).

About 10% of patients with supratentorial infarction will develop life-threatening, space-occupying brain edema ("malignant infarction") usually on the second to fifth day after stroke.[86] The prognosis of patients with malignant MCA territory infarctions is poor, with mortality rates of around 80%[87] and no effective medical therapy. There is evidence from three European randomized trials (DECIMAL, DESTINY and HAMLET) that suggests that decompressive surgery improves functional outcomes in patients with malignant MCA infarction[88–90] (**Level A**).

Pooled data from these three trials (n = 93) showed that patients in the decompressive surgery group (treated within 48 hours, mean age 45) were more likely than controls to survive their stroke, free of severe disability (75% vs 24%; pooled ARR 51%; 95% CI 34–69).[91] Surgery in these trials was performed within 48 hours of stroke onset and the NNT = 4 for survival with a moderate deficit or better. These results highlight that decompressive hemicraniectomy increases survival at a cost of more survivors with at least moderate deficits. The timing of surgery and the clinical characteristics of patients' most likely to benefit are still not well established. Decompressive hemicraniectomy is usually reserved for younger patients and after discussion about the potential outcomes, including survival with moderate to severe disability (**Class II, Level B**).

The only other clear indication for surgery in acute stroke is for space-occupying cerebellar infarction (**Class I, Level B**). In about 11–25% of cerebellar stroke the edema becomes space occupying within the posterior fossa, and brainstem compression and acute obstructive hydrocephalus result.[92] The indications for surgical intervention in cerebellar strokes are a decreased level of consciousness and/or clinical signs of brainstem compression. The management involves the insertion of an external ventricular drain (EVD) and/or suboccipital decompressive craniectomy; however, the optimal procedure is controversial.[93] While the efficacy is not supported by clinical trials, case series have established decompressive surgical evacuation of space-occupying cerebellar infarction as a potentially life-saving procedure.[94]

Conclusion

Over the past decade, there have been significant advances in our knowledge of the epidemiology, pathophysiology, and treatment of acute stroke. Management of acute stroke has emerged from a long period of therapeutic nihilism, largely the result of the recognition that, with emergent evaluation and treatment, ischemic brain can be salvaged and patient outcomes improved.

Perhaps the most significant advance in acute stroke management is the development of specialized stroke units. From a population health perspective, stroke care units have the potential to be widely implemented and benefits can extend to almost all stroke patients. Stroke units provide an opportunity to implement evidence-based treatment pathways focused on salvaging penumbral tissue, preventing post-stroke complications, initiating secondary prevention regimens, and promoting recovery through early rehabilitation. Compared to stroke units, no other acute stroke treatment strategy has the potential to have such a large impact on saving lives and reducing long-term dependency.

Almost all patients with AIS can benefit from the early administration of ASA. ASA is the only medical therapy proven to improve stroke outcomes, prevent recurrent stroke, and reduce stroke mortality. In comparison, the narrow time window for administration of IV tPA limits the potential benefit to only a small percentage of stroke patients. IV tPA remains, however, the only approved reperfusion therapy and when administered within three hours of symptom onset, results in a more than 30% increase in the number of patients returning to their pre-morbid level of functioning.

Novel neuroimaging methods and new strategies to open occluded vessels offer the potential to extend the therapeutic window for reperfusion of penumbral tissue although at present there is a paucity of evidence to support the expanded use of these treatment approaches. The challenge of the next decades will be to expand the availability of those acute stroke therapies with well-established evidence of efficacy to help offset the predicted rise in stroke-related morbidity and mortality expected over the next decades.

Secondary prevention of stroke

Craig Anderson

Introduction

With an estimated 20 million events occurring in the world each year, stroke is ranked as the sixth leading cause of global disease burden.[97] Although declines in stroke incidence are emerging,[98–100] aging and adverse lifestyle changes in populations will further intensify the impact of stroke and re-emphasize the importance of prevention and management strategies.[101] Patients who experience a stroke or transient ischemic attack (TIA) are at substantial risk of a further serious vascular event (recurrent stroke, myocardial infarction or death from vascular cause). The risks of recurrent stroke are about 10% in the first week, 14% at one month, and 20% by three months after onset.[102,103] Thereafter, the annual risks of recurrent stroke and myocardial infarction are around 5% and 2–3%, respectively.[104] Given that 30–40% of patients with ischemic stroke have had a preceding TIA or minor stroke,[105] and accumulating evidence indicates benefits from early assessment and management,[106,107] TIAs serve as an important opportunity to intervene to prevent stroke.

This section reviews current evidence-based medical and surgical strategies used in reducing the risk of recurrent stroke and other vascular events after an ischemic stroke or TIA, or an intracerebral hemorrhage. Approaches to the prevention of subarachnoid hemorrhage or rarer forms of stroke, such as arterial dissection, are not considered.

Diagnosis of stroke and transient ischemic attack

Stroke is a clinical diagnosis, as outlined in a standard definition, of "rapidly developing clinical signs of focal (or global) disturbance of cerebral function with symptoms lasting 24 hours or longer (or leading to death), with no apparent cause other than vascular origin".[108] The term TIA refers to acute stroke symptoms (and signs) of the brain or eye that resolve within 24 hours.[109] However, the advent of modern neuroimaging and use of thrombolysis for acute ischemic stroke has called into question the usefulness of the definition of TIA with a 24-hour time window for clinical decision making in the first few hours after the onset of symptoms.[110] Even so, TIA remains a useful concept, both clinically and epidemiologically, as it does not rely on brain imaging and is a well-accepted diagnosis all over the world.

Pathologically, stroke generally occurs as a result of either ischemia or hemorrhage. Ischemic stroke, which accounts for about 80% of strokes in "white" populations, may occur via various mechanisms that include cardio-embolism (20–25% in Western population, e.g. secondary to atrial fibrillation (AF), valvular heart disease or patent foramen ovale), large-vessel atherosclerosis (approximately 50%, e.g. *in situ* occlusion of intracerebral arteries, or artery-to-artery embolism from carotid atheroma or aortic plaques), small vessel disease (10–20%; lacunar stroke) and, more rarely, secondary to arterial dissection, hematologic or other disorders. In black African-Americans, Hispanics and Asians, the proportion of lacunar ischemic strokes is increased and the proportion of cardioembolic strokes is decreased. In addition, the distribution of atheroma also differs between ethnic groups: Caucasians tend to have the disease around the extracranial carotid vessels, whereas intracranial large vessel disease is more common in Asian populations.[111–114] However, it is often difficult to assign an exact single etiologic mechanism in a case of ischemic stroke because of non-specific or overlapping risk factors, clinical features and underlying pathology. Hemorrhagic stroke includes primary intracerebral hemorrhage occurring in 10–15% of non-Asian and 20–40% of Asian cases (due mainly to spontaneous rupture of an intracerebral vessel)[114] and subarachnoid hemorrhage in 5–8% (due mainly to rupture of an intracranial aneurysm),[115] which are both associated with a worse prognosis than ischemic stroke.

Blood pressure-lowering therapy

Elevated blood pressure (BP) is the single most important reversible risk factor for both first-ever and recurrent (secondary) stroke,[116–119] with near continuous associations

between risk and usual levels of BP, without threshold. The association attenuates with increasing age, but remains strongly positive at all ages, across different ethnic populations,[118,120,121] and is greater for intracerebral hemorrhage than ischemic stroke.[118,121]

Substantial evidence indicates beneficial effects of lowering BP after stroke or TIA (**Class I, Level A**). Randomized trials support the observational data in demonstrating that a modest (e.g. 8/4 mm Hg) average reduction in BP is associated with a 20–25% reduction in the risk of serious vascular events.[118,119] From the trials in which there was about a 5% annual risk of vascular events among control group patients, BP-lowering treatment produces an absolute reduction of 1%, or 10 vascular events avoided per 1000 patients treated per year.[119,122] Meta-analyses of all the trials of BP lowering among different types of patients, including those with stroke or TIA, indicate that the degree of BP lowering is far more important than the particular BP-lowering agent used in determining the size of the benefit in reducing the risks of stroke, myocardial infarction and all other vascular outcomes including heart failure[122] (**Class I, Level A**). Among the agents that inhibit the renin-angiotensin system, though, evidence is emerging that angiotension receptor blockers (ARBs) are better tolerated and may be modestly superior to angiotensin-converting enzyme (ACE) inhibitors in preventing stroke[123–125] (**Class IIa, Level A**).

Who should be treated?

The relative benefits of BP-lowering treatment after stroke or TIA are similar irrespective of different characteristics of patients including the initial level of BP, age, and pathologic type of stroke[122] (**Class I, Level A**). BP-lowering therapy should, therefore, be commenced in almost all patients with a stroke or TIA, irrespective of whether or not they would be considered "hypertensive" according to standard definitions (**Class I, Level A**). However, in very old patients with consistently low levels of BP (i.e. below 130 systolic), it would seem reasonable to consider withholding such therapy, given the risks associated with hypotension, including dizziness and falls, and less certainty regarding the net benefit of treatment at such low levels (**Class IIb, Level C**).

How soon to commence treatment after a stroke or TIA?

With a paucity of randomized data, and observational studies showing U- or J-shaped associations between levels of BP and the risk of a poor outcome after ischemic stroke, there is much uncertainty about the effects of early intensive BP lowering with intravenous agents in the acute phase of stroke,[126,127] including intracerebral hemorrhage.[128]

Therefore, various guidelines recommend that such treatment be avoided in the first 24–48 hours, unless the BP is very high (systolic >180–220 mm Hg or diastolic >110–120 mm Hg), and depending on whether the stroke is hemorrhagic or rtPA is being used for cerebral ischemia[129] (**Class IIb, Level B**). Otherwise, BP-lowering treatment should be started promptly within the first week in almost all patients with mild- or non-disabling stroke, to not only maximize efficacy but also adherence. Although direct evidence of benefit is lacking,[123,130] trials have not shown any excess in adverse effects related to potential cerebral hypoperfusion due to impaired cerebral auto-regulation worsening cerebral ischemia, from such an approach (**Class IIb, Level B**).

How low should the BP be lowered?

Secondary analyses of the Perindopril Protection against Recurrent Stroke Study (PROGRESS) trial[131] indicate that the lowest risk of recurrent stroke occurs in patients with the lowest levels of BP during follow-up. However, the intensity of treatment (use of an ACE inhibitor alone or in combination with a diuretic) in PROGRESS was determined by the randomizing clinician, who took into account the various characteristics of patients, including the level of BP, at baseline. Thus, the lower risks seen in patients with lower BP levels during follow-up may not necessarily have been due entirely to the treatment. Moreover, PROGRESS and most other trials of BP lowering have tested a specific agent(s) added onto a background of standard care and/or have included patients whose BP had been stabilized (usually less than 160 mm Hg systolic and 90 mm Hg diastolic) prior to randomization. Therefore, as shown in the recently completed Ongoing Telmisartan Alone and in Combination with Ramipril Global Endpoint Trial (ONTARGET) study,[120] the benefit of additional BP lowering at levels below 140 mm Hg systolic in patients with cardiovascular disease, including a history of stroke, has yet to be determined.

It seems reasonable, therefore, to be more aggressive with treatment in those patients with initially high levels, with the aim of achieving target levels of 130/80 mm Hg, as recommended in most current guidelines (**Class I, Level A**). Moreover, since most of the evidence of benefit specifically in patients with stroke or TIA has come from either a thiazide alone or the combination of a thiazide with an ACE inhibitor, similar such therapy is recommended (**Class I, Level A**). Ultimately, though, the choice of agent(s) will likely to depend on the patient's age, associated co-morbid factors and treatment, tolerance, adherence issues, and cost (**Class I, Level A**). Such treatment is recommended for as long as the benefits are considered worthwhile for the patient, and even in those who are very elderly (over 80 years of age)[132] (**Class I, Level A**).

Antiplatelet therapy

Strong evidence exists for the benefits of long-term antiplatelet therapy, with relative reduction of about one-fifth in serous vascular events (including stroke), in patients with prior stroke or TIA[133,134] (**Class I, Level A**). With about an average 7% annual rate of vascular events among patients in the control groups of the relevant trials, this effect translates into an absolute reduction of about 14 vascular events per 1000 patients treated per year. The absolute excess risk of major bleeding in the trials was less than one intracranial hemorrhage, and 102 serious extracranial hemorrhages per 1000 patients treated per year. Thus, the overall benefits of antiplatelet therapy greatly outweigh the bleeding risks, so the therapy is appropriate for all patients with ischemic stroke or TIA unless there are specific contraindications, such as aspirin sensitivity, or if anticoagulation to reduce the risk of cardioembolic events is considered more appropriate (**Class I, Level A**). Patients with recent gastrointestinal or other major bleeding, or with symptoms suggestive of active peptic ulceration, should generally not receive antiplatelet drugs, although the addition of a proton pump inhibitor can reduce upper gastrointestinal adverse effects[135] (**Class IIa, Level A**). It seems reasonable and safe to use them in patients with a history of intracerebral hemorrhage if they are at high risk of future ischemic vascular events, for example in those with ischemic heart disease or prior ischemic stroke[136] (**Class IIb, Level C**).

How soon to commence antiplatelet therapy after an ischemic stroke or TIA?

Two large randomized trials which between them included nearly 40 000 patients showed a net benefit from aspirin 160–300 mg daily commenced within 48 hours of acute ischemic stroke[137] (**Class I, Level A**). A CT is recommended to exclude intracerebral hemorrhage before commencing aspirin. However, significant proportions of the patients included in these two trials were given aspirin prior to CT, and were later shown to have had an intracerebral hemorrhage, but they did not experience any adverse effects of the treatment. Thus, it is probably safe to give low-dose aspirin to patients with a mild disabling stroke or TIA should there be a delay in obtaining a CT (**Class IIa, Level A**). In situations where the CT shows a hemorrhagic transformation of an ischemic stroke, which is often the situation with large MCA cardioembolic cerebral infarcts, it is probably wise to wait for 1–2 weeks before commencing antiplatelet therapy (**Class IIb, Level C**).

Which single antiplatelet agent to use?

Until recently, aspirin has been the undisputed gold standard antiplatelet agent for the long-term prevention of ath-

erothrombotic events.[134] The optimal dose for both efficacy and tolerability has been established as low, anything from 30 mg to 300 mg daily[134,138] (**Class I, Level A**). Gastrointestinal side effects such as gastritis and hemorrhage are more common in older people, and with higher doses and longer duration of treatment with aspirin (**Class I, Level A**). In one study, treatment with dipyridamole alone was found to reduce the risk of major vascular events by a similar amount as aspirin,[139] while clopidogrel was shown to be slightly superior to aspirin in the trial of Clopidogrel versus Aspirin in Patients at Risk of Ischemic Events (CAPRIE), which overall reducing the risk of stroke and other major vascular events by about 10%, from about 6.0% (aspirin) to 5.4% (clopridogrel) per year, in a broad group of patients with a history of cardiovascular disease[140,141] (**Class I, Level A**). There was no statistically significant difference in the subset of patients with previous ischemic stroke in CAPRIE, with an average annual event rate of 7.2% for clopidogrel versus 7.7% for aspirin, for a relative risk reduction of about 7.3%. However, a meta-analysis confirms a modest superiority of clopidogrel over aspirin, but also differences in their side effect profile[141,142] (**Class I, Level A**). While aspirin produces more upper gastrointestinal adverse effects, clopidogrel produces more diarrhea and skin rash, and a very small risk of thrombocytopenia and thrombotic thrombocytopenic purpura. Moreover, prior to the availability of generic versions, clopidogrel has been substantially more expensive than aspirin, so it is generally recommended as an alternative to aspirin in patients who are genuinely intolerant or allergic to aspirin.[142] In the meta-analyses, dipyridamole and trifusal have not been shown to clearly reduce vascular events, and may be inferior, compared with aspirin alone[134] (**Class I, Level A**).

Does a combination of antiplatelet agents offer benefits over aspirin alone?

Clinical trials have shown that, in long-term secondary prevention, the combination of aspirin and clopidogrel is associated with a higher risk of bleeding complications, most importantly intracranial hemorrhage, than either agent alone, which offsets any modest additional benefit in terms of reducing vascular events[143,144] (**Class I, Level A**). However, in subgroup analysis of these studies, data showing a reduction in embolic signals seen on transcranial Doppler ultrasound in patients with severe carotid stenosis,[145] and the benefit seen in acute coronary syndromes,[146,147] suggest that such combination therapy may be beneficial very early after ischemic stroke or TIA when the risk of recurrence is very high.[106,148]

Two randomized trials which included nearly 6000 patients with ischemic stroke or TIA have both shown that the combination of low-dose (25 mg) aspirin and dipyridaomle (specifically modified-release dipyridamole 200 mg)

twice daily reduces the risk of vascular events by about one-fifth compared with aspirin alone, without an increase in the risk of major bleeding[139,149] (**Class I, Level A**). The benefits of adding dypyridamole were independent of gender, history of ischemic heart disease, and dose of aspirin (**Class I, Level A**). Most recently, the Prevention Regime for Effectively avoiding Second Strokes (PRoFESS) trial which involved nearly 20 000 patients showed that the aspirin-dipyridamole combination regime offered comparable overall efficacy in preventing future serious vascular events to clopidogrel alone in patients with recent ischemic stroke, although statistically it failed to demonstrate a non-inferior difference of 7.5%.[150] Thus, it is appropriate to consider the addition of dipyridamole to aspirin (or use of the marketed aspirin and extended-release dipyridamole combination pill) for modest superior beneficial effect over aspirin for secondary prevention, so long as clinicians and patients consider the additional absolute benefit and increased costs to be worthwhile (**Class I, Level A**). Patients should be warned about the potential for dipyridamole-related headache, which may occur in up to a third of people taking the medication, but which usually settles after a few weeks.

Anticoagulation

Valvular and non-valvular AF (including paroxysmal AF and atrial flutter) are major risk factors for stroke, although the former is now uncommon in developed countries due to low rates of rheumatic heart disease. Non-valvular AF predisposes to the formation of intracardiac thrombi, mainly within the atria, which can embolize to the brain and other organs. AF affects about 1% of the population, with the prevalence increasing sharply with age from 0.5% in those aged 50–59 years to about 9% in those over the age of 70 years.[151] AF is associated with a fivefold increase in stroke risk, and the strokes tend to be larger, more disabling and have a worse prognosis.[152] Overall, the annual risk of stroke in the setting of AF is about 5%, but rates vary from less than 2% to more than 10% according to the presence of one or more clinical characteristics such as congestive cardiac failure, hypertension, older age (≥75 years), diabetes, and a history of stroke or TIA[153] (**Class I, Level A**).

Substantial evidence indicates that warfarin is highly efficacious in preventing stroke (and other vascular and embolic events) in patients with AF, even in people up to 85 years and over[154] (**Class I, Level A**). Several systematic reviews and meta-analyses of randomized trials of antithrombotic agents in patients with non valvular AF[155–157] show that adjusted-dose warfarin (with an average achieved international normalized ratio (INR) of about 2.5) reduces the risk of stroke by about two-thirds, whereas aspirin reduces the risk of stroke by about one-fifth. In direct comparison, adjusted-dose warfarin was substantially more efficacious than antiplatelet therapy (including aspirin and clopidogrel).[158] Excess risks of intracranial hemorrhage and major extracranial hemorrhage with warfarin are small, about 1–2% and less than 0.3% per year, respectively. Therefore, since patients with co-existing AF and a prior ischemic stroke or TIA are at very high risk of recurrent stroke (about 12% per year), the absolute benefit in these patients is substantial, about 70 strokes prevented per 1000 patients treated for a year with warfarin compared to about 50 strokes prevented per 1000 patients treated a year for aspirin. Thus, for most patients with ischemic stroke or TIA that is related to AF, the benefits of adjusted-dose warfarin with a target INR of around 2.5 far outweigh the risks, provided there are no major contraindications and good monitoring of the INR can be organized (**Class I, Level A**).

Which patients should not be treated with warfarin?

Contraindications to warfarin include an active source of gastrointestinal bleeding, alcoholic liver disease, dementia, prior major hemorrhage, and an inability to ensure regular monitoring of INR (**Class IIb, Level C**). *Post hoc* analysis of trials[159] suggests an increased risk of intracerebral hemorrhage in patients with extensive cerebral white matter disease ("leukoaraiosis") and in older people with a high tendency to fall[160] (**Class IIb, Level C**). In some of these situations, warfarin can still be justified as the estimated net benefit from reducing the risk of future ischemic stroke far outweighs the potential hazards of bleeding. For patients unable or unwilling to take warfarin, aspirin is a reasonable but less effective alternative (**Class I, Level A**).

When to start treatment?

There is no randomized evidence to support the early (within the first 1–2 weeks) use of anticoagulation following an ischemic stroke that is related to AF in order to prevent recurrent cardioembolic events. Given that AF-related ischemic strokes tend to be larger and more likely to have *in situ* micro-hemorrhage due to cerebral reperfusion, consideration should be given to early use of anticoagulation increasing the risk of hemorrhagic transformation of the infarct while the risks of recurrent ischemic stroke are around 5% in the first two weeks after the initial event[161] (**Class IIb, Level C**). It is recommended, therefore, to wait 1–2 weeks before commencing warfarin, although it seems reasonable to commence such treatment earlier in patients who have experienced a small ischemic stroke or TIAs, or in situations where the embolic risk is considered to be extremely high. In the latter case, LMWH may be used as a bridge before the therapeutic effect of warfarin is achieved (**Class IIb, Level C**).

What is the target INR?

Data from both randomized trials and observational studies suggest that the optimal target INR is about 2.5. Below 2.0, the risks of both ischemic stroke and extracranial bleeding increase, while above 3.0 there is an increased risk of major bleeding, death and hospitalization[162–164] (**Class I, Level A**).

What are the benefits of combining antiplatelet therapy with warfarin?

Randomized trials and observational data indicate that the combination of aspirin (or other antiplatelet agent) and warfarin should generally be avoided because of an increased risk of major bleeding[165] (**Class I, Level A**). However, in situations where the risk of cardio-emboli is particularly high, such as with mechanical heart values, the potential benefits outweigh the increased risks of bleeding[166] (**Class I, Level A**).

Are there any benefits of anticoagulation in patients without AF?

In patients with a presumed non-cardio-embolic source of an ischemic stroke or TIA, that is in those with presumed or established large artery atheromatous disease of the intra- or extracranial vessels, there is no evidence of a benefit of oral anticoagulation (mainly warfarin, with target INRs in the range of 1.4–4.5) over antiplatelet therapy (mainly aspirin) and an increase in the risk of hemorrhage[167–170] (**Class I, Level A**).

Cholesterol-lowering therapy

The relation between serum cholesterol and stroke is complex due largely to the diversity of stroke pathogenesis, with qualitatively different associations of serum cholesterol with the risks of ischemic and hemorrhagic stroke.[171–175] Elevated serum cholesterol is an important risk factor for ischemic stroke, more so in Western populations than in Asian populations,[175] whereas a weak inversion association is apparent between serum cholesterol and the risk of intracerebral hemorrhage. Part of the latter association may relate to the confounding influence of heavy alcohol consumption which tends to lower cholesterol levels.[176]

Evidence from systematic reviews of randomized trials shows that reducing total (and more importantly low-density lipoprotein (LDL)) cholesterol with a 3-hydrozy-3-methylglutaryl co-enzyme A reductase inhibitor (statin) significantly reduces the risks of major cardiovascular events, including stroke, across a wide range of lipid levels in patients with high cardiovascular risk (**Class I, Level A**). Relative risk reductions are proportional to the absolute reduction in LDL cholesterol, such that a 1 mmol reduction is associated with almost a one-quarter reduction in the risk of coronary events, and about a 15% reduction in the risk of stroke, over about five years of treatment[177] (**Class I, Level A**). Two major randomized controlled trials have specifically evaluated the benefits of statin therapy against placebo by including patients with a history of ischemic stroke or TIA. In the Heart Protection Study (HPS)[178] undertaken in a broad population of patients with high cardiovascular risk, simvastatin 40 mg per day, which reduced LDL cholesterol by 1 mmol/L, resulted in about a 20% reduction in major vascular events and non-significantly by a similar amount for ischemic stroke. In the Stroke Prevention by Aggressive Reduction in Cholesterol Levels (SPARCL),[179] specifically undertaken in patients with principally ischemic stroke, atorvastatin 80 mg daily, which reduced LDL cholesterol by 1.4 mmol/L, was associated with about a 25% reduction in major vascular events, including a significant 20% reduction in the risk of recurrent ischemic stroke, as well as a 30% reduction in the risk of coronary events. In contrast to a meta-analysis of randomized trials which did not find a specific effect of treatment on hemorrhagic stroke,[180] both of these trials showed a slight increase in the risk of intracerebral hemorrhage. Secondary analysis of SPARCL has shown that hemorrhagic stroke was more frequent in those patients with a hemorrhagic stroke at entry, in men, with older age, and in those high BP levels during follow-up. However, there was no relationship between hemorrhage risk and baseline LDL cholesterol level or the most recent LDL cholesterol level in treated patients.[181] In the trials, the average annual risk of serious vascular events among patients in the placebo groups was about 6%, so that the observed one-fifth relative reduction equates to an absolute reduction of about 12 vascular events avoided per 1000 patients treated by year.

Who should be and should not be treated?

The randomized evidence indicates that statin therapy should be used routinely in most patients with a history of ischemic stroke or TIA, since the trials demonstrated substantial benefits in patients whose baseline total cholesterol level was greater than 3.5 mmol/L or LDL cholesterol levels of greater than 2.6 mmol/L, which would account for most patients with vascular disease in developing countries (**Class I, Level A**). Moreover, there are benefits in terms of the prevention of not only recurrent ischemic stroke but also myocardial infarction, indicating that underlying coronary artery disease is common in patients with cerebrovascular disease (**Class I, Level A**). As statins are expensive, the cost–benefit ratio is likely to be favorable in those patients without frailty or major non-vascular co-morbidity who are likely to derive the most benefit from the avoidance of future vascular events.

What statin and at what dose?

Systematic overviews of trials and observational studies indicate that greater benefits can be derived from larger degrees of cholesterol lowering[175,177,181] (**Class I, Level A**). While direct comparisons of different intensities of statin-based cholesterol-lowering regimes have been undertaken in patients with coronary heart disease,[182–184] the benefit of intensive cholesterol lowering has not been reliably established in patients with ischemic stroke and is potentially complicated by an increase in the frequency of myalgia and gastrointestinal symptoms. In the absence of direct evidence, it seems reasonable to use standard doses of statins in patients with ischemic stroke or TIA, reserving an increase in dose and/or combining with other lipid-lowering agents in those people with a persistently abnormal lipid profile and high risk of large vessel atheromatous ischemic events.

When to start therapy after ischemic stroke or TIA?

There is no definite evidence that statins, through any non-lipid lowering (antithrombotic) effects, offer benefits in the acute phase of ischemic stroke or early after TIA.[148] However, as statins are safe and well tolerated, and treatments commenced in hospital are likely to lead to better compliance, it seems reasonable to commence a statin within a few days after the onset of ischemic stroke or TIA (**Class IIb, Level C**). As statins are expensive, they should be ceased in those patients with significant stroke-related disability and/or who require long-term residential care, where it is unlikely that quality of life will be improved by avoiding recurrent stroke and other vascular events.

Carotid revascularization

Atherosclerotic disease of the extracranial vessels is an important cause of stroke, particularly in Caucasian populations, where the atheromatous narrowing at, or around, the origin of the internal carotid artery accounts for up to 50% of "large artery" ischemic stroke and TIA. Patients with higher degrees of carotid stenosis are at higher risks of ipsilateral ischemic stroke, but they are also more likely to have advanced atheroma elsewhere in the body, especially the heart.

Carotid stenosis carries a risk of embolization from the atheromatous plaque debris or thrombus which may block a more distal vessel in the cerebral circulation. Carotid stenosis rarely causes stroke due to low flow (i.e. hemodynamic compromise), only doing so if the underlying stenosis is very severe (>95% stenosis), and even then there appears to be a reduced risk of ipsilateral

stroke on medical treatment,[185,186] possibly due to the presence of good collateral circulation. Most of the strokes that occur in the first few years after a minor stroke or TIA in patients with carotid stenosis are ischemic, and they occur in the territory of the "symptomatic" vessel. The risk of stroke is related to the severity of stenosis and is time dependent.[187] The risk of stroke is highest in the first few days after a TIA, remains fairly high for the next year and then falls. Overall, the risks of stroke are approximately 10% for the first month, 15% for the subsequent year, 5% for the second year and 2% thereafter.[188,189] The high early risk of stroke is probably caused by plaque "activation". Atheromatous plaques are typically slow growing or quiescent for long periods but may develop ruptures or fissures, which trigger platelet activation and thrombus formation. Ulcerated carotid plaques are more likely than smooth plaques to be associated with coronary vascular events, suggesting the plaque activation is a systemic phenomenon.[190]

Who benefits from carotid endarterectomy?

Several randomized trials including the North American Symptomatic Carotid Endarterectomy Trial (NASCET) and the European Carotid Surgery Trial (ECST) have shown that the addition of carotid endarterectomy to best medical therapy is beneficial in reducing the absolute risk of stroke or death over the next few years by about 16% for patients with severe (≥70%) and 8% for patients with moderate (50–69%) degrees of symptomatic carotid stenosis,[191] and of some benefit (5%) in patients with neurologically asymptomatic severe (60–99%) carotid stenosis.[192] Furthermore, the durability of carotid endarterectomy in preventing ipsilateral ischemic stroke has been shown up to 13 years of follow-up[188] (**Class I, Level A**). However, the benefits of carotid endarterectomy are dependent on two important caveats, first that the surgical complication rate undertaken by experienced surgeons must be low (<5%) and second that the measurement of the degree of stenosis is robust. Conventional angiography carries a 1% risk of stroke, and one out of every five of these is disabling.[193] Modern non-invasive carotid imaging such as MRI, CT, and duplex and Doppler ultrasound avoids the risk associated with conventional intra-arterial catheter carotid angiography, but it is important that reliable images are obtained in order to avoid operating on patients with false-positive scans, or denying benefits of the intervention to those with false-negative scans.[194] Moreover, carotid ultrasound alone will not identify important lesions of the intracranial arteries where aneurysms and stenosis of intracranial vessels exist in about 2% and 5% of patients symptomatic with extracranial stenosis, respectively.

A systematic review of the randomized data provides information about the effects of treatment according to dif-

ferent patient characteristics (**Class I, Level A**). The benefit of surgery appears greatest in the elderly, in men, after stroke compared with TIA, decreased with time from the last ischemic event, and tended to be greater in patients with ulcerated plaques than in those with smooth plaques[192] (**Class I, Level A**). In particular, the subgroup in whom the benefit of surgery was highest was patients who were randomized within two weeks of an ischemic event, again emphasizing the need for rapid assessment and treatment of patients with stroke and TIA to identify those with carotid stenosis (**Class I, Level A**).

Is carotid stenting more effective than carotid endarterectomy?

The last decade has witnessed a rapid growth in the use of percutaneous, transluminal stenting techniques for carotid stenosis, in part to avoid some of the drawbacks (i.e. admission to hospital, general anesthetic, incision in the neck) and complications associated with endarterectomy, and in part due to the awareness and accessibility of the carotid to such treatment. Initial endovascular techniques primarily used angioplasty, which was randomly evaluated in the Carotid and Vertebral Artery Transluminal Angioplasty Study (CAVATAS) involving over 500 patients, most of whom had symptomatic carotid stenosis. The results showed 30-day outcomes were comparable between the randomized groups[195]; the rate of death or any major stroke was 9.9% after surgery and 10.0% after angioplasty. However, analysis of the other risks confirmed that angioplasty was safer than surgery in terms of minor morbidity and reduced hospital length of stay, but was associated with a higher rate of (asymptomatic) restenosis during follow-up.

Subsequently, there have been several more randomized trials that have compared the safety and efficacy of endovascular techniques by means of angioplasty or stenting with carotid endarterectomy, involving a total of 3.227 patients.[196] Overall, the results to date suggest similar risks of early stroke (about 5–8%) or death (about 1%), although among the individual larger trials, the results vary from favoring stenting (SAPPHIRE[197]), equivalence (CAVATAS[195] and SPACE[198]), to favoring endarterectomy (EVA-35[199]). However, the characteristics of patients and the revascularization techniques used varied across the studies. Long-term follow-up data suggest that there are no significant differences between the treatments in preventing stroke or death, but there are wide confidence intervals around the effect estimates and significant heterogeneity across studies (**Class I, Level A**). Endovascular procedures clearly reduce the risk of local complications (e.g. cranial nerve injury and hematoma) but may be associated with a greater risk of silent cerebral ischemic lesions detected on MRI irrespec-

tive of whether or not a distal embolic protection device was used.[200,201] Despite the presence of such lesions, though, one study has shown similar risk of cognitive changes between endarterectomy and stenting.[202] Finally, as well as advancing age,[203] unfavorable anatomic aspects of the carotid artery, such as calcification, great vessel origin stenosis, tortuosity and the severity of the stenosis may make stenting of the carotid artery more difficult and hazardous[204] (**Class IIa, Level A**).

What is the appropriate timing of carotid revascularization after ischemic stroke or TIA?

Histologic examination of carotid endarterectomy specimens has highlighted certain features such as the presence of a large lipid-rich necrotic core, a thin overlying fibrous cap, an inflammatory infiltrate, neovasculature growth, and intraplaque hemorrhage, which support the "vulnerable plaque" theory to produce an embolic source of thrombosis.[205,206] In the meta-analysis of the trials, the benefits of carotid endarterectomy were highest in patients randomized within two weeks of an ischemic event[192] (**Class I, Level A**). Thus, it is probably best to perform carotid endarterectomy early (within the first few weeks) of a non- or mildly disabling ischemic stroke or TIA. Conversely, early use of carotid stenting appears more hazardous[199,207] and should be reserved for when the patient is stable several weeks or more after the onset of the event (**Class IIa, Level B**).

Conclusion

Major progress has been made in the evidence base supporting approaches to the prevention of second stroke. Several key points emerge.
• Given continuous associations of risk factors and stroke rates, effective prevention of stroke involves the management of the patient as a *whole* person defined by their absolute risk of future major vascular events rather than by a single variable defined by a particular threshold level of BP or cholesterol.
• BP-lowering therapy is pivotal to the prevention of recurrent stroke in all patients with cerebrovascular disease, irrespective of BP levels, age and other characteristics.
• Aspirin (optimal dose 30–300 mg) is cheap, safe, familiar and acceptable as the antiplatelet agent of first choice for patients with vascular disease, but clopidogrel and the combination of low-dose aspirin and dypridamole provide comparable modest additional benefit over aspirin.
• Warfarin is indicated in patients with a cardiac (embolic) source of stroke including AF unless there are contraindications or the risk of stroke is low, in which case aspirin is recommended.

- Cholesterol-lowering therapy with statins is safe, well tolerated and effective in preventing major vascular events including stroke in all high-risk individuals irrespective of baseline cholesterol levels.
- Carotid endarterectomy or stenting is indicated for patients with severe carotid artery stenosis who have had symptoms of retinal or brain ischemia appropriate to the stenosis, and are willing to undergo a small but definite risk of death or disability related to the procedure undertaken by an experienced proceduralist.

62 Heart disease and pregnancy

Rachel M Wald[1] and Samuel C Siu[2]

[1]Toronto General Hospital and Mount Sinai Hospital, University Health Network, University of Toronto, Toronto, Ontario, Canada

[2]London Health Science Centre, University of Western Ontario, London, Ontario, Canada

Introduction

Women with heart disease comprise approximately 1% of the population in obstetric referral centers.[1] The majority of pregnant women with heart disease seen at referral centers have congenital or rheumatic lesions.[1,2] Other important but less frequently encountered conditions include cardiac arrhythmias, peripartum cardiomyopathy, hypertrophic cardiomyopathy and coronary artery disease. Most current management recommendations have been based on expert opinion and/or retrospective series. To date, there has been only one large multicenter study to prospectively ascertain maternal and fetal outcomes in women with cardiac disease. This Canadian study also derived and validated a risk index for the prediction of maternal cardiac complications during pregnancy.[1]

With the exception of patients with pulmonary vascular obstructive disease, Marfan syndrome with aortopathy, peripartum cardiomyopathy, severe aortic stenosis or mechanical heart valves, maternal death during pregnancy in women with heart disease is rare.[1–6] However, pregnant women with heart disease do remain at risk for cardiac, obstetric, and fetoneonatal complications.[1,2,7–9] Commonly encountered complications include congestive heart failure (CHF) and arrhythmia.[1,2,9,10]

Cardiovascular physiology and pregnancy

Increases in blood volume, red cell mass, and heart rate result in a 50% antepartum increase in cardiac output.[11]

Increases in left ventricular (LV) volume are present by 14 weeks gestation and reach maximum levels early in the third trimester but contractility remains in the normal range. Gestational hormones, circulating prostaglandins, and the low-resistance vascular bed in the placenta result in decreased peripheral vascular resistance and blood pressure. During labor and delivery, there are additional increases in cardiac output and oxygen consumption. Immediately following delivery, relief of caval compression and autotransfusion from the emptied uterus result in a transient increase in cardiac output. Most of the hemodynamic changes of pregnancy have resolved by the second postpartum week but complete return to baseline may not occur until six months after delivery.

Outcomes associated with specific cardiac lesions

Congenital heart lesions

Volume overload lesions

Left-to-right shunts The effect of increased cardiac output on the volume-loaded right ventricle (RV) in atrial septal defect (ASD) or LV in ventricular septal defect (VSD) and patent ductus arteriosus (PDA) is counterbalanced by a decrease in peripheral vascular resistance during pregnancy. Therefore, pregnancy and delivery are well tolerated in the absence of pulmonary hypertension.[1,12–15] In a recent overview, significant arrhythmia requiring therapy was reported in 1/123 pregnancies with ASD (0.8%) and in no pregnancies with VSD; there were no reports of CHF.[9] Paradoxic embolization may be encountered, albeit infrequently, if systemic vasodilation and/or elevation of pulmonary resistance promotes transient right-to-left shunting (particularly in the setting of an ASD).

Atrioventricular septal defect (AVSD), a more complex form of septal defect, may be less well tolerated in preg-

nancy as compared with simpler defects described above. A recent retrospective review of 48 pregnancies reported postpartum persistence of NYHA class deterioration, arrhythmias and worsening of pre-existing left atrioventricular valvular regurgitation in 23%, 19% and 17%, respectively.[16]

Regurgitant valves Significant pulmonary regurgitation (PR) is commonly seen after tetralogy of Fallot (TOF) repair, particularly if a transannular patch was applied. Sequelae of severe PR include RV dilation and dysfunction. From a retrospective review of 82 successful pregnancies (including 20 pregnancies in women with unrepaired TOF), cardiovascular events occurred in six women (14%) and included supraventricular arrhythmia, CHF, pulmonary hypertension and pulmonary embolus. In 5/6 women, cardiovascular complications were associated with the following: severe PR with RV dilation, RV hypertension and peripartum LV dysfunction.[17] Another study of 50 pregnancies in women with corrected TOF found cardiac complications in 12% of pregnancies, consisting of CHF, arrhythmia or both.[18]

Important congenital tricuspid valve insufficiency is commonly related to structural disease, such as Ebstein anomaly. Apical displacement of the tricuspid valve results in atrialization of the RV and commensurate compromise in functional RV size. A diminutive functional RV may not be able to accommodate the increased stroke volume of pregnancy, resulting in worsening tricuspid insufficiency, raised right atrial pressure and right-to-left shunting across the atrial septum. A study of 111 pregnancies in women with Ebstein anomaly did not find any serious maternal complications but did note increased risk of prematurity and fetal loss; birth weight was significantly lower in those born to cyanotic women.[19]

Both mitral and aortic regurgitation during pregnancy are generally well tolerated, even if severe, due to reduced antenatal systemic vascular resistance resulting in reduced afterload. Symptoms usually respond to medical therapy.[20,21]

Pressure overload lesions: left heart

Left ventricular outflow tract obstruction When aortic stenosis (AS) complicates pregnancy it is usually due to a bicuspid aortic valve (BAV), which may also be associated with aortic coarctation and/or ascending aortopathy. Subvalvular and supravalvular AS have similar hemodynamic consequences to valvular AS. Women with symptomatic AS should delay pregnancy until after surgical correction[20] (**Class I, Level C2**). Women with moderate or severe AS continue to be at increased risk for pulmonary edema or arrhythmia during pregnancy, even if they are asymptomatic prior to conception.[1,12,22,23] Contemporary studies report either no or low maternal mortality despite including a significant number of women with severe AS.[23–25] Antena-

tal percutaneous balloon valvuloplasty for symptomatic AS is preferable to cardiac surgery which carries substantial fetal mortality (**Class I, Level C1**).[22,26–29] In the absence of prosthetic valve dysfunction or residual AS, those with a tissue prosthesis usually tolerate pregnancy well. Pregnancy has not been clearly shown to accelerate degeneration of bioprosthetic or homograft valves.[30,31] In two reports, 24 completed pregnancies in women post Ross operation (pulmonary autograft aortic valve replacement) were described and no cardiac complications were reported during pregnancy; one woman developed a dilated cardiomyopathy six months after delivery unrelated to aortic valve dysfunction.[32,33]

Pregnancy in a woman with a mechanical valve prosthesis carries increased risk of valve thrombosis as a result of the prothombotic state of pregnancy. Thrombosis risk during pregnancy is also influenced by valve type (more likely in older-generation valves), position (greater in the mitral as compared with the aortic position), prenatal level of valve function, and type of anticoagulation used.[34]

Coarctation of the aorta In 308 pregnancies reported in four contemporary studies, the only maternal death occurred as a result of dissection in a woman with Turner syndrome who had previously undergone coarctation repair.[1,12,35,36] In uncorrected coarctation, satisfactory control of upper body hypertension may lead to excessive hypotension below the coarctation site, compromising the fetus. Intrauterine growth restriction and premature labor are more common. Following coarctation repair, the risk of dissection and rupture is reduced but not eliminated.[35,37] Medical therapy with beta-blockade may reduce aortic wall stress but its clinical efficacy has not been formally studied in pregnancy. Pregnant women with repaired coarctation are at increased risk for pregnancy-induced hypertension, likely as a result of abnormal aortic compliance.[1,12,35]

Aortopathies Life-threatening aortic complications of Marfan syndrome are primarily due to aortic dissection resulting from medial aortopathy which often manifests as aortic dilation. Risk is increased in pregnancy due to hemodynamic stress and perhaps hormonal effects. A prospective study of 45 pregnancies in 21 patients reported no increase in obstetric complications or significant change in aortic root size in patients with normal aortic roots. Importantly, in the eight patients with a dilated aortic root (>40 mm) or prior aortic root surgery, 3/9 pregnancies were complicated by aortic dissection in two and rapid aortic dilation in one. Of note, beta-blockade therapy was withheld during pregnancy in the majority of women in this study.[38] A later prospective study of 33 pregnancies in 23 women with Marfan syndrome reported favorable outcomes with aortic root diameter <45 mm and no previ-

ous history of dissection. There was a small but statistically significant increase in aortic root diameter during pregnancy in women with an initial diameter >40 mm as compared with those <40 mm.[39] Surgical repair should be offered to women prior to conception if the aortic root diameter is >40–45 mm,[20] though this is unlikely to normalize the risk of dissection thereafter.[40] Thus, patients with aortic root involvement should receive preconception counseling emphasizing their risk, and in early pregnancy should be offered termination (**Class 1, Level C1**) In contrast, women with normal aortic root diameter may tolerate pregnancy well, though there remains a possibility of dissection even with normal aortic dimensions. Serial echocardiography should be used to identify progressive aortic root dilation during pregnancy and for six months post partum.[41] Despite the absence of trials specifically evaluating beta-blocker therapy in pregnancy, the potential benefit likely outweighs the relatively small risk of use of this medication during pregnancy (**Class 1, Level C2**).

Less is known about risk factors for dissection in pregnant women with a dilated aorta in the context of a BAV, although this complication has been reported in the pregnant population.[42] The histologic features of aortopathy related to a BAV are similar to what has been described in Marfan syndrome.[43] Some have suggested that management guidelines as described for Marfan syndrome should be applied to those with aortopathy related to a BAV (**Class IIa, Level C2**).[20,42]

With assisted reproductive technology, women with Turner syndrome can now become pregnant. These women are at particular risk of dissection, relatively early in life,[44] even in the absence of recognized aortic root pathology or hypertension.[45] Pregnancy appears to significantly increase the risk of cardiovascular mortality.[46]

Pressure overload lesions: right heart
Pulmonary stenosis Unlike aortic stenosis, pulmonary stenosis (PS) is not associated with significant cardiovascular complications during pregnancy.[1,12,25] Two recent studies examining 68 women have reported no major cardiac complications.[47,48] One study also reported hypertension, thromboembolism and premature delivery in 15%, 4%, and 17% of pregnancies respectively.[48] Balloon valvuloplasty during pregnancy is feasible if symptoms of PS progress (**Class I, Level C2**).

Pulmonary vascular obstructive disease Maternal mortality in Eisenmenger syndrome continues to be high and is approximately 30% in each pregnancy.[5] Most complications occur at term and during the first week post partum. Current consensus is to advise against conception and to offer termination in the event of a pregnancy[49] (**Class I, Level C1**). The vasodilation associated with pregnancy will increase the magnitude of right-to-left shunting, exacerbating maternal cyanosis with adverse effect on fetal outcome. Consequently, these women are particularly sensitive to volume depletion and hypotension, situations which augment right-to-left shunting resulting in worsening cyanosis, hypoxemia and vasoconstriction. Overall, spontaneous abortion is common, intrauterine growth restriction is seen in 30% of pregnancies, and preterm labor is frequent. The high perinatal mortality rate (28%) is largely due to prematurity.

In an overview of 125 pregnancies in patients with Eisenmenger syndrome, primary and secondary pulmonary hypertension, maternal mortality was uniformly high at 36%, 30%, and 56% respectively.[5] The overall neonatal mortality was 13%.

Cyanotic heart disease: unrepaired and repaired
In the absence of pulmonary hypertension, mortality associated with pregnancy is rare in women with uncorrected cyanotic congenital heart disease (CHD) although morbidity may be substantial.[50] The usual pregnancy-associated fall in systemic vascular resistance and rise in cardiac output exacerbate right-to-left shunting, leading to increased maternal hypoxemia and cyanosis. A study examining the outcomes of 96 pregnancies in 44 women with a variety of cyanotic congenital heart defects reported a high rate of maternal cardiac events (32%) and prematurity (37%) as well as a low livebirth rate (43%).[50] The lowest livebirth rate (12%) was observed in mothers with arterial oxygen saturation ≤85%.

Abnormalities of the systemic ventricle: systemic right ventricle and functional single ventricle
Transposition of the great arteries: systemic right ventricle The original repair for ventriculo-arterial discordance or complete transposition of the great arteries (TGA) was the atrial switch procedure (Mustard or Senning operation). Contemporary surgical management has replaced the atrial switch procedure with the arterial switch operation (Jatene procedure). Virtually all published data regarding pregnancy in women with TGA are derived from women after atrial redirection. As the morphologic RV supports the systemic circulation, tricuspid regurgitation, RV dilation and RV dysfunction are commonly seen. Additional sequelae may include sinus node dysfunction, atrial tachyarrhythmia and baffle leak/obstruction.

Two retrospective studies of pregnancy post atrial redirection in 68 women (139 pregnancies) were recently published. The most commonly reported complications were arrhythmias (13–22%), CHF (7–15%) and maternal death/ transplant (8%).[51,52] When serial echocardiography was utilized to examine impact of pregnancy on the systemic RV after the Mustard operation, progressive RV dilation occurred in 5/18 women (21%) and worsening RV function

was noted in 4/21 (25%) women during pregnancy. At a mean follow-up 33 months after delivery, the RV remained enlarged in all five women (100%) and the RV dysfunction persisted in three-quarters of women (75%).[53] Although these data suggest that pregnancy may affect subsequent systemic RV function, these observations require confirmation using more objective and reproducible methods of RV quantification.

Women managed with an arterial switch operation have only recently reached child-bearing age and there are no published case series examining this population. However, in the absence of ventricular dysfunction, coronary obstruction, or other important residua or sequelae, a good outcome may be anticipated.

In congenitally corrected transposition, characterized by atrioventricular and ventriculo-arterial discordance (double discordance), the morphologic RV supports the systemic circulation. Consequently, tricuspid regurgitation and RV dilation and dysfunction are frequently seen. In two large studies of 105 pregnancies in 41 women, the most common complication was CHF (9–16%) and no maternal deaths were reported.[54,55]

Fontan palliation: functional single ventricle By surgically redirecting systemic venous return to the pulmonary arteries in those with single ventricle physiology, the Fontan palliation decreases volume overload on the systemic ventricle and reduces or eliminates cyanosis. However, there remains an inherent limitation in the heart's ability to augment cardiac output. Long-term sequelae may include arrhythmia, ventricular dysfunction, protein-losing enteropathy and thromboembolic events. As the 10-year survival following the Fontan operation is only 60–80%, it is important that long-term maternal prognosis be discussed during preconception counseling.

In the largest series of pregnant women with Fontan palliation published to date, 33 pregnancies in 14 mothers were reviewed. The single cardiac complication reported in this study was supraventricular tachycardia in one woman.[56] In two subsequent studies examining 14 pregnancies in nine women, maternal cardiac complications included atrial tachyarrhythmia (three women), symptomatic ventricular dysfunction (two women), and right heart failure (two women); the rate of premature birth was high.[57,58] There have been no reported maternal deaths.[59]

Rheumatic heart disease

Mitral stenosis (MS) is the most common rheumatic valvular lesion encountered during pregnancy. The hypervolemia and tachycardia associated with pregnancy exacerbate the impact of mitral valve obstruction. The resultant elevation in left atrial pressure increases the likelihood of atrial

fibrillation.[21] Thus, even patients with mild to moderate MS, who are asymptomatic prior to pregnancy, may develop atrial fibrillation and heart failure during the antepartum and peripartum periods, contributing to substantial morbidity[1,12,25,60] Atrial fibrillation is a frequent precipitant of CHF in pregnant patients with MS. In a study of 80 pregnancies (moderate or severe MS in 47%), the first episode of pulmonary edema occurred at a mean gestational age of 30 weeks and occurred in the setting of atrial tacharhythmias in 20%.[60]

Percutaneous mitral valvuloplasty should be considered in patients with functional class III or IV symptoms despite optimal medical therapy and hospitalization[61–63] (**Class I, Level C1**).

Pregnant women whose dominant lesion is rheumatic AS have a similar outcome to those with congenital AS.

Peripartum cardiomyopathy

Peripartum cardiomyopathy is diagnosed by otherwise unexplained LV systolic dysfunction presenting during the last antepartum month or in the first five postpartum months.[64] Proposed echocardiographic criteria of LV systolic dysfunction include ejection fraction <45%, fractional shortening <30%, and end-diastolic dimension >2.7 cm/m^2.[65] This entity can manifest as CHF, arrhythmia or embolic events. Many affected women will show improvement in functional status and ventricular function post partum, but others may have persistent or progressive dysfunction. The relapse rate during subsequent pregnancies is substantial in women with evidence of persisting cardiac enlargement or LV dysfunction. In a multicenter survey examining the outcomes of 60 pregnancies in women with peripartum cardiomyopathy diagnosed during a prior pregnancy, 44% of women with persistent LV systolic dysfunction (ejection fraction <50%) developed symptoms of CHF during subsequent pregnancies, with an associated mortality rate of 19%. In contrast, symptoms of CHF developed in 21% of women with normalized LV systolic function (ejection fraction ≥50%) and none of this group died.[4] For women who are planning on another pregnancy, angiotensin-converting enzyme inhibitors should be avoided due to their teratogenic effects.[66] In another survey of 100 pregnancies in women with peripartum cardiomyopathy and no subsequent pregnancies, the majority of cases (75%) were diagnosed in the first month postpartum; normalization of LV systolic function occurred in 54% and was more likely if ejection fraction was >30% at diagnosis.[67] These authors suggest that the criteria for diagnosis of peripartum cardiomyopathy based on timing of presentation may be unnecessarily restrictive as those with "pregnancy-associated cardiomyopathy" diagnosed earlier in pregnancy are indistinguishable in terms of baseline characteristics and outcome.[67] Women with peripartum

cardiomyopathy and significant residual LV dysfunction are advised against further pregnancies (**Class I, Level C1**).

Hypertrophic cardiomyopathy

In patients who have either resting or provocable LV outflow tract obstruction, the degree of LV outflow tract obstruction during pregnancy is variable and is a result of interplay between increases in preload (which reduces severity of obstruction) and decreases in afterload (which worsens obstruction). Diastolic dysfunction magnifies preload dependence of cardiac output and may result in worsening symptoms even in the absence of LV outflow tract obstruction.

Maternal outcomes are often good, though several deaths have been reported, and serious complications (CHF, tachyarrhythmias, syncope) may occur, especially in women with preconceptual symptoms, and in those with substantial LV diastolic and/or systolic dysfunction or significant LV outflow tract obstruction. In a multicenter retrospective review of 199 pregnancies, there were two sudden deaths in women known to be at high risk who were counseled against pregnancy (one with severe LV outflow tract obstruction and symptomatic heart failure and one with a malignant family history); clinical decompensation during pregnancy occurred in 15% and was significantly associated with prepregnancy functional class.[68] In a recent single-center retrospective review of 271 pregnancies, there were no maternal deaths and >90% of women with cardiac symptoms during pregnancy experienced cardiac symptoms prior to pregnancy; symptomatic deterioration occurred in <10%.[69] Fetal outcomes are good. Beta-blockers may be used, as in the non-pregnant state. Dual-chamber pacing may be of value in patients with symptoms refractory to medical therapy (**Class IIb, Level C2**). The role of septal alcohol ablation or surgical myectomy during pregnancy has not been defined.

Coronary artery disease

The risk of myocardial infarction (MI) appears to be increased by pregnancy. A study examining hospital discharge data of >23 million pregnancies between 2000 and 2002 determined that the incidence of pregnancy-related acute MI in pregnancy was 6.2/100 000 deliveries with a mortality rate of 0.35/100 000 deliveries.[70] Of 859 cases of acute MI related to pregnancy reviewed, 73% occurred during pregnancy and 27% occurred post partum necessitating readmission to hospital. The risk of acute MI was 3–4 times higher in pregnancy as compared with the published incidence of MI among reproductive-aged women. Risk factors for MI included advanced maternal age, hypertension, diabetes mellitus, smoking, thrombophilia, need for transfusion and postpartum infection. Earlier studies dem-

onstrating lower incidences of MI may relate to better ascertainment in recent studies, improved diagnosis related to widespread troponin use, or increased number of pregnancies in older women.[71,72] Guidelines for the cardiopulmonary resuscitation of the pregnant patient have been recently published.[73]

Diagnosis of infarction may be confounded peripartum because of release of CK-MB isoenzyme from the uterus.[74] Thrombolysis is not contraindicated[75] but the diagnosis of coronary thrombosis as opposed to other causes of coronary occlusion cannot be routinely assumed; if immediately available, coronary angiography with the option of primary angioplasty should be considered, especially as other causes of myocardial ischemia/infarction are more frequent in or aggravated by pregnancy. These may include coronary artery dissection, coronary artery embolism, vascular complications of vasoactive obstetric therapies (e.g. ergot derivatives, prostaglandins), and collagen vascular diseases. The long-term residua of childhood Kawasaki disease include coronary artery stenoses and aneurysms, which may become symptomatic during pregnancy. Cocaine abuse must be considered in any young person with an acute coronary event.[75] Fetal exposure to radiation from routine coronary angiography is <5 mGy (<500 mrad).[76] Adverse fetal consequences of this amount of radiation are extremely small or negligible.

Management

Risk stratification and counseling

Risk stratification and counseling of women with heart disease is best accomplished prior to conception. The data required for risk stratification can be acquired readily from a thorough cardiovascular history and examination (including percutaneous oximetry, when appropriate), 12-lead electrocardiogram, and transthoracic echocardiogram. In counseling, the following four areas should be considered: identification of the risk factors for maternal and fetoneonatal complications, recurrence risk of CHD in offspring, anepartum management, and peripartum management.

Risk stratification
Definition of the underlying cardiac lesion is the first step of risk stratification and determining management. Review of prior catheterization and operative reports may be necessary to clarify the diagnosis and define the nature of residua and sequelae such as ventricular function, pulmonary pressure, severity of obstructive lesions, persistence of shunts, and presence of hypoxemia. Almost all patients can be stratified into low-, intermediate-, or high-risk groups using a risk index (Table 62.1), with additional risk data supplemented by results of lesion-specific studies (**Class I,**

Table 62.1 Risk factors for maternal cardiac adverse events during pregnancy (adapted from Siu et al.[1])

Adverse maternal cardiac event	Maternal risk factors
	General*
Pulmonary edema	NYHA functional classification III
Arrhythmia	or IV or cyanosis
Stroke	Systemic ventricular ejection
Death	fraction <40%
	Left heart obstruction (mitral
	valve area <2 cm², aortic valve
	area <1.5 cm², peak left
	ventricular outflow gradient
	>30 mm Hg
	Cardiac event (arrhythmia,
	stroke, pulmonary edema)
	prior to pregnancy
	Lesion specific
	As discussed in the text

*The general risk factors can be used to create a maternal risk index for adverse cardiac events related to pregnancy: 0 risk factors <5% risk, 1 risk factor ~ 27% risk, ≥2 risk factors ~ 75% risk

Figure 62.1 The frequency of maternal cardiac complications (pulmonary edema, cardiac arrhythmia, stroke, or cardiac death), as predicted by the number of risk factors, observed in the derivation and validation groups (n = number of pregnancies). (From Siu et al.[1]).

Figure 62.2 The frequency of any primary or secondary cardiac events (deterioration in maternal functional class, need for urgent cardiac interventions during the ante- or postpartum periods, pulmonary edema, cardiac arrhythmia, stroke, or cardiac death), as predicted by the number of risk factors, observed in the derivation and validation groups (n = number of pregnancies). (From Siu et al.[1]).

Level C1). Poor functional status (NYHA >II) or cyanosis, systemic ventricular systolic dysfunction, left heart obstruction, and history of cardiac events prior to pregnancy (arrhythmia, stroke or pulmonary edema) are independent predictors of maternal cardiac complications.[1]

The four above-mentioned risk factors are the components of a risk index and have been prospectively validated (see Table 62.1). The risk of a cardiac event (cardiac death, stroke, pulmonary edema or arrhythmia) during pregnancy increases with the number of predictors present during the antepartum evaluation (Fig. 62.1).[1] Pregnancies with 0, 1 or >1 predictor correspond to low, intermediate or high-level risk, respectively. The above-mentioned predictors were also predictive of the combined endpoint of cardiac event (as defined above), deterioration of maternal functional class during pregnancy or need for an urgent cardiac intervention during the ante- or postpartum periods (Fig. 62.2). This risk index, together with lesion-specific risk estimates, can be applied at the time of preconception counseling or during pregnancy. If lesion-specific and index estimates of maternal cardiac risk are discordant, then the higher of the two risk estimates should be applied. Furthermore, if no lesion-specific data are present or the lesion was not included in current risk indices, it may be prudent to assume an intermediate level of risk.

In a subsequent single-center retrospective study examining women with CHD, the global predictors of risk as listed above were again validated, and subpulmonary ventricular dysfunction and severe pulmonary regurgitation were proposed as additional predictors of adverse cardiac outcomes.[10]

Identification of potentially treatable risk factors is crucial. Both maternal and fetal outcomes are improved by surgery to correct cyanosis, which should be undertaken prior to conception when possible.[13] Similarly, patients with symptomatic obstructive lesions should undergo intervention prior to pregnancy[20] (**Class I, Level C1**). A systematic overview of the outcome of cardiovascular surgery performed during pregnancy reported a maternal and fetal mortality of 6% and 30% respectively.[77] Planning for valve replacement prior to pregnancy nessesitates weighing the need for ongoing anticoagulation with a mechanical valve against the likelihood of early reoperation if a tissue valve is used. For women with AS, an attractive alternative is the pulmonary autograft.

Table 62.2 Maternal risk factors for fetoneonatal adverse events during pregnancy (adapted from Siu et al.[1,7])

Adverse neonatal events	Maternal risk factors
Premature birth Small-for-gestational-age birthweight Respiratory distress syndrome Intraventricular hemorrhage Death (fetal or neonatal)	**Cardiac** NYHA functional classification III or IV, or cyanosis Left heart obstruction (mitral valve area <2 cm², aortic valve area <1.5 cm², peak left ventricular outflow gradient >30 mm Hg) **General** Maternal age <20 or >35 years Anticoagulant therapy Smoking during pregnancy Multiple gestation pregnancy **Obstetric** Premature delivery/premature membrane rupture Incompetent cervix Cesarean section Intrauterine growth retardation Bleeding >12 weeks gestation Febrile illness Uterine/placental abnormalities

Additional associated risk factors that may complicate pregnancy include prosthetic valves and conduits, anticoagulant therapy, and the use of teratogenic drugs such as warfarin and angiotensin-converting enzyme inhibitors.

Maternal life expectancy and ability to care for a child need to be considered. A patient with limited physical capacity or with a condition that may result in premature maternal death should be advised of her potential inability to look after her child. Women whose condition imparts a high likelihood of fetal complications, such as those with cyanosis or on anticoagulants, must be apprised of these added risks.

Some of the same factors that are predictive of maternal cardiac risk (poor maternal functional class or cyanosis, left heart obstruction) are also predictors of fetoneonatal complications. Furthermore, there is an interaction between baseline obstetric and cardiac characteristics in determining fetoneonatal outcomes (Table 62.2, Fig. 62.3).[1,7] Women with heart disease and additional obstetrical risk factors (such as very young or advanced maternal age, or smoking) are at the highest risk of fetoneonatal complications. Obstetrical outcomes such as premature labor, pregnancy induced hypertension, and postpartum hemorrhage have been examined in only a few studies to date.[1,7,12,24,48]
Figure 62.3 The frequency of fetoneonatal complications in two groups defined by the presence or absence of maternal noncardiac characteristics (obstetric high-risk characteristics, smoking, use of anticoagulation, multiple gestation, and maternal age). Control group is represented by white bars. Heart disease group with neither left heart obstruction nor poor functional class/cyanosis is in gray. Heart disease group with left heart obstruction or poor functional class/cyanosis is in black.

Recurrence risk of congenital heart disease

The *risk of recurrence of CHD in offspring* should be addressed in the context of ~0.5% risk in the general population. The risk with a first-degree relative affected increases about 10-fold. A multicenter study examining offspring of patients with major congenital heart defects who survived cardiac surgery described an overall recurrence rate of 4% in their offspring.[78] The type of CHD seen in offspring can differ from the lesion seen in the mother.[79] Recurrence risk of CHD in offspring varies by lesion and in some reports is as low as 0.6% in association with maternal TGA[9] and as high as 18% in the presence of maternal LV outflow tract obstruction.[80] Certain conditions such as Marfan syndrome and 22q11 deletion syndrome are autosomal dominant, conferring a 50% recurrence risk in her offspring. BAV may also be transmitted in a familial or autosomal dominant pattern. Patients with CHD who reach reproductive age should be offered formal genetic counseling so that they are fully informed of the mode of inheritance and recurrence risk as well as the prenatal diagnosis options available to them (**Class I, Level C1**). Preventive strategies to decrease the incidence of congenital defects such as preconception use of multivitamins containing folic acid can be discussed at the time of such counseling[81] (**Class I, Level B**). Antepartum fetal echocardiography should be offered to pregnant women with CHD and will exclude major congenital lesions (**Class I, Level C1**).[82] Pediatric cardiac assessment is of additional diagnosic utility even if the fetal echocardiogram was normal.[83]

Antepartum management

General principles Women with heart disease who are at intermediate or high risk for complications should be

Table 62.3 Management of pregnancy in women with heart disease

All patients
- Define the lesion, the residua and the sequelae
- Assess functional status
- Determine predictors of risk: general and lesion specific
- Eliminate teratogens
- Arrange genetic counseling when relevant
- Consider consultation with a regional center
- Assess need for endocarditis prophylaxis during labor and delivery

Intermediate and high-risk patients
- Arrange management at a regional center for high-risk pregnancy
- Consider antepartum interventions to reduce pregnancy risk
- Engage a multidisciplinary team, as appropriate
- Consider a multidisciplinary case conference
- Develop and disseminate a management plan
- Anticipate vaginal delivery in almost all cases, unless there are obstetric contraindications
- Consider early epidural anesthesia
- Modify labor and delivery to reduce cardiac work
- Plan postpartum monitoring

managed in a high-risk pregnancy unit by a multidisciplinary team from obstetrics, cardiology, anesthesia, and pediatrics (**Class I, Level C2**) (Table 62.3). When dealing with a complex problem the medical team should meet early in the pregnancy, develop and distribute a written management plan. Consultation at a regional referral center should be encouraged with subsequent management at a community hospital setting for women who are confirmed to be in a "low-risk" group.

Activity limitation and hospital admission by mid second trimester may be advisable in some women with structural cardiac lesions and NYHA III or IV symptoms. Gestational hypertension, hyperthyroidism, infection and anemia should be identified early and treated vigorously.

For patients with functionally significant MS, beta-adrenergic blockers should be used to control heart rate (**Class I, Level C1**). Digitalis is often ineffective in blunting pregnancy-induced tachycardia. Diuretics should be used cautiously in the treatment of pulmonary congestion or right heart failure as aggressive diuresis may lead to decreased uteroplacental perfusion. Some have advocated for the use of anticoagulation prophylaxis in the presence of severe MS and an enlarged left atrium, even in the absence of an atrial tachyarrhythmia, due to the hypercoagulability inherent in pregnancy.[84] Rheumatic fever penicillin prophylaxis should continue as in the non-pregnant state.[20] We also offer empiric therapy with beta-adrenergic blockers to patients with coarctation or Marfan syndrome or those with dilated aorta in the presence of a BAV (**Class IIa, Level C2**).

Special circumstances

Arrhythmias The pregnant state may increase arrhythmia propensity related to several factors including altered hormonal milieu, enhanced sympathetic tone and cardiac chamber dilation.[85] Premature atrial or ventricular beats are common in normal pregnancy; sustained tachyarrhythmias have also been reported. Women with a previous history of arrhythmia are at increased risk of recurrence during pregnancy. Adverse fetal and neonatal outcomes have been related to recurrent arrhythmia during pregnancy.[86] In a recent overview, women at particular risk of arrhythmia were those with atrial redirection surgery (for transposition), those after Fontan repair, and those with AVSD.[9]

Pharmacologic treatment is usually reserved for patients with frequent or sustained episodes, particularly if poorly tolerated and/or in the presence of structural cardiac abnormalities. Sustained tachyarrhythmias such as atrial flutter or atrial fibrillation should be treated promptly, avoiding teratogenic antiarrhythmic drugs. Electrical cardioversion is safe in pregnancy. Digoxin and beta-adrenergic blockers are antiarrhythmic drugs of choice in view of their known safety profiles (**Class I, Level C1**).[20,87] Quinidine, adenosine, sotalol, and lidocaine are generally considered "safe" but published data on their use during pregnancy are more limited. Amiodarone is more problematic and standard texts classify it as contraindicated in pregnancy, although there are case reports describing successful use with careful follow-up; it is not teratogenic, but may impair neonatal thyroid function.[88,89] Pregnancies in women with implantable cardioverter-defibrillators were associated with favorable maternal and fetal outcomes.[90]

Anticoagulation for mechanical heart valve In a systematic overview of pregnancy outcomes in women with prosthetic heart valves, the overall pooled maternal mortality was 2.9% and was mostly related to valve thrombosis.[3] The choices of anticoagulants include oral warfarin, unfractionated heparin, and low molecular weight heparin (LMWH). Warfarin is easier to administer and is effective but has the associated risk of embryopathy during organogenesis, and fetal intracranial bleeding can occur throughout pregnancy. Although the incidence of embryopathy was lowest when a daily warfarin dose of ≤5 mg was utilized,[91] there are ongoing concerns about neurodevelopmental abnormalities from intracranial bleeding. Fetal intracranial hemorrhage during vaginal delivery is a risk with warfarin unless it has been stopped for at least two weeks. Adjusted-dose subcutaneous unfractionated heparin has no teratogenic effects, as the drug does not cross the placenta, but there is risk of maternal thrombocytopenia and osteoporosis. Claims of inadequate effectiveness of heparin in patients with mechanical heart valves have been countered

by arguments that inadequate doses were used. LMWH has better bioavailability and has been suggested as an alternative to adjusted-dose unfractionated heparin, particularly in the context of meticulously monitored plasma anti-Xa levels.

In the absence of systematic data on the optimal anticoagulation regimen in pregnant women with mechanical heart valves, current practice guidelines are all based on expert opinion and are not in agreement with one another.[20,92,93] The American College of Chest Physicians (ACCP) recommends that either LMWH or unfractionated heparin be used throughout pregnancy with dose adjustments based on careful monitoring; the European Society of Cardiology does not endorse the use of LMWH during pregnancy for women with prosthetic heart valves.[20,92,93] Some have proposed alternative strategies for patients deemed at "higher risk" as compared to those deemed to be at "lower risk" for thromboembolism.[34] The practice within our group is based on ACCP guidelines with LMWH at least during the first trimester. Monitoring of both peak and trough levels of anti-Xa may be necessary to ensure adequate anticoagulation in women with mechanical heart valves receiving LMWH.[34] Adjunctive use of low-dose aspirin should also be considered.[20,92,93] Aspirin in low dose is safe for the fetus, even at term[94] (**Class I, Level B**) although high maternal doses may promote premature fetal ductus arteriosus closure.

Eisenmenger syndrome If a woman with Eisenmenger syndrome does not accept counseling to terminate or presents late in pregnancy, meticulous antepartum management is necessary including early hospitalization, supplemental oxygen and possibly empiric anticoagulation (**Class IIa, Level C2**). The efficacy of nitric oxide therapy in these patients has yet to be demonstrated. Experience with targeted pulmonary vasodilator therapy is limited to case reports, which suggest that agents may improve pulmonary pressures.[95–98]

Hypertension in pregnancy Mild pre-existing hypertension may not require pharmacotherapy in pregnancy, as fetal outcomes are unaffected, maternal blood pressure falls lower than baseline during the first 20 weeks of gestation, and excessive lowering of maternal blood pressure may compromise placental perfusion.[99] Therapy should be initiated or reinstituted if moderate-to-severe hypertension develops (systolic BP ≥150–160, diastolic BP ≥100–110 or both) or there is target organ damage. A recent meta-analysis of 46 randomized trials evaluating antihypertensive therapy in women with mild-to-moderate hypertension (140–169 mm Hg systolic, 90–109 mm Hg diastolic) during pregnancy did not find any significant difference in fetal outcome or risk of developing superimposed gestational hypertension with proteinuria (pre-eclampsia), although

the risk of developing severe hypertension was halved in treated women.[100] If treatment is indicated, drug therapy established as safe includes methyldopa, hydralazine, labetalol and other beta-blockers, and nifedipine (**Class I, Level C1**).[101,102] As there are no clear benefits of one class of medication over another, choice of an antihypertensive should be based on the potential for side effects and the experience of the prescribing clinician with a particular drug.[103] Diuretics are indicated for the management of volume overload in renal failure or CHF and may be used as adjuncts in the management of pre-existing (chronic) hypertension, but should be avoided in gestational hypertension (pre-eclampsia), which is a volume-contracted state.[99,104] Due to increased risk of fetopathy, angiotensin-converting enzyme inhibitors, and angiotensin-receptor blocking agents by extension, are not considered safe at any point during pregnancy (**Class I, Level C1**).

Gestational hypertension with proteinuria (pre-eclampsia) is treated effectively only by delivery of the fetus and placenta. Delay in delivery to allow maturation of the fetus can often be accomplished if the syndrome is mild, the patient is under very close surveillance in a hospital or obstetric day unit, and pregnancy is terminated as soon as further benefit to the fetus is unlikely or maternal safety is compromised.[99]

Management during labor and delivery

Vaginal delivery is recommended, with cesarean delivery for cardiac indications reserved for aortic dissection, Marfan syndrome with dilated aortic root, and failure to switch from warfarin to heparin within two weeks prior to labor. Preterm induction is rarely indicated, but once fetal lung maturity is assured a planned induction is preferred in high-risk situations so that appropriate support will be available. There is no consensus on the use of invasive hemodynamic peripartum monitoring. We commonly utilize intra-arterial monitoring and often use central venous pressure monitoring as well in cases where there are concerns about the interpretation and deleterious effects of a sudden drop in systemic blood pressure (severe AS, pulmonary hypertension or moderate or severe systemic ventricular systolic dysfunction). The utility of an indwelling pulmonary artery catheter has not been studied during pregnancy, and it is rarely utilized; risk may be increased with complex anatomy such as atrial baffles or in the setting of pulmonary hypertension because of possible pulmonary infarction or rupture.

Heparin anticoagulation is discontinued 12–24 hours prior to induction or reversed with protamine if spontaneous labor develops, and can usually be resumed 6–12 hours post partum. According to current guidelines,[105] routine prophylactic antibiotic therapy is not indicated but has been recommended by some because of the possibility of

bacteremia during labor and delivery, particularly in the setting of a complicated delivery.[21]

Epidural anesthesia with adequate volume preloading is the technique of choice (**Class I, Level C2**). Epidural fentanyl is particularly advantageous in cyanotic patients with shunt lesions as it does not lower peripheral vascular resistance. In the presence of a shunt, air and particulate filters should be placed in all intravenous lines.

Labor is conducted in the left lateral decubitus position to attenuate hemodynamic fluctuations associated with contractions in the supine position. A shortened second stage of labor will reduce need for maternal expulsive efforts. As hemodynamics do not approach baseline for many days after delivery, those patients at intermediate or high risk may require monitoring for a minimum of 72 hours post partum. Patients with Eisenmenger syndrome require longer close postpartum observation, since mortality risk persists for seven days or more.

Conclusion

With important exceptions, most women with cardiac disease can be expected to do well during pregnancy with appropriate management based on systematic risk stratification. A preconceptual cardiac evaluation is of great value as baseline testing can be arranged, medications can be reviewed and revised if need be, pregnancy-related risk stratification can be established and interventions can be planned prior to pregnancy, when necessary. Pregnancies deemed to be at intermediate or high risk should be managed and delivered in a tertiary care setting. An antepartum multidisciplinary conference to co-ordinate management should take place if complex care is anticipated. If intervention is required during pregnancy, a percutaneous approach, if at all possible, should be undertaken and cardiac surgery should be avoided. In some cardiac conditions, conception should be avoided and in the event of pregnancy, termination should be offered; these include pulmonary vascular obstructive disease, Marfan syndrome with aortopathy, and peripartum cardiomyopathy with residual ventricular dysfunction (**Class I, Level C1**).

63 Adult congenital heart disease

Elisabeth Bédard and Michael A Gatzoulis

Royal Brompton Hospital, London, UK

Introduction: prevalence of congenital heart disease

Congenital heart disease (CHD) is defined as a cardiovascular abnormality that is present from birth, and approximately 4–10 liveborn infants per 1000 are affected.[1,2] However, the true prevalence may be much higher, as these estimates often exclude bicuspid aortic valve and prolapse of the mitral valve, the most common cardiac malformations.[1] A more accurate estimation has been reported to be around 50 per 1000 live births.[1] Table 63.1 summarizes the recently reported incidence of the common congenital heart defects.[2] The great successes of pediatric cardiac care in the past 25 years have resulted in a marked increase in adult patients with CHD. About 85% of children with CHD are now expected to survive into adulthood.[3] The most recent epidemiologic study, conducted in Quebec, Canada, revealed that the prevalence of adults with CHD was 4.09 per 1000 for the year 2000, representing an increase of 85% compared with 1985, while this increase was only 22% in children for the same period.[4] The authors extrapolated their results to the US population and estimated that about 900 000 adults had CHD in the year 2000 in the USA.

Most early interventions carried out on patients with CHD have not been curative and a significant proportion of them will need further surgery or experience various complications such as arrhythmia and heart failure. Their cardiovascular disease is complex and their management poses a real challenge, requiring expert cardiologic care. Indeed, initial assessment of suspected CHD, follow-up of patients with CHD of moderate severity and complex lesions as well as risk assessment for non-cardiac surgery

and pregnancy should ideally take place in a tertiary adult care center. However, there are currently not enough such specialists worldwide. Education on the principles of CHD for a broader professional audience is therefore imperative to improve the lifetime care of this population.[5] Primary care physicians, general adult cardiologists, obstetricians, surgeons and anesthesiologists should also be aware of the various issues in the general medical management of CHD because most patients will also need local follow-up for economic, social and geographic reasons.[6,7]

This chapter provides key clinical information and guidelines for the management of adults with CHD.[7a]

Etiology

Genetic basis of CHD

In recent years, there have been tremendous advances not only in diagnosis and treatment of CHD but also in our knowledge of the etiologies of CHD. Improvements in genetic techniques have resulted in identification of several loci and genes associated with CHD. In their extensive review of the current genetic basis for congenital heart defects, Pierpont *et al*[1] emphasized the reasons why it is very important to determine whether there is an underlying genetic abnormality:

- other organ systems may be involved
- it may provide prognostic information
- there may be significant risks of transmission to the offspring
- genetic testing in other family members may be appropriate.

A *chromosome* deletion can be identified by fluorescence *in situ* hybridization (FISH) in some syndromes associated with heart defects. For example, a 22q11 deletion is present in ~90% of patients with DiGeorge syndrome, which is characterized by cardiac defects (such as aortic arch anomalies, truncus arteriosus, tetralogy of Fallot (TOF) or ven-

tricular septal defect (VSD)), specific facial features, palate anomalies, hypoplasia of the thymus, aplasia or hypoplasia of the parathyroid glands, and psychiatric disorders. The 22q11 deletion syndrome is an autosomal dominant syndrome which carries a 50% risk of transmission from an affected parent to the offspring.[1] Therefore, FISH testing should be considered for patients with such cardiac defects, especially if one of the other features of the 22q11 deletion syndrome listed above is present.[1] A chromosome microdeletion (7q11.23) is also found in ~90% of patients with Williams syndrome, which is associated with supravalvular aortic stenosis (AS) and often supravalvular or peripheral pulmonary stenosis (PS). Mutations in various single genes have been found in several syndromes, namely Holt–Oram, Alagille, Char, Noonan, LEOPARD, CHARGE association, Ellis–van Creveld and Marfan. Single-gene disorders can also result in non-syndromic congenital heart defects, such as familial congenital atrial septal defect (ASD) and atrioventricular block (AVB).[1] However, a more complex combination of multiple genetic alterations and environmental factors instead of a single gene mutation is likely to be the cause in many cases of non-syndromic CHD.[1] Our knowledge of the association between CHD and genetic alterations will continue to grow with ongoing research and current availability of genetic testing.

Non-inherited risk factors for CHD

During the past decade, there has been an increase in epidemiologic literature concerning modifiable risk factors that may have an adverse effect on the fetal heart,[8] especially with an exposure during the first pregnancy trimester and the 3 months before conception (Table 63.2).[8]

We now provide information on specific lesions.

Atrial septal defect

Anatomic findings and pathophysiology

Interatrial communications are common and can be classified in four types: ostium secundum defects, the most common, are located within the region of the fossa ovalis; ostium primum, part of an atrioventricular septal defect (AVSD), includes a common atrioventricular junction with a trileaflet left atrioventricular valve (AVV); superior sinus venosus defects are frequently associated with partial anomalous pulmonary vein return; and coronary sinus

defects are characterized by a deficiency in the roof between the coronary sinus and the left atrium (Fig. 63.1). The size of the defect and the ventricular diastolic filling pressures (right and left) determine the degree of left-to-right shunting. A Qp:Qs ratio greater than 1.5/1.0 or the presence of right heart dilation is considered an indication for closure.[9]

Clinical presentation

Dyspnea and fatigue on exertion are the most common symptoms in adults. Patients can also present with palpitations from atrial fibrillation or flutter, which rarely occurs before 40 years of age.[10,11] On examination, a right ventricular lift and a wide and fixed splitting of the second heart sound are distinctive clinical signs of ASD. A pulmonary ejection systolic murmur and a mid-diastolic rumble reflect increased flow through the pulmonary and tricuspid valves.

Diagnostic evaluation

Electrocardiogram
The ECG in ASD can reveal sinus rhythm, atrial fibrillation or atrial flutter, rightward axis deviation in secundum ASD (leftward or extreme right in primum ASD), prolonged PR interval, and right bundle branch block pattern (RBBB).[12–14] In superior sinus venosus defect, sinus node dysfunction may lead to inverted P-waves in inferior leads.[10,15,16]
Figure 63.1 Anatomic location of ASDs. A, indicates secundum ASD; B, ostium primum ASD or partial AV septal defect; C, superior sinus venosus ASD; D, inferior sinus venosus ASD; E, coronary sinus ASD.

Chest radiography
Signs of increased pulmonary blood flow,[17,18] as well as enlarged central pulmonary arteries, cardiomegaly (right heart dilation), and small aortic knuckle from chronic low systemic cardiac output, are present in significant defects.[10]

Exercise testing
Useful to document exercise capacity when there is discrepancy between symptoms and clinical findings, or to show changes in oxygen saturation in patients with mild or moderate pulmonary arterial hypertension (PAH) (**Class IIa, Level C**).

Echocardiography
Transthoracic echocardiogram (TTE) usually demonstrates the location, shape and size of the defect and its septal margins.[19] TTE can also provide the direction of the shunt, an estimation of the shunt ratio (Qp:Qs)[20] and an estimation of the pulmonary artery pressures (PAP) from the Doppler velocity of the tricuspid regurgitation (TR). An enlarged right ventricle (RV),[21] with or without paradoxic septal motion.[22] might be the only initial findings of a significant ASD. Transesophageal echocardiogram may better visualize the pulmonary venous return, and is used to guide device closure of the defect.

Cardiac magnetic resonance imaging (CMR)
Cardiac magnetic resonance imaging is the modality of choice to assess right ventricular size and function. Pulmonary venous return can also be accurately demonstrated.[23]

Management

Indications for ASD closure are shown in Table 63.3.[7a,10] Most centers favor percutaneous closure when the anatomy is suitable.[24,25] Device closure is safe (complication rate less than 1%) and effective, and minimizes hospital stay.[26] It

Table 63.3 ASD closure

Indications
ASD associated with RA and RV enlargement, with or without symptoms (**Class I, Level B**)
Paradoxic embolism (**Class IIa, Level C**)
Documented orthodeoxia-platypnea (**Class IIa, Level B**)
Contraindications
Advanced pulmonary arterial hypertension (PAH) (**Class III, Level B**)
Pregnancy (defer closure for 6 months after delivery) (**Level C**)
Severe left ventricular dysfunction (**Level C**)
RA, Right atrium.

also improves RV size and function[27] and exercise capacity,[24] as does surgical closure. However, surgical closure is required for patients with ostium primum and sinus venosus ASDs (**Class I, Level B**), as well as ostium secundum defects with one or more of the following features: stretched diameter >36–40 mm, inadequate atrial septal rims to allow device deployment, or proximity of the defect to the AVV, coronary sinus or vena cavae[10,25] (**Class IIa, Level C**).

Outcomes and complications

Normal long-term survival has been reported after surgical ASD closure when patients were operated on before 25 years of age.[28] Nevertheless, benefits (reduced morbidity and mortality) have also been demonstrated with surgical ASD closure compared with medical treatment in patients over 40 years of age.[29,30] The risk of developing late atrial flutter or fibrillation is clearly higher if surgical repair is performed after 40 years of age.[11] Other complications are summarized in Table 63.4.

Ventricular septal defect

Anatomic findings and pathophysiology

Ventricular septal defect (VSD) is a very common congenital heart malformation (up to 53.2 per 1000 liveborn infants).[33] VSDs are classified into (1) perimembranous, (2) muscular, and (3) double committed subarterial (Fig. 63.2). In perimembranous VSDs, part of the rim of the defect is formed by part of the central fibrous body, which is between the leaflets of an AVV and an arterial valve. Muscular VSDs possess completely muscular rims. Finally, double committed subarterial VSDs are present when the aortic and pulmonary valves are contiguous in the roof of the defect.[34]

The magnitude of and direction of flow through the VSD are determined by the size of the defect, the right and left ventricular pressures, and the pulmonary vascular resistance. In small (restrictive) VSDs, there is a significant
Figure 63.2 Anatomic location of VSDs. A, indicates perimembranous VSD; B, muscular VSDs; C, doubly committed and subarterial VSD.

pressure gradient between the left and right ventricles. In large non-restrictive VSDs, the pulmonary pressures are at or close to systemic levels. With the development of pulmonary vascular disease, the degree of left-to-right shunting decreases and then reverses, leading to Eisenmenger syndrome.

Clinical presentation

Patients with small VSDs are usually asymptomatic. Moderately restrictive and large VSDs can cause dyspnea on exertion, and/or palpitations if arrhythmias arise. As mentioned above, non-restrictive VSDs can lead to Eisenmenger syndrome. On examination, a holosystolic murmur is heard on the left sternal edge, which is loudest and may be accompanied by a thrill in small defects. In moderate and large defects, the apical impulse is laterally displaced. There is a widely split second heart sound that varies with respiration. With large shunts, a diastolic rumble of increased mitral flow may be heard. Large non-restrictive VSDs may have signs of PAH, including a RV heave and a loud P2.

Diagnostic evaluation

Electrocardiogram

In small VSDs, the ECG is usually normal. In moderate VSDs, ECG may reveal left atrial hypertrophy and signs of left ventricular overload. In large non-restrictive VSDs

with PAH, the QRS axis shifts to the right and right atrial/ventricular hypertrophy is present. Following surgical repair, RBBB is found in 29–65% of patients more than 25 years after surgery[35,36] and 0.7–3.5% may develop late complete AVB.[36,37]

Chest radiography

Small VSDs have normal chest X-rays. Pulmonary plethora and cardiomegaly are present with larger defects. When significant PAH develops, the chest X-ray shows dilated central pulmonary arteries and right heart enlargement.

Echocardiography

The size and location of VSDs can be accurately assessed by TTE.[38,39] Shunt ratio (Qp:Qs) and PAP can be estimated[20] and, most importantly, hemodynamic consequences such as left ventricular enlargement or hypertrophy can be ascertained. Associated lesions should be sought (aortic regurgitation (AR), right or left ventricular outflow tract obstruction). Transesophageal or three-dimensional echocardiography may be occasionally required when the TTE quality is poor.[40]

Cardiac catheterization

Cardiac catheterization is useful when non-invasive data are inconclusive and further information is needed (**Class IIa**), such as assessment of pulmonary vascular resistance, magnitude of shunts, and pulmonary vasoreactivity (**Level B**).

Management

Table 63.5 summarizes the indications for VSD closure.[7a] Surgical closure in the current era carries low perioperative mortality risk (less than 1%),[41] with a low risk of AVB requiring permanent pacemaker (0.7–3%).[37,41,42] Transcatheter closure is currently in the investigational stage and should be considered only in selected cases of muscular and perimembranous VSDs (**Class IIb, Level C**). Butera *et al* recently reported their 38.5 months follow-up of 104 patients who underwent percutaneous closure of perimembranous VSDs, and the occlusion rate reached 99% at follow-up. However, pacemaker implantation for complete AVB occurred in 5.6% (all in patients <6 years old).

Outcomes and complications

Small restrictive VSDs with normal PVR have an excellent prognosis.[43] Twenty-five year survival rate decreases with increasing size of the VSD (small, 96%; moderate, 86%; large, 61%; Eisenmenger, 42%).[44] Following surgical closure in patients without previous PAH, life expectancy should be close to normal. Even small VSDs, in unoperated patients or as residual defects following surgery, can lead to

Table 63.5 VSD closure

Indications

Left-to-right shunt (Qp:Qs) >2 by echocardiography, CMR or cardiac catheterization and evidence of LV volume overload (**Class I, Level B**)

Left-to-right shunt (Qp:Qs) >1.5:1 with pulmonary artery pressure < two-thirds of systemic pressure and PVR < two-thirds of systemic vascular resistance (**Class IIa, Level B**)

Left-to-right shunt (Qp:Qs) >1.5:1 in the presence of LV systolic or diastolic dysfunction (**Class IIa, Level B**)

Regardless of the size:

History of endocarditis (**Class I, Level C**)

May be considered in patients with aortic regurgitation (**Level C**)

Contraindications

Advanced PAH (**Class III, Level B**)

Pregnancy (defer closure for 6 months after delivery) (**Level C**)

LV, left ventricle; EF, ejection fraction.

Table 63.6 Complications of VSDs

Arrhythmias[47]
Atrial fibrillation
Ventricular arrhythmias, sudden cardiac death
Aortic regurgitation
Endocarditis
LV dysfunction (in large defects)
PAH and Eisenmenger syndrome (if large, unrestrictive defect)

complications such as endocarditis, aortic regurgitation or arrhythmias.[45,46] Other possible complications of VSDs are listed in Table 63.6.

Atrioventricular septal defect

Anatomic findings and pathophysiology

The morphologic hallmark of an AVSD is a common atrioventricular junction, with abnormalities of the AVV. In complete AVSD, there is a common AVV with five leaflets, while in partial AVSD (ostium primum ASD), the AVV is divided into two orifices (Fig. 63.3). The left AVV has three leaflets (mural leaflet, inferior and superior bridging leaflets). In complete AVSD, there is usually a primum ASD and a large VSD. In partial AVSD, only a primum ASD is present. Other common features include an inlet-to-outlet disproportion of the left ventricle and unwedged position of the aortic valve, which result in an elongated left ventricular outflow tract (LVOT) ("goose neck deformity"), predisposing to subaortic obstruction. Septal chordal

Figure 63.3 Complete and partial AVSDs. A illustrates common valvar orifice (a, superior bridging leaflet; b, left mural leaflet; c, inferior bridging leaflet; d, right inferior leaflet; e, right antero-superior leaflet). B illustrates separate right and left valvar orifices.

(a)   (b)
attachments of the left AVV contribute to this complication.[48] The conduction system is also abnormal in patients with AVSD, leading to an increased risk of AVB.[49]

Complete AVSD is associated with abnormal karyotype in 49% of cases diagnosed in fetal life (39% having trisomy 21),[51] while some surgical series report Down syndrome in up to 73% of patients undergoing complete AVSD repair.[52]

Complete AVSDs have a significant degree of left-to-right shunting through the primum ASD and the large VSD, leading to left ventricular enlargement and early PAH. Partial AVSDs (with only a primum ASD) will usually have similar pathophysiology to other isolated interatrial shunts, unless the left AVV is very dysplastic, leading to severe stenosis and/or regurgitation.

Clinical presentation

The clinical presentation relates to the morphology of the defect. Large left-to-right shunts and severe left AVV regurgitation will present with congestive heart failure (CHF) in infancy and will develop PAH and cyanosis. Adults with unrepaired complete AVSDs may present with exercise intolerance and fatigue, Eisenmenger syndrome (see below), palpitations from atrial arrhythmias or bradycardia from complete AVB. Examination may reveal cyanosis and clubbing, right ventricular impulse, increased pulmonary component of the second sound, variable ejection systolic murmurs, mid-diastolic murmur in large left-to-right shunt, and pansystolic murmur with left AVV regurgitation. Isolated ostium primum ASDs will share the clinical features of ASDs described above but may also have signs of left AVV dysfunction.

Diagnostic evaluation

Electrocardiogram

Left axis deviation, RBBB, and first-degree AVB are common ECG findings in patients with AVSD.[53,54] Atrial fibrillation can also be present.[53]

Chest radiography

Cardiomegaly from left heart dilation usually present in patients with large VSD and/or significant left AVV regurgitation. Large primum ASD will give rise to right heart enlargement and increased pulmonary vascular markings. Patients with Eisenmenger syndrome will have dilated central pulmonary arteries and peripheral pruning.

Echocardiography

Diagnosis of AVSD can accurately be made by TTE.[55] The following features should be assessed.[56–58]
• Abnormal configuration of the AVVs are at the same level.
• Left AVV has three leaflets.
• May have some degree of regurgitation.
• Presence of ASD and VSD, and the magnitude of left-to-right shunting.
• Estimated right ventricular systolic pressure.
• Inlet-to-outlet disproportion with elongated LVOT and possible LVOT obstruction.
• Abnormal position of the papillary muscles.
• Left ventricular size and function.

Cardiac magnetic resonance

This provides detailed morphologic information and accurately estimates the size of the VSD.[59]

Cardiac catheterization and angiography

Echocardiography and CMR have replaced cardiac catheterization for the diagnostic and preoperative evaluation of AVSDs. However, cardiac catheterization may be necessary to assess formally the pulmonary vascular resistance and vasoreactivity (**Class IIa, Level B**).

Management

Patients with complete AVSD should have early surgical correction (including repair of the AVV[60,61]) within the first few months of life to prevent pulmonary vascular disease. Most patients who present with partial AVSDs in later life

Table 63.7 Late complications of VSDs

(>40 years old) will also benefit from surgical repair.[62] However, patients with irreversible pulmonary vascular disease and/or Eisenmenger syndrome should usually be treated medically (see below). Indications of reintervention in adults include:[7a]

• significant left AVV regurgitation or stenosis with symptoms, atrial or ventricular arrhythmias, a progressive increase in LV dimensions or deterioration of LV function (**Class I, Level B**)
• significant LVOT obstruction (**Class I, Level B**)
• residual ASD or VSD with significant left-to-right shunting (**Class I, Level B**)
• complete AVB (pacemaker implantation) (**Class IIa, Level B**).

Outcomes and complications

Without surgical repair, only 4% of patients with complete AVSD will survive beyond 5 years of age.[63] Conversely, the 10-year survival rate in patients following complete AVSD repair is 83%[60] and 93% after partial AVSD repair.[64] Table 63.7 summarizes late complications of AVSD, including the most common, left AVV regurgitation (10% of patients).[50,60,64]

Left ventricular outflow tract obstruction and bicuspid aortic valve

Anatomic findings and pathophysiology

Left ventricular outflow tract obstructions (LVOTOs) comprise a group of stenotic lesions which may be located at the subvalvar, valvar or supravalvar level. Significant LVOTO creates an increase in afterload, resulting in elevated end-diastolic left ventricular pressure and concentric hypertrophy.

Subvalvar aortic stenosis (SAS)

Fixed SAS ranges from discrete fibrous membrane (91% of cases) to tunnel-like fibromuscular band.[65,66] Nearly one-quarter of patients also have bicuspid aortic valve (BAV).[65] Other associated cardiac defects include VSD, coarctation of the aorta and Shone syndrome (parachute mitral valve, mitral stenosis, SAS, aortic coarctation, BAV). SAS is usually progressive; AR is common but usually mild.[67]

Congenital valvar AS

Abnormal valve and cusp formation may result in unicuspid, bicuspid, trileaflet bicommissural or rarely quadricuspid valves. Fifty-four percent of patients with significant AS requiring surgery have congenitally malformed valves, of which more than 90% are bicuspid.[68] The estimated incidence of BAV in the general population is 1–2%, affecting more males than females.[69] The high incidence (37%) of BAV in first-degree relatives suggests an autosomal dominant inheritance with reduced penetrance.[70] BAV is associated with abnormal aortic root tissue structure, including medial disease,[71] explaining why patients may develop aortic root dilation and aortic dissection.

Supravalvar AS (SVAS)

SVAS is the less common LVOTO. The morphologic feature of this condition is aortic narrowing at the level of the sinotubular junction. The entire ascending aorta may be involved and, less commonly, the aortic arch and peripheral arteries.[66] SVAS is frequently associated with Williams syndrome, which is characterized by intellectual impairment, elfin facies, short stature and, often, peripheral pulmonary artery stenosis. A mutation of elastin gene on chromosome 7q11.23 has been detected in most patients,[72] irrespective of the form of SVAS (autosomal dominant form, sporadic form or associated with Williams syndrome).

Clinical presentation

Symptoms may develop in childhood or adulthood, depending on the degree of obstruction. Patients with significant LVOTO (subvalvar, valvar or supravalvar) may present with dyspnea, angina, syncope, congestive heart failure or signs of endocarditis. The following signs may be found on examination.
• Slow-rising, diminished carotid pulse
• Apex-to-carotid delay (severe)
• Sustained apical impulse
• Ejection click (with BAV, if valve pliable, or with dilated aortic root)
• Diminished aortic component of S2, paradoxic splitting if severe
• S4, S3 if ventricular dysfunction
• Crescendo-decrescendo systolic murmur, late peaking if severe
• Diastolic murmur if AR present

Diagnostic evaluation

Electrocardiogram

Left axis deviation, left ventricular hypertrophy, T-wave inversion with ST segment depression in lateral leads and left atrial enlargement.

Chest radiography

Cardiomegaly (mild, unless significant AR and/or left ventricular dysfunction are present), dilation of ascending aorta (common with BAV), calcifications of the aortic valve.

Echocardiography

Modality of choice to identify and quantify the severity and level of LVOTO (**Class I, Level B**). Peak instantaneous Doppler velocity and gradient help to determine prognosis and guide the timing of intervention.[73,74] Aortic root diameter, left ventricular size/hypertrophy, and systolic/diastolic function should also be assessed.

Exercise stress testing

May be useful if the patient anticipates athletic participation or pregnancy, if clinical findings differ from non-invasive measurements, or in asymptomatic young adults with a mean Doppler gradient greater than 40 mmHg or a peak Doppler gradient greater than 64 mmHg (**Class IIa, Level C**).

CMR and CT angiography

Both helpful for visualizing the entire intrathoracic aorta and detect associated lesions (**Class IIa, Level C**).

Cardiac catheterization and angiography

Cardiac catheterization is useful before aortic valve replacement (AVR):[75]

• when non-invasive imaging is suboptimal or discordant with the clinical evaluation (**Class I, Level C**)

• to determine if there is co-existent coronary artery disease (CAD) (**Class I, Level B**)

• to identify the origin of coronary arteries when a Ross procedure (see below) is contemplated, if non-invasive imaging is inadequate (**Class I, Level C**).

Management

SAS

Surgical resection is the treatment of choice, but the timing of intervention remains controversial. Some authors advocate anearly aggressive approach to prevent AR,[65,76,77] while others consider the significant risk of recurrence and are more conservative. Table 63.8 proposes some indications for operative resection.[66,74]

Congenital valvar AS

There are currently no proven medical treatments to delay the disease process in patients with AS. It is reasonable to use beta-blockers for dilation of the ascending aorta.[66] Management and recommendations for AVR in adults with valvar AS are discussed in Chapter 55.[75] Table 63.8 summarizes the indications for balloon valvotomy in adolescents and young adults with congenital valvar AS.[75] When valve replacement is required, the Ross procedure may be

Aortic regurgitation
Recurrent AS after surgical or balloon intervention in BAV, or
    following surgical resection in SAS
Aortic root dilation or dissection (BAV)
Sudden cardiac death
Left ventricular failure

Ligamentum
arteriosum

Figure 63.4 Aortic coarctation.

considered (particularly for young women of reproductive age).

Outcomes and complications

SAS

Recurrence rates following surgical resection vary and are probably close to 15%.[65,78,79] Risk factors for recurrence include proximity of the obstructive lesion to the aortic valve and severe obstruction.[78] Infective endocarditis and AR are other complications of SAS. AR may develop despite surgical resection of the SAS.[66]

Congenital valvar AS

It has been suggested that the 3 year-mortality for symptomatic patients with AS, not undergoing surgery, is approximately 75%.[80] In asymptomatic patients, however, the risk of sudden cardiac death is less than 1%/year, even in hemodynamically significant AS.[73] Complications for patients with LVOTO are listed in Table 63.9.

Coarctation of the aorta

Anatomic findings and pathophysiology

Coarctation of the aorta is a localized narrowing usually located just below the origin of the left subclavian artery (LSCA), in the region of the ligamentum arteriosum (Fig. 63.4). Less commonly, a diffuse form with tubular hypoplasia may involve the aortic arch or the aorta distal to the LSCA. Aortic medial abnormalities may be present.[71] Extensive arterial collaterals often develop through the intercostal, subclavian, internal thoracic and scapular arteries to supply the lower body. Aortic coarctation is more frequent in men than women (1.5:1).[66] The reported incidence of BAV in patients with coarctation varies from 27% to 85%.[81–83] Coarctation may also occur in conjunction with VSD, mitral valve abnormalities, intracranial aneurysms (in up to 10% of patients[84]) and Turner syndrome.

Clinical presentation

Adults are most often asymptomatic and diagnosis is suspected after fortuitous systemic arterial hypertension or murmurs are found. Other possible clinical presentations include headache, epistaxis, intracranial hemorrhage, leg fatigue on exertion, CHF, angina and aortic dissection.[85] Physical examination classically reveals:
• upper body systemic hypertension (blood pressure should be taken in the right arm)
• blood pressure drop between upper and lower extremities
• delayed and weak femoral pulses
• palpable arteries over the scapulae or lateral chest wall
• systolic thrill in suprasternal notch
• sustained apex (pressure overload)
• loud aortic component of S2
• ejection click if BAV ± ejection systolic murmur
• continuous murmurs over the back (collaterals).

Diagnostic evaluation

Electrocardiogram

The ECG may show left atrial and ventricular hypertrophy.

Chest radiography

The so-called "3" sign (double contour in the region of descending aorta) and rib notching (erosion of the posteroinferior border of third to ninth ribs, caused by intercostal collaterals) are two characteristic features on the chest X-ray. The ascending aorta may appear dilated, and overall heart size is normal in the majority of patients.[85]

Echocardiography

Continuous wave Doppler assessment of the distal aortic arch via the suprasternal notch provides peak pressure gradient through the coarctation. Velocities proximal and distal to the stenosis should be included in an expanded Bernouilli equation to avoid overestimation of the gradient.[86] Doppler systolic velocities may be affected by lesion length,[87] presence of collateral flow,[86,88] and aortic compliance.[89] Diastolic velocities should therefore also be measured; the presence of a diastolic tail (elevated diastolic velocities) correlates with significant aortic coarctation.[90–92] TTE can also show LVH, associated BAV or dilated ascending aorta.

CMR and CT angiography

CMR and CT angiography are the imaging modalities of choice to evaluate coarctation before and after surgical or transcatheter intervention (site, extent and severity[93] of stenosis, presence of aneurysms,[94] anatomy of intracranial vessels, and extent of collateral network).

Cardiac catheterization and angiography

A peak-to-peak catheter gradient ≥20 mmHg is generally accepted as *significant coarctation*.[66] Cardiac catheterization is mainly employed for catheter intervention and for screening the coronary arteries.

Management

Timing of intervention or reintervention (surgery or angioplasty ± stent) in adults with coarctation may be challenging. Nevertheless, intervention should be considered when:
• peak-to-peak catheter gradient is greater than or equal to 20 mmHg across the coarctation (**Class I, Level C**)
• peak-to-peak catheter gradient is less than 20 mmHg across the coarctation in the presence of significant coarctation demonstrated by imaging studies, with radiologic evidence of significant collateral flow.[7a,95]
The presence of symptoms, systemic hypertension (at rest or with 24-hour monitoring) or LVH should be considered in the intervention decision-making process.

Surgical repair may involve end-to-end anastomosis, interposition graft, patch aortoplasty (abandoned because of the high incidence of aneurysms), ascending to descending aorta conduit repair (for complex/hypoplastic aortic arch) and subclavian flap repair (for neonates). Balloon angioplasty represents an alternative with encouraging results, although more aneurysm formation is reported compared with surgery.[96] The incidence of aneurysm seems to decrease substantially with primary stent implantation, however.[97] Catheter interventions appear to be safe and effective, and thus should be considered for simple native and recurrent coarctation (with catheter gradient >20 mmHg) (**Class I, Level B**).

Table 63.10 Residua following repair of coarctation

Persistent systemic hypertension
Recoarctation
Aneurysm of the aorta
Coronary artery disease
AS/AR (if BAV present)
Endocarditis/endarteritis
Rupture of aortic or cerebral aneurysm
Postsurgical repair paraplegia (rare)

Outcomes and complications

Seventy-five percent of unoperated patients will have died by 46 years of age.[66,98] Estimated 30-year survival following repair is 72%.[99]

Patent ductus arteriosus

Anatomic findings and pathophysiology

The patent ductus arteriosus (PDA) is a blood vessel that connects the descending aorta (just distal to the LSCA) to the proximal left pulmonary artery (Fig. 63.5). In fetal life, this structure is vital as it carries the blood from the right ventricle to the descending aorta, bypassing the lungs. The ductus normally closes soon after birth. When it remains patent, it can lead to left-to-right shunting with increased pulmonary flow and left heart volume overload.

Clinical presentation

Patients with small PDAs are asymptomatic and present with a murmur. Moderate and large PDAs may cause exercise intolerance, palpitations secondary to onset of atrial fibrillation, or even CHF. Eisenmenger syndrome can occur with long-standing left-to-right shunting through a large PDA. With moderate to large PDAs, the physical examination may reveal:
• bouncy pulses, wide pulse pressure, low diastolic pressure
• prominent ventricular impulse
• occasional paradoxic S2
• continuous "machinery" murmur in the upper left sternal edge, radiating to the back
• diastolic rumble
• in patients with Eisenmenger syndrome (see below), differential cyanosis (cyanosis and clubbing of toes but not fingers), usually no murmurs.
Figure 63.5 Patent ductus arteriosus.

Diagnostic evaluation

Electrocardiogram

Moderate and large PDAs may show left atrial enlargement and LVH. Atrial fibrillation may also occur.

Chest radiography

Significant shunting may lead to cardiomegaly from left heart enlargement, increased pulmonary vascular markings and dilated central pulmonary arteries.

Echocardiography

TTE may confirm the diagnosis, clarify the PDA size and degree of shunting, assess the left ventricular size and function, and estimate the right ventricular pressure from peak velocity of the tricuspid insufficiency. PAP curve can also be obtained from the PDA Doppler flow velocity signal.[100]

CMR and CT angiography

These modalities may be useful to clarify some anatomic variations such as ductus arteriosus aneurysm,[101] vascular ring and right aortic arch.[102]

Cardiac catheterization and angiography

Cardiac catheterization allows assessment of pulmonary vascular resistance and pulmonary vasoreactivity before transcatheter closure.

Table 63.11 Closure of PDA

Indications
Significant left-to-right shunting and left heart enlargement
   (**Class I, Level C**)
Prior endarteritis (**Class I, Level C**)

Debatable indications
Tiny silent PDAs to eliminate the risk of endarteritis (**Class IIa, Level C**)
Patients with PAH and a net left-to-right shunt (**Class IIa, Level C**)

Contraindication
Eisenmenger's syndrome (**Class III, Level C**)

Management

Transcatheter closure has become the procedure of choice. Table 63.11 summarizes indications for PDA closure.[7a,103–106] Surgical closure is reserved for PDAs that are not suitable for transcatheter approach, often because they are too large (**Class I, Level C**) or distorted (**Class I, Level B**).

Outcomes and complications

Patients with silent PDAs or PDAs closed in infancy have normal life expectancy. Prognosis worsens in the presence of pulmonary vascular disease. Complications of PDAs include CHF, arrhythmias, pulmonary vascular disease, endarteritis, and aneurysm of the ductus arteriosus.

Pulmonary valve stenosis

Anatomic findings and pathophysiology

The most common form of RV outflow tract (OT) obstruction is the typical dome-shaped pulmonary valve stenosis, characterized by fusion of the pulmonary valve leaflets and narrowed central orifice. The valve is usually mobile and associated with medial abnormalities and dilation of the pulmonary trunk. PVS may be associated with Noonan, Williams, Alagille, Keutel or rubella syndromes.[1,107]

Clinical presentation

Most patients with mild to moderate PVS are asymptomatic. Severe PVS may cause exertional dyspnea and fatigue, chest pain, palpitations and syncope. Mild cyanosis reflects high right atrial (RA) pressure with right-to-left shunt through a patent foramen ovale (PFO). Physical examination depends on the severity of the PVS. Findings in patients with severe PVS include:

- increased "a" wave
- RV lift
- thrill along the left sternal edge
- widely split S2 with reduced or absent P2
- short S1-to-ejection click interval or no ejection click
- right-sided S4
- long systolic ejection murmur, late peak.

Diagnostic evaluation

Electrocardiogram
Right axis deviation, RA enlargement and RV hypertrophy may be detected on ECG.

Chest radiography
Dilation of the main (and left) pulmonary arteries is common.[108] Cardiomegaly secondary to right heart enlargement occurs if there is right ventricular failure.

Echocardiography
Echocardiography, the imaging modality of choice, assesses morphology and mobility of PVS, severity of stenosis, RV size and function, and associated lesions.

Management

Table 63.12 summarizes the recommendations for percutaneous balloon valvuloplasty in patients with PVS.[7a] The procedure has excellent 10-year outcomes,[109] which are comparable to surgical valvotomy,[110] and is considered successful if the post-valvuloplasty Doppler gradient is <30 mmHg. Patients with dysplastic PV may need surgical valvectomy and PV replacement (PVR). PVR (with bioprosthesis or homograft) is also required when there is significant pulmonary regurgitation (PR).

Outcomes and complications

The 25-year surgery-free survival in unoperated patients with PV gradient >50 mmHg is only 31%, compared with

Table 63.12 Indications for balloon valvuloplasty in adolescents and young adults with PS

Asymptomatic patients with peak Doppler gradient >60 mmHg or mean gradient >40 mmHg and less than moderate PR (**Class I, Level B**)

Symptomatic patients with peak Doppler gradient >50 mmHg or mean gradient >30 mmHg and less than moderate PR (**Class I, Level C**)

Surgical therapy is recommended for dysplastic PV, hypoplastic pulmonary annulus, severe PR, subvalvular PS or supravalvular PS (**Class I, Level C**)

Modified from Bonow *et al.*[75]

96% in patients with gradient <25 mmHg.[111] Prognosis following repair is excellent, with a near-normal life expectancy.[111] Late complications after pulmonary valvotomy are residual PS, PR with progressive RV dilation that may require PVR, and arrhythmias.

Ebstein anomaly of the tricuspid valve

Anatomic findings and pathophysiology

Ebstein anomaly of the tricuspid valve (TV) is composed of[112]:
- downward (apical) displacement of the septal and often the mural leaflet
- adherence of the septal and mural leaflets to the underlying myocardium
- dilation of the "atrialized" portion of the RV
- redundant, malformed anterior leaflet.

The abnormal TV leads to variable degrees of tricuspid regurgitation which compromises further forward pulmonary blood flow and exaggerates right heart enlargement. ASD or PFO have been reported in up to 94% of patients.[112] Other associated lesions include multiple accessory atrioventricular pathways, pulmonary stenosis or atresia, BAV, coarctation, VSD, congenitally corrected transposition of the great arteries, and left-sided heart abnormalities.[112,113]

Clinical presentation

Symptoms depend on anatomic severity, associated defects and degree of right-to-left shunting. Patients may present with cyanosis, right heart failure, exercise intolerance, palpitations secondary to arrhythmias and sudden cardiac death. Physical examination may reveal:
- cyanosis ± digital clubbing in patients with right-to-left shunting
- large V-wave is rare despite severe TR
- widely split S1 and S2 and added sounds are common
- holosystolic murmur of TR
- hepatomegaly.

Diagnostic evaluation

Pulse oximetry
Pulse oximetry (at rest and/or during exercise) is useful in the evaluation of Ebstein anomaly (**Class IIa, Level C**).

Electrocardiogram
Tall P-waves secondary to RA enlargement, first-degree AVB, RBBB, low QRS voltage, and delta wave secondary to accessory pathway are common ECG features associated with Ebstein anomaly. Supraventricular tachyarrhythmias and atrial fibrillation can also occur.

Chest radiography

Cardiomegaly from right heart enlargement with globular cardiac silhouette, and small aortic knuckle from chronic low systemic blood flow are typical findings.

Echocardiography

The anatomy of the abnormal TV, the RV size and function, and the associated lesions should all be assessed by echocardiography. An apical displacement of the septal leaflet from the insertion of the mitral valve by >8 mm/m^2 is characteristic of Ebstein anomaly.[112]

Outcomes and complications

The actuarial survival for all live-born patients with Ebstein anomaly is 67% at 1 year and 59% at 10 years[114] but some patients survive to their 70s. Complications may include:

- arrhythmias (supraventricular tachycardia from accessory pathways, atrial flutter or fibrillation, and ventricular tachycardia)
- cyanosis
- right heart failure
- paradoxic embolism
- endocarditis
- sudden cardiac death.

Management

Tachyarrhythmias secondary to accessory pathways should be treated with catheter ablation (**Class IIa, Level B**), although success rates are lower and the risk of recurrence higher compared to patients with normal cardiac morphology.[115,116] TV surgery (repair or replacement with RA plasty and a MAZE procedure; Table 63.13) has evolved and encouraging mid-term results are now reported.[112]

For high-risk patients with impaired RV function, a bidirectional cavopulmonary shunt has been proposed,[117] although many would advocate transplantation (**Level C**).

Table 63.13 Indications for tricuspid valve surgery in patients with Ebstein anomaly

Symptomatic patients despite medical treatment (**Class I, Level B**)

Progressive right heart enlargement/reduced RV systolic function/early RV failure (**Class I, Level B**)

Significant cyanosis (**Class I, Level B**)

Paradoxic emboli (**Class I, Level B**)

May be considered in patients with recurrent supraventricular tachycardia despite medical and catheter ablative therapy (**Level C**)

Tetralogy of Fallot

Anatomic findings and pathophysiology

Tetralogy of Fallot (TOF) is the most common cyanotic heart defect. As Etienne-Louis Arthur Fallot described in 1888, this malformation is composed of four morphologic characteristics: VSD (usually large), aorta over-riding the ventricular septum, obstruction of the RVOT, and RV hypertrophy. However, the essential anatomic features of TOF are the anterocephalad deviation of the outlet septum and hypertrophy of the septoparietal trabeculations, creating obstruction of the RVOT. The PV is often small and bicuspid. Pulmonary artery hypoplasia and pulmonary branch stenosis may also occur. The degree of aortic override varies widely and >50% may come from the RV (so-called double-outlet RV). The magnitude of the right-to-left shunting depends on the severity of the RVOT obstruction.

TOF can be associated with other malformations, such as right aortic arch (~25%), ASD, AVSD, and coronary arterial anomalies. Indeed, the left anterior descending coronary artery arises anteriorly from the right coronary artery and
Figure 63.6 Tetralogy of Fallot.

crosses the RV outflow in about 3% of cases. It has been suggested that between 8% and 35% of patients with TOF have a 22q11 deletion (see above, *Genetic basis of CHD*)[1]; screening should therefore be offered (**Class I, Level C**).

Clinical presentation

Most adults will have had previous repair in childhood and present with late symptoms related to complications (see below), such as exertional dyspnea, palpitations, syncope or heart failure. Unoperated patients invariably develop cyanosis. On examination, blood pressure and brachial pulse may be difficult to take on the side of a previous Blalock–Taussig shunt. Unless TR or RV failure develops, the jugular venous pressure will be normal. A right ventricular lift is often present. On auscultation, a residual RVOT obstruction and/or an increased flow due to PR will create an ejection systolic murmur on the pulmonary area. Diastolic murmurs of AR (related to aortic root dilation) and/or PR can also be noted. The pulmonary component of the second sound is often not audible.

Diagnostic evaluation

Electrocardiogram

Patients who underwent surgery commonly have RBBB. Right axis deviation and RV hypertrophy are other common findings. Atrial tachyarrhythmia can occur in up to one-third of patients who had previous repair.[118] Ventricular tachycardia and sudden cardiac death are relatively uncommon.[119] and risk factors include QRS duration >180 ms, QRS prolongation over time and increased QT dispersion.[119–121] Incidence of atrial and ventricular arrhythmias seems to decrease after PVR for chronic PR in patients with previous repair.[122]

Chest radiography

A right-sided aortic arch is noted in ~25% of patients. Dilation of the ascending aorta[123,124] and/or central pulmonary arteries may be present. Cardiomegaly can be the result of:
• significant pulmonary and/or tricuspid regurgitation with RV enlargement
• significant residual VSD, aortic regurgitation or LV dysfunction with related LV dilation.

Echocardiography

Most important observations should include[125]:
• assessment of RV size and function
• RVOT imaging for assessment of residual PS and PR, including continuous-wave Doppler velocities
• detection and quantification of TR, and estimation of RV systolic pressure
• assessment of left ventricular size and function
• measurement of aortic root and detection of AR.

Exercise testing

Objective functional capacity and decline in exercise capacity over time are useful for predicting prognosis[126] and defining optimal timing of intervention.[125]

CMR

CMR can accurately assess right and left ventricular size and function, identify RVOT aneurysms or akinetic regions and quantify PR. RV volume measurements may help to determine the optimal timing for PVR, as RV end-diastolic volume >160–170 mL/m^2 does not normalize after surgery.[127,128] CMR with late gadolinium enhancement can detect the presence of ventricular fibrosis, which is a marker of adverse outcome.[129] CMR also demonstrates pulmonary artery and aortic anomalies.

Cardiac catheterization and angiography

Non-invasive imaging nowadays provides most important information. However, coronary anomalies, atherosclerosis, systemic–pulmonary collaterals, residual shunts and presence of PAH can all be documented by cardiac catheterization.[107]

Management

Surgical strategies have evolved and a transatrial-transpulmonary approach (with a limited RV incision) is now widely employed to relieve the RVOT obstruction and close the VSD. Although still controversial, early primary repair, rather than a staged approach with initial arterial-to-pulmonary shunt, is favored in many centers. Unoperated adults should still be considered for late repair to improve quality of life and prognosis.[130,131] Indications for

Table 63.14 Indications for reintervention in TOF

Severe PR associated with:
Symptoms or deterioration in exercise capacity (**Class I, Level B**)
RV enlargement/dysfunction (**Class IIa, Level B**)
Moderate or severe TR (**Class IIa, Level C**)
Development of clinical arrhythmias (atrial or ventricular) (**Class IIa, Level C**)
Residual RVOT obstruction (valvular or subvalvular) with:
Peak echocardiography gradient >50 mmHg (**Class IIa, Level C**)
RV/LV pressures > 0.67 (**Class IIa, Level C**)
Residual VSD with Qp : Qs >1.5 : 1 (**Class IIa, Level B**)
Significant AR with LV enlargement/dysfunction (**Class IIa, Level C**)
Should be considered in patients with aortic root enlargement (>55 mm) (**Level C**)

Table 63.15 Late complications after TOF repair

Residual PR
Residual RVOT obstruction
RV dysfunction/RVOT aneurysm

AR ± aortic root dilation
Endocarditis
Atrial tachyarrhythmia
Sustained VT/sudden death
Heart block (uncommon)

reintervention in patients who underwent a previous surgical correction are listed in Table 63.14.[7a,125] Recently, percutaneous PVR has been used with good initial success in selected patients with postoperative pulmonary homograft or conduit stenosis and/or regurgitation.[132]

Outcomes and complications

Nearly 70% of patients die before 10 years of age without surgery.[133] Survival rates after repair are 86% and 85% at 32 and 36 years.[131,134] Sudden death occurs in up to 6% of patients in late follow-up.[134] Older age at the time of repair is consistently a marker of poor prognosis. Table 63.15 summarizes late complications after TOF repair.

Transposition of the great arteries

Complete TGA (d-TGA)

Anatomic findings and pathophysiology

In complete TGA, the aorta arises from the morphologic right ventricle (on the right and anterior in 95% of cases) and the pulmonary artery arises from the morphologic left ventricle (ventriculoarterial discordance). The two great vessels are parallel to each other, without their usual cross-over arrangement. The pulmonary and systemic circulations are running in parallel; this is incompatible with life unless there is a communication (ASD, VSD or PDA) between the two circulations. Complete TGA is associated with VSD (~40–45%), LVOTO (~25%), and aortic coarctation (~5%).[135]

Clinical presentation

Almost all adults with complete TGA have had prior repair, but some with a large VSD reach adulthood with Eisenmenger physiology. Clinical presentation in adult patients who had previous surgery are related to late complications (see below) and include palpitations, dyspnea on exertion, CHF, syncope, sudden death, and signs of endocarditis.

Management options and late complications

Atrial switch procedure (Senning and Mustard procedures) The blood from the systemic venous return is redirected through the mitral valve into the subpulmonary left ventricle, and the pulmonary venous blood is redirected through the TV into the subaortic morphologic right ventricle. In the Senning operation,[136] the atrial baffle is made of autologous tissue while in the Mustard procedure, synthetic material or pericardium is used to create the baffle. Senning operations seem to have better long-term outcomes, with a 25-year survival rate of 91% compared with 76% in patients with previous Mustard procedure.[137] Late complications following either procedure are summarized in Table 63.16.[138]

Arterial switch procedure This procedure conveys anatomic repair by switching the great arteries and including the coronaries to their normal position. This operation, performed within the first month of life, has the advantage of restoring a systemic left ventricle. Survival rates at 15 years are 88%.[151] Nearly 10% of patients will require reoperation.[151] Long-term complications include pulmonary artery stenosis, dilation of the neo-aortic root with aortic regurgitation, and coronary ostia stenosis.

Rastelli procedure This procedure is used for patients with combination of TGA, LVOTO and a large VSD. An intracardiac baffle tunnels the LV through the VSD to the aorta, and an extracardiac conduit is inserted between the RV and the pulmonary artery. The LV becomes the systemic ventricle, but late complications such as conduit stenosis, atrial and ventricular arrhythmias or ventricular failure (right and left) may occur.

Congenitally corrected TGA (cc-TGA)

Anatomic findings

In this condition, the RA communicates with the morphologic LV, which is connected to the PA, and the LA enters the morphologic RV, which is connected to the aorta (double discordance). The RV is therefore the systemic ventricle. cc-TGA may be associated with several other malformations such as VSD (70%), PS (40%), abnormalities of the systemic AVV (Ebstein like – 90%), abnormalities of the conduction system (complete AVB), and dextrocardia.[138]

Clinical presentation

Adult patients with cc-TGA may develop CHF with exertional dyspnea, palpitations, syncope secondary to complete AVB, or cyanosis (if LVOTO and VSD are present). Physical examination depends on presence of associated lesions and complications. The ECG may show left axis deviation, Q-waves in right precordial leads and absence

Table 63.16 Complications following atrial switch procedures and their management

Complications	Management
Tachyarrhythmias: atrial re-entry tachycardia (flutter) Develops in 14% of patients[139] Predictor of sudden cardiac death[140] and marker of RV dysfunction[141]	Restore sinus rhythm Antiarrhythmic drugs with caution (risk of bradyarrhythmia) Radiofrequency ablation (success rate ~70%)[142]
Bradyarrhythmias: sinus node dysfunction and AVB (less common) Nearly 48% develop sinus node dysfunction[143] ~11% need a pacemaker[139]	Pacemaker implantation (may be technically difficult) (**Class I, Level B**)
Sudden death Reported in ~4–7% of patients[137,139,144]	Implantable cardiac defibrillator (ICD) implantation (**Level C**)
Systemic ventricular dysfunction Common late complication	No large prospective studies available Beta-blockers may improve exercise capacity and prevent RV remodeling[145]; use with caution (risk of bradyarrhythmia) (**Level C**) No proven effect with ACE inhibitors[146]; may be used empirically (**Level C**) Consider arterial switch conversion preceded by LV reconditioning (PA banding) in selected young patients; less favourable outcomes in adults[147,148] (**Level C**) Consider transplantation in selected cases with end-stage heart failure
Tricuspid regurgitation	TV replacement in some cases with severe TR (**Class I, Level B**); less useful if due to annular dilation[138]
Baffle obstruction SVC obstruction more common than IVC	Percutaneous balloon dilation and stenting[149] (**Class IIa, Level B**); surgery if not amenable to percutaneous treatment (**Class I, Level B**)
Significant baffle leak	Percutaneous or surgical closure (**Class IIa, Level B**); surgery if not amenable to percutaneous treatment (**Class I, Level B**)
PAH Occurs in ~7% of patients[150]	Consider advanced pulmonary vasodilator therapy (**Level C**)

of Q-waves in left precordial leads, and prominent Q-waves in inferior leads. In TGA (complete or congenitally corrected), a small vascular pedicle is the rule on chest radiograph because of the parallel arrangement of the vessels.

Outcomes, complications and management
Twenty-five percent of unoperated patients have developed CHF by 45 years of age (isolated cc-TGA), compared with 67% if associated lesions are present.[152] Long-term complications include:
• RV dysfunction and CHF
• systemic AVV regurgitation
• complete AVB (3% risk per year)
• arrhythmias (atrial and ventricular)
• sudden cardiac death
• endocarditis.

Patients with severe left AVV (tricuspid) regurgitation should be considered for tricuspid valve replacement, ideally before significant systemic RV dysfunction occurs (**Class I, Level B**). Double-switch procedures, combining an atrial switch with either an arterial switch or Rastelli repair (in cases in which the left ventricle is functioning at systemic pressures), have been performed in young patients with encouraging early outcomes (**Class I, Level B**), but reinterventions are common and long-term survival rates are not available.[153]

Univentricular physiology and the Fontan procedure

Nomenclature, anatomic findings, and pathophysiology
Although some patients with univentricular hearts may survive into their sixth decade without operation,[154] most of them presenting in adulthood will have had previous surgical interventions. This section focuses on patients with the Fontan circulation.

Univentricular heart or "single ventricle" Despite controversial nomenclature and classification, the term

"univentricular heart" usually refers to several congenital cardiac defects in which a biventricular repair is not possible,[155] such as tricuspid and mitral atresia, double-inlet ventricle, hypoplastic left heart syndrome, heterotaxy syndromes, etc. The pathophysiology of the univentricular heart depends on the underlying anatomy and physiology; the most favorable involves an unrestrictive ASD, a well-balanced systemic and pulmonary circulation and preserved ventricular function.[155]

Palliative procedures as a prelude for the Fontan operation (neonatal period)
• Arterial-to-pulmonary shunt: performed in patients with severe pulmonary obstruction.
• Blalock–Taussig shunt: end-to-side anastomosis of the subclavian and pulmonary artery.
• Modified Blalock–Taussig shunt: tube graft connecting the subclavian artery to the ipsilateral pulmonary artery.
• Waterston shunt: connection between the ascending aorta and the pulmonary artery.
• Potts shunt: connection between the descending aorta and the left pulmonary artery.
• Pulmonary artery banding: initial palliation for infants with unrestricted pulmonary blood flow.

Second- stage palliation (~4–12 months of age) Bidirectional Glenn shunt: end-to-side anastomosis of the superior vena cava to the right PA. Older patients may have had a classic Glenn (end-to-end anastomosis of the SVC to the disconnected right PA).

Fontan operation (usually 18 months to 4 years of age or later) Consists of a connection of the systemic venous return to the PAs without the interposition of a subpulmonary ventricle. In the classic Fontan repair (no longer used), the RA was anastomosed to the PA via a valved conduit.[156] Many adults today will have had a modified Fontan, in which the right atrium was directly anastomosed to the PA.[157]

Total cavopulmonary connection (TCPC) (Fig. 63.7) Currently, TCPC is the surgical technique of choice. It combines a bidirectional Glenn (see above), together with a connection of the inferior vena cava to the PA by a lateral tunnel[158] or an extracardiac conduit. A fenestration is also created between the tunnel conduit and the pulmonary atrium to allow a right-to-left shunting, which helps the immediate postoperative course and can be closed later with a catheter approach.[159]

Clinical presentation of adults with Fontan circulation
Adults with Fontan physiology often present with the clinical picture related to the long-term sequelae of this
Figure 63.7 Univentricular physiology and total cavopulmonary connection.

procedure (see below). Physical examination reveals elevated non-pulsatile jugular venous pressure with prominent A-wave, and single (often accentuated) second sound. Heart murmurs are normally not present. If the patient has a dominant left ventricle, the ECG will show left axis deviation, tall and broad P-wave, and left ventricular strain, while a dominant right ventricle will create superior frontal QRS axis and right ventricular hypertrophy.[155] Intra-atrial re-entry tachycardia (or atypical atrial flutter) is common, and sinus node dysfunction can also occur following the Fontan procedure.[160] Chest radiograph and echocardiogram also depend on the initial anatomic defect.

Outcomes
Earlier studies reported a 10-year survival of ~70% following initial Fontan operations.[161,162] Modified Fontans with lateral tunnel or extracardiac conduit seem to have better outcomes, with a 10-year survival ranging between 85% and 94%.[163,164] In a recent study from a single center, the 15-year survival after atriopulmonary connection was 81% versus 94% for lateral tunnel.[165]

Complications and their management (Table 63.17)
Supraventricular tachycardias (SVT, most often intra-atrial re-entry tachycardia) are a major cause of late morbidity[166]; incidence increases with time. The 15-year freedom from SVT is 61% for atriopulmonary connections versus 87% for the lateral tunnel technique.[165] Transcatheter

Table 63.17 Complications

Tachyarrhythmias (often intra-atrial re-entry tachycardia)
Bradyarrhythmias: sinus node dysfunction
Thromboembolic events
Hepatic dysfunction
Protein-losing enteropathy
Cyanosis
Pulmonary arteriovenous malformations
Obstruction of pulmonary veins (giant RA or aorta)
Residual interatrial communication
Systemic venous collateralization
Hepatic venous connection to the coronary sinus or LA
Ventricular dysfunction and failure
Obstruction or leaks in the Fontan pathway

Table 63.18 Common causes of Eisenmenger syndrome

Simple lesions
VSD
ASD
PDA
Aortopulmonary window
Total or partial anomalous pulmonary venous return

Complex lesions
AVSD
Truncus arteriosus
Univentricular heart with unobstructed pulmonary blood flow
TGA with large ventricular or arterial shunt

radiofrequency ablation is the treatment of choice, although recurrence is common.[167] When tachyarrhythmias occur, underlying hemodynamic lesions such as obstruction of the Fontan pathway should be excluded[155] (**Class I, Level C**). Patients with failing Fontan should be considered for reoperation (**Class I, Level C**). Revision of the circuit to an extracardiac conduit or lateral tunnel, in combination with MAZE procedure, can be useful in selected cases.[168] Heart transplantation may be considered for severe ventricular dysfunction or protein-losing enteropathy (**Class IIb, Level C**).

Eisenmenger syndrome

Definition, classification, and pathophysiology

Eisenmenger syndrome represents the extreme end of the spectrum of pulmonary PAH in patients with CHD.[169] It consists of PAH with reversed (right-to-left) or bidirectional shunting and cyanosis.[170] Patients who develop Eisenmenger syndrome have a large communication at atrial, ventricular or arterial level with consequent increase in pulmonary blood flow, resulting with time in pulmonary vascular disease.

Clinical presentation

Most patients with Eisenmenger syndrome have shortness of breath and exercise intolerance.[31,171] Palpitations, chest pain, edema or syncope may occur. Patients can also present with symptoms related to one of the complications of Eisenmenger syndrome (see below). Examination depends on the underlying defect, but physical findings usually include:
• central cyanosis
• clubbing

• RV lift
• loud P2 ± pulmonary ejection click
• holosystolic murmur of TR or PR may be present.

Diagnostic evaluation

Electrocardiogram
The ECG may show right axis deviation, RA enlargement and RV hypertrophy. Arrhythmias may occur.

Chest radiography
Central pulmonary arteries are most often dilated or aneurysmal, and calcifications may be present. Chest radiogram may also reveal cardiomegaly due to right atrial and ventricular enlargement.

Digital oximetry
Pulse oximetry, both with and without supplemental oxygen therapy, should be assessed at least yearly (**Class I, Level C**).

Echocardiography
Echocardiography should:
• specify the underlying defect and anatomy
• estimate RV systolic pressure
• determine the level, size and direction of shunting.

Exercise testing
The 6-minute walk test and cardiopulmonary exercise testing with peak oxygen consumption can both be used to assess functional capacity. Exercise-induced desaturation provides prognostic information[31,169] and helps to assess response to advanced therapies (**Class IIa, Level C**).

CMR and CT angiography
CMR allows a more precise visualization of the anatomy, while CT angiography is useful to exclude the possibility of pulmonary embolism and assess the lung parenchyma.

Cardiac catheterization and angiography

Cardiac catheterization in patients with Eisenmenger syndrome may be useful to confirm the diagnosis and evaluate severity of PAH. Furthermore, it can assess the pulmonary vascular resistance and determine vasoreactivity; the latter seems to have prognostic value[172] (**Class I, Level C**).

Laboratory testing

Full blood count, electrolytes, urea, creatinine, liver function tests and uric acid should be part of the routine laboratory assessment (**Class I, Level C**). Secondary erythrocytosis facilitates tissue oxygenation.[169] Moreover, iron status should be carefully evaluated by measurement of transferrin saturation and ferritin. Indeed, iron deficiency is common in patients with Eisenmenger syndrome, whereas the classic microcytosis and hypochromia are often absent.[169,173,174] Iron deficiency in this population has been associated with decreased exercise tolerance and increased risk of stroke.[175,176]

Outcomes and complications

Actuarial survival of patients with Eisenmenger syndrome has been reported to be 75%, 70%, and 55% at the age of 30, 40, and 50 years respectively.[171] Eisenmenger syndrome is a multiorgan disease (Table 63.19).

Table 63.19 Complications of Eisenmenger syndrome

Hematologic complications
Secondary erythrocytosis
Hyperviscosity symptoms (may be due to iron deficiency)
Headache, altered mentation, blurred vision, paresthesia, myalgia
Thrombocytopenia
Iron deficiency

Bleeding complications
Hemoptysis, pulmonary hemorrhage, cerebral bleeding, epistaxis

Thrombotic and thromboembolic events
Intrapulmonary thrombosis
Cerebrovascular accidents
Arrhythmias (supraventricular or ventricular) and sudden cardiac death

Viral and bacterial infections
Endocarditis
Cerebral abcess
Pneumonia

Renal dysfunction
Glomerular abnormalities
Hyperuricemia and gout
Gallstones and cholecystitis
Hypertrophic osteoarthropathy

Management

The main goal is to avoid complications. The following general recommendations apply.
• Iron deficiency should be treated with iron supplementation (**Class I, Level B**).
• Routine phlebotomy is contraindicated (**Class III**). Phlebotomy should be restricted to patients with hemoglobin greater than 20 g/dL and hematocrit greater than 65%, associated with severe hyperviscosity symptoms, in the absence of dehydration and iron deficiency (**Class I, Level C**).
• Anemia and dehydration should be avoided and treated promptly (**Class I, Level C**).
• Contraception advice should be provided and pregnancy strongly discouraged (risk of death reported as 30–50%) (**Class I, Level B**).
• Strenuous exercise and chronic high altitude should be avoided (**Class I, Level C**).
• Anticoagulation should be discussed with the patient (**Level C**).
• Long-term nocturnal oxygen may have a role for selected patients[177] (**Level C**).
• Vaccination: flu shot annually + Pneumovax every 5 years (**Level C**).
• Non-selective endothelin receptor antagonist (such as bosentan) or phosphodiesterase inhibitors (such as sildenafil) should be considered for patients in WHO functional class ≥III[172,178–180] (**Class IIa, Level C**).

Arrhythmias in adult congenital heart disease

Arrhythmias represent one of the most common long-term complications in patients with CHD, posing new challenges in terms of management. Rhythm anomalies can be part of the natural history of the underlying defect itself, but most of them arise from consequences of surgical interventions or from long-standing abnormal hemodynamics. Specific arrhythmias associated with CHD and their management[181] are summarized below and in Table 63.20.

Intra-atrial re-entrant tachycardia (IART)

Intra-atrial re-entrant tachycardia is the most common arrhythmia in this population. The mechanism is a macrore-entry circuit within the atrium, usually occurring years after surgical intervention involving the right atrial tissue. This "atypical" atrial flutter is more frequent in patients with previous *Mustard* and *Senning* procedures, or classic *Fontan* operations (severe dilation and scarring of the RA), but it can also occur even after simple ASD closure. Atrial rates are usually between 150 and 250 per minute

Table 63.20 Most frequent arrhythmias in CHD lesions

CHD/arrhythmia	IART	WPW	Atrial fibrillation	VT	Sinus node dysfunction	AV block
ASD	x		x		x	
AVSD			x			x
TOF	x		x	x		
Mustard/Senning	x		x	x	x	
cc-TGA		x	x	x		x
Fontan	x		x		x	
AS/coarctation			x			
Ebstein	x	x	x	x		

and 1:1 AV conduction can lead to severe symptoms such as syncope and even cardiac arrest. Therapeutic options include[181]:

• acute episode can be terminated with electrical cardioversion, antiarrhythmic drugs or overdrive pacing
• long-term antiarrhythmic drug therapy: often ineffective
• catheter ablation[182]: often used as an early intervention. Good short- to mid-term success, reduces the frequency of episodes, but relatively high recurrence rates have been reported
• pacemaker implantation: used for patients with tachybrady syndrome; decrease in IART frequency by addressing bradycardia and by incorporating antitachycardia pacing facility
• surgical ablation with a modified right atrial MAZE operation: low rates of recurrence but associated with surgical risks; often performed in patients who already have other surgical indications.

Re-entrant tachycardia secondary to accessory pathways

Wolff–Parkinson–White syndrome occurs in ~20% of patients with *Ebstein anomaly*. About half of them have multiple accessory pathways. Even if the success rate is lower than in the general population, catheter ablation remains the procedure of choice for Wolff–Parkinson–White syndrome in Ebstein patients.[181]

Atrial fibrillation

Congenital heart disease conditions associated with left atrial pressure and/or volume overload predispose to atrial fibrillation. Mitral valve abnormalities (or left AVV in the setting of an AVSD), AS, left ventricular dysfunction (or systemic right ventricular dysfunction in the setting of a cc-TGA) with elevated end-diastolic pressures, and

unrepaired single ventricle are such defects. General management of atrial fibrillation is the same as for other groups. Early intervention to improve or restore target hemodynamic lesions should be encouraged.

Ventricular tachycardia

Ventricular tachycardia and sudden cardiac death have become a major issue in selected patients with CHD reaching adulthood. Macrore-entrant circuits in the regions of a previous surgical scar can occur following a ventriculotomy or patching for a VSD. Other mechanisms that might be involved in arrhythmogenesis are severe ventricular dysfunction and/or hypertrophy with fibrosis. *TOF, aortic valve disease, cc-TGA* with systemic RV dysfunction, *Eisenmenger syndrome,* and severe *Ebstein anomaly* are lesions with increased risk of VT.

Sinus node dysfunction

Sinus node dysfunction late after surgical repair is the most common cause of sinus bradycardia in patients with CHD. *Mustard, Senning, Glenn,* and *Fontan* operations can all be associated with sinus node dysfunction. Pacemaker implantation is indicated if the bradycardia is associated with symptoms. *Left atrial isomerism* is associated with absence of sinus node and atrial or junctional escape rhythm with bradycardia.

AV block

Congenitally corrected TGA and *AVSD* both carry an intrinsic risk of developing complete AVB with time. Complete AVB can also result from surgical trauma following VSD closure, resection of LVOTO or replacement/repair of an AVV. Postoperative AVB is often transient, but pacemaker implantation is indicated if it does not recover within 7–10 days from surgery.

64 Venous thromboembolic disease

Lori-Ann Linkins and Clive Kearon

Henderson Hospital and McMaster University, Hamilton, Ontario, Canada

Introduction and historical perspective

Venous thromboembolic disease includes deep vein thrombosis (DVT) and pulmonary embolism (PE). The first recorded case of thrombosis of the lower limb is believed to be found in the Hindu medicine writings of Susruta, an Indian healer who lived around 800 BC, where he described a patient with a "swollen and painful leg, which was difficult to treat".[1] While only a few thrombosis specialists will be familiar with Susruta's contribution to the field, all are familiar with the contributions of Rudolph Virchow. Virchow, a Prussian physician born in 1821, is credited with coining the term "embolism" after discovering the relationship between a blood clot that forms within a blood vessel (thrombus), and a blood clot that breaks loose from the original and travels through the bloodstream to occlude the pulmonary vessels (embolus).[1] In addition, Virchow was the first to identify the pathogenic triad for thrombosis: stasis, vessel wall damage, and hypercoagulability. Virchow's triad has stood the test of time and today, it is still the foundation upon which prevention and treatment of venous thromboembolism (VTE) is based.

The first randomized trial for the treatment of VTE was performed by Barritt and Jordan in 1960.[2] They showed that treatment of PE with heparin and oral anticoagulants reduced the risk of recurrent PE and reduced mortality compared with no anticoagulant therapy (Table 64.1). Since then, there has been considerable progress in the development of new anticoagulants (e.g. low molecular weight heparin (LMWH), fondaparinux) for the prevention and treatment of VTE. Unfortunately, despite these advances, VTE remains a leading cause of morbidity and mortality.

In this chapter, we will briefly review the natural history and pathogenesis of VTE and provide an overview of evidence-based management of VTE divided into three categories: diagnosis, treatment, and prevention.

Nomenclature and definitions

Proximal deep vein thrombosis is defined as a DVT that involves the popliteal and more proximal veins. *Distal deep vein thrombosis* is defined as a DVT that is confined to the calf veins (including the calf trifurcation).

Incidence, natural history and prognosis

Venous thromboembolism is rare before the age of 16 years, probably because the immature coagulation system is resistant to thrombosis. However, the risk of VTE increases exponentially with advancing age (i.e. 1.9-fold per decade), rising from an annual incidence of approximately 30/100000 at 40 years, to 90/100000 at 60 years, and 260/100000 at 80 years.[3–5]

DVT usually starts in the calf veins.[6] When DVT causes symptoms, over 80% involve the popliteal or more proximal veins.[6,7] However, if venography is used to diagnose DVT in asymptomatic high-risk patients (e.g. following orthopedic surgery) only about one-third of venous thrombi are proximal. The majority of isolated calf DVT will undergo spontaneous lysis; however, 20% of these thrombi subsequently extend to involve the proximal veins, usually within a week of presentation.[8] Non-extending calf DVT rarely causes PE, whereas proximal DVT often does.[9] The majority (70%) of patients with symptomatic proximal DVT have asymptomatic PE and vice versa.[10] Only about 25% of patients with symptomatic PE have symptoms or signs of DVT.[11]

It is estimated that 10% of symptomatic PE cause death within an hour of onset[12] and that, left untreated, about one-third of patients with initially non-fatal PE will have a fatal recurrence.[2] Untreated, symptomatic proximal DVT progresses to symptomatic PE in about one half of cases

Populat., population studied; 95% CI, 95% confidence interval of relative risk; OA, oral anticoagulants; LD, low-dose subcutaneous heparin; DVT, deep vein thrombosis; PE, pulmonary embolism; LMWH, low molecular weight heparin; IVC, inferior vena caval filter; * secondary outcome measure; ** DVT detected on mandatory bilateral venography; # additional prophylaxis used: heparin 18%, LMWH 26% and compression stockings 30%; ^ fixed, weight-adjusted dose without laboratory monitoring.

and, in general, the risk of recurrent VTE is highest within days or weeks of an acute event.[13] The risk of recurrent VTE remains elevated in patients with thrombosis that was unprovoked or associated with persistent risk factors (e.g. malignancy, congenital hypercoagulable states) compared to those in whom VTE was associated with a transient risk factor (e.g. surgery).[14–19]

Pathophysiology

Venous thrombi are composed primarily of fibrin and red blood cells. They form when the following elements are present: venous stasis, vessel wall damage, and hypercoaguability (Virchow's triad). Classification of risk factors for VTE according to this pathogenic triad remains valuable.

Venous stasis

The importance of venous stasis as a risk factor for VTE is demonstrated by the fact that most DVT associated with stroke affect the paralyzed leg,[20] and most DVT associated with pregnancy affect the left leg,[21] the iliac veins of which are prone to extrinsic compression by the pregnant uterus and the right common iliac artery.

Vessel wall damage

Venous endothelial damage, usually as a consequence of accidental injury, manipulation during surgery (e.g. hip replacement) or iatrogenic injury, is an important risk factor for VTE. Hence, three-quarters of proximal DVT which complicate hip surgery occur in the operated leg[22] and thrombosis is common with indwelling venous catheters.[23]

Hypercoagulability

A complex balance of naturally occurring coagulation and fibrinolytic factors, and their inhibitors, serves to maintain blood fluidity and hemostasis. Inherited or acquired changes in this balance predispose to thrombosis. The most important inherited biochemical disorders associated with VTE are due to:
• defects in the naturally occurring inhibitors of coagulation including deficiencies of antithrombin, protein C or protein S
• resistance to activated protein C caused by factor V Leiden
• a mutation in the 3' untranslated region of the prothrombin gene (G20210A) which is associated with a 25% increase in prothrombin levels.
The first three of these disorders are rare in the normal population (combined prevalence of <1%), have a combined prevalence of 5% in patients with a first episode of VTE[24] and are associated with a 10 to 40-fold increase in the risk of

VTE.[25] The factor V Leiden mutation is common, occurring in 5% of Caucasians and 20% of patients with a first episode of VTE (i.e. fourfold increase in VTE risk).[25,26] The prothrombin gene mutation occurs in 2% of Caucasians and about 5% of those with a first episode of VTE (i.e. 2.5-fold increase in risk).[25–27] Hyperhomocysteinemia, due to hereditary and acquired factors, is also associated with VTE.[28]

Elevated levels of a number of coagulation factors (I, II, VIII, IX, XI) are associated with thrombosis in a "dose-dependent" manner.[29–31] It is probable that such elevations are often inherited, with strong evidence for this with factor VIII.[29] Prothrombotic abnormalities of the fibrinolytic system have questionable importance.

Acquired hypercoagulable states include estrogen therapy, antiphospholipid antibodies (anticardiolipin antibodies and/or lupus anticoagulants), systemic lupus erythematosus, malignancy, combination chemotherapy, and surgery.[3] Patients who develop immunologically related heparin-induced thrombocytopenia (HIT) also have a very high risk of developing arterial and venous thromboembolism.[32] Unlike the congenital abnormalities, acquired risk factors are often transient, which has important implications for the duration of anticoagulant prophylaxis and treatment.

Combinations of risk factors and risk stratification

The risk of developing VTE depends on the prevalence and severity of risk factors (Box 64.1).[3]

BOX 64.1 Risk factors for venous thromboembolism

Patient factors
Previous venous thromboembolism*
Age over 40
Pregnancy, puerperium
Marked obesity
Inherited hypercoagulable state

Underlying condition and acquired factors
Malignancy*
Estrogen therapy
Cancer chemotherapy
Paralysis*
Prolonged immobility
Major trauma*
Lower limb injuries*
Heparin-induced thrombocytopenia
Antiphospholipid antibodies

Type of surgery
Lower limb orthopedic surgery*
General anesthesia >30 min

*Common major risk factors for venous thromboembolism

Diagnosis

Objective testing for DVT and PE is important because clinical assessment alone is unreliable. Failure to diagnose VTE exposes patients to the risk of fatal PE. However, inappropriate use of anticoagulants exposes patients to the risk of serious bleeding complications including fatal hemorrhage.

Diagnosis of deep vein thrombosis

Venography is the criterion standard for the diagnosis of DVT.[7,33] However, because of its invasive nature, technical demands, costs, and risks associated with contrast media, non-invasive tests have been developed, of which venous ultrasound imaging (VUI) and D-dimer testing are the most important.

Clinical assessment

Although clinical assessment cannot unequivocally confirm or exclude DVT, clinical evaluation using empiric assessment or a structured clinical model (Table 64.2) can stratify patients as having a low (5% prevalence), moderate (25%

Table 64.2 Clinical model for determining clinical suspicion of DVT[171]

Variables	Points
Active cancer (treatment ongoing or within previous 6 months or palliative)	1
Paralysis, paresis or recent plaster immobilization of the lower extremities	1
Recently bedridden >3 days or major surgery within the previous 12 weeks requiring general or regional anesthesia	1
Localized tenderness along the distribution of the deep venous system	1
Entire leg swollen	1
Calf swelling 3 cm > asymptomatic side (measured 10 cm below tibial tuberosity)	1
Pitting edema confined to the symptomatic leg	1
Collateral superficial veins (non-varicose)	1
Previously documented deep vein thrombosis	1
Alternative diagnosis as likely or greater than that of DVT	-2

Total points (pretest probability for DVT):

Score >2:   High
Score 1–2:   Moderate
Score 0:   Low

NOTE: In patients with symptoms in both legs, the more symptomatic leg is used.

prevalence) or high (60% prevalence) probability of DVT.[34] Such categorization is useful in guiding the performance and interpretation of objective testing.[34–38]

Venous ultrasound imaging (VUI)

With this modality, pressure is applied to the proximal veins with an ultrasound probe to determine compressibility.[7,39] Incompressibility of a vein is considered diagnostic for DVT. VUI has a sensitivity for proximal DVT of 97% and a specificity of 94% in symptomatic patients which, on average, translates into a positive predictive value of 97% and a negative predictive value of 98% for proximal DVT.[7,40]

The utility of VUI for diagnosing calf vein thrombosis is more controversial. VUI is technically more difficult to perform in the calf and some studies have reported the accuracy of this approach to be poor (e.g. sensitivity of 70%).[7,40] Recently, investigators have proposed that a single complete compression ultrasound that includes examination of the calf veins should be used to exclude DVT. Studies using this method have reported an incidence of VTE of 0.5% during 3 months follow-up after a negative examination, establishing that negative VUI that includes the calf veins excludes VTE.[41–43] However, this method has the potential to diagnose calf DVT that would have spontaneously lysed without treatment and to yield false-positive results, thereby exposing patients to the risk of bleeding due to anticoagulant therapy without clear benefit.

At most centers, if DVT cannot be excluded by a normal proximal VUI in combination with other results (e.g. low clinical probability or normal D-dimer (Table 64.3)) treatment is withheld and a follow-up VUI is performed after 1 week to detect extending calf vein thrombosis (2% of patients).[7] If the second VUI examination is normal, the risk of symptomatic VTE during the next 6 months is less than 2%.[7]

The accuracy of VUI in asymptomatic postoperative patients who have a high risk for DVT is poor with a sensitivity for proximal DVT of only 62%,[7] and such screening is not recommended in patients who have received prophylaxis.[44]

Computed tomographic (CT) venography and magnetic resonance (MR) venography

The limitations of VUI in diagnosing DVT in certain clinical settings, e.g. isolated pelvic DVT and asymptomatic patients, has stimulated interest in alternative imaging modalities such as CT venography and MR venography. In one review of studies comparing CT venography with VUI, the sensitivity and specificity were reported as 89–100% and 94–100%, respectively, for all DVT.[45] However, the majority of the studies included in the review were case series and given the cost, exposure to radiation, and limited availability of CT venography, it is unlikely that this modality will play an important role in the diagnosis of DVT.

Table 64.3 Diagnostic tests which confirm or exclude DVT

Diagnostic test	Confirms DVT	Excludes DVT
First acute DVT		
Venography	Intraluminal filling defect	No intraluminal filling defect; all deep veins seen
Venous ultrasound	Non-compressible at CFV, PopV or C-tri	Fully compressible proximal veins **AND**
		a) low cPTP for DVT **OR**
		b) normal D-dimer with sensitivity ≥85% **OR**
		c) normal ultrasound on repeat testing at day 7
		Normal whole-leg ultrasound
D-dimer		Normal D-dimer with sensitivity >98% **OR**
		Normal D-dimer with sensitivity > 85% **AND**
		a) low cPTP **OR**
		b) negative proximal ultrasound
Recurrent DVT		
Venography	Intraluminal filling defect	No intraluminal filling defect; all deep veins seen
Venous ultrasound	New non-compressible CFV or PopV **OR**	Normal **OR**
	4.0 mm increase in diameter of CFV or PopV compared with recent previous test	≤1 mm increase in diameter of CFV or PopV compared with recent previous test **AND** remains unchanged on repeat ultrasound testing on day 2 and day 7
D-dimer		Normal D-dimer with sensitivity >98%
		Normal D-dimer with sensitivity >85% **AND**
		a) low cPTP **OR**
		b) ≤1 mm increase in diameter of CFV or PopV

CFV, common femoral vein; PopV, popliteal vein; C-tri, calf vein trifurcation; cPTP, clinical pretest probability.

Magnetic resonance venography can be performed with injection of gadolinium or without any contrast (MR direct thrombus imaging). A recent meta-analysis of studies comparing MR venography with conventional venography reported a pooled sensitivity of 92% and specificity of 95% of MR venography for proximal DVT.[46] However, there was significant heterogeneity between the studies and, therefore, these pooled estimates should be interpreted with caution. MR direct thrombus imaging looks promising, but has only been evaluated in a single accuracy study to date.[47] As with CT venography, cost and availability will inhibit the widespread use of MR for diagnosis of DVT.

D-dimer blood testing
D-dimer is formed when cross-linked fibrin is broken down by plasmin and levels are usually elevated with DVT and/or PE. Normal levels can help to exclude VTE, but elevated D-dimer levels are non-specific and have low positive predictive value.[48,49] D-dimer tests differ markedly as diagnostic procedures for VTE. A normal result with a very sensitive (i.e. 98%) D-dimer assay excludes VTE on its own.[48–50] However, very sensitive D-dimer tests have low specificity (40%) which limits their utility because of high false-positive rates.[50] In order to exclude DVT and/or PE, a normal result with a less sensitive D-dimer assay (i.e. 85%) needs to be combined with either a low clinical probability or another objective test that has negative predictive value but is also non-diagnostic on its own (see Table 64.3).[35,38,51–53] As less sensitive D-dimer assays are more specific (70%), they yield fewer false-positive results. Specificity of D-dimer decreases with aging[54] and with co-morbid illness such as cancer.[55] Consequently, D-dimer testing has limited value in the diagnosis of VTE in hospitalized patients and is unhelpful in the early postoperative period.

Diagnosis of recurrent DVT
Persistent abnormalities of the deep veins are common following DVT.[7,56] Therefore, diagnosis of recurrent DVT requires evidence of new clot formation. Tests that can diagnose or exclude recurrent DVT are noted in Table 64.3.[7,56,57]

Diagnosis of pulmonary embolism

Pulmonary angiography is the criterion standard for the diagnosis of PE, but it has similar limitations to venography.[58]

Computed tomographic pulmonary angiography (CTPA)
Computed tomographic pulmonary angiography (also known as spiral or helical CT) with peripheral injection of

contrast dye is the current standard diagnostic test for PE.[59–62] Helical CT technology has rapidly advanced from use of single detector scanners to use of progressively larger numbers of detectors (termed multidetector CT), which enable more detailed examination of the pulmonary arteries.

Current evidence suggests that CTPA is non-diagnostic in 6% of patients, and that among adequate examinations, sensitivity is 83%, specificity is 96%, positive predictive value is 86% and negative predictive value is 95%.[59] Accuracy varies according to the size of the largest pulmonary artery involved: positive predictive value was 97% for pulmonary emboli in the main or lobar artery, 68% for segmental arteries, and 25% for subsegmental arteries. Predictive values were also influenced by clinical assessment of pulmonary embolism probability: positive predictive value is 96% with high, 92% with intermediate, and 58% with low clinical probability (8% of patients); negative predictive value is 96% with low, 89% with intermediate, and 60% with high clinical probability (5% of patients).[59]

The ability of CTPA to exclude pulmonary embolism has also been evaluated in management studies in which anticoagulant therapy was withheld in patients with negative CTPA.[61] More recent studies suggest that less than 2% of patients with a negative CTPA for pulmonary embolism will return with symptomatic VTE during follow-up.[60–62] Taken together, these observations suggest the following:
• intraluminal filling defects in lobar or larger pulmonary arteries are generally diagnostic for PE
• a good-quality normal CTPA excludes PE if clinical suspicion is low or moderate
• intraluminal defects confined to segmental pulmonary arteries are generally diagnostic for PE if clinical suspicion is moderate or high, but should be considered non-diagnostic if suspicion is low or there are discordant findings (e.g. negative D-dimer)
• intraluminal defects confined to subsegmental pulmonary arteries are non-diagnostic and patients with such findings require further testing.
CTPA delivers a substantial dose of radiation to the chest, which increases the risk of cancer. For this reason, CTPA should be used selectively, particularly in younger women.[63]

Magnetic resonance angiography (MRA)
Gadolinium-enhanced pulmonary MRA offers advantages over CTPA in that it can be performed on patients with an allergy to iodinated contrast media and it avoids exposure to radiation. However, only a limited number of small studies evaluating MRA for diagnosis of PE have been performed.[64] In addition, a warning has been issued by the Federal Drug Administration about an increased risk of nephrogenic systemic fibrosis in patients with severe renal insufficiency (glomerular filtration rate <30 mL/min) who

are exposed to gadolinium. Like CTPA, MRA is able to identify alternative pulmonary diagnoses, and can be extended to look for concomitant DVT.

Ventilation-perfusion lung scanning
In the past, the imaging modality typically used to investigate patients with suspected PE was a ventilation-perfusion lung scan. More recently, CTPA has supplanted this imaging modality, although lung scanning is still used, particularly when CTPA is contraindicated because of renal failure or associated radiation exposure to the chest (e.g. in young women). A normal perfusion scan excludes PE[65,66] but is found in a minority (10–40%) of patients.[11,54,67] Perfusion defects are non-specific; only about one-third of patients with defects have PE.[67,68] The probability that a perfusion defect is due to PE increases with size and number of defects, and the presence of a normal ventilation scan ("mismatched" defect).[67,68] A lung scan with mismatched segmental or larger perfusion defects is termed "high probability."[68] A single mismatched defect is associated with a prevalence of PE of 80%.[69] Three or more mismatched defects are associated with a prevalence of PE of 90%.[69] Lung scan findings are highly age dependent with a relatively high proportion of normal scans, and a low proportion of non-diagnostic scans, in younger patients.[54]

Clinical assessment
As with suspected DVT, clinical assessment is useful at categorizing probability of PE (Table 64.4).[37,70]

D-dimer testing
As previously discussed when considering diagnosis of DVT, a normal D-dimer result, alone[50] or in combination with another negative test,[49,62,70,71] can be used to exclude PE (Table 64.5).

Management of patients with non-diagnostic combinations of non-invasive tests for PE
Patients with non-diagnostic imaging for PE at presentation have, on average, a prevalence of PE of 20% and therefore further investigations to exclude this diagnosis are required.[39,67] The first step is to perform imaging investigations (venous ultrasound, venography) to look for DVT. If DVT is confirmed, it can be concluded that the patient's symptoms are due to PE. If imaging studies are negative for DVT, we recommend one of the following management approaches (Table 64.5):
• withhold anticoagulants and perform serial venous ultrasounds to check for evolving proximal DVT (after 1 and 2 weeks)
• perform CTPA or lung scanning if either of these tests has not been performed, or
• repeat CTPA after 24 hours (to reduce the risk of contrast-induced nephrotoxicity).

If serial VUI for DVT (two additional tests a week apart) is negative, the subsequent risk of recurrent VTE during the next 3 months is less than 1%[11,70] which is similar to that after a normal pulmonary angiogram.[58]

Treatment

Anticoagulants are the mainstay of treatment for VTE. The objectives of anticoagulant therapy are to prevent extension and potentially fatal embolization of the initial thrombus, and to prevent recurrent VTE (early and late).

Acute treatment of VTE

Low molecular weight heparin for a minimum of 5 days, administered by subcutaneous injection on an outpatient basis, has become standard practice for initial treatment of patients with an uncomplicated DVT and normal renal function[72] (**Class I, Level A**). Many trials have established that weight-adjusted LMWH (without laboratory monitoring) is as safe and effective as adjusted-dose unfractionated intravenous heparin (UFH) for the treatment of acute VTE[73] (see Table 64.1). Alternatives to LMWH include twice-daily subcutaneous UFH (with or without laboratory monitoring) and fondaparinux administered once daily by subcutaneous injection (without laboratory monitoring)[74–76] (see Table 64.1) (**Class I, Level A**). If unmonitored subcutaneous UFH is used it should be administered in weight-adjusted doses (i.e. 333 units/kg initially followed by 250 units/kg every 12 hours).[75] Patients with severe renal impairment or those who are considered at high risk for bleeding should be treated in hospital with intravenous UFH titrated according to activated partial thromboplastin

Table 64.4 Model for determining clinical suspicion of PE[71,172]

Variables	Points
Clinical signs and symptoms of deep vein thrombosis (minimum leg swelling and pain with palpation of the deep veins)	3.0
An alternative diagnosis is less likely than pulmonary embolism	3.0
Heart rate >100 beats/min	1.5
Immobilization or surgery in the previous 4 weeks	1.5
Previous deep vein thrombosis/pulmonary embolism	1.5
Hemoptysis	1.0
Malignancy (treatment ongoing or within previous 6 months or palliative)	1.0
Total points (pretest probability for PE):	
Score <4: PE unlikely*	
Score ≥4: PE likely**

time corresponding to plasma heparin levels from 0.3 to 0.7 IU/mL anti-Xa activity by the amidolytic assay[77] (**Class II, Level C**). Patients with thrombosis associated with HIT or with a past history of HIT should be treated with danaparoid, argatroban or lepirudin[78–80] (**Class I, Level C**).

A similar approach can be used for the initial treatment of PE, including treatment as an outpatient, as long as the patient is hemodynamically stable[72,81,82] (**Class I, Level A**). No trials have specifically randomized acute PE patients to be treated either in hospital or at home. However, in one randomized controlled trial comparing fixed-dose UFH and LMWH, 39% (52/134) of patients who had PE were treated entirely at home[75] (see Table 64.1). Further support for the safety of this approach is derived from two observational studies in which 30% of patients with PE were treated with LMWH at home.[83,84] Patients with severe symptoms and signs, and particularly if there is evidence of hemodynamic compromise, should be assessed for thrombolytic therapy (discussed below).

For both DVT and PE, the currently recommended approach to is to start treatment with a vitamin K antagonist (e.g. warfarin) concurrently with LMWH (or UFH or fondaparinux) at the time of diagnosis.[72,85,86] Two trials performed in hospitalized patients showed that starting warfarin at a dose of 5 mg, compared to 10 mg, is associated with less excessive anticoagulation.[87,88] A similar study in outpatients failed to demonstrate an advantage to starting warfarin at a dose of 5 mg compared with 10 mg.[89] Observational studies have shown that lower VKA maintenance doses are required in older patients, women, and those with impaired nutrition and vitamin K deficiency.[90,91] Taken together, these data suggest that warfarin can usually be started at a dose of 10 mg in younger (e.g. less than 60 years) otherwise healthy outpatients, and at a dose of 5 mg in older patients and those who are hospitalized.

Idraparinux, a long-acting inhibitor of factor Xa which is administered subcutaneously once weekly, has recently been shown to be as effective as standard therapy for the first 3–6 months of treatment for DVT, but is less effective than standard therapy in patients with PE.[92]

Ximelagatran, an oral direct thrombin inhibitor, has been shown to be effective for the acute and long-term treatment of VTE, but is not used because of hepatic toxicity.[93]

Recommendation

- LMWH (or UFH or fondaparinux) and a vitamin K antagonist should be started on the day of diagnosis. LMWH (or UFH or fondaparinux) should be stopped once the international normalization ration (INR) is 2.0 or above for at least 24 hours and the patient has received a minimum of 5 days of treatment (**Class I, Level C**).

Subacute and long-term treatment of VTE

A randomized trial of patients with DVT which compared 3 months of warfarin (INR 3.0–4.0) with low-dose UFH after initial treatment with full-dose UFH established the necessity for prolonged oral anticoagulation after initial heparin therapy[13] (see Table 64.1). Prolonged high-dose subcutaneous UFH[94] and, subsequently, LMWH (50–75% of acute treatment dose) were shown to be as effective as warfarin therapy.[95,96] In the 1970s it was recognized that, because of differences in the responsiveness of thromboplastins to oral anticoagulants, a prothrombin time ratio of 2.0 reflected a much more intense level of anticoagulation in North America than in Europe. This prompted a comparison of two intensities of warfarin therapy (corresponding to mean INRs of 2.1 and 3.2) for the treatment of DVT[97] (see Table 64.1). This study found that the lower intensity of oral anticoagulation was as effective as the higher intensity but caused less bleeding.

Duration of anticoagulant treatment of VTE
During the last decade, a series of well-designed studies have helped to define the optimal duration of anticoagulation. The findings can be summarized as follows.
- Shortening the duration of anticoagulation from 3 or 6 months to 4 or 6 weeks results in a doubling of the frequency of recurrent VTE during 1–2 years of follow-up[15,16,18,19] (**Class I, Level A**).
- Patients with VTE provoked by a transient risk factor have a lower (about one-third) risk of recurrence than those with an unprovoked VTE or a persistent risk factor[14,15,17–19,98] (**Class I, Level A**).
- Risk of recurrent VTE after 3 months of anticoagulant therapy for VTE *provoked* by a transient risk factor is about 3% in the first year and 10% in the first 5 years after stopping anticoagulant therapy[17–19,98–100] (**Class I, Level A**).

Recommendation

Three months of anticoagulation is adequate treatment for VTE provoked by a transient risk factor. **Class I, Level A**

- Risk of recurrent VTE after 3 months of anticoagulant therapy for *unprovoked* VTE is about 10% in the first year and 30% in the first 5 years after stopping anticoagulant therapy[15,17,99,101,102] (**Class I, Level A**).
- After 3 months of anticoagulation, recurrent DVT is at least as likely to affect the contralateral leg (**Class I, Level A**); this suggests that "systemic" rather than "local" (including inadequate treatment) factors are responsible for recurrences after 3 months of treatment.[103]
- Extending duration of anticoagulation beyond 3 months to 6 or 12 months may delay, but ultimately not reduce the risk of recurrence if anticoagulant therapy is then stopped.[101,102]

• Oral anticoagulants targeted at an INR of ~2.5 are very effective (risk reduction ≥90%) at preventing recurrent unprovoked VTE after the first 3 months of treatment[104,105] (**Class I, Level A**).

Recommendation

Patients with unprovoked DVT should receive anticoagulant therapy for a minimum of three months. **Class I, Level A** After three months, these patients should be assessed for indefinite anticoagulant therapy. Calculation of the risk to benefit ratio of indefinite anticoagulant therapy for an individual patient should include evaluation of risk of bleeding, quality of anticoagulant monitoring, and patient preference. **Class I, Level A** Patients who remain on long-term anticoagulant therapy should be reassessed at periodic intervals to ensure the risk to benefit ratio remains in favour of anticoagulant therapy. **Class I, Level C**

• A second episode of VTE is associated with an increased risk of recurrence (RR 1.5)[106–108] (**Class I, Level A**).

Recommendation

Patients with a second episode of unprovoked VTE should be assessed for indefinite anticoagulant therapy. **Class I, Level A**

• An isolated distal DVT (provoked or unprovoked) is associated with a low risk of recurrence (2% in the first year) compared to proximal DVT or PE (6% in the first year).[15,99]

Recommendation

Three months of anticoagulant therapy is adequate for patients with unprovoked isolated distal DVT. **Class I, Level B**

• Risk of recurrence is about threefold higher in patients with active cancer.[14,109,110]
• Long-term treatment with LMWH is more effective than warfarin in patients with VTE associated with cancer.[111]

Recommendation

Patients with VTE and cancer should be treated with LMWH for the first 3 to 6 months of long-term anticoagulant therapy. **Class I, Level B**. Anticoagulant therapy should be continued with a vitamin K antagonist or LMWH indefinitely or until the cancer is resolved.

• Men appear to have about a 50% higher risk of recurrent VTE than women.[112]
• Risk of recurrence appears to be somewhat higher in patients with antiphospholipid antibodies[104,107,113] and in patients with inherited thrombophilias.[17,114–116]
• Other risk factors for recurrence may include: elevated levels of clotting factors VIII, IX, XI and homocysteine, and

deficiencies of protein C and protein S; elevated D-dimer levels after stopping anticoagulant therapy[117]; residual DVT on ultrasound[118]; and presence of the post-thrombotic syndrome. Currently, these factors do not have clear implications for duration of treatment.[119]

Bleeding during anticoagulant therapy

Risk of bleeding on anticoagulants differs markedly among patients depending on the prevalence of risk factors (e.g. age greater than 75; previous gastrointestinal bleeding or stroke; renal failure; anemia; antiplatelet therapy; malignancy; poor anticoagulant control).[120,121] Approximately 13% of episodes of major bleeding during the first 3 months of anticoagulant therapy are fatal and greater than 50% of intracranial bleeds are fatal.[122] The risk of major bleeding in younger patients (e.g. less than 60 years) who do not have risk factors for bleeding and have good anticoagulant control (target INR 2–3) is about 1% per year.[90,123,124] The risk of major bleeding is expected to be as much as 10-fold higher in patients with multiple risk factors for bleeding.[120,121]

Inferior vena caval filters

No randomized trial or prospective cohort study has evaluated inferior vena caval filters as sole therapy in patients with DVT (i.e. without concurrent anticoagulant therapy). Permanent inferior vena caval filter insertion as an adjunct to anticoagulant therapy has been evaluated in a single large randomized controlled trial of patients with acute DVT who were considered to be at high risk for PE.[125] The findings of this study, which were reported after 2 years[125] and 8 years,[126] indicated that filters decrease the rate of PE, increase the rate of DVT, and have no effect on overall rate of VTE or mortality. Indirectly, this study supports the use of vena caval filters to prevent PE in patients with acute DVT and/or PE who cannot be anticoagulated (i.e. bleeding), but does not support more liberal use of filters (**Class I, Level C**). Patients should receive a course of anticoagulation if this subsequently becomes safe, which should be continued for the same duration as for similar patients who do not have an inferior vena caval filter.

Thrombolytic therapy

Systemic thrombolytic therapy accelerates the rate of resolution of DVT and PE, which can be life-saving for patients with PE and hemodynamic compromise.[127,128] However, the cost of thrombolytic therapy is a twofold or greater increase in frequency of major bleeding, and probably a greater increase in intracranial bleeding.[127,129,130] Right ventricular dysfunction on echocardiography, right ventricular dilation on echocardiography or CTPA, elevated troponin levels, and elevated brain natriuretic hormone levels are associated with increased early mortality in patients with acute PE.[131–136] Thrombolytic therapy may

reduce the risk of the prothrombotic syndrome following DVT, but this does not appear to justify its associated risks.[130] Catheter-based treatments (i.e. thrombolytic therapy or removal of thrombus) require further evaluation before they can be recommended.

Recommendation

Patients with PE and hemodynamic compromise should be treated with thrombolytic therapy unless they have a high risk of bleeding. **Class I, Level B**. Thrombolytic therapy may also be given to selected high-risk patients without hypotension who are judged to have a high risk of dying from PE and have a low risk of bleeding. **Class II, Level B**

Prevention

Postoperative fatal PE is rarely preceded by symptomatic DVT.[137] Consequently, primary prophylaxis is the best way to prevent fatal PE. Use of primary prophylaxis is strongly supported by cost-effectiveness analyses, which indicate that it reduces overall costs in addition to reducing morbidity.[138]

Postoperative patients: pharmacologic prophylaxis

Surgical patients can be categorized as at low, moderate or high risk of VTE depending upon the type of surgery and patient-related risk factors (Table 64.6).

Low-dose unfractionated heparin has been shown to reduce postoperative DVT and fatal PE by two-thirds.[139] LMWH is more effective (odds ratio 0.83) than low-dose UFH following orthopedic surgery and is associated with a similar frequency of bleeding.[140] An additional 3 or 4 weeks of LMWH after hospital discharge further reduces the frequency of symptomatic VTE after orthopedic surgery.[141–143] At a minimum, extended prophylaxis after major orthopedic surgery is recommended for the highest risk patients (i.e. previous VTE, active malignancy). Warfarin (target INR 2–3 for about 7–10 days) is less effective than LMWH at preventing DVT that are detected by venography soon after orthopedic surgery[144] but appears to be similarly effective at preventing symptomatic VTE over a 3-month period.[142–144] Fondaparinux has been shown to be more effective than LMWH following major orthopedic surgery, but causes marginally more bleeding.[145]

Table 64.6 Risk stratification for postoperative VTE, frequency of VTE without prophylaxis, and recommendations[144]

	Venographic DVT*		Pulmonary embolism		Recommended prophylaxis
	Calf	Proximal	Symptomatic	Fatal	
Low risk <40 years of age and uncomplicated surgery and no additional risk factors	2%	0.4%	0.2%	<0.01%	Early mobilization
Moderate risk Minor surgery in patients with additional risk factors Surgery in patients 40–60 years old with no additional risk factors	20%	5%	2%	0.5%	Low-dose UFH (q12h) LMWH (~3000 U per day) GCS or IPC
High risk Surgery in patients >60 years or age 40–60 with additional risk factors Major surgery in patients with malignancy or previous VTE Knee/hip surgery or heparin-induced thrombocytopenia	50%	15%	5%	2%	LMWH (>3000 U per day) Warfarin (INR 2–3) Fondaparinux IPC/GCS and low-dose UFH or LMWH

* Asymptomatic DVT detected by surveillance bilateral venography.
Low-dose UFH: 5000 U of subcutaneous unfractionated heparin preoperatively, and twice or three times daily postoperatively.
LMWH: subcutaneous low molecular weight heparin; higher doses (e.g. ~4000 U once daily with a preoperative start or ~3000 U twice daily with a postoperative start) are used in high-risk patients than in moderate-risk patients (~3000 U daily with a preoperative start).
GCS: graduated compression stockings, alone or in combination with pharmacologic methods.
IPC devices: intermittent pneumatic compression devices, alone or in combination with graduated compression stockings and/or pharmacologic methods.
Warfarin: usually started postoperatively and adjusted to achieve an INR of 2.0–3.0.
Fondaparinux: postoperative start at dose of 2.5 mg subcutaneous daily.

Recently, two new oral anticoagulants have received approval in Canada and Europe for prophylaxis following hip and knee arthroplasty. Dabigatran etexilate, an oral direct thrombin inhibitor, given at a dose of 220 mg once-daily has been evaluated in 3 randomized trials and found to be non-inferior to enoxaparin 40 mg once-daily.[146–148] Rivaroxaban, an oral Factor Xa inhibitor, given at dose of 10 mg once-daily, has been evaluated in 4 randomized trials and found to be superior to enoxaparin 40 mg once-daily and enoxaparin 30 mg twice-daily.[149–152]

There is evidence that aspirin reduces the risk of postoperative VTE by one-third.[153] A study of over 17 000 patients, mostly following hip fracture repair, confirmed these findings, including a reduction in fatal PE (0.27% v 0.65%) during the month following surgery.[154] However, as warfarin, LMWH and fondaparinux are expected to be more effective (at least a two-thirds reduction in VTE), aspirin alone is not recommended during the initial postoperative period.[144] Indirect evidence suggests that a month of aspirin therapy following a short period of prophylaxis with anticoagulant therapy (e.g. 10 days) is likely to be beneficial in patients who undergo major orthopedic surgery.[143,154]

Medical patients: pharmacologic prophylaxis

The evidence that short-term prophylaxis with low-dose UFH prevents clinically important VTE in immobilized medical patients is less convincing, partly because it has been less extensively studied in this population and because there is concern that medical patients remain at high risk of VTE after prophylaxis is stopped.[144,155,156] In recent years, three large randomized controlled trials have shown that LMWH (enoxaparin 40 mg or dalteparin 5000 IU subcutaneously once daily for 10 days) and fondaparinux (2.5 mg once daily) reduce the rate of VTE by about 50% (range 45–63%) compared with placebo in acutely ill medical patients.[157–159]

Mechanical VTE prophylaxis

Graduated compression stockings prevent postoperative VTE in moderate-risk patients (risk reduction of 68%)[160] and intermittent pneumatic compression devices prevent postoperative VTE in high-risk orthopedic patients.[144,161,162] Mechanical methods of prophylaxis should be used in patients who have a moderate or high risk of VTE if anticoagulants are contraindicated (e.g. neurosurgical patients).[144]

Recommendation

Primary prophylaxis with anticoagulants and/or mechanical methods should be used in hospitalized patients who have a moderate or high risk of VTE **Class I, Level A**

Conclusion

Venous thromboembolism is a leading cause of morbidity and mortality in both inpatients and outpatients. Objective testing for VTE is essential because clinical assessment alone is unreliable. Failure to diagnose VTE exposes patients to the risk of fatal PE. However, inappropriate use of anticoagulants exposes patients to the risk of serious bleeding complications, including fatal hemorrhage. Current treatment for acute VTE consists of LMWH or UFH or fondaparinux for a minimum of 5 days, usually administered by subcutaneous injection, as an outpatient in stable patients. A vitamin K antagonist is started the same day and continued for a length of time determined by the individual patient's risk factors for recurrent VTE, risk factors for bleeding, and patient preferences. In general, VTE associated with a reversible risk factor is treated for 3 months, VTE associated with active cancer is treated indefinitely, and unprovoked proximal DVT or PE is treated for a minimum of 3 months and often indefinitely, if anticoagulant therapy is well tolerated and associated with a low risk of bleeding. Patients with confirmed PE and hemodynamic compromise should be treated with thrombolytic therapy unless they have a high risk of bleeding. Most hospitalized patients should receive pharmacologic or mechanical prophylaxis for VTE.

65 Peripheral arterial disease

Catherine McGorrian and Sonia S Anand
McMaster University, Hamilton, Ontario, Canada

Introduction

Peripheral arterial disease (PAD) is usually defined as arterial disease which affects the arterial vasculature outside the heart. Aortic, renal and cerebral vascular diseases are addressed elsewhere in this text; therefore this chapter will focus on peripheral arterial disease of the lower extremities, distal to the aortic bifurcation.

The underlying pathologic abnormality of PAD of the lower extremities is obstruction of arterial flow, most commonly caused by atherosclerosis. However, other causes of arterial obstruction must also be entertained during diagnosis and include inflammatory diseases such as arteritis, entrapment syndromes, aneurysms and thrombosis *in situ* or thromboembolism. Atherosclerosis is a disease which primarily affects the intimal layer of elastic arteries, with the formation initially of a fatty streak, caused by adhesion molecule-dependent infiltration of the intima of mononuclear leukocytes, potentiated by chemoattractant chemokines. The leukocytes then become lipid laden, becoming macrophage foam cells, and the fatty streak is formed. Smooth muscle cells also infiltrate the plaque, with varying degrees of collagen formation. The resultant lipid-rich lesion, which is separated from the lumen of the artery only by a fibrous cap, can either rupture into the artery's lumen, triggering a thrombotic cascade and resulting in atherothrombosis and infarction, or become organized and ultimately even calcified, causing local obstruction to distal blood flow or stenosis.

PAD is an insidious condition, usually having a gradual onset and long latency before symptoms arise. It is associated with an increased risk of cardiovascular morbidity and mortality, and therefore evidence of PAD should direct health professionals to ensure that aggressive cardiovascular secondary prevention strategies are implemented.

Epidemiology and natural history

The prevalence of PAD depends on the age of the population surveyed and the method of diagnosis. The most commonly used method of PAD diagnosis is the Ankle Brachial Index (ABI). Data from several population-based studies indicate that PAD prevalence ranges between 3% and 10%, and increases to 15–20% among individuals over 70 years of age.[1–3] The annual incidence of intermittent claudication is greater among men than women, and is reported as 4.1–12.9/1000 men and 3.3–8.2/1000 women aged 55 and over attending a primary care setting.[4] The primary symptom of PAD of the lower extremities is limb claudication which is defined by a history of muscular leg pain on exercise that is relieved by a short rest. Claudication occurs when a stenosis in the artery restricts blood flow to the distal extremity to such an extent that when the person exercises and tissue oxygen demand increases, blood flow velocity cannot increase enough to cross the stenosis in adequate amounts to prevent tissue ischemia. Critical ischemia occurs when the arterial stenosis is so severe that blood flow is insufficient at rest, and the person has "rest pain", which is initially resolved by placing the limb in a dependent position.

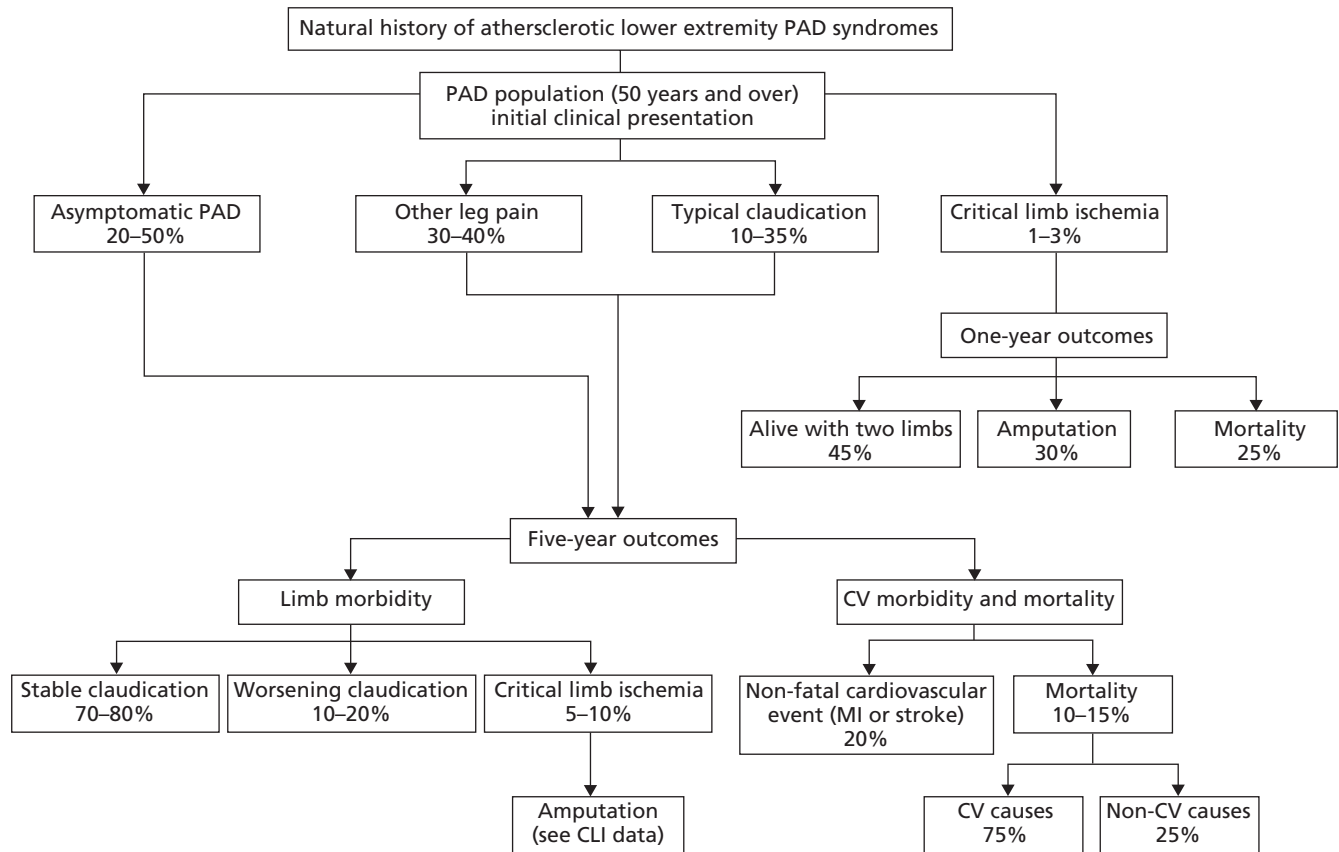
While the clinical interventions among patients with PAD traditionally focused on the impact of the arterial disease on the limbs, more recently the emphasis has shifted towards the risk of cardiovascular (CV) complications such as fatal and non-fatal myocardial infarction, and stroke faced by individuals with PAD. With respect to morbidity in the affected leg(s), only 1–3.3% of patients with intermittent claudication require amputation over a five-year period.[5] However, some subgroups of PAD patients remain at higher risk of further limb pathology. Specifically, 25% of patients with critical limb ischemia require amputation as the primary treatment[5]; patients who present with premature onset of PAD (i.e. at an age of ≤45 years) have an increased need for repeat limb intervention[6] and those who continue to smoke after their PAD diagnosis


Figure 65.1 Natural history of atherosclerotic lower limb PAD over five years. PAD, peripheral arterial disease; CLI, critical limb ischemia; CV, cardiovascular; MI, myocardial infarction. (From Hirsch *et al.*[18], with permission.)

have a worse prognosis for limb-related morbidity.[7] A more ominous threat to patients with PAD is their poor CV prognosis, as approximately 40–60% of patients with PAD have concurrent coronary artery disease (CAD) and cerebrovascular disease. The annual major adverse cardiovascular event rate (myocardial infarction, ischemic stroke and vascular death) in PAD patients is 5–7%, with a five-year probability of a major non-fatal or fatal CV complication of 30–35%, and there is a 70% mortality rate after 15 years. A low ABI has also been shown to have a high specificity for future cardiovascular events, including stroke and myocardial infarction.[8] Figure 65.1 shows the natural history of atherosclerotic lower limb PAD.

Risk factors

Risk factors for PAD are similar to the major risk factors of atherosclerosis, although the relative impact of each risk factor varies somewhat. The major risk factors for PAD include male sex, tobacco exposure, advancing age, dyslipidiemia, diabetes, and hypertension.

Male sex is reported as a PAD risk factor, as there are more men than women with PAD in younger age groups, which is likely due to the greater prevalence of smoking among men than women. However, because of the increased life span of women compared with men, and the increased incidence of PAD with increasing age, the overall incidence of PAD is actually similar in both sexes (Fig. 65.2). *Tobacco exposure* is the major risk factor for PAD, with the risk in current smokers being 2.3 times that of non-smokers.[9] In one population-based study, the prevalence of current or former smoking in persons with PAD with an ABI of less than 0.9 was 85% in men and 47% in women,[10] which results in a population attributable risk of tobacco exposure for PAD of 50–76%.[9] Furthermore, the degree of tobacco exposure has a dose–response relationship with PAD risk, increasing with increasing pack-years of smoking. Other risk factors for the development of PAD include *increasing age* (see Fig. 65.1), *dyslipidemia*, *diabetes* (increase in PAD risk of 2–4-fold[3]), *hypertension* (increase in PAD risk of 2–4-fold[11]), *impaired renal function* (increase in PAD risk of threefold in women with a creatinine clearance of <30mL/min/ 1.73m^2 [12]),
Figure 65.2 The age- and sex-specific prevalence of PAD (and 95% CI) according to age for men (white bars) and women (shaded bars). (From Meijer *et al*[10], with permission.)

Risk factor*	Point
Age	+1 point for every increase in age by 5 years, starting at age 55 (i.e. 1 point for age 60–64, +2 for 65–69, etc.)
Smoking	0 for never smoked, +2 for ever smoked
Hypertension	0 for no hypertension, +1 for adequately treated hypertension, +3 for inadequately treated hypertension

Score	Prevalence of ABI <0.9
0–3	7.0%
4	11.9%
5	14.5%
6	17.5%
7	19.3%
8	23.5%
9	25.9%
10	24.3%
11	25.1%
12	31.1%
≥13	40.6%

(Adapted from Bendermacher *et al.*[16], with permission.)

and *prior history of coronary artery disease* (increase in PAD risk of 1.5-fold[11]). Dyslipidemia is a well-recognized risk factor, with an association between decreased ABI and increased total cholesterol and decreasing HDL cholesterol shown in the Cardiovascular Health Study.[13] Similarly, a trend towards decreased ABI with higher triglyceride levels was noted, though this did not persist in multivariate analysis.[13] Persons with diabetes mellitus are at particular risk of developing PAD, with a relative risk of 2–4 times that of non-diabetics.[10] For every 1% increase in HbA1C in type 2 diabetes, the risk of PAD increases by 28%.[14] Diabetics are also much more likely to develop further PAD complications, with a risk of major amputation 7–15 times greater than non-diabetics with PAD. This is likely due to the peripheral sensory neuropathy associated with diabetic foot conditions, meaning that diabetics often present later, as their disease has been asymptomatic. Diabetes also causes rheologic changes, with increased blood coagulability, and a greater predisposition to acute and subacute thrombotic episodes, and increased vascular inflammation with calcification of the intima and more widespread vascular disease.

The Framingham investigators have reported that age, sex, cholesterol, hypertension, cigarette smoking, diabetes and pre-existing CAD are associated with increased risk of intermittent claudication, and have developed and published an intermittent claudication risk score based on these risk factors.[15] Bendermacher *et al*[16] have also developed a prediction rule to guide general and family practitioners with regard to which patients to screen for PAD, based on age, smoking status and hypertension (Fig. 65.3).

Diagnosis

Despite the prognostic importance of asymptomatic as well as symptomatic PAD, it is underdiagnosed in routine medical practice.[17] The initial clinical assessment for PAD is a history and physical examination. A history of intermittent claudication is useful in raising the suspicion of PAD, and symptoms are usually assessed by asking the person about the presence of exercise-induced calf pain, not present at rest, and which is relieved within 10 minutes by rest. The most recent ACC/AHA guidelines for the management of PAD[18] recommend a vascular "review of symptoms" in every clinical history, where people are asked routinely about leg symptoms on exertion, rest pain in the lower leg or foot, and the presence of poorly healing leg or foot wounds. However, reliance on symptoms alone significantly underestimates the true prevalence of PAD. Persons with PAD may have atypical symptoms, or even no symptoms,[10,17] and reliance on a classic history of claudication alone for screening purposes will miss 85–90% of PAD diagnoses.[17] Persons with PAD are more than twice as likely as those without PAD to have a history of

myocardial infarction, angina, congestive heart failure, stroke or transient ischemic attack[13] and therefore PAD screening must be considered in these patients.

Physical examination is an important part of the PAD evaluation, and a number of bedside tests can be performed. The most useful positively predictive clinical features for screening asymptomatic persons for PAD are a positive history of claudication (likelihood ratio (LR) for PAD 3.3, 95% confidence interval (CI) 2.3–4.8), listening for a femoral, iliac or popliteal bruit (LR 4.8, 95% CI 2.4–9.5, for the presence of one bruit at rest) and palpation for a pulse abnormality (femoral, popliteal, dorsalis pedis or posterior tibial; LR 3.1, 95% CI 1.4–6.6). For people with symptomatic PAD, clinical features such as cool skin (L 5.9, 95% CI 4.1–8.6), the presence of a bruit (LR 5.6, 95% CI 4.7–6.7, for the presence of one bruit at rest), and a pulse abnormality (LR 4.7, 95% CI 2.2–9.9) are positive predictors of PAD.[19] However, reliance on a pulse abnormality alone can overestimate the incidence of PAD.[1] A scoring system for PAD risk using arterial Doppler signals has been published[20] and is useful for identifying those patients who require further testing with an ABI test. Commonly, patients with intermittent claudication are classified using either the Rutherford or the Fontaine staging approach. The Rutherford staging is currently recommended[5] (Table 65.1).

Ankle Brachial Index

The ABI is a simple bedside test which can be rapidly performed, and which is most often used in epidemiologic studies to assess the presence of PAD (Fig. 65.4). The ABI is useful for both diagnosis and assessment of the efficacy of therapeutic interventions, and has been shown to have a high sensitivity and specificity for PAD, with a sensitivity of +90% and specificity of 95% for detecting angiographically significant disease with an ABI of 0.9 or less.[21] An ABI

of <0.9 has typically been used to diagnose PAD in large epidemiologic studies, and is recommended as the cut-off by both the American Heart Association[18] and the Transatlantic Inter-Society (TASC) guidelines.[5] Furthermore, the presence of a low ABI is highly specific for adverse CV prognosis, although its sensitivity is low. For example, a low ABI (<0.8–0.9) has a sensitivity and specificity for the prediction of incident CAD of 16.5% and 92.7%, of incident stroke of 16.0% and 92.2%, and of CV mortality of 41.0% and 87.9% respectively.[8] The ABI shows a U-shaped relationship with both all-cause and cardiovascular mortality (Fig. 65.5), with both ABIs of <0.9 and >1.4 associated with increased risk.[22] Higher ABIs >1.4 are associated with abnormal calcification of the arterial wall and resultant non-compressibility of the vessel, such as is common in diabetes.

Performing an ABI

With the patient in a supine position, the brachial systolic pressure is taken in both arms and the highest pressure recorded. Some recommend that the pressure be recorded ideally with a handheld 5 or 10 mHz Doppler ultrasound[17] though use of a stethoscope is acceptable, as long as the methods are consistent over time. Then the systolic pressure at the ankle, in both the anterior tibial and dorsalis pedis arteries, is determined using a 10–12 cm sphygmomanometer cuff around the ankle and the Doppler, and the highest pressure is recorded. The ABI is the ankle pressure divided by the brachial pressure. If the ankle arteries are non-compressible (such as in patients with diabetes mellitus or the very elderly) the ankle toe index can be a more informative test of distal disease, with an index of <0.70 indicating PAD. Some patients, in particular those with iliac disease, may not have a detectable abnormality on the ABI at rest, but complain of symptoms on exercise. The abnormality in these patients may only become apparent on exercise, as the inflow velocity increases, so a treadmill or plantarflexion test may be performed, with the ABI measurement repeated after exercise. Other useful non-invasive testing includes segmental Doppler pressure measurements, which uses a cuff method to identify pressure drops along the lower limbs, to try and isolate the lesion. However, weaknesses of this test are the possibility of missing iliac lesions, and the difficulty in interpreting results in the very old or diabetic subjects.

Treadmill testing

Treadmill testing is particularly useful for identifying PAD in patients in whom the disease is suspected but who have no reduction in ABI at rest. This is sometimes the case in patients with isolated iliac lesions. The procedure requires an initial measurement of either the ABI or full segmental Doppler leg pressures at rest. The patient is then asked to

Table 65.1 Classification of peripheral arterial disease: Rutherford categories

Grade	Category	Clinical description
0	0	Asymptomatic
I	1	Mild claudication
I	2	Moderate claudication
I	3	Severe claudication
II	4	Ischemic rest pain
III	5	Minor tissue loss
III	6	Major tissue loss

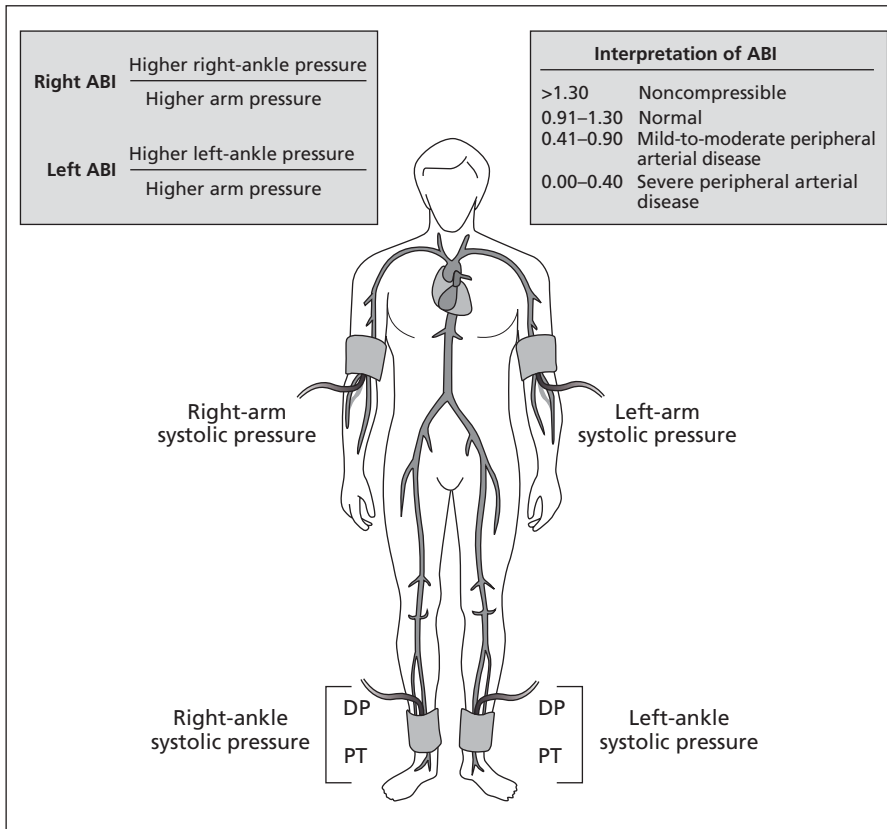

Figure 65.4 Measurement of the Ankle Brachial Index. Systolic blood pressure is measured in both brachial arteries, and in the posterior tibial and dorsalis pedis arteries using a Doppler ultrasound device. The higher of the pedal systolic pressures is chosen on each side, and the higher of the two brachial pressures is chosen. The ABI for each side is calculated by dividing the ankle pressure by the arm pressure. (Reproduced with permission from Hiatt WR. *N Engl J Med* 2001; **344**(21):1608–21.)
Figure 65.5 All-cause and CVD mortality in a population-based cohort of American Indians, showing the "U" shaped relationship with ABI. (Reproduced from Resnick *et al*[22], with permission.)

walk (typically on a motorized treadmill with a programmed schedule, such as at 3.2 km/h (2 mph), 10–12% grade) for a maximum of five minutes or until maximal claudication pain occurs, unless another reason to stop such as coronary ischemia arises. Following this, the ankle pressure is again measured. A decrease in ABI of 15–20% is diagnostic of PAD. For patients who are uncomfortable using a treadmill, especially older patients, a six-minute

walk test along a corridor can also be an effective exercise modality

Diagnostic imaging

This is usually reserved for patients in whom an intervention is being planned or to follow up graft patency. Historically, the gold standard for diagnosis of PAD has been

conventional angiography, but because of its invasive and labor-intensive nature and the risks associated with it, non-invasive imaging tools are frequently used.

The primary use of *angiography* is detection of disease in the arterial tree in persons in whom an intervention is being planned, such as those with critical ischemia or severe intermittent claudication symptoms unresponsive to lifestyle or medical therapy. The advantages of angiography are that definition of the vascular tree is optimized, and hemodynamic parameters may be measured directly. However, as an invasive procedure, angiography carries risks of contrast nephropathy and/or anaphylaxis, access site bleeding or hematoma, atheroembolism, and rarely vascular disruption with dissection or rupture. It is therefore best reserved for carefully chosen patients.

Duplex ultrasound is used to identify exact lesion sites in persons with symptoms or an abnormal ABI, and also has utility in venous graft surveillance post peripheral bypass procedures. The sensitivity and specificity for detecting lesions are high, reported as 94% by one meta-analysis.[23] Duplex ultrasound is especially powerful when using color-guided methods. However, it is labor intensive and requires a high level of technical expertise.

Contrast computed tomographic (CT) angiography is a further option for imaging the peripheral arterial system. Previously hampered by poorer image quality and slow scanning times, the new generation of multidetector array CT scanners offer high-quality images at high imaging speeds, although image reconstruction can be time consuming. Multidetector row spiral CT angiography (CTA) has been shown to provide sufficient clinical information, although at lower therapeutic confidence, when compared with digital subtraction angiography (DSA). It has excellent sensitivity and specificity for depicting arterial occlusions (sensitivity and specificity of 88.6% and 97.7%) and stenoses of at least 75% (92.2% and 96.8% respectively).[24] A meta-analysis of CTA compared with DSA showed sensitivity and specificity of detecting a stenosis >50% for CTA of 92% and 93%, respectively.[25] Another study randomized patients to either contrast MR angiography or multi-detector row CTA and found similar clinical utilities, but decreased costs in the CTA group.[26] However, the limitations of CTA include difficulty in interpretation of images in which there is a high degree of scatter caused by highly calcified vascular segments, the potential for renal impairment due to contrast injections, and the exposure to ionizing radiation.

Contrast-enhanced magnetic resonance (MR) angiography is an alternative to CTA and has the clear advantage of providing a "road map" of the arterial system of the lower limbs. Again, it is operator dependent, of limited use in patients with a contrast allergy, pacemaker or cardiac stent, and is expensive. Nevertheless, it has been shown to have better diagnostic accuracy than duplex US and to have similar accuracy to DSA, with sensitivity and specificity of greater than 90% quoted for stenoses of >50% in studies using three-dimensional gadolinium-enhanced methods.[27]

Therapeutics

Therapy for PAD can be divided into general lifestyle measures, measures aimed at improving symptoms, and measures to optimize secondary prevention of CV events. Therapies mentioned will be graded as per the *Evidence Based Cardiology* grading system. We will also discuss emerging therapies and the evidence for these to date.

Lifestyle measures

Smoking cessation

Our understanding of the effects of smoking cessation in PAD patients comes primarily from observational studies, as there have been no prospective randomized controlled trials (RCTs) of smoking cessation and its effects on CVD outcomes in patients with PAD. Nevertheless, reports show that smoking cessation is associated with improvements in claudication symptoms, reduced rest pain, improved graft patency rates post lower limb bypass procedures, and decreased risk of death, MI or amputation. Patients who have undergone lower extremity bypass surgery also have a higher rate of major amputation if they are heavy smokers (≥15 cigarettes per day) compared with more moderate smokers (21% amputation rate vs 2%, $P < 0.001$).[28] Smoking cessation rates have also been associated with reduced mortality in an RCT of small infrarenal aneurysm outcomes,[29] where the mortality benefit in the surgical vs surveillance group could be explained by the 12-fold increase in the odds of smoking cessation in the surgical group.[30]

Smoking cessation can be difficult to achieve, but effective interventions include physician guidance (2% of patients advised by their physician to quit had remained off cigarettes at one year[31]) and cessation aids including nicotine replacement therapy, varenicline (Champix™), bupropion, and other antidepressant therapies.

Simple physician advice to quit smoking in a brief clinical encounter has been shown to increase quit rates by 5%.[32] Nicotine replacement therapy (NRT) has been shown to be up to 13% effective in achieving adherence to non-smoking at one year,[31] with a meta-analysis of data from 16 RCTs of transdermal NRT patches reporting an odds ratio (OR) for 12-month abstinence of 1.75 (95% CI 1.49–2.05).[33] An increase in success for smoking cessation of 50–70% with all types of NRT was reported in a Cochrane review and meta-analysis of 132 trials by Stead *et al*.[34] Bupropion (Zyban™), an atypical antidepressant agent, has been found to be superior to placebo and NRT, with 12-month

abstinence rates of 30%, although there was a high withdrawal rate from therapy (11%) and an unusually high quit rate in the placebo group.[35] A second RCT also found that bupropion doubled the success of smoking cessation, with an odds ratio of abstinence at 12 months for bupropion of 2.78 (95% CI 1.70–4.63), compared with placebo and usual care.[36] However, bupropion should not be used in patients with epilepsy, and only used with great caution in patients with low seizure thresholds.

A newer agent which has recently entered the marketplace is varenicline tartrate (Champix™), a partial nicotine receptor agonist. A Phase II RCT comparing varenicline to placebo demonstrated significantly higher quit rates of 14.4% with varenicline, compared with 4.9% for placebo, $P = 0.002$.[37] This was followed by a Phase III study which showed continuous abstinence rates for 9–52 weeks were significantly higher among patients receiving varenicline (21.9%) or bupropion (16.1%) compared to placebo (8.4%).[38] Varenicline is reasonably well tolerated, with better adherence rates than for bupropion, although larger and longer term trials of varenicline are needed.

Smoking cessation aids have been shown to be cost effective, with cost per life-year saved less for smoking cessation aids than for other secondary prevention steps commonly used post myocardial infarction (Fig. 65.6).

Recommendations

- Smoking cessation in all patients, to reduce PAD symptoms and future adverse CVD events (**Class 1, Level C1**).
- Use of smoking cessation aids such as physician advice, NRT, bupropion or varenicline to aid in quitting (**Class 1, Level B**).

Exercise

Patients with PAD benefit from a regular exercise program to optimize walking ability and maximal walking time.[39] A meta-analysis of 21 trials of walking therapy found that walking to near maximal pain, for 30 minutes and as part of a program lasting more than six months, increased the distance to onset of claudication pain by 179% (225.3 m) and the distance to maximal claudication pain by 122% (397.5 m).[40] Resistance training is not as beneficial as regular walking to near maximal pain threshold for 30 minutes at least four times a week, and supervised programs have been shown to be more beneficial than non-supervised, although there are nevertheless benefits to be gained from the home-based programs. There is also preliminary evidence from two small RCTs (n = 35[41] and n = 67[42]) which
Figure 65.6 Cost effectiveness of smoking cessation strategies post MI when compared with other routine secondary prevention methods. (Reproduced with permission from Parrott S, Godfrey C. *BMJ* 2004;**328**:947–9.)

suggests that arm ergonometry may be as successful as treadmill training in increasing initial claudication distance and maximal walking distance. This may offer an exercise alternative to those with severely reduced mobility.

Although one theory is that walking induces angiogenesis and collateral growth around the occluded or stenosed area, it is actually more likely that the benefits are due to improvements in muscle tone with muscle hypertrophy, improved endothelial function and altered gait.[18] It was also shown in one trial that exercise therapy was more beneficial for walking times than percutaneous revascularization therapies[43] although this has not been replicated elsewhere. Exercise training for patients with PAD is optimally supervised by an exercise physiologist, physical therapist or nurse, in the setting of a cardiac rehabilitation program or similar,[18] with the option of further non-invasive monitoring, since these patients may have concomitant cardiac disease. Supervised exercise sessions are typically scheduled three times a week, for a period of three months, with 30–60-minute sessions each time.[5] Exercise also has further benefits in that it can improve dyslipidemia, hypertension and risk of type 2 diabetes mellitus, as well as reducing overall adiposity and Body Mass Index.

Recommendations

- A graded supervised exercise program should be advised to improve walking distance and other cardiovascular risk factors in patients with PAD (Class 1, Level B).
- There is less evidence to support home-based exercise programs (**Class IIa, Level B**).
- Arm ergonometry may be an acceptable alternative to walking-based programs (**Class IIa, Level B**).

Therapies for secondary event prevention

As discussed, patients with PAD are at very high risk of adverse vascular events elsewhere in the arterial tree, such as MI and stroke. Diabetes, hypertension and elevated cholesterol are not only etiologic factors in the pathogenesis of PAD, they also contribute to high rates of CV events among patients with established PAD. Therefore, it is generally accepted that control of etiologic risk factors will result in improved cardiovascular prognosis. Below we present evidence to support this practice.

Glycemic control in patients with diabetes

Control of blood glucose is advisable in patients with diabetes, to reduce the risk of adverse CVD events. The Steno-2 trial[44] randomized 160 type 2 diabetes patients to conventional or intensive control with a target HBA1C of <6.5%, in conjunction with tight blood pressure and lipid

control with a mean follow-up of 13.3 years. It reported reduced risks of cardiovascular mortality (hazard ratio (HR) 0.43, 95% CI 0.19–0.94, $P = 0.04$) and of cardiovascular events (HR 0.41, 95% CI 0.25–0.67, $P < 0.001$) with intensive glycemic control. However, a conflicting message has been given by the ACCORD study, in which an increase in total mortality was noted in the intensive control intervention arm, which aimed to reduce HBA1C in type 2 diabetes patients to <6.4%.[45] Further analysis of the ACCORD results is awaited.

The major trials of strict diabetic control in both type 1[46] and type 2[47] diabetes mellitus were not sufficiently powered nor designed to examine changes in PAD symptoms or outcomes, with the latter study showing no significant reduction in amputation from PAD in the intensive control group. Nevertheless, the results showing improvements in micro- and macrovascular conditions have been widely extrapolated and, in keeping with the American Diabetes Association recommendations among patients with established diabetes, it is reasonable to aim for a HbA1C of <7% in patients with PAD.[48]

Recommendation

- Persons with PAD should aim for optimal glycemic control, with HbA1C maintained at <7%, using medication, weight control and exercise (**Class I, Level C**).

Antihypertensive agents

Two trials have recently shown clear benefit of antihypertensive therapy in PAD patients. HOPE-PAD[49] examined the incidence of PAD within the HOPE RCT and the effects of ramipril within PAD groups. In total, of the 9541 patients in HOPE, 1715 had symptomatic PAD and a further 2118 had PAD by ABI criteria (ABI <0.9). Ramipril was associated with a significant relative risk reduction (RRR) in fatal CVD events, non-fatal MI and non-fatal stroke, with a RRR of 0.75 (95% CI 0.61–0.92) in persons with symptomatic PAD. The Appropriate Blood Pressure Control in Diabetes trial[50] randomized patients with diabetes to usual care (moderate blood pressure control) or intensive blood pressure control with enalapril and nisoldipine, and found that intensive control in the PAD subgroup (n = 53) had a protective effect on cardiovascular events, even for those patients with lower ABIs, who had more events in the control group.

There is, however, a paucity of data on the effects of antihypertensive agents on the symptoms and progression of PAD itself, and a Cochrane meta-analysis only identified two small trials, involving perindopril and verapamil.[51] Although we cannot therefore draw definite conclusions on the possible beneficial effects of blood pressure lowering, the findings in the HOPE-PAD trial, in conjunction

with the growing body of evidence recommending antihypertensive agents (and ACE inhibitors in particular) in secondary prevention, would indicate that we should recommend intensive blood pressure lowering in this high-risk group. There has historically been a concern that lowering blood pressure will concomitantly lower limb perfusion pressure, and possibly worsen limb ischemic symptoms. However, a meta-analysis of the effects of beta-blockers on limb symptoms showed no consistent concern with their use in PAD,[52] and the JNC 7 recommendations for treatment of hypertension have suggested that all antihypertensive agents are suitable for use in PAD, depending also of course on patient-specific factors.[53] Nevertheless, in patients with critical ischemia unresponsive to medical therapy, some clinicians will replace a beta-blocker with an alternative antihypertensive agent.

Recommendation

- Antihypertensive agents should be administered to PAD patients to reduce risk of secondary CVD events, to aim for a blood pressure of less than 140/90 in non-diabetic persons and less than 130/80 for diabetic persons (**Class I, Level A**).

Lipid-lowering regimens

Use of HMG co-enzyme A reductase inhibitors (statins) and other lipid-lowering agents has been a cornerstone of coronary and cerebral atherosclerotic disease management for a number of years. The Heart Protection Study which had a large representation of patients with PAD demonstrated that use of simvastatin in PAD patients even with normal levels of LDL cholesterol was associated with a reduction in recurrent non-fatal MI, stroke and also a lowering in mortality.[54] The impact of lipid lowering on intermittent claudication in PAD patients was examined in a large meta-analysis (pooling data from 19 studies with 10049 patients).[55] Patients in the lipid-lowering arm were found to have statistically significant improvements in total walking distance and pain-free walking distance, though no improvement in ABI, when a number of smaller trials assessing these outcomes were pooled, with improvements in either total mortality or total cardiovascular events. However, these analyses are a little difficult to extrapolate to clinical practice, as so many different lipid-lowering modalities were used in the component trials.

Looking at the fibrate group specifically, a trial of gemfibrozil in coronary heart disease has previously shown reductions in non-fatal MI and CVD death in persons with low HDL levels.[56] However, a trial of bezafibrate in PAD patients has shown that although claudication severity improved in the fibrate group, there was no effect on mortality or cardiovascular events, despite a reduction in non-fatal coronary events.[57] Niacin is used in patients with CVD and low HDL. Studies have shown that niacin therapy is safe in PAD and raises HDL, but data on long-term CVD benefits are sparse, and a recent study which used carotid intima-media thickness (IMT)as a surrogate for CVD events in niacin and statin combination therapy showed only a non-significant trend to reduction in carotid IMT.[58]

Similarly, in HMG co-enzyme inhibitor or statin trials, statin use has been found in a number of small randomized studies to be associated with improvements in claudication times.[59–61] The Heart Protection Study randomized patients with vascular disease or diabetes to simvastatin 40 mg or placebo, and had a large number of patients with PAD (n = 6748).[54] This study showed that the simvastatin group had a 19% RRR and a 6.3% absolute risk reduction (ARR) of major vascular events, and this effect persisted even in the patients who did not have high levels of LDL cholesterol at baseline.

Recommendations

- Statins are first-choice lipid-lowering therapy in patients with PAD to reduce the risk of secondary vascular events, regardless of initial cholesterol level (**Class I, Level A**).
- Statins may also improve pain-free walking time and six-minute walk test performance in patients with symptomatic PAD, regardless of initial cholesterol level (**Class IIa, Level A**).
- Fibrate therapy may be used as second-line therapy to decrease CVD events (**Class IIa, Level B**).
- Niacin can be used to raise HDL in PAD patients, but there are no convincing data to support a benefit in CVD outcomes (**Class IIa, Level A**).

Antiplatelet therapies

Antiplatelet therapies include acetylsalicylic acid or aspirin, dipyridamole, thromboxane antagonists including picotamide, and the thienopyridine group (ticlodipine and clopidogrel). From the Antiplatelet Trialists' Collaboration, 287 studies were included in a meta-analysis[62] to examine the effects of antiplatelet therapies in those with vascular disease. In data pooled from 42 trials of 9214 patients with PAD, antiplatelet agents were found to be associated with an odds reduction of serious vascular events of 23% (standard error 8%, $P = 0.001$), for patients with intermittent claudication, post vascular bypass operations or undergoing percutaneous therapies. Similarly, Anand and Tran noted an odds reduction in vascular events with antiplatelet therapy (aspirin, ticlodipine, picotamide, dipyridamole or aspirin + dipyridamole) vs control of 23% (95% CI 7.9–35.5, $P < 0.004$).[63]

Aspirin is an inhibitor of platelet cyclo-oxygenase and thromboxane production. Collins *et al* performed a meta-analysis examining antiplatelet agents vs placebo after infra-inguinal bypass grafting[64] and combined data from seven trials, six of which studied aspirin or an aspirin/dipyridamole combination. Antiplatelet therapy was associated with an odds reduction for mortality of 30% (95% CI 5–49%), for graft occlusion of 57% (95% CI 33–73%), and a non-significant increase of bleeding side effects (OR 1.82, 95% CI 0.43–7.73). Data on aspirin dosing have not specifically addressed optimum dose in PAD patients, but the Antiplatelet Trialists' Collaboration data would suggest that a dose of between 75 and 150 mg daily would achieve maximum efficacy with a lower risk of bleeding.[65]

Antiplatelet agents and aspirin have also been shown to have a role in maintaining the patency of vessels after lower extremity bypass or percutaneous angioplasty procedures. The 1994 meta-analysis by the Antiplatelet Trialists' Collaboration[65] pooled data on 3226 patients with intermittent claudication or who had undergone lower extremity bypass or percutaneous angioplasty, and found graft occlusion rates of 16% with antiplatelet therapy (mainly aspirin, or aspirin and dipyridamole in combination) vs 25% with control, resulting in a proportional reduction of occlusion of 43% (SD 8%, $2P < 0.0001$). Collins *et al*[64] also examined graft patency after lower extremity bypass surgery in studies which had greater than 12 months of follow-up, and found an odds reduction of 64% (95% CI 34–68%) for graft occlusion in the antithrombotic group (seven trials of antiplatelet therapy, three trials of oral anticoagulant therapy) vs the control group. Analyses from the Cochrane Group also suggest that antiplatelet agents are superior to placebo in maintaining vessel patency post surgical bypass.[66] A subgroup analysis of a large trial comparing oral anticoagulants (OAC) to antiplatelet therapy suggests that OAC may be superior in maintaining patency of venous grafts[67] whereas antiplatelet agents may be preferable in artificial grafts.[68] However, in light of the excess risk of bleeding with OAC vs antiplatelet agents observed in the WAVE trial,[69] the decision to use OAC over aspirin in patients with venous grafts to improve patency must be made on an indivdual patient basis. For percutaneous revascularization, there is no significant difference in occlusion rates with aspirin vs oral anticoagulants.[70] Aspirin has also been shown to reduce the rate of peripheral bypass surgery in a large RCT of aspirin vs control over 60.2 months in healthy participants (RR for surgery 0.54, 95% CI 0.30–0.95, $P = 0.03$: data from the Physicians Health Study[71]).

Thienopyridines (clopidogrel and ticlodipine) have been shown in meta-analyses to be effective in reducing postoperative occlusion and need for revascularization in patients undergoing lower limb interventions,[72] and to have a mortality benefit in patients with intermittent claudication.[73] The thienopyridines block adenosine diphosphate-mediated platelet activation, and therefore they may have a different efficacy to aspirin in secondary prevention. This theory was examined by a Cochrane Collaboration study, which performed a meta-analysis of pooled data from four studies and 22 565 patients at high risk of secondary vascular events.[74] Two of these studies (CAPRIE[75] and Schoop[76]) randomized patients with PAD. From the pooled data, the thienopyridine group had a reduced odds of a serious vascular event (OR 0.91, 95% CI 0.84–0.98) and a decreased odds of major hemorrhage (OR 0.71, 95% CI 0.59–0.86), though an increased risk of skin rash and neutropenia (most associated with ticlodipine).[74] Within CAPRIE alone, which compared aspirin 325 mg daily with clopidogrel 75 mg daily, the overall RR comparing clopidogrel to aspirin was 8.7% (95% CI 0.3–16.5%), although given their higher baseline risk, the PAD patients had a greater RRR with clopidogrel than the other at-risk vascular subgroups (RRR 23.8%, 95% CI 8.9–36.2%).[75] However, in the CHARISMA trial,[77] the use of dual antiplatelet therapy (i.e. aspirin and clopidogrel) was not significantly more effective in the prevention of CVD than aspirin alone (RR of stroke, MI or CV death 0.93, 95% CI 0.83–1.05) and was associated with an increase in severe and moderate bleeding complications (RR for severe bleeding with dual therapy 1.25, 95% CI 0.97–1.61) in patients with atherosclerotic CVD and high CVD risk.

At present, there seems to be no clear role for regular or extended-release dipyridamole alone in PAD. Early trials examined dipyridamole in conjunction with aspirin in maintaining patency of lower extremity bypass grafts/percutaneous procedures, and suggested that this was an advantageous combination. However, in terms of secondary prevention, the Antiplatelet Trialists' Collaboration suggested that the combination of aspirin plus dipyridamole was not superior to aspirin alone.[62] A Cochrane meta-analysis[78] included data from 27 studies which randomized people with vascular disease to dipyridamole and found that dipyridamole was not superior to control in preventing CVD death, and was only superior to control in preventing CVD events in patients with cerebral ischemia.

There has been interest in the use of antiplatelet agents in the treatment of intermittent claudication. Ticlodipine has been investigated in a small blinded placebo-controlled trial for improvements in ABI and walking times; an improvement was shown but the trial numbers were small (n = 151) and the placebo group had worse ABIs and walking times at baseline.[79] Another trial (n = 296) randomized patients to aspirin and dipyridamole, ticlodipine or xanthinol nicotinate, and found again that the ABI improved with aspirin/dipyridamole and ticlodipine, but not with xanthinol.[80]

- Patients with PAD, including patients who have undergone peripheral vascular bypass or percutaneous revascularization procedures, should take lifelong antiplatelet therapy with aspirin 75–150 mg per day. Clopidogrel 75 mg per day is a useful alternative, as demonstrated in the CAPRIE trial (**Class I, Level A**).
- There is no additional benefit in using aspirin in conjunction with clopidogrel for the long-term management of PAD patients (**Class IIb, Level A**).
- There is no additional benefit in using aspirin in conjunction with dipyridamole in PAD patients, unless there is a concomitant history of cerebrovascular disease (**Class IIb, Level A**).

Vitamin K antagonists

Oral anticoagulants, like antiplatelet agents, have a theoretically appealing role in PAD, both in preventing vascular occlusion and preventing other systemic atherothrombotic events. A meta-analysis by the WAVE investigators has shown that OAC are better than placebo at reducing mortality and graft occlusion, but have an increased risk of major bleeding.[81] Comparing oral anticoagulants with aspirin showed no benefit for mortality or graft occlusion in the oral anticoagulation group above that achieved with aspirin, again at an increased risk of bleeding. Most recently, the WAVE trial, which evaluated combined OAC and antiplatelet therapy in 2161 patients with PAD, showed that combined therapy was not superior to treatment with antiplatelet therapy alone for the combined outcome of fatal and non-fatal cardiovascular events (RR for combination therapy 0.91, 95% CI 0.74–1.12, $P = 0.37$). Combined OAC and antiplatelet therapy was associated with a substantially higher risk of life-threatening bleeding complications (RR 3.41, 95% CI 1.84–6.35, $P < 0.0001$).[69] Therefore, oral anticoagulation for secondary prevention in PAD should only be used if there is a supplemental indication for anticoagulation, such as atrial fibrillation.

- OAC should not be used routinely in patients with PAD, without a secondary indication (**Class II, Level A**).

Therapies aimed at the circulatory disease itself

Aside from the lifestyle measures, therapies aiming to improve the circulation to the affected limb(s) and to ameliorate symptoms may be pharmacologic, percutaneous or surgical.

Pharmacologic treatments for intermittent claudication

The TASC II guidelines[5] suggest two medications for the amelioration of intermittent claudication symptoms – cilostazol and naftidrofuryl – and discuss the lack of evidence supporting others such as pentoxifylline.

Pentoxifylline is thought to act by decreasing blood viscosity and increasing erythrocyte flexibility. It has long been used for intermittent claudication symptoms, but the evidence regarding its efficacy is sparse and it does not have a large safety record. Girolami *et al*[39] examined 13 RCTs of pentoxifylline vs placebo in intermittent claudication and found that mean walking distance was improved on pentoxifylline (increase in mean walking distance of 43.8 m, 95% CI 14.1–73.6 m). In another meta-analysis (of 11 trials, n = 612), Hood *et al*[82] similarly found that pentoxifylline increased pain-free walking distance (weighted mean difference 29.4 m, 95% CI 13.0–45.9 m) and absolute claudication time (weighted mean difference 48.4 m, 95% CI 18.3–78.6 m) compared with placebo. Whilst smaller trials have shown benefits for pentoxifylline, a larger RCT (n = 471 patients in the pentoxifylline vs placebo arm) showed no difference between pentoxyifylline and placebo.[83] At present, the TASC group suggests that there is insufficient evidence to use pentoxifylline in intermittent claudication.[5]

Naftidrofuryl is a serotonin antagonist, which is thought to work by promoting aerobic metabolism in oxygen-depleted tissues and by reducing platelet and erythrocyte aggregation. It has been shown to reduce disease-related limitations in quality of life when compared with placebo in a meta-analysis of three RCTs (n = 754)[84] and to increase pain-free walking distance in another meta-analysis.[85] However, like pentoxifylline, the absolute increases in walking distances achieved with naftidrofuryl are small (increase in mean total walking distance with naftidrofuryl 71.2 m, 95% CI 13.3–129.0 m).[39]

Cilostazol is a phosphodiesterase III inhibitor, which inhibits platelet activation and relaxes vascular smooth muscle. A 2002 meta-analysis synthesized the results of six randomized trials of cilostazol vs control (n = 1751), and reported that cilostazol increased maximal treadmill walking, with improvements in the Walking Impairment Questionnaire and also in health-related quality of life.[86] A Cochrane meta-analysis synthesized data from eight trials and reported that cilostazol was associated with an improvement in initial claudication distance (ICD) and absolute claudication distance (ACD), with a weighted mean difference in ICD of 31.1 m (95% CI 21.4–40.9 m) with cilostazol.[87] Cilostazol is contraindicated in patients with congestive cardiac failure, although the safety analysis in the Cochrane review did not show any increase in CV events with cilostazol. One study also compared cilostazol directly with pentoxifylline and found that cilostazol

significantly reduced ACD, whereas the effects of pentoxi-fylline were similar to those of placebo.[83] Serious adverse events and withdrawals from therapy were similar in the two treatment groups, although the incidence of minor side effects was greater in the cilostazol group.

Other agents

Other agents which have been proposed for use in inter-mittent claudication include buflomedil, arteriolar vasodi-lators, and prostaglandins. Buflomedil is a vasodilator which also has antiplatelet actions. However, a Cochrane review could only find appropriate data on 127 patients with improvements in pain-free walking distance with buflomedil, leading to concerns about safety and publica-tion bias.[88] Vasodilators such as calcium channel blockers have been used in an attempt to increase local blood flow, but there is scant evidence for their use. Intravenous pros-taglandin infusions have been used in critical limb isch-emia, and an oral prostaglandin called beraprost has been investigated but the trials in intermittent claudication are negative to date.[5] There has also been interest in angiogenic growth factors, but again the trials have not proved con-clusive. In relation to the treatment of critical limb isch-emia, the TASC group suggests that treatments like vasodilators, naftidrofuryl, pentoxifylline and unfraction-ated heparin have no proven benefit.

Recommendations

- Cilostazol is recommended for use in intermittent claudication to improve ICD and ACD, although side effects are common (**Class I–IIa, Level A**).
- Naftidrofuryl can be used as an alternative to cilostazole, although there is less evidence regarding its use (**Class IIa, Level A**).
- There is currently insufficient evidence to recommend the use of pentoxifylline, buflomedil, vasodilators and oral prostaglandins in intermittent claudication (**Class III, Level B**).

Surgical

Percutaneous angioplasty Percutaneous angioplasty (PCA) is an appealing therapy for peripheral arterial disease, but it is far from a cure-all. The AHA/ACC guidelines suggest that only certain patients be considered for percutaneous therapies, these being patients who have not responded to exercise or pharmacotherapies, patients who have a severe disability with their claudication symptoms, patients in whom other co-conditions are not also limiting exercise tolerance, and patients with a focal lesion amenable to per-cutaneous treatment.[18] One chief difficulty is that patients with severe PAD frequently have multiple or long lesions which are not suitable for angioplasty, with only 10% of

participants screened in one trial of PCA vs medical therapy found to be suitable for PCA.[89] Furthermore, it has been shown in one trial only that exercise therapy was more beneficial for walking times than percutaneous therapies.[43]

There is a paucity of data regarding direct comparisons of PCA with medical and lifestyle therapies for PAD. Whyman randomized 62 patients to medical therapy or PCA + medical therapy, reporting that at six months fol-low-up, the PCA patients had higher mean ABI (0.88, stan-dard error 0.03, vs 0.74, standard error 0.03; $P < 0.01$) and higher quality of life scores.[89] Another study examined 56 patients with stable claudication who were randomized to PCA vs exercise therapy, and found that while the PCA group made short-term improvements in ABI, at six years follow-up there was no difference between the groups with respect to ABI and maximal walking distance.[90] Spronk *et al* compared functional capacity and quality of life scores in five studies of exercise therapy and three of PCA, and found that while ABIs were higher in the PCA groups at six months, there was no difference in reported quality of life.[91]

Focal lesions of the iliac arteries can cause both periph-eral claudication symptoms and Leriche's syndrome, where a terminal aorta lesion causes erectile dysfunction and buttock claudication. Endovascular stenting can be recommended for TASC type lesions A to B of the iliac arteries (short stenoses <3 cm long, not extending into the superficial femoral artery) in patients who are persistently symptomatic despite optimal medical and lifestyle thera-pies.[5] The iliac arteries are particularly prone to disruption and dissection, and primary stenting (without prior balloon angioplasty) is usually recommended. Infrainguinal disease is more technically challenging, with common femoral disease being associated with poorer endovascular outcomes due to acute vessel closure or late restenosis. Superficial femoral artery disease is commonly diffuse and not amenable to stent placement, and stents in the arterial portion within the adductor canal can be subject to extra strain and torsion, predisposing to stent fractures. Balloon angioplasty has traditionally been the percutaneous treat-ment of choice in the superficial femoral artery, with stents reserved for "bail out" in case of dissection or acute vessel closure. However, techniques have improved and stenting is becoming more commonplace. A recent RCT of superfi-cial femoral artery PCA vs nitinol stent implantation in 104 patients reported better ABIs and better maximal treadmill walking distance at 12 months in the stent group (387 vs 267 m, $P = 0.04$).[92]

Although the use of antiproliferative drug-eluting stents has effectively reduced in-stent restenosis in coronary revascularization, the results with sirolimus-eluting stents in superficial femoral peripheral arterial interventions have been mixed. However, in the preliminary THUNDER (Local Taxane with Short Exposure for Reduction of

Restenosis in Distal Arteries) trial,[93] a randomized, double-blind study of 154 patients who underwent percutaneous femoropopliteal angioplasty interventions, 17 of whom also required nitinol stent implantation. 48 patients were randomized to a paclitaxel-coated balloon; 52 to a usual balloon, with paclitaxel in the contrast medium; and 54 received usual care. The paclitaxel balloon (but not the paclitaxel contrast) group saw significant reductions both in mean late lumen loss and target lesion revascularization (2/48 (4%) with the paclitavel balloon vs 20/54 (37%) in the control group, $P < 0.001$) at six months follow-up. Whilst further studies are needed, this suggests potential for future improvements in peripheral PCA.

Atherectomy devices, including laser atherectomy, extraction atherectomy and cutting balloon atherectomy, have been proposed for use in superficial femoral lesions, including chronic total occlusions. However, the published randomized controlled data for atherectomy are not indicative of benefit above balloon angioplasty, and cutting balloons have recently been recalled. Laser atherectomy has shown promising results in observational studies and registries but a RCT is awaited. Therefore, the use of these devices must be viewed with appropriate caution.

Recommendations

- PCA is recommended for patients with aorto-iliac disease which is disabling and refractory to medical and lifestyle therapies, and technically amenable to PCA (**Class I, Level B**).
- Endovascular stenting can be recommended in aorto-iliac disease as either primary or bail-out therapy (**Class I, Level B**).
- PCA can be used in patients with femoral, popliteal or tibial disease which is disabling and refractory to medical and lifestyle therapies, and technically amenable to PCA (**Class IIa, Level C**). There is less information on the use of primary stenting in this group.
- The usefulness of atherectomy devices and/or cutting balloons is not established from the literature.

Surgical revascularization Surgical revascularization is subject to the same caveats as percutaneous therapies, in that it should only be undertaken if the symptoms are severely limiting, and if medical and lifestyle therapies have not achieved sufficient improvement. Aorto-bifemoral bypass procedures are considered the standard of care for aorto-iliac occlusive disease where the patient is refractory to medical and exercise therapy, and where symptoms are sufficient to warrant further treatment. One metasynthesis of outcomes post aorto-iliac bypass procedures found an operative mortality rate of 3.3%, with a systemic morbidity rate of 8.3% for procedures in studies started since 1975. Limb-based patency rates at five and 10 years

were 91.0% and 86.8% respectively for patients with claudication and 87.5% and 81.8% for patients with critical limb ischemia.[94] Tobacco smoking is associated with worse patency rates. A synthesis of four RCTs (which randomized patients to different types of grafts) and 12 prospective studies of the influence of smoking on graft patency in lower limb arterial revascularization reported that ongoing smoking was associated with a 3.09-fold (95% CI 2.34–4.08, $P < 0.0001$) increase in graft failure, with a dose–response effect with increasing numbers of cigarettes smoked.[95] Infrainguinal procedures also have worse five-year graft patency rates, ranging from 29% to 62%, with worse rates associated with prosthetic grafts below the knee and with continued smoking. Procedures involving the tibioperoneal trunk and tibial vessels are associated with the greatest postoperative morbidity and tissue loss. Other studies have also shown that venous grafts have better long-term patency than prosthetic (polytetrafluoroethylene coated) grafts, with the long saphenous vein being the graft of choice. A requirement for infrainguinal surgical bypass procedures is a patent and uncompromised inflow artery.

Postoperatively, clinical surveillance programs are advised up to two years postoperatively, with regular clinical review with ABI and a vascular history noted. Patients should also be treated with long-term antiplatelet therapy. Cohort studies have identified factors which can be associated with decreased long-term patency such as female sex, redo procedures, diabetes mellitus and African-American ethnicity, as well as the technical expertise of the surgeon.

Comparisons between surgical and percutaneous therapies are limited by the differing profiles and anatomy of patients who are referred for these procedures. Feinglass *et al* examined outcomes in a prospective cohort of patients who underwent percutaneous transluminal angioplasty (PTA) or surgery or medical therapy, and reported that mean walking distances and ABIs were improved in the interventional groups.[96] The BASIL study[97] randomized 452 patients with severe limb ischemia to surgery or PTA and found similar outcomes in both groups, with amputation-free survival at six months in 60 surgical vs 48 PTA patients (HR 1.07, 95% CI 0.72–1.60), with PTA noted to be less costly than surgical bypass procedures. Other studies have noted the superior cost effectiveness of PTA vs surgery.

Recommendations

- Aorto-iliac disease which is disabling and refractory to medical and exercise therapy can be treated with aorto-iliac bypass procedures, if PTA is not appropriate (**Class I, Level B**).
- Infrainguinal bypass procedures can be used in cases of severe ischemia, and should be performed using autologous vein grafts as first choice, with artifical grafts used as a second option (**Class IIa, Level B**).

Special considerations: critical limb ischemia and acute limb ischemia

Critical limb ischemia (CLI) is said to occur when the patient has symptoms of ischemic rest pain for at least two weeks or an ischemic ulcer or gangrene, with the ankle pressure usually below 50 mmHg. In this situation, a multidisciplinary approach is needed, and perfusion needs to be restored using either surgical or percutaneous approaches. Intravenous vasodilator prostaglandins, such as ilioprost and PGE-1, are sometimes used in patients with CLI, although the trials of these drugs have typically had small sample sizes. The most recent large trial randomized 1560 patients with CLI to PGE-1, and noted that there was a short-term reduction in death, amputation and major CV events, but that this effect became less at six months follow-up.[98] A meta analysis of PGE-1 studies also showed improved survival with PGE-1.[99] Oral iloprost (a synthetic PGI-2 analog) has not been shown to improve time to major amputation or stroke or death up to 12 months. The usual secondary prevention steps as outlined above should also be taken. The treatment priorities are to alleviate pain, to heal the ulcer and prevent further tissue loss, with the aim of improving the patient's quality of life and long-term survival.

Acute limb ischemia (ALI) is a surgical emergency and can be characterized by some (or all) of the Five "Ps": Pain in the affected limb, Pallor, Pulselessness, Paresthesia and Paralysis. The aims in ALI are to restore circulatory flow, relieve ischemia and prevent further thrombus propagation. Patients are treated with heparin and may receive catheter-delivered thrombolysis or surgical embolectomy. Urokinase is the thrombolytic agent of choice, as streptokinase is associated with a lower efficacy and more bleeding complications. Furthermore, there is no role for systemic thrombolysis, as this is also associated with higher bleeding rates and lower efficacy. Both catheter-delivered thrombolysis and surgical embolectomy have a potential role, with no significant difference in limb salvage or death up to one year,[100,101] albeit with higher rates of stroke and major bleeding associated with thrombolysis therapy (in one meta-analysis, the OR for excess bleeding with thrombolysis vs vascular surgery was 2.95; 95% CI 1.62–5.32, $P = 0.001$[100]). The TOPAS (Thrombolysis Or Peripheral Arterial Surgery) trial[101] was a large multicenter randomized trial of catheter-delivered urokinase compared with surgery for ALI of <14 days duration: again, there was no significant difference in amputation rates or death up to one year, but an increase in major bleeding with thrombolysis (12.5% vs 5.5%, $P = 0.005$). The STILE trial again showed similar limb salvage rates between the catheter-delivered thrombolysis group and the surgical group, and even a one-year mortality benefit in the thrombolysis group

(84% vs 58%, $P = 0.01$), although the study numbers were small.[102] A further subgroup analysis of the STILE data noted that native artery occlusions had a poorer amputation-free survival with thrombolysis than with surgery.

Recommendations

- Intravenous prostaglandins can be a useful adjunct to therapy in CLI (**Class IIa, Level A**).
- There is no role for oral prostaglandin agents in CLI (**Class III, Level A**).
- All patients with ALI should be treated with heparin (**Class I, Level C**).
- Revascularization is a priority in ALI, and can be performed using surgical or endovascular techniques or with catheter-directed thrombolysis with urokinase if the occlusion is less than 14 days duration (**Class I, Level A**).

Conclusion

PAD of the lower extremities is primarily due to atherosclerosis and is increasing in prevalence worldwide. PAD is a frequently underdiagnosed and when present, indicates that patients are at high risk of future cardiovascular complications. The mainstay of treatment for intermittent claudication is smoking cessation and supervised exercise, as well as aggressive CV prevention therapies including antiplatelet therapy, blood pressure and lipid-lowering therapies, as well as tight glucose control among diabetics for secondary prevention. Percutaneous catheter-based therapies and surgical bypass procedures should be reserved for highly selected patients with severe limb ischemia in whom medical and lifestyle therapies have not succeeded.

66 Cardiac risk in those undergoing non-cardiac surgery

Ameeth Vedre and Kim A Eagle
University of Michigan, Ann Arbor, MI, USA

Introduction and historical perspective

The prevalence of cardiovascular disease increases with age, and it is estimated that the number of persons older than 65 years in the United States will increase 25–35% over the next 30 years.[1] The number of non-cardiac surgical procedures performed in older persons will increase from the current 6 million to nearly 12 million per year, and nearly a fourth of these – major intra-abdominal, thoracic, vascular, and orthopedic procedures – have been associated with significant perioperative cardiovascular morbidity and mortality.[2]

Guidelines on the assessment and management of perioperative cardiovascular risk for patients undergoing non-cardiac surgery were published by American College of Cardiology/American Heart Association (ACC/AHA) Task Force in 1996 and updated in 2002 and 2006 and revised in 2007.[2–4] Guidelines published in 2006 by the ACC/AHA focused the management from non-invasive risk stratification to risk reduction through strategies such as the use of perioperative beta-blockade.

Assessment of preoperative risk for non-cardiac surgery

The range of risk seen in current practice was illustrated in a retrospective study of 663 665 adults with no contraindications to beta-blockers who underwent major non-cardiac surgery in 2000 and 2001 at 329 hospitals in the United States. Orthopedic and abdominal surgery accounted for 70% of cases. In-hospital mortality in patients not treated with beta-blockers increased progressively from 1.4% to 7.4% according to a preoperative assessment of risk using the revised Goldman Cardiac Risk Index[5,6] (**Level C1**).

Eagle *et al* retrospectively studied 254 consecutive patients presenting to the nuclear cardiology laboratory for dipyridamole-thallium imaging before proposed vascular surgery.[7] Logistic regression analysis identified five clinical predictors of postoperative cardiac events in patients undergoing major vascular surgery: Q-waves on the ECG, history of angina, ventricular ectopy requiring treatment, diabetes mellitus requiring therapy other than diet, and age above 70 years (**Level C1**).

A subsequent validation study by Vanzetto added three more clinical predictors to the Eagle criteria which were ischemic ST segment abnormalities on resting ECG, hypertension with severe left ventricular hypertrophy and history of heart failure (HF). This author also identified two independent dipyridamole-thallium test predictors of ischemic events: thallium redistribution and ischemic ECG changes during or after dipyridamole infusion[8] (**Level C1**).

Fleisher and Eagle[9] emphasized six factors in a further report, the first five of which are also in the revised Goldman Cardiac Risk Index,[6] and are all associated with increased cardiac risk in patients undergoing non-cardiac surgery, including vascular surgery (**Level C1**).

- Ischemic heart disease (angina or prior MI)
- Heart failure
- High-risk surgery (including intraperitoneal, intrathoracic, and suprainguinal vascular procedures)
- Diabetes mellitus (especially requiring insulin)
- Renal insufficiency
- Poor functional status (defined as the inability to walk four blocks or climb two flights of stairs)

General approach to the patient

Preoperative cardiac evaluation must be carefully tailored to the circumstances that have prompted the consultation and the nature of the proposed surgery. Given an acute surgical emergency, preoperative evaluation might have to be limited to rapid bedside assessment including assessment of vital signs, volume status, basic metabolic

panel and electrocardiogram (ECG)[2,10] (**Class I, Level B**). The physician should review available patient data, obtain a history, and perform a physical examination pertinent to the patient's problem and the proposed surgery.

History and physical examination

Cardiac conditions such as prior angina, recent or past MI, HF, symptomatic arrhythmias, and history of a pacemaker or implantable cardioverter defibrillator (ICD) should be identified. Modifiable risk factors for coronary heart disease (CHD) should be recorded along with evidence of associated diseases, such as peripheral vascular disease, cerebrovascular disease, diabetes mellitus, renal impairment, and chronic pulmonary disease (Table 66.1).

• *Major* predictors, when present, mandate intensive management, which may result in delay or cancellation of surgery unless it is urgent.

• *Intermediate* predictors are well-validated markers of enhanced risk of perioperative cardiac complications and justify careful assessment of the patient's current status.

Table 66.1 Clinical predictors of increased perioperative cardiovascular risk (myocardial infarction, congestive heart failure, death)

Major
Unstable coronary syndromes
  Recent myocardial infarction* with evidence of important ischemic risk by clinical symptoms or non-invasive study
  Unstable or severe† angina (Canadian class III or IV)
Decompensated congestive heart failure
Significant arrhythmias
  High-grade atrioventricular block
  Symptomatic ventricular arrhythmias in the presence of underlying heart disease
  Supraventricular arrhythmias with uncontrolled ventricular rate
Severe valvular disease

Intermediate
Mild angina pectoris (Canadian class I or II)
Prior myocardial infarction by history or pathologic Q-waves
Compensated or prior congestive heart failure
Diabetes mellitus
Chronic renal insufficiency

Minor
Advanced age
Abnormal electrocardiogram (left ventricular hypertrophy, left bundle branch block, ST-T abnormalities)
Rhythm other than sinus (e.g. atrial fibrillation)
Low functional capacity (e.g. inability to climb one flight of stairs with a bag of groceries)
History of stroke
Uncontrolled systemic hypertension

Reproduced with permission from Eagle *et al.*[2]

• *Minor* predictors are recognized markers for cardiovascular disease that have not been proven to independently increase perioperative risk.[2]

A careful cardiovascular examination should include an assessment of vital signs (including measurement of blood pressure in both arms), carotid pulse, contour and bruits, jugular venous pressure and pattern, auscultation of the lungs, precordial palpation, cardiac auscultation and examination of the extremities for edema and vascular integrity.[2] The history should also seek to determine the patient's functional capacity (Table 66.2).

An assessment of an individual's capacity to perform a spectrum of common daily tasks has been shown to correlate well with maximum oxygen uptake by treadmill testing[10] (**Level C**).

A patient classified as high risk owing to age or known CAD but who is asymptomatic and runs for 30 minutes daily may need no further evaluation. In contrast, a sedentary patient without a history of cardiovascular disease but with clinical factors that suggest increased perioperative risk may benefit from a more extensive preoperative evaluation (**Class II, Level C1**).

Management of co-morbid conditions

The stress of non-cardiac surgery may raise heart rate and blood pressure and has been associated with a high incidence of symptomatic and asymptomatic myocardial ischemia in patients with known vascular disease.

Associated conditions often heighten the risk of anesthesia and may complicate cardiac management. The most common of these conditions are discussed below.

If significant pulmonary disease is suspected by history or physical examination, determination of functional capacity, response to bronchodilators, and/or evaluation for the presence of carbon dioxide retention through arterial blood gas analysis may be justified[2] (**Class I, Level C1**).

Management of blood glucose levels in the perioperative period may be difficult. Fragile diabetic patients need careful treatment with adjusted doses or infusions of short-acting insulin based on frequent blood sugar determinations. Historically, it has been acceptable to maintain relatively high glucose levels perioperatively to avoid the attendant risks of hypoglycemic episodes. However, aggressive perioperative glucose control in coronary bypass surgery patients by a continuous, intravenous insulin infusion was superior to intermittent subcutaneous insulin administration in significantly reducing postoperative wound infection.[11] Similar benefit may occur surrounding non-cardiac surgery[12] (**Class I, Level C**).

Anemia imposes a stress on the cardiovascular system that may exacerbate myocardial ischemia and aggravate HF.[13] Preoperative transfusion, when used appropriately in patients with advanced CAD and/or HF, may reduce peri-

operative cardiac morbidity (**Class II, Level C1**). Hematocrits less than 28% are associated with an increased incidence of perioperative ischemia and postoperative complications in patients undergoing prostate and vascular surgery[14,15] (**Level B**).

Due to high risk for the development of further decompensation and death during the perioperative period, patients facing high-stress surgery who have acute coronary syndromes (e.g. unstable angina or decompensated HF of ischemic origin) and stable patients with likelihood of advanced multivessel coronary artery disease, with or without left ventricular dysfunction, will benefit from coronary angiography[2] (**Class II, Level B**). If the non-cardiac surgery is truly urgent, intra-aortic balloon bump counterpulsation as a means of providing short-term myocardial protection in addition to maximal medical therapy[4] (**Class I, Level C1**).

If the patient does not demonstrate unstable symptoms, the identification of known or symptomatic stable CAD or risk factors for CAD can guide the need for further diagnostic evaluation or changes in perioperative management (**Class I, Level C**). In determining the extent of the preoperative evaluation, it must be remembered that testing should not be performed unless the results would affect perioperative management. These management changes include cancellation of surgery because of prohibitive risk compared with benefit, delay of surgery for further medical management, coronary interventions before non-cardiac surgery, and utilization of an intensive care unit.

Multiple studies have demonstrated an increased incidence of reinfarction after non-cardiac surgery if the prior MI was within 6 months of the operation and especially within 6–12 weeks[16,17] (**Level C1**). Severe hypertension of a chronic nature, e.g. diastolic blood pressure higher than 110 mmHg, should be controlled before any elective non-cardiac surgery.[2] The Study of Perioperative Ischemia Research Group trial (POISE), in which patients had continuous perioperative electrocardiographic monitoring, showed that a history of hypertension was one of five independent predictors of postoperative ischemia and one of three independent predictors of increased postoperative mortality.[18] Patients with a history of hypertension had almost twice the risk of postoperative myocardial ischemia and almost four times the risk of postoperative death compared with patients without hypertension in the first 48 hours postoperatively[19] (**Level B**).

For patients who present for non-cardiac surgery with signs or symptoms of HF, the goal of the preoperative evaluation should be identification of the underlying disease processes and assessment of the severity of systolic and diastolic dysfunction (**Class I, Level B**). Ischemic cardiomyopathy is of greatest concern because the patient has a substantial risk for developing further ischemia, leading to myocardial necrosis and potentially a downward spiral. In such patients, a pulmonary artery catheter or intraoperative transesophageal echocardiography may be helpful[4] (**Level C1**). Since both severe stenotic and/or regurgitant valve disease can cause or complicate heart failure, clarification of underlying valve function is important when suspected based on the history of physical exam (**Class II, Level C**).

The presence of critical aortic stenosis is associated with a very high risk of cardiac decompensation in patients undergoing elective non-cardiac surgery. The presence of any of the classic triad of angina, syncope, and heart failure in a patient with aortic stenosis should alert the clinician to the need for further evaluation and potential interventions, usually valve replacement. However, many patients with severe or critical aortic stenosis may be asymptomatic, and preoperative patients with aortic systolic murmurs warrant a careful history and physical examination and often further evaluation. There are several case series of patients with critical aortic stenosis demonstrating that, when necessary, non-cardiac surgery can be performed with acceptable risk[20] (**Class I, Level C1**).

Decision to undergo diagnostic testing

Several groups have published meta-analyses examining the various preoperative diagnostic tests (Table 66.3). Mantha and colleagues demonstrated good predictive values of ambulatory electrocardiographic monitoring, radionuclide angiography, dipyridamole-thallium imaging, and dobutamine stress echocardiography[21] (**Level C2**).

Table 66.3 Recommendations for use of ancillary tests in patients undergoing non-cardiac surgery

Indication	Class I (indicated)	Class IIa	Class IIb	Class III (not indicated)
Preoperative 12-lead rest ECG	1. Recent episode of chest pain or ischemic equivalent in clinically intermediate- or high-risk patients scheduled for an intermediate- or high-risk operative procedure.	1. Asymptomatic persons with diabetes mellitus.	1. Patients with prior coronary revascularization.	1. As a routine test in asymptomatic subjects undergoing low-risk operative procedures.
			2. Asymptomatic male older than 45 yr or female older than 55 yr with two or more atherosclerotic risk factors.	
			3. Prior hospital admission for cardiac causes.	
Preoperative non-invasive evaluation of left ventricular function	1. Patients with current or poorly controlled heart failure.	1. Patients with prior heart failure and patients with dyspnea of unknown origin.		1. As a routine test of left ventricular function in patients without prior heart failure.
Exercise or pharmacological stress testing	1. Diagnosis of adult patients with intermediate pretest probability of CAD.	1. Evaluation of exercise capacity when subjective assessment is unreliable.	1. Diagnosis of CAD patients with high or low pretest probability; those with resting ST depression less than 1 mm, those undergoing digitalis therapy, and those with ECG criteria for left ventricular hypertrophy.	1. For *exercise* stress testing, diagnosis of patients with resting ECG abnormalities that preclude adequate assessment, e.g. pre-excitation syndrome, electronically paced ventricular rhythm, rest ST depression greater than 1 mm, or left bundle branch block.
	2. Prognostic assessment of patients undergoing initial evaluation for suspected or proven CAD; evaluation of subjects with significant change in clinical status.		2. Detection of restenosis in high-risk asymptomatic subjects within the initial months after PCI.	2. Severe co-morbidity likely to limit life expectancy or candidacy for revascularization.
	3. Demonstration of proof of myocardial ischemia before coronary revascularization.			3. Routine screening of asymptomatic men or women without evidence of CAD.
	4. Evaluation of adequacy of medical therapy; prognostic assessment after an acute coronary syndrome			4. Investigation of isolated ectopic beats in young patients.
Coronary angiography in perioperative evaluation before (or after) non-cardiac surgery	Patients with suspected or known CAD:	1. Multiple markers of intermediate clinical risk† and planned vascular surgery (non-invasive testing should be considered first).	1. Perioperative MI.	1. Low-risk* non-cardiac surgery with known CAD and no high-risk results on non-invasive testing.

Table 66.3 *Continued*

Indication	Class I (indicated)	Class IIa	Class IIb	Class III (not indicated)
	1. Evidence for high risk of adverse outcome based on noninvasive test results.		2. Medically stabilized class III or IV angina and planned low-risk or minor* surgery.	2. Asymptomatic after coronary revascularization with excellent exercise capacity (greater than or equal to 7 METs).
	2. Angina unresponsive to adequate medical therapy.	2. Moderate to large region of ischemia on non-invasive testing but without high-risk features and without lower LVEF.		3. Mild stable angina with good left ventricular function and no high-risk non-invasive test results.
	3. Unstable angina, particularly when facing intermediate-risk* or high-risk* non-cardiac surgery.	3. Non-diagnostic non-invasive test results in patients of intermediate clinical risk† undergoing high-risk* non-cardiac surgery.		4. Non-candidate for coronary revascularization owing to concomitant medical illness, severe left ventricular dysfunction (e.g., LVEF less than 0.20), or refusal to consider revascularization.
	4. Equivocal non-invasive test results in patients at high clinical risk† undergoing high-risk* surgery.	4. Urgent non-cardiac surgery while convalescing from acute MI.		5. Candidate for liver, lung, or renal transplantation older than 40 yr as part of evaluation for transplantation, unless non-invasive testing reveals high risk for adverse outcome.

CAD, coronary artery disease; ECG, electrocardiogram; HF, heart failure; LVEF, left ventricular ejection fraction; MET, metabolic equivalent; MI, myocardial infarction; PCI, percutaneous coronary intervention. In: Lily LS, ed. *Braunwald's heart disease review and assessment*, 7th edn. Philadelphia: Elsevier Saunders, 2005.

Shaw and co-workers also demonstrated excellent predictive values for both dipyridamole-thallium imaging and dobutamine stress echocardiography[22] (**Level C1**).

Type of surgery

Cardiac complications after non-cardiac surgery are a reflection of factors specific to the patient, the operation, and the circumstances under which the operation is undertaken. To the extent that preoperative cardiac evaluation reliably predicts postoperative cardiac outcomes, it may lead to interventions that lower perioperative risk, decrease long-term mortality or alter the surgical decision-making process (**Class I**).

When, for example, surgery in asymptomatic individuals is undertaken with the objective of prolonging life (e.g. elective repair of aortic aneurysm) or preventing a future stroke (e.g. carotid endarterectomy), the decision to intervene must be made with the expectation that the patient will live long enough to benefit from the prophylactic intervention.

For elective surgery, cardiac risk can be stratified according to a number of factors, including the magnitude of the surgical procedure. Some operations are simply more dangerous than others (Table 66.4). Backer *et al*[16] encountered no cardiac complications after 288 ophthalmologic procedures in 195 patients with a prior history of MI compared with a reinfarction rate of 6.1% for a number of non-ophthalmologic surgeries at the same center (**Level C1**). In general, major vascular, thoracic, abdominal and/or emergency surgeries are placed into a moderate- or high-risk category, while orthopedic, breast, prostate, ophthalmologic, and endoscopic procedures are considered lower risk.

The AHA/ACC Task Force on Perioperative Evaluation of Cardiac Patients Undergoing Non-cardiac Surgery has proposed an algorithm (Fig. 66.1) for decisions regarding the need for further evaluation. First, the clinician must evaluate the urgency of the surgery and the appropriateness of a formal preoperative assessment. Next, he or she must determine whether the patient has had a previous revascularization procedure or coronary evaluation. Patients with unstable

Table 66.4 Cardiac risk* stratification for non-cardiac surgical procedures

High (reported cardiac risk often >5%)
Emergency major operations, particularly in elderly people
Aortic and other major vascular
Peripheral vascular
Anticipated prolonged surgical procedures associated with large fluid shifts and/or blood loss

Intermediate (reported cardiac risk generally <5%)
Carotid endarterectomy
Head and neck
Intraperitoneal and intrathoracic
Orthopedic
Prostate

Low†(reported cardiac risk generally <1%)
Endoscopic procedures
Superficial procedure
Cataract
Breast

BOX 66.1 Recommendations for beta-blocker therapy during perioperative medical therapy

Class I
1. Beta-blockers should be continued in patients undergoing surgery who are receiving beta-blockers to treat angina, symptomatic arrhythmias, hypertension **or** other ACC/AHA Class I guideline indications.
2. Beta-blockers should be given to patients undergoing vascular surgery at high cardiac risk owing to the finding of ischemia on preoperative testing (**Level B**).

Class IIa
1. Beta-blockers are probably recommended for patients undergoing vascular surgery in which preoperative assessment identifies coronary heart disease (**Level B**).
2. Beta-blockers are probably recommended for patients in whom preoperative assessment for vascular surgery identifies high cardiac risk as defined by the presence of multiple clinical risk factors* (**Level B**).
3. Beta-blockers are probably recommended for patients in whom preoperative assessment identifies coronary heart disease or high cardiac risk as defined by the presence of multiple clinical risk factors* and who are undergoing intermediate- or high-risk procedures as defined in these guidelines (**Level B**).

Class IIb
1. Beta-blockers may be considered for patients who are undergoing intermediate- or high-risk procedures as defined in these guidelines, including vascular surgery, in whom preoperative assessment identifies intermediate cardiac risk as defined by the presence of a single clinical risk factor* (**Level C**).
2. Beta-blockers may be considered in patients undergoing vascular surgery with low cardiac risk (as defined in these guidelines) who are not currently on beta-blockers (**Level C**).

Class III
1. Beta-blockers should not be given to patients undergoing surgery who have absolute contraindications to beta-blockade (**Level C**).

*Clinical risk factors. High cardiac risk includes patients with major and intermediate clinical predictors. Care should be taken in applying recommendations on beta-blocker therapy to patients with decompensated heart failure, non-ischemic cardiomyopathy, high-degree AV block, or severe valvular heart disease in the absence of coronary heart disease.

coronary syndromes should be identified, and appropriate treatment should be instituted. The decision to have further testing depends on the interaction of the clinical risk factors, surgery-specific risk, and functional capacity.

Implementation of the ACC/AHA guidelines into clinical practice has been demonstrated to be effective in reducing use of preoperative stress myocardial imaging (44.3% versus 20.6%; $P < 0.05$) and coronary revascularization (7.7% versus 0.8%; $P < 0.05$) in patients undergoing elective vascular surgery. During the intervention period, there was a significant decrease in the incidence of cardiac complications (from 11.3% to 4.5%) and an increase in event-free survival at 1 year after surgery (from 91.3 to 98.2%).[23] Froehlich and colleagues compared 102 historical control patients with 94 patients directly after guideline implementation and 104 patients later after guideline implementation.[24] Resource utilization and costs were reduced after guideline implementation, and the effect was sustained for 2 years (**Level C1**).

Perioperative beta-blocker therapy

Studies on the outcomes of perioperative beta-blockade have initially shown benefits, but recently a few randomized trials have not shown a beneficial effect.

As per the ACC/AHA 2007 guideline update by Fleisher *et al*, Box 66.1 shows the recommendations for beta-blocker therapy during perioperative medical therapy.[3,4]

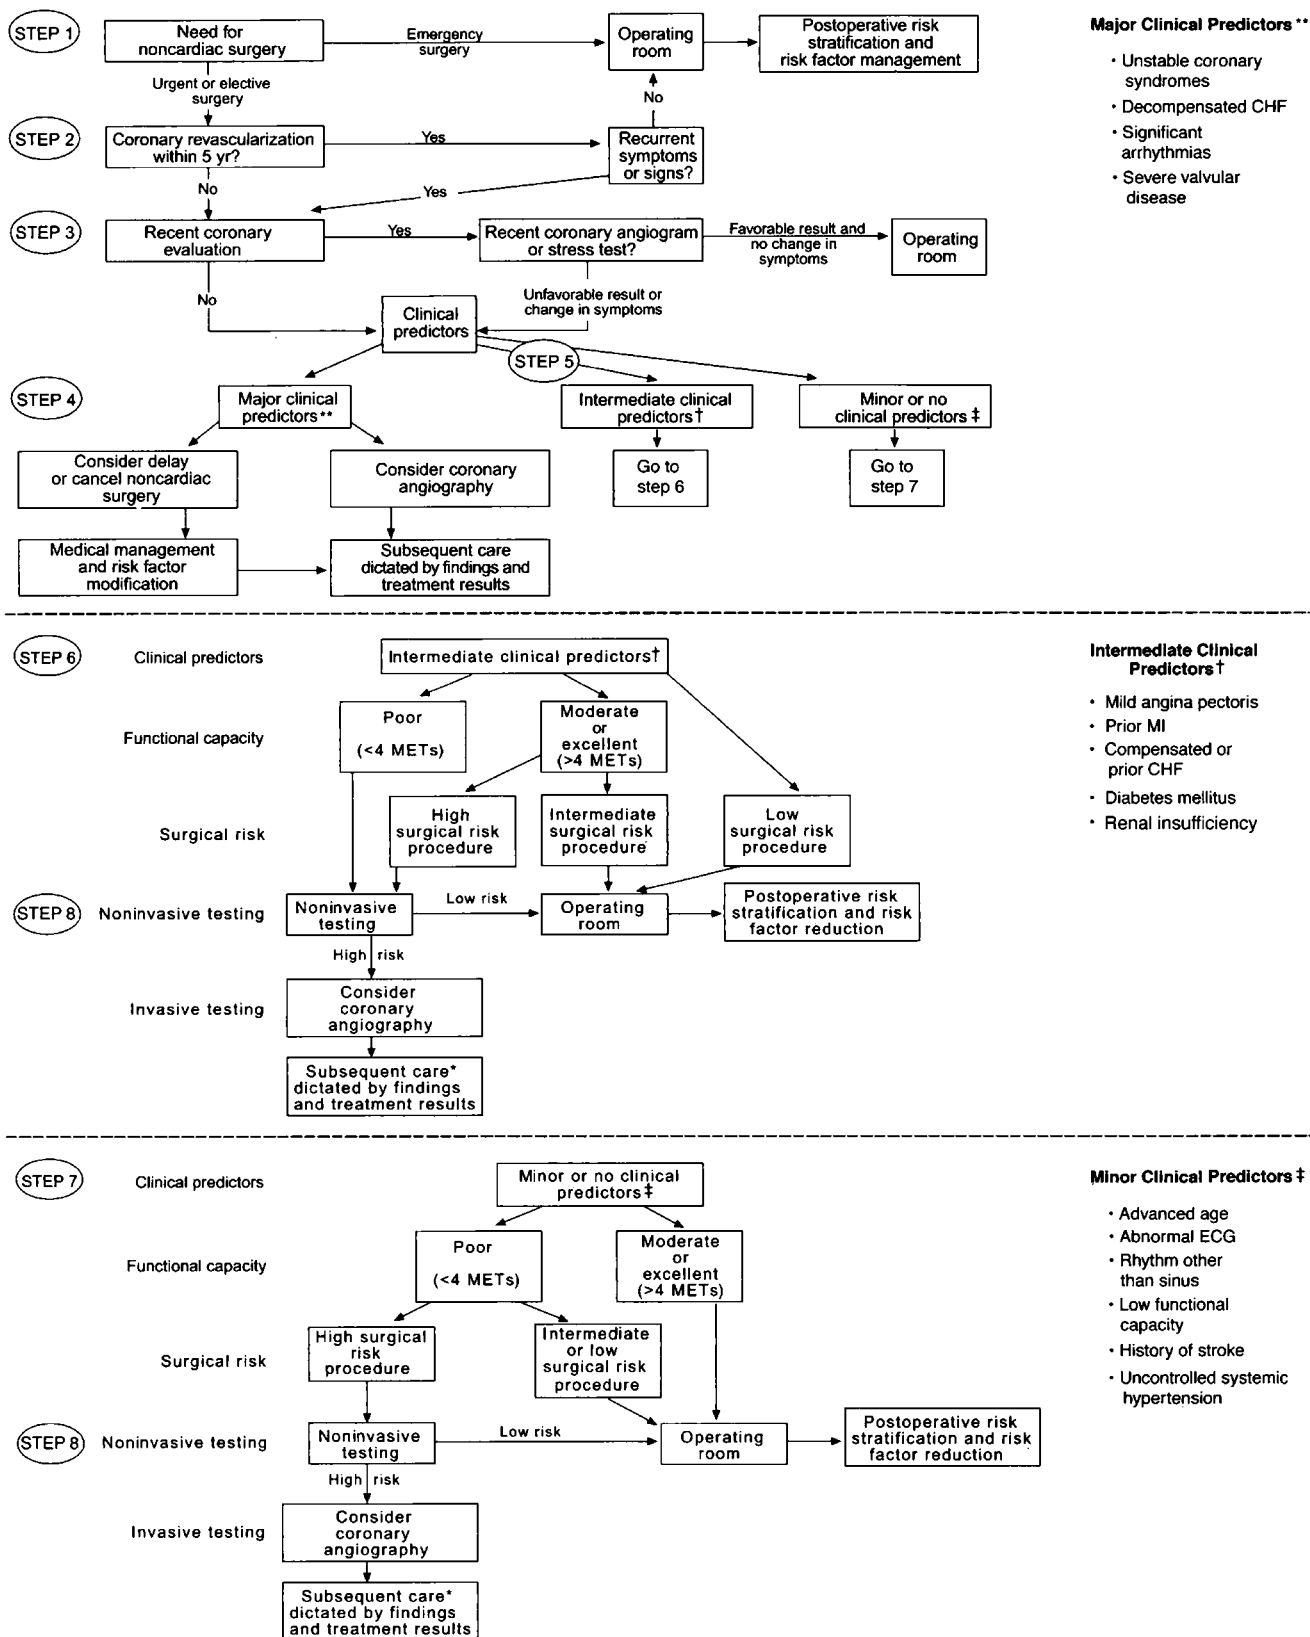
Since publication of the ACC/AHA focused update on perioperative beta-blocker therapy, several randomized trials have been published that have not demonstrated the efficacy of these agents. Despite several meta-analyses, some


Figure 66.1 Stepwise approach to preoperative cardiac assessment. Steps are discussed in text.

*Subsequent care may include cancellation or delay of surgery, coronary revascularization followed by non-cardiac surgery or intensified care.

(Reproduced with permission from Eagle *et al.*[2])

of which reached conflicting conclusions, there are still very few randomized trials of this issue.[4] Randomized controlled trials are still needed to explore the observation that there may be some harm associated with beta-blocker therapy in low-risk patients[25] (**Level C**). In fact, studies involving the shorter-acting agent metoprolol have shown lower or no efficacy[26,27] (**Level C1, B**). In summary, the best approach on how to protect patients medically from cardiovascular complications during non-cardiac surgery is still unknown.

Several randomized trials examined the effect of perioperative beta-blockers on cardiac events surrounding surgery. Poldermans *et al* examined the effect of bisoprolol on patients undergoing vascular surgery and in patients at high risk for perioperative cardiac complications who were scheduled for vascular surgery[28] (**Level C1**). The Multicenter Study of Perioperative Ischemia Research Group[27,29] reported on 200 patients undergoing general surgery randomized to a combination of intravenous and oral atenolol versus placebo for 7 days. Although they found no difference in perioperative MI or death, they reported significantly fewer episodes of ischemia by Holter monitoring in the atenolol versus placebo groups (24% versus 39%, respectively; $P = 0.03$). They then conducted follow-up on these patients after discharge and documented fewer deaths in the atenolol group over the subsequent 6 months (1% versus 10%; $P < 0.001$) (**Level B**).

In POISE[30] (Perioperative Ischemia) trial 8351 patients with, or at risk of, atherosclerotic disease who were undergoing non-cardiac surgery were randomly assigned to receive extended-release metoprolol succinate. Fewer patients in the metoprolol group than in the placebo group had a myocardial infarction (176 [4.2%] vs 239 [5.7%] patients; 0.73, 0.60–0.89; $P = 0.0017$). However, there were more deaths in the metoprolol group than in the placebo group (129 [3.1%] vs 97 [2.3%] patients; 1.33, 1.03–1.74; $P = 0.0317$). More patients in the metoprolol group than in the placebo group had a stroke (41 [1.0%] vs 19 [0.5%] patients; 2.17, 1.26–3.74; $P = 0.0053$).

These data indicate that although perioperative extended-release metoprolol reduced the risk of myocardial infarction, cardiac revascularization, and clinically significant atrial fibrillation 30 days after randomization compared with placebo, the drug also resulted in a significant excess risk of death and non fatal stroke probably due to excess dose leading to hypotension and with it more infections, stroke and noncardiac death. POISE study group authors highlighted the risk in assuming a perioperative β-blocker regimen has benefit without substantial harm, and the importance and need for large randomized trials in the perioperative setting (**Class 1, Level A**).[30]

Recent meta analysis of 33 trials determined that β blockers were not associated with any significant reduction in the risk of all-cause mortality, cardiovascular mortality, or heart failure, but were associated with a decrease in non-fatal myocardial infarction and decrease in myocardial ischemia (**Class 1, Level A**).[31]

Limitations in the perioperative beta-blocker literature include the following: few randomized trials have examined the role of perioperative beta-blocker therapy, there is particularly a lack of trials that focus on high-risk patients and there is a lack of studies to determine the role and type of beta-blockers in intermediate- and low-risk populations.

Perioperative statin therapy

Lipid lowering has proven to be highly effective in the secondary prevention of cardiac events. The bulk of this evidence applies to hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase inhibitors or statin therapy.[4]

Durazzo *et al*[32] randomly assigned 100 patients to receive 20 mg atorvastatin or placebo once a day for 45 days, irrespective of their serum cholesterol concentration. Vascular surgery was performed on average 30 days after randomization, and patients were prospectively followed up over 6 months. The cardiovascular events studied were death from cardiac cause, non-fatal myocardial infarction, unstable angina, and stroke. During the 6-month follow-up, primary endpoints occurred in 17 patients: four in the atorvastatin group (incidence of 8%) and 13 in the placebo group (incidence of 26%) ($P = 0.31$). The risk for an event was compared between the groups with the Kaplan–Meier method, as event-free survival after vascular surgery. Patients given atorvastatin exhibited a significant decrease in the rate of cardiac events, compared with the placebo group, within 6 months after vascular surgery. Outcome measures included death from cardiac causes, non-fatal acute myocardial infarction, ischemic stroke, and unstable angina. Rate of event-free survival at 6 months (180 days) was 91.4% in the atorvastatin group and 73.5% in the placebo group ($P = 0.018$).

BOX 66.2 Recommendations for perioperative statin therapy

Class I
1. For patients currently taking statins and scheduled for non-cardiac surgery, statins should be continued (**Level B**).

Class IIa
1. For patients undergoing vascular surgery with or without clinical risk factors, statin use is reasonable (**Level B**).

Class IIb
1. For patients with at least one clinical risk factor who are undergoing intermediate-risk procedures, statins may be considered (**Level C**).

Short-term treatment with atorvastatin significantly reduces the incidence of major adverse cardiovascular events after vascular surgery (**Class II, Level B**).

Kapoor et al[33] carried out an exhaustive meta-analysis to determine the strength of evidence for using statins during the perioperative period to reduce the risk of cardiovascular events. There were 18 studies included: two randomized trials (n = 177), 15 cohort studies (n = 799 632), and one case–control study (n = 480) which assessed whether statins provide perioperative cardiovascular protection. Twelve studies enrolled patients undergoing non-cardiac vascular surgery, four enrolled patients undergoing coronary bypass surgery, and two enrolled patients undergoing various surgical procedures. In the randomized trials the summary odds ratio (OR) for death or acute coronary syndrome during the perioperative period with statin use was 0.26 (95% confidence interval (CI) 0.07–0.99) and the summary odds ratio in the cohort studies was 0.70 (95% CI 0.57–0.87). Results in retrospective cohort studies were larger (OR 0.65, 95% CI 0.50–0.84) than those in the prospective cohorts (OR 0.91, 95% CI 0.65–1.27), and dose, duration, and safety of statin use were not reported. The authors concluded that the evidence base for routine administration of statins to reduce perioperative cardiovascular risk was inadequate.

The evidence so far accumulated suggests a protective effect of perioperative statin use on cardiac complications during non-cardiac surgery (**Level C1**). Most of these data are observational and identify patients in whom time of initiation of statin therapy and duration of statin therapy are unclear. Furthermore, statin dose, target or achieved low-density lipoprotein levels, and indications for statin therapy are also largely unclear. Sufficiently powered randomized trials are needed to determine whether these observed associations translate into a benefit for statin therapy prescribed perioperatively for the purpose of lowering cardiac event rates surrounding non-cardiac surgery. Utilizing the perioperative period as an opportunity to impact long-term health, consideration should be given to starting statin therapy in patients who meet National Cholesterol Education Program criteria[4,33,34] (**Class I, Level B**).

Eagle et al found that patients undergoing low-risk procedures are unlikely to derive benefit from coronary artery bypass grafting (CABG) before low-risk surgery; however, patients with multivessel disease and severe angina undergoing high-risk surgery might well benefit from revascularization before non-cardiac surgery[35] (**Class II, Level C**).

Successful perioperative evaluation and management of high-risk cardiac patients undergoing non-cardiac surgery requires careful teamwork and communication between surgeon, anesthesiologist, the patient's primary caregiver, and the consultant.[4] For many patients, non-cardiac surgery represents their first opportunity to receive an appropriate assessment of both short- and long-term cardiac risk. Thus, the consultant best serves the patient by making recom-

mendations aimed at lowering the immediate perioperative cardiac risk, as well as assessing the need for subsequent postoperative risk stratification and interventions directed at modifying coronary risk factors.

It is also appropriate to recommend secondary risk reduction in the relatively large number of elective surgery patients in whom cardiovascular abnormalities are detected during preoperative evaluations. Although the occasion of surgery is often taken as a specifically high-risk time, most of the patients who have known or newly detected CAD during their preoperative evaluations will not have any events during elective non-cardiac surgery. A review of a national Medicare population sample identified a cohort of patients (n = 6895) who underwent elective vascular surgery during a 17-month period in 1991 and 1992.[23] The authors noted a relatively high mortality rate (15%) at 1 year of follow-up among patients who did not undergo preoperative stress testing. However, in those patients (19%) undergoing preoperative stress testing with or without subsequent coronary bypass surgery, the mortality rate was lower (less than 6%).[36]

It was postulated that part of this difference may have been due to effective preventive and medical treatment of patients with evident ischemic heart disease. Therefore, it is important to consider which preoperative clinical risk factors and non-invasive testing parameters can be used to help predict long-term cardiac risk.[4]

Randomized controlled trials are still needed to explore the observation that there may be some harm associated with beta-blocker therapy in low-risk patients.

Recent observational studies have shown the benefit of statins during the perioperative period. Future research should be directed at determining the value of routine prophylactic medical therapy versus more extensive diagnostic testing and interventions.

In the approach to the long-term postoperative management of non-cardiac surgery patients, one should first appreciate that the occurrence of an intraoperative non-fatal MI carries a high risk for future cardiac events, including cardiovascular death.[37] Therefore, patients who sustain an acute myocardial injury in the perioperative or postoperative period should receive careful medical evaluation for residual ischemia and overall left ventricular function (**Class I, Level B**).

The ACC/AHA guidelines for post-MI evaluation in these types of patients should be followed as soon as possible after surgical recovery. The use of pharmacologic stress or dynamic exercise for risk stratification should also be a priority in patients to help determine who would benefit from coronary revascularization. In all cases, the appropriate evaluation and management of complications and risk factors such as angina, HF, hypertension, hyperlipidemia, cigarette smoking, diabetes (hyperglycemia), and other cardiac abnormalities should commence before hos-

Table 66.5 Recommendations for use of interventions in patients undergoing non-cardiac surgery

Indication	Class I (indicated)	Class IIa	Class IIb	Class III (not indicated)
Perioperative medical therapy	Beta-blockers required in the recent past to control symptoms of angina or patients with symptomatic arrhythmias or hypertension.	Beta-blockers: preoperative assessment identifies untreated hypertension, known coronary disease, or major risk factors for coronary disease.	Alpha$_2$-agonists: perioperative control of hypertension, or known CAD or major risk factors for CAD.	Beta-blockers: contraindication to beta-blockade.
	Beta-blockers: patients at high cardiac risk owing to the finding of ischemia on preoperative testing who are undergoing vascular surgery.			Alpha$_2$-agonists: contraindication to alpha$_2$-agonists.
Intraoperative nitroglycerin	High-risk patients previously taking nitroglycerin who have active signs of myocardial ischemia without hypotension.	As a prophylactic agent for high-risk patients to prevent myocardial ischemia and cardiac morbidity, particularly in those who have required nitrate therapy to control angina.		Patients with signs of hypovolemia or hypotension.
Intraoperative use of pulmonary artery catheters		Patients at risk for major hemodynamic disturbances that are most easily detected by a pulmonary artery catheter who are undergoing a procedure that is likely to cause these hemodynamic changes (e.g. suprarenal aortic aneurysm repair in a patient with angina) in a setting with experience in interpreting the results.	Either the patient's condition or the surgical procedure (but not both) places the patient at risk for hemodynamic disturbances (e.g., supraceliac aortic aneurysm repair in a patient with a negative stress test).	No risk of hemodynamic disturbances.
Perioperative ST segment monitoring		When available, proper use of computerized ST segment analysis in patients with known CAD or undergoing vascular surgery may provide increased sensitivity to detect myocardial ischemia during the perioperative period and may identify patients who would benefit from further postoperative and long-term interventions.	Patients with single or multiple risk factors for CAD.	Patients at low risk for CAD.

CAD, coronary artery disease. Reproduced with permission from Eagle *et al.*[2]

pital discharge. It is also important to communicate these new observations and determinations of cardiac status and risk to the physician who will be responsible for arranging subsequent medical care and follow-up (**Class I, Level C**).

67 Clinical management of diseases of the aorta

Thoralf M Sundt III
Mayo Clinic, Rochester, MN, USA

Introduction

The complexity of the diagnostic and clinical management aspects of thoracic aortic aneurysmal disease is reflected in Sir William Osler's famous aphorism "there is no disease more conducive to clinical humility than aneurysm of the aorta."[1] Shennan drew attention to a particularly lethal aortic pathology – aortic dissection – in his 1934 monograph published by the Medical Research Council.[2] It was, however, only with the advent of successful surgical therapies introduced by DeBakey and Cooley in the 1950s[3,4] that medical attention in these conditions moved from curiosity to cure.

Joyce noted in his seminal observational series of aortic aneurysmal disease in Olmsted County in 1960 that the advent of a realistic surgical option rendered an understanding of the natural history of the disease critical to assessment of the relative risks and benefits of intervention.[5] In this series of patients seen at the Mayo Clinic between 1945 and 1956 with thoracic aortic aneurysmal disease, 50% were dead within 5 years of diagnosis. Even then, he and his co-authors identified aortic diameter as a powerful predictor of rupture, the parameter which has dominated our understanding since. Indeed, it is remarkable that they focused on 6 cm as a particularly critical dimension, with less than 40% of patients presenting with aneurysms greater than 6 cm in diameter alive at 5 years. Follow-up studies from Olmsted County portrayed an even worse prognosis, with only 13% of 72 patients individuals presenting with thoracic aneurysms between 1951 and 1980 alive at 5 years.[6] This may not be surprising as over half of the patients in the latter series presented with rupture as their first indication of the disease, given the limited diagnostic modalities of the day. Perhaps as a reflection of improved radiologic techniques, the apparent natural history would appear to have improved, with more recent studies from the same institution reporting a 20% risk of rupture at 5 years for thoracic aneurysms.[7] At the same time, there was an apparent threefold increase in the incidence of thoracic aortic aneurysms. Incidentally, given our dependence on imaging modalities for detection of aortic disease, this phenomenon of interplay between diagnostic technology and apparent clinical behavior continues to impact our understanding of conditions of the aorta today.

Just as diagnostic modalities have improved over the last several decades, so have therapeutic options. Beginning with DeBakey's introduction of Dacron prosthetic grafts for aortic replacement,[8] landmark improvements have included Bentall's introduction of the technique for root replacement[9] as well as Griepp's introduction of profound hypothermia and circulatory arrest for the management of aneurysmal disease of the aortic arch.[10] Today aortic root replacement can be accomplished with a mortality rate less than 5% in experienced hands[11] and arch replacement with similar risk under elective circumstances.[12,13] Using appropriate adjuncts, the risks have also dropped dramatically in recent years for elective repair of descending thoracic[14] and thoracoabdominal aortic aneurysms[15,16] in centers of excellence. Most recently, endovascular technologies have been introduced for repair of descending thoracic aortic aneurysms, again challenging us to find the balance between risks of the intervention and the natural history of the disease. Equally the advent of valve-sparing aortic root repair has altered the risk/benefit analysis and threshold for recommending prophylactic aortic surgery.[17]

Nomenclature and definitions

By far the majority of aortic conditions presenting in adults requiring surgical intervention are aneurysmal in nature. While coarctation and even interrupted aortic arch may present in adults, these are uncommon and are perhaps most fruitfully discussed in the context of adult congenital heart disease. The majority of aneurysms are "degenerative" in nature, in contrast to traumatic pseudoaneurysms

and chronic dissections. By definition, the wall of a pseudoaneurysm lacks all three layers of the normal aortic wall – intima, media and adventitia – and accordingly chronic dissections fall into this classification as well, although they are seldom referred to as such. Postsurgical anastomotic pseudoaneurysms may also occur, although they are remarkably uncommon.[18]

The term "degenerative" is applied to aneurysms associated with a wide variety of conditions ranging from mundane to exotic. Chronic hypertension, particularly when combined with tobacco abuse, accounts for the majority of aneurysms of the ascending aorta, with connective tissue diseases of defined or undefined type accounting for a smaller but significant fraction.[19] Giant cell arteritis is increasingly recognized as a cause of aneurysmal disease, particularly among women.[20] Finally, ascending aortic aneurysms associated with bicuspid aortic valve disease are also generally considered "degenerative" and account for a considerable fraction of ascending aneurysms coming to surgery today.

The distinction between aortic ectasia and true aneurysmal dilation is subject to some degree of interpretation. Nomograms depicting normal aortic dimensions versus body surface area may be useful,[21] particularly in pediatric populations; however, there is no bright line between enlargement and aneurysm. Furthermore, changes in body mass, which may occur with age, can certainly influence these assessments in the adult. Perhaps a more practical definition of aneurysm as suggested by Crawford is enlargement to greater than twice the diameter of the adjacent normal aorta.[22]

Full characterization of aortic disease must also include a description of the location and extent of the aneurysm itself. This should ideally include distinction between dilation of the ascending aorta and of the root. Either or both may be enlarged. Accordingly, in our institution, we have adopted a classification scheme as depicted in Figure 67.1. Unfortunately this distinction is not always made in the literature. Accordingly there is sometimes confusion over what best to do with a patient having enlargement of the sinuses but not the ascending aorta (Fig. 67.2) when guidelines refer to the ascending aorta specifically. Safi has proposed a classification scheme for aneurysms of the descending thoracic aorta as well (Fig. 67.3), and has demonstrated its correlation with operative risk.[15] Thoracoabdominal aneurysms in turn are conventionally classified according to Crawford's schema as shown in Figure 67.4.[23]

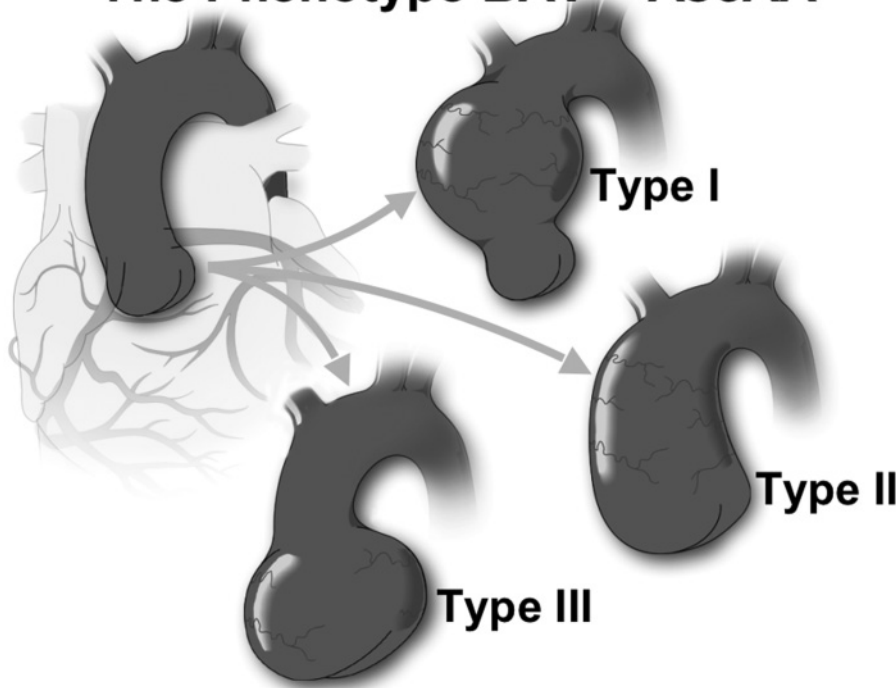
The location and extent of aortic dissection are critical in clinical decision making as well. Acute aortic dissection represents a mechanical failure of the aortic wall with the propagation of a plane of dissection within a weakened media creating a "double-barrel" aorta with a channel of flow into a true and false lumen. Uncommonly, the latter may thrombose completely; more often the false lumen remains at least partially patent and is actually larger than the true lumen. In some instances the false channel may


Figure 67.1 Although it is widely recognized that bicuspid aortic valve is associated with ascending aortic aneurysm, in point of fact, there are at least three phenotypes which should be distinguished. The most common is a supracoronary aneurysm confined to the ascending aorta. We refer to this as a Type I aneurysm. The Type II aneurysm demonstrates effacement of the sinotubular junction with generalized enlargement of the ascending aorta and root. This pathology more commonly demands complete root replacement surgically. Type I in contrast can be managed with a separate valve and graft. The least common is Type III with aneurysmal dilatation of the root reminiscent of Marfan syndrome. The ascending aorta can, in fact, be of entirely normal diameter with quite significant enlargement of the sinuses.

compress the true lumen, causing a pseudo-coarctation, or in the extreme may cut off blood flow to end-organs, causing a malperfusion syndrome. Originally classified
Figure 67.2 This sagittal CT scan demonstrates a Type III aneurysm with significant enlargement of the sinuses of Valsalva but a relatively normal ascending aorta.

by DeBakey into three types (Fig. 67.6),[4] a simpler if somewhat less informative system proposed by Shumway's group (Fig. 67.6)[24] has become more popular, particularly among non-surgeons. In the latter system, those dissections involving the ascending aorta, including both DeBakey type I and II, are classified as "Stanford type A" which is easily remembered ("A" for "ascending") and is of practical value as the immediate clinical management is the same. Those not involving the ascending aorta (DeBakey type III) are by elimination "Stanford type B."

Aortic dissections are also the principal causes of "acute aortic syndromes," a term coined by Vilacosta and Roman in reference to clinical presentation of a variety of aortic pathologies intended to draw attention to these entities in contrast with the much more common causes of chest pain – "acute coronary syndromes."[25] Unfortunately, the former continues frequently to be mistaken for the latter even in today's age of advanced imaging modalities.[26] Given the opposing aims of therapies for each – anticoagulation versus surgical intervention – this misdiagnosis can have tragic consequences.

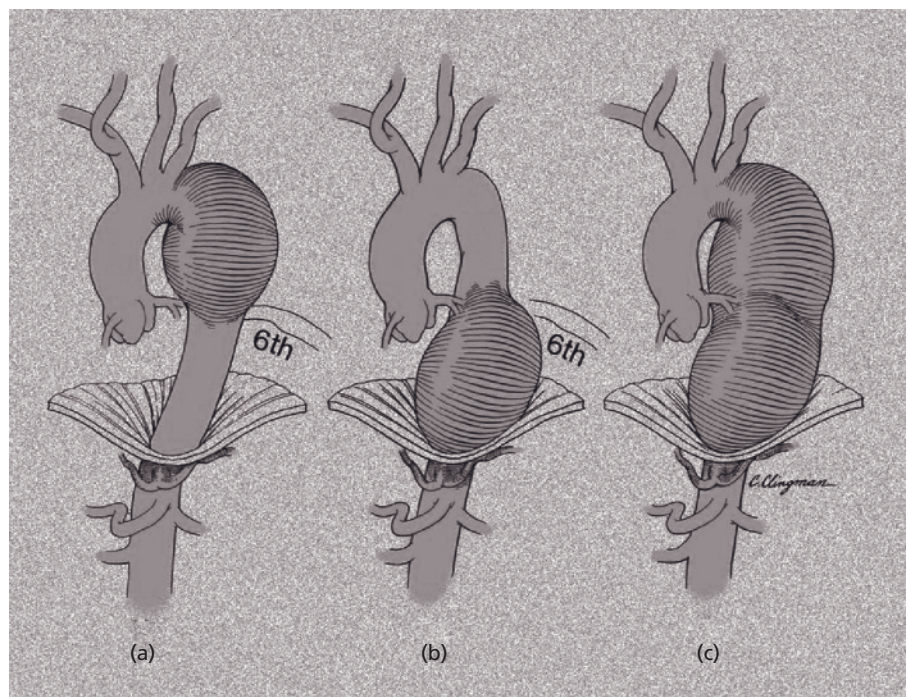
Other causes of acute aortic syndrome include symptomatic thoracic aortic aneurysm (a relatively uncommon condition) and the so-called "variant forms" of acute dissection – intramural hematoma (IMH) and penetrating atherosclerotic ulcer (PAU). By definition, the term intramural hematoma refers to the presence of hematoma within the wall of the aorta without apparent intimal disruption as described in 1920 by Krukenberg.[27] This definition was created at a time when the diagnosis of intramural hematoma was made at autopsy or, somewhat more recently, at


Figure 67.3 Safi has defined three types of descending thoracic aortic aneurysms with, from right to left, Type A aneurysms involving the upper descending thoracic aorta alone, Type B aneurysms involving the lower descending thoracic aorta and, Type C aneurysms involving the entire descending thoracic aorta. The risks associated with surgical intervention are correspondingly associated with the extent of the disease.
Figure 67.4 The Crawford classification of thoracoabdominal aneurysmal disease includes Type I aneurysm with involvement of the entire descending thoracic aorta and upper abdominal aorta including the origins of the visceral vessels, a Type II aneurysm involving the descending thoracic aorta and entire abdominal aorta, Type III – an aneurysm involving the lower descending thoracic aorta and abdominal component and Type IV – perivisceral abdominal aortic aneurysm involving the origins of the visceral vessels but sparing the majority of the descending thoracic aorta.

open surgical intervention. In the current era, the diagnosis of these conditions is most often made radiologically and accordingly a distinction between IMH and so-called "non-communicating dissection" with complete thrombosis of the false lumen can be difficult. Indeed, one could argue that such a distinction is impossible, as it relies upon the demonstration of absence of a disruption. Lack of active flow communication is more straightforward, of course, and from a practical standpoint may be more important as IMH and non-communicating aortic dissection with thrombosis of the false lumen likely behave very much alike.

Penetrating atherosclerotic ulcer as a distinct entity was most clearly defined by Stanson and colleagues in 1986.[28] Penetrating atherosclerotic ulcers represent intimal disruptions with extension into the medial layer. They most often occur in the heavily atherosclerotic descending thoracic aorta with a propensity to arise in the distal descending thoracic aorta. Typically they are surrounded by at least some element of IMH (although if one is adherent to Krukenberg's definition above one would question the use of this term). Penetrating atherosclerotic ulcers are most often discussed in the context of acute aortic syndromes, although a significant percentage are identified as incidental findings during radiologic studies for other reasons.[29] The principal radiologic challenge is differentiating this entity from heavy intraluminal thrombus with surface irregularities.

A variety of congenital conditions can also cause aneurysms of the aorta. Among these the most common is dilation of the origin of an aberrant subclavian artery (Fig. 67.7). Most often this is an aberrant right subclavian artery in the presence of a left aortic arch although the converse may occur as well. The origins of such vessels are often somewhat dilated and again as noted above, the distinction between a diverticulum of Kommeral and true aneurysm is somewhat subjective. The indication for intervention is as often dysphagia lusoria from compression of the esophagus as it is the actual dimensions of the structure.

Incidence

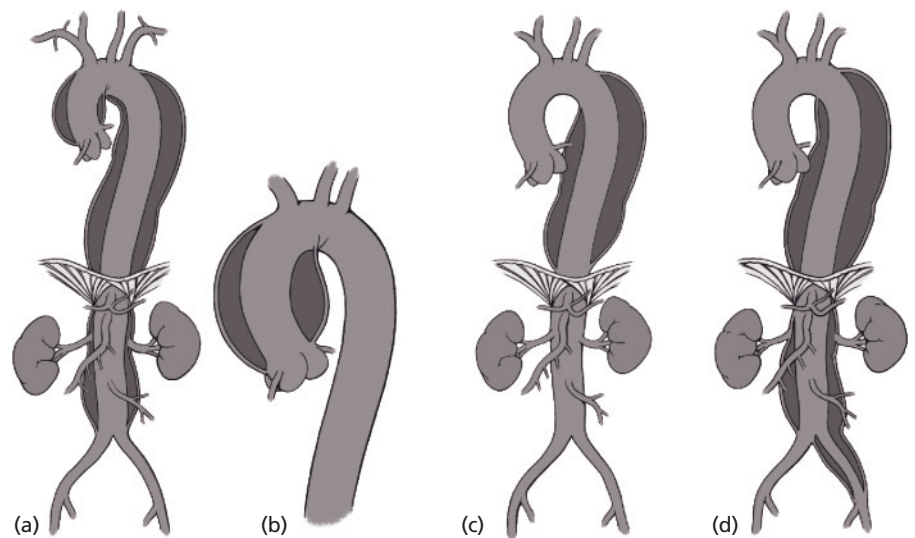
As noted above, both the estimated incidence and apparent natural history of thoracic aortic aneurysmal disease depend to an extraordinary degree on imaging technology, in terms of both technical resolution and clinical application, since most aneurysmal disease is asymptomatic until disaster strikes. Still, in most modern studies the incidence of thoracic aortic aneurysms is estimated at
Figure 67.5 The pathogenesis of aortic dissection is thought to originate with an intimal tear which allows blood entry into the media with propagation of the dissection distally. In some instances, the false channel will thrombose resulting in a "noncommunicating dissection." It is currently held that intramural hematoma begins with rupture of the vasorum progressing to a clotted hematoma. In some instances, that hematoma may rupture into the lumen allowing dissection to form.


Figure 67.6 The classification of aortic dissection may be either the DeBakey or Stanford classification. From left to right, the most common is the DeBakey Type I or Stanford Type A dissection involving the entire aorta. DeBakey Type II dissection involves the ascending aorta alone. Because it involves the ascending aorta, it is also classified as a Stanford Type A. The DeBakey Type III dissection involves the descending thoracic (III-A) or thoracoabdominal (III-B) aorta and may also be termed a Stanford Type B dissection.

Figure 67.7 Aberrant origin of the left subclavian artery from a right aortic arch with a diverticulum of Kommeral.

between 8 and 12 per 100,000 person-years. In the Olmsted County study mentioned above, Clouse and colleagues estimated the incidence of thoracic aneurysms in that population to be 10.4/100,000 person-years.[7] Perhaps the most comprehensive study of thoracic aortic aneurysmal disease to date was reported by Olsson in 2006, with unique tracking of the population of Sweden over a 16-year period.[30] This study encompasses a population of 8.7 million. Thoracic aortic aneurysms greater than 5 cm in diameter, true dissections and intramural hematomas were tracked. The incidence appeared to gradually rise over the time of the study with approximately 16.3 males/100,000 person-years and 9.1 females/100,000 person-years diagnosed in 2002. As the apparent incidence rose, prognosis

improved with an increasing frequency of surgical procedures performed and a declining operative mortality.

With regard to acute aortic syndromes and aortic dissection, in another Olmsted County study, Clouse and colleagues estimated the incidence of aortic dissection at 2.9 per 100,000 persons per year.[31] Meszaros has estimated the incidence in a Western European study to be 3.5 per 100,000 persons per year.[32] Two-thirds of these dissections involve the ascending aorta.[33] Intramural hematomas are generally thought to represent approximately 5–10% of acute aortic syndromes[34] whereas PAU are far less common. The latter two conditions tend to occur in patients of somewhat more advanced age.

Natural history and prognosis

The natural history of thoracic aortic aneurysmal disease is progressive. The most commonly cited predictor of behavior as identified by Joyce in all subsequent studies is aortic diameter, with risk rising particularly beyond 6 cm.[5,35] In the study by Clouse *et al*, the rupture risk for aneurysms less than 4 cm in diameter was negligible, while that for aneurysms between 4 and 5.9 cm was 16% and that for aneurysms 6 cm or larger was 31%.[7] Other factors enter play as well, although less well recognized perhaps. Clouse identified female gender and advanced age as risk factors for rupture.[7] Juvonen and Griepp performed a sophisticated analysis of risk factors for rupture of thoracoabdominal aneurysms,[36] confirming these risk factors as well as chronic obstructive pulmonary disease. Not surprisingly, hypertension has been identified as a risk factor as well.[37]

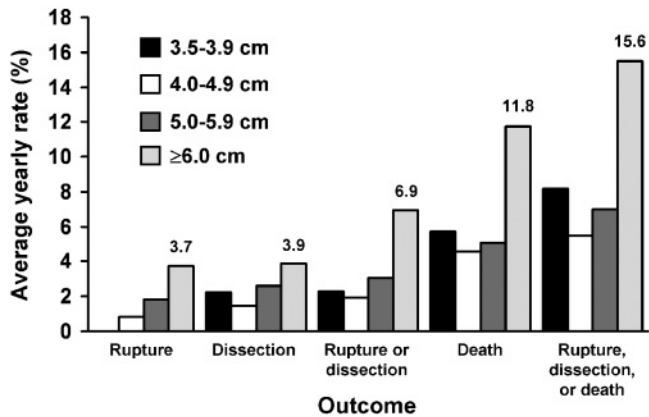
The most comprehensive analysis of the impact of diameter on rupture risk has been performed at Yale University through the efforts of Elefteriades and Rizzo using their thoracic aortic aneurysm database. A number of important publications have derived from this work. Coady identified a hinge point for rupture of the ascending aorta at 6 cm while that for descending thoracic aorta was 7.2 cm.[38] As intervention at this dimension would be at the expense of a significant number of ruptures, most surgeons have adopted 5.5 cm for the ascending aorta and 6.5 cm for the descending thoracic aorta as criteria for intervention (**Class I, Level C**). Subsequent work has demonstrated that the annual risk of aortic catastrophe, taking rupture, dissection or death as the composite endpoint, rises to 15.6% for aneurysms greater than 6 cm in diameter as shown in Figure 67.8.[37] The correlation is even stronger when the diameter is indexed as body surface area: an indexed dimension of $2.75 \, \text{cm/m}^2$ is associated with a risk of 4% per year while that greater than $4.25 \, \text{cm/m}^2$ is associated with a risk of approximately 20% per year.[39] Unfortunately, the weakness of these data is that they are derived from a surgical database, and therefore may be somewhat biased toward malignant behavior as in any such database the cases entered


Figure 67.8 The risks associated with aortic aneurysms of various diameter as determined by Davies *et al.* from the Yale University Thoracic Aortic Database.
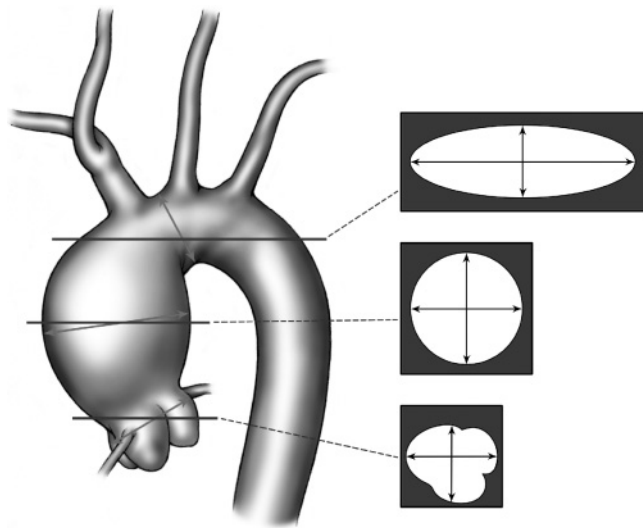

Figure 67.9 The true diameter of the aorta at any given level as derived by 2-D axial imaging will be the smallest diameter as measured on the image at that level. Oblique images will yield an oval, of which the smallest diameter is most accurate assuming a cylindrical structure. Three-D reconstructions permit more accurate assessments measuring the diameter normal to the axis of blood flow.

represent those referred for consideration, in contrast to population-based studies.

Implicit in these guidelines is the accurate measurement of aortic dimensions. Whether by echocardiography or computed tomography, the dimensions measured depend upon the selection of the optimal image with maximal dimensions while appropriately placing the measurement cursor normal to the long axis of the vessel. As shown in Figure 67.9, oblique images will provide deceptively large measures if one is not cautious. Surgeons therefore speak of using the smallest measured diameter on the image with the largest dimensions. On the other hand, asymmetric or saccular aneurysms should be measured in the longer dimension. In our view, the advent of three-dimensional

reconstructions of aortic images has proven very beneficial. It should also be noted that the sinuses of Valsalva are always somewhat larger than the ascending aorta and the majority of studies reporting ascending aortic dimensions do not distinguish whether they were evaluating the ascending aorta or root. In all likelihood, the majority are referable to the ascending aorta. Still, we apply these dimensions even when the dilation is largely in the root. In particular in the setting of Marfan syndrome and some familial thoracic aortic aneurysms, the ascending aorta itself may be remarkably normal in dimension with almost all the dilation in the sinuses themselves. Therefore, one may be just as readily lulled into a false sense of security with a falsely low aortic dimension if only those dimensions in the ascending aorta are considered.

It is likely that the risk of rupture can be reduced through the administration of antihypertensive medications (**Class IIa, Level B**). Among patients with Marfan syndrome, studies by Schor and colleagues[40] and Rossi-Foulkes and co-workers[41] have demonstrated the protective effect of beta-blockers or calcium antagonists respectively on aortic dilation and, in the former case, aortic complications. Yetman and associates have also utilized the angiotensin-converting enzyme enalapril in patients with Marfan syndrome demonstrating improved aortic distensibility, reduced aortic stiffness, and a smaller increase in aortic diameter.[42] Exciting data from the Dietz laboratory at Johns Hopkins have also suggested that use of the angiotensin receptor blocker losartan may have a favorable impact on aortic remodeling as well.[43]

Although the details of the pathophysiologic basis of aortic aneurysmal disease are largely beyond the scope of this chapter, they may have an impact on clinical behavior. This is most obvious in the case of Marfan syndrome in which it is widely accepted that the risks of dissection and rupture are, size for size, greater than for aneurysms of other etiology.[44] The association between mutations in the fibrillin gene and Marfan syndrome has been known for many years now.[45] The pathogenesis was assumed to relate to the critical role of fibrillin in the extracellular matrix as the main component of the 10–20 nm microfibrils which associate with elastin in the media. Such mutations have been shown to increase susceptibility to proteolysis and, as a consequence, microfibril and elastin fragmentation. In the last several years, however, intriguing results from the Dietz laboratory have suggested a role for dysregulation of transforming growth factor beta (TGF-β) signaling in Marfan syndrome.[46] Amino acid sequence homology identified in silico between fibrillin-1 and latent TGB-β proteins (LTBPs) suggested that alterations in fibrillin might impact TGB-β levels in the tissues due to decreased binding. Indeed, laboratory studies have shown that alterations in TGB-β signaling may lead to alterations in extracellular matrix homeostasis in the lung as well as the aorta. Subsequent

studies have demonstrated an important role for TGB-β in other related aortopathies including mutations in the TGB-β receptor type I and II genes in the "Marfan syndrome II" phenotype and other familial thoracic aortic aneurysm syndromes.[47–49] A particularly malignant form of such a familial syndrome is the recently defined Loeys–Dietz syndrome which may be secondary to mutations in TGF BRI or TGF BRII.[50] Individuals so affected are particularly susceptible to widespread aneurysmal dilation early in life. The clinical significance of such findings is the potential for genetic testing, permitting prophylactic operative repair of the susceptible aortas of family members who may well be susceptible to dissection at lower aortic diameters.

The association between bicuspid aortic valve and ascending aortic dilation has long been recognized.[51] There is mounting evidence that the aortopathy is primary, and not secondary to altered flow dynamics, as it may be present even with a functionally normal valve.[52] Structural abnormalities including gross degenerative histologic abnormalities commonly referred to as "cystic medial necrosis,"[53] thinning of elastic lamellae,[54] smooth muscle cell apoptosis[55] and increased matrix metalloproteinases[56] have been observed in the associated aneurysmal aorta. While there is agreement that the risk of dissection is higher among patients with a bicuspid valve,[57] the relationship between dissection and aortic diameter is less so, with no studies thus far documenting a higher risk of aortic complications at a given dimension than other aortic dilations. Accordingly, while the presence of documented Marfan syndrome or another familial syndrome can be cogently argued as a rationale for predicting a worse outcome and therefore more aggressive approach to management, the same cannot as clearly be said for bicuspid disease. Having said this, a small study by Svensson and colleagues substantiates the notion that patients with bicuspid disease may dissect at dimensions less than 5 cm.[58] Recent data from the IRAD database demonstrate that this may be true even in patients with trileaflet valves,[59] although such studies look only at the numerator and accordingly cannot address actual risk for the population as a whole. Since a very large number of patients have an aortic diameter less than 5.0 or 5.5 cm, the occurrence of dissections among these individuals may take place at a very low incidence – potentially far less than the risk of aortic replacement surgery. The argument for treating patients with bicuspid disease differently with a specifically lower threshold for replacement is therefore weakened. Nonetheless, it is well documented that the ascending aorta may continue to dilate even after aortic valve replacement in the setting of bicuspid disease.[60,61] Accordingly, a number of investigators have advocated prophylactic replacement of the ascending aorta at the time of bicuspid valve repair or replacement should it exceed 4.5–5 cm (**Class IIb, Level C**). These criteria are generally accepted.

Diagnosis

The diagnostic modalities employed in evaluation of aortic disease are similar regardless of the etiology of the condition. By far the most commonly employed technology is computed tomography. This is in part due to its widespread availability. Image acquisition is also less operator dependent although interpretation still requires special expertise. Indeed, the majority of thoracic aortic aneurysms are asymptomatic and are identified at the time of CT scanning for other reasons. CT scanning is also the most common first modality employed in the diagnosis of thoracic aortic dissection.[33] Frequently such a study is performed for the purpose of ruling out pulmonary embolism in the patient with acute-onset chest pain without ECG changes or enzymatic evidence of myocardial infarction. It should be noted that since aortic aneurysmal disease is commonly multifocal,[22,62] complete imaging of the entire thoracic and abdominal aorta should be performed in all patients with a diagnosis of thoracic aortic aneurysm.

Echocardiography is also commonly employed in the evaluation of patients with thoracic aortic disease. Indeed, many ascending aortic aneurysms are discovered incidentally during echocardiography for suspected valvular conditions. This highlights the importance of imaging of the ascending aorta, arch to the extent possible, and descending thoracic aorta as a standard part of routine transthoracic and transesophageal echocardiography. Transesophageal echocardiography is the second most common modality used in the diagnosis of acute dissection and is particularly helpful in that context for evaluating the function of the aortic valve in that setting.[33]

Magnetic resonance imaging is less commonly performed as the initial diagnosis test.[63] It has a greater role perhaps in serial follow-up of patients with aneurysmal disease as it does not subject the patient to radiation. In the case of a young individual, the amount of radiation delivered by annual or biannual CT scanning for follow-up of thoracic aortic aneurysm can be quite considerable. In many cases, MRI is selected as the technique of choice for serial exams. Most surgeons find these images cumbersome, however, and prefer CT scanning.

Management

Management of thoracic aortic aneurysmal disease is dependent upon the location within the aorta, the etiology of the aneurysm and the acuity of its presentation. The thoracic aorta is itself a more complex structure than might be presumed. Far from being a simple tube, it has significant elastin content that serves a "Windkessel function" of storing energy in systole and returning it in diastole.[64] This

improves coronary artery blood flow proximally, and likely helps to distribute forces within the vascular tree more effectively. Elastin content varies along the length of the aorta, with the highest content proximally. Given very different forces[65] and mechanical properties,[66] it should come as no surprise that the behavior of pathologic entities such as classic aneurysm, IMH or acute dissection varies according to location. The etiologic basis of the aneurysmal condition may also play a role in determining the optimal management. This is particularly true for individuals with genetic causes of aneurysmal disease including Marfan syndrome, familial thoracic aortic aneurysm, and bicuspid aortic valve in whom the mechanical properties of the aorta itself appear altered.[67] While our understanding of these conditions is still in its adolescence, if not infancy, in general a more aggressive posture is adopted towards those aneurysms and dissections associated with an underlying genetic cause.[68] Finally, the acuity of presentation is an important determinant of the management strategy and will be reflected below by our separation of the management strategies according to this parameter.

Acute aortic syndrome

As noted above, the term acute aortic syndrome was coined in reference to conditions presenting acutely with chest pain secondary to the abnormalities of the thoracic aorta.[25] Accordingly, it includes aortic dissection and its related conditions, IMH and PAU. Broadly speaking, it may also include post-traumatic pseudoaneurysms to the extent that these are acute aortic events. Finally, it may be argued that an acutely symptomatic thoracic aortic aneurysm without dissection should be considered under this heading.

Essentially all causes of acute aortic syndromes are treated acutely with anti-impulse therapy while the diagnosis is made in the interest of reducing hydrodynamic stress.[69] This is accomplished first with beta-blockade to reduce dP/dt.[70] Other vasodilating agents are then added as needed to reduce systolic blood pressure (**Class I, Level C**).

The root, ascending aorta and arch

Acute aortic syndromes involving the ascending aorta are managed surgically in almost all instances. (**Class I, Level C**). The case is most clearly and unequivocally made for acute dissection, an entity for which the non-operative management carries a mortality rate of 50% or more,[33,71] even in the current era. The mortality rate associated with surgical repair varies among series roughly from 10% to 25%,[72–74] depending upon the age and hemodynamic state of the patients preoperatively[75,76] and, likely, the experience of the surgical team.

Early reports of IMH involving the ascending aorta indicated a high mortality rate with non-operative management, leading to recommendations that all such lesions be treated surgically.[77,78] This view was supported by the majority of subsequent studies,[79,80] including a multicenter European study[81] and recent meta-analysis.[82] In recent years, there has been an alternative view of the management of intramural hematoma of the ascending aorta expressed by some Asian authors. Several institutions have reported satisfactory results with an expectant approach to type A IMH.[83–87] Importantly, however, this approach as practiced by these authors involved hospitalization of patients for up to 1 week in the intensive care unit and 1 month in hospital with assiduous blood pressure control, frequent imaging, and a willingness to convert emergently to surgical therapy if the IMH progressed. Among those reported by Kaji's group, for example, 43% had surgery during their hospitalization and 60% eventually progressed,[87] as did 50% of those treated in Moizumi's series.[88] A significant number of late IMH-related deaths occurred in the latter series as well. There may be a cost in terms of operative risk as well, with this approach of necessity bringing patients to surgery under urgent or emergent circumstances rather than semi-electively. In Song's series the operative mortality rate was fully 20%,[89] much higher than that reported by others in the 5% range.[84,90]

Predictors of successful non-operative management include younger age, diameter less than 50 mm and thickness less than 11–12 mm.[87,88,91] The presence of a PAU is seen by most as a predictor of bad outcome, and there seems to be no disagreement that "type A" PAU should be treated operatively.[80]

The principal surgical approach for management of an acutely symptomatic aneurysm or dissection involving the ascending aorta is graft replacement of the affected segment. This is most often accomplished with a Dacron graft, essentially the same as that introduced by DeBakey almost a half-century ago.[8] Aortoplasty procedures for degenerative aneurysms in which a portion of the wall is excised and repaired primarily[92–95] have largely fallen by the wayside due to the risk of recurrent dilation.

Repair of aneurysms of the proximal aorta may be accomplished with or without root replacement/repair (Fig. 67.10). If only the ascending aorta is involved and the valve and sinuses are spared, tube graft replacement of the ascending aorta may be performed. If the valve is dysfunctional but the sinuses of Valsalva are spared, a separate valve replacement and supracoronary graft may be appropriate. Alternatively, if the sinuses of Valsalva are diseased, as may be the case in the setting of acute dissection or in cases of aneurysmal disease secondary to underlying genetic abnormalities such as Marfan syndrome, complete root replacement is appropriate. This may be accomplished with a mechanical valved conduit which is purchased directly from the manufacturer with the valve prosthesis, with the Dacron graft integral to the mechanical prosthesis. For older patients in whom one would likely

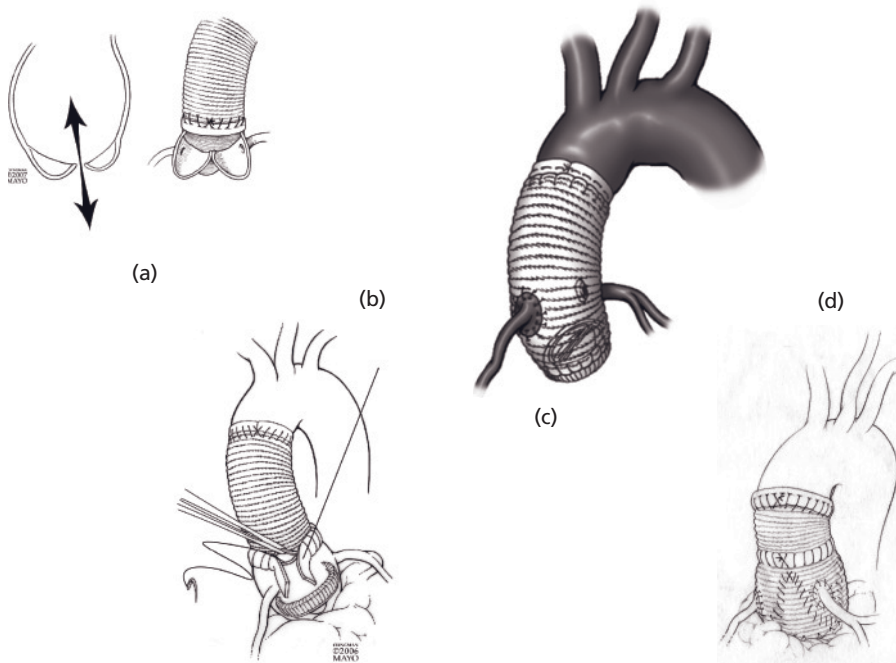
(d)


Figure 67.10 Surgical options for the ascending aorta and root in the presence of valvular disease include: (a) tube-graft replacement of the ascending aorta with correction of the sinotubular junction to correct aortic regurgitation secondary to displacement of he commissures, (b) separate valve-and-graft repair of the supra-coronary aorta, (c) Composite root replacement, and (d) valve-sparing root repair.

select a biologic prosthesis under elective conditions, a biologic root replacement can be accomplished either by using a free-standing biologic root prosthesis such as a human allograft or stentless Porcine xenograft, or simply by fashioning a "home-made" biologic composite by sewing a Dacron graft to a stented tissue valve. The operative risk associated with root replacement has been reported to be less than 5% in experienced hands, although data from the Society of Thoracic Surgeons database suggest that in the practice of cardiac surgery at large, adding root replacement to aortic valve replacement increases operative risk almost threefold.[96]

Finally, for individuals whose valve leaflets are relatively normal and in whom the disease is confined to the aortic wall itself, several valve-sparing root repair procedures have been developed. By far the most popular today is the valve reimplantation technique of David.[17] In this procedure, the aortic wall including aortic sinuses are debrided, leaving the valve itself intact. The Dacron graft is lowered over the root and the valve leaflets resuspended within the Dacron graft itself such that the sinuses have been replaced in their entirety. Coronary arteries are reimplanted into this Dacron graft as they are in the composite and root grafts noted above. There is some uncertainty regarding the long-term durability of this final option as it has been employed for only slightly over a decade. Early results are promising, however, and it is being embraced with increasing enthusiasm by the surgical community.

The extent of distal replacement is dependent upon the extent of disease. In the case of a symptomatic aneurysm confined to the ascending aorta or a DeBakey type II dis-

section or intramural hematoma, replacement of the ascending aorta alone may be all that is required. Very commonly, these procedures are performed under profound hypothermia with circulatory arrest to permit extirpation of the entire ascending aorta right to the orifice of the brachiocephalic trunk. Although data demonstrating an impact of using circulatory arrest for conduct of an "open distal anastomosis" on late outcomes are mixed,[97–99] it has been widely adopted (**Class IIa, Level C**). In the setting of acute dissection, particularly DeBakey type I dissections which extend through the arch, there is greater debate over the extent of repair required. It is commonly stated that the resection must "encompass the distal tear." Unfortunately, from a practical standpoint, there are often multiple tears throughout the arch. Many authors will simply primarily repair the tear and perform hemiarch replacement (Fig. 67.11) in order to avoid total arch replacement.[100]

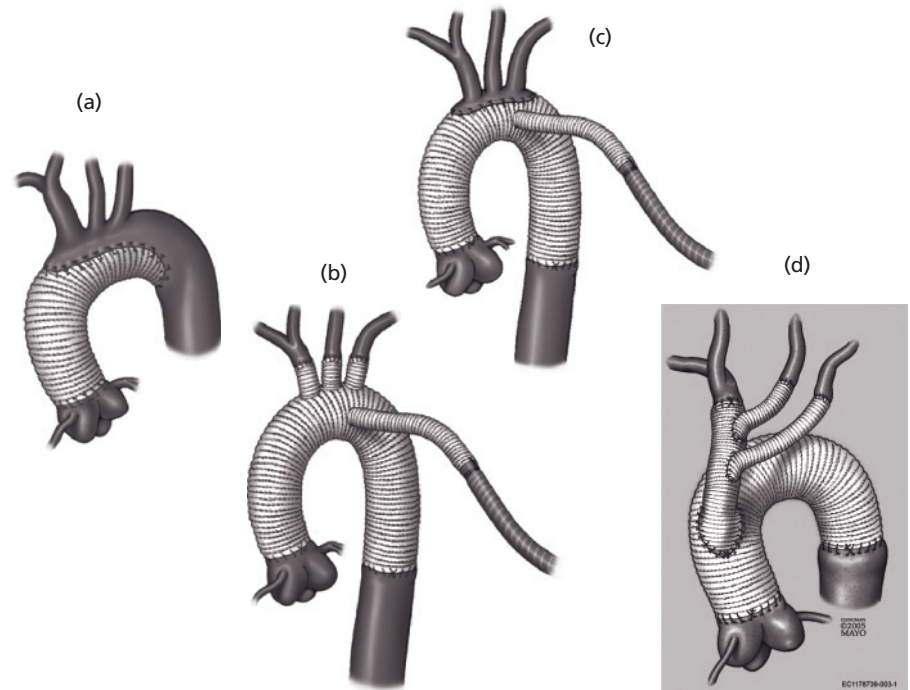
Total arch replacement is a major technical undertaking, as it demands a thoughtful approach to neurologic protection while the brachiocephalic vessels are being reconstructed. In the setting of acute dissection, authors from Japan have reported outstanding results with mortality rates less than 10%.[101,102] Western authors have been reluctant to advocate the same in the setting of acute dissection despite improving results for arch replacement in elective procedures.[12] This may in part be due to studies published thus far which fail to demonstrate an impact of the more aggressive distal repair on reoperation rate.[103,104] Accordingly, surgeons in the United States have tended to be rather conservative, performing the hemiarch replacement predominantly.


Figure 67.11 Surgical options for the aortic arch include: (a) hemi-arch replacement, (b) total arch replacement with branch-graft reconstruction of the brachiocephalic vessels, (c) total arch replacement with reimplantation of the brachiocephalic vessels as an island, (d) total arch replacement with double-Y graft reconstruction of the brachiocephalic vessels.

Descending thoracic and thoracoabdominal aorta

Those acute aortic syndromes due to pathology involving the descending thoracic aorta are, in general, treated non-operatively (**Class IIa, Level C**). In the classic study by Glower and Miller comparing surgical and medical management of acute (and chronic) type B dissection, early and late survival were equivalent regardless of treatment strategy.[105] As the trend shifted toward medical management unless complications such as continued pain or expansion, rupture or malperfusion due to branch vessel occlusion occurred, more recent studies have demonstrated a higher mortality rate among surgically treated patients. In the large multicenter IRAD database, the in-hospital mortality rate for acute type B dissection was approximately 10% as compared with approximately 30% for the surgical patients.[33,106] While a 10% mortality rate is not low, this number includes both complicated and uncomplicated dissections. If one considers only uncomplicated type B dissections, the mortality rate is in the low single digits.[107] These data of course beg the question of the place of endovascular stent grafting for uncomplicated dissection.

The variant forms IMH and PAU are generally treated non-operatively as well (**Class IIa, Level C**). Malperfusion is uncommon with these entities,[108] drawing an equivalency with uncomplicated dissection in the view of many. A number of studies have documented better behavior of IMH as compared with acute dissection.[34,79,81,87,109] It must be noted, however, that some authors have argued that the plane of dissection in IMH is closer to the adventitia than that for dissection, and they therefore argue for a more

aggressive approach.[90,110] Still, the majority view is that type B IMH may be treated pharmacologiacally, a view supported by a comprehensive meta-analysis performed by Maraj and colleagues.[82] Although acute behavior in general is superior with intramural hematoma, this is not to trivialize the risk as IMH may progress rapidly to acute dissection or rupture.[109] Elefteriades has emphasized the importance of careful follow-up.[79]

In the setting of malperfusion manifest as stroke or paraplegia, gastrointestinal ischemia, renal impairment or limb ischemia, intervention is indicated (**Class IIa, Level C**). Unilateral limb ischemia may be addressed by an extra-anatomic bypass such as a femoral–femoral bypass. More complex malperfusion syndromes are better addressed with fenestration, either open[111] or percutaneous,[112,113] or with endovascular stent grafting.[114] Insertion of a covered stent graft proximally with or without distal implantation of uncovered stents has been shown to restore flow in the true lumen, redirecting blood flow and restoring visceral perfusion. While no stent grafts are currently FDA approved in the United States for this application, this is likely the most common indication for stent grafting in the setting of acute dissection in the United States and the world today.

Traumatic transsection

Finally, a special word should be said about the current management of acute aortic transsections with pseudoaneurysm as a cause of acute aortic syndrome. Traumatic transsections occur as a consequence of acute deceleration injury and are typically located adjacent to the ligamentum

arteriosum. A variety of mechanisms have been proposed but it is clear that this region of the aorta is subjected to particular stress as it transitions from a relatively fixed mediastinal arch to a more mobile intrathoracic descending thoracic aorta. The aorta is also tethered at this location by the ligamentum arteriosum and this may in turn exert particular traction forces at this location, accounting for the typical location of these pseudoaneurysms on the underside of the arch.

Traditional teaching has been to treat all aortic transsections surgically at the time of diagnosis (**Class IIa, Level C**). This is often complicated by concomitant injuries which have been suffered by these multi-trauma patients. A school of thought has therefore arisen concerning delayed treatment of such pseudoaneurysms with aggressive anti-impulse therapy in the interim.[115] The results of this approach have been reported by only a few groups but seem to be satisfactory. Indeed, if one looks at the original studies of aortic transsection upon which the philosophy of immediate surgical repair is based, the landmark study by Parmely and associates was an autopsy study performed at the Armed Forces Institute of Pathology.[116] Not surprisingly, the majority of these patients died. In point of fact, what this study demonstrates more than anything is the time course of death among patients with transsection who do in fact succumb. It does not address in any way the patients who experience partial transsection who survive. A more recent multicenter study reported by Fabian and associates reinforces this view with significant mortality and morbidity associated with transsection.[117] The majority of patients succumbing, however, do so in the first 36 hours, suggesting that individuals who come to medical attention with this condition beyond this point have "survived the trial of life" and perhaps might be treated non-operatively. The advent of stent grafting provides yet another approach.[114,118–120] The principal limitation here relates to the dimensions of the aorta as many of the individuals suffering traumatic transsection are young and have relatively small aortas for which currently available stent grafts are too large. Nonetheless, this is an appealing application of stent graft technology and likely an area that will grow in importance over time.

Subacute disease

Because of the highly lethal nature of acute aortic syndromes, those presenting subacutely are most often treated similarly to the acute conditions. An exception may be the subacute type A intramural hematoma as noted above. On the basis of the results reported from the Far East, it is likely that patients presenting subacutely who have the aortic characteristics associated with successful non-operative management may be treated with anti-impulse therapy alone (**Class IIb, Level C**). Specifically, those with maximum

aortic dimension less than 50 mm and intramural hematoma measuring less than 1 cm in thickness without evidence of intimal disruption to suggest penetrating ulcer or non-communicating dissection may be candidates for aggressive antihypertensive therapy.

Chronic disease

Regarding thoracic aortic aneurysmal disease in the chronic setting, both those due to degenerative disease and those secondary to chronic dissection are discussed together.

Aneurysms of the root, ascending aorta and arch

Aneurysmal dilation of the ascending aorta and arch commonly co-exist and accordingly present a similar challenge from a management standpoint. In general, their appropriate treatment algorithm is dictated primarily by the dimensions of the aorta itself. The majority of natural history studies have demonstrated a profound impact of aortic dimension on risk of rupture, dissection or death as discussed above. The risk of complications secondary to thoracic aortic aneurysm is dictated predominantly by the Law of LaPlace. While tension is related both to the aortic diameter and to internal pressure, the critical dimension for the ascending aorta in numerous series centers about 6 cm. This is as true in the 1963 study by Joyce[5] as it has been in subsequent studies by Perko and colleagues[35] as well as those by Elefteriades, Rizzo and associates at the Yale University Thoracic Aortic Aneurysm Database.[37,38] Recent biomechanical data also from Yale University demonstrate a dramatic increase in wall stress and drop in aortic extensibility as the thoracic aorta reaches 6 cm.[121] This finding is consonant with an observed 27-fold increase in aortic complications when the diameter exceeds 6 cm as reported by these same investigators from their clinical database.

These findings have lead to a general consensus among surgeons that intervention on the ascending aorta is indicated at 5.5 cm in maximum diameter[37](**Class IIa, Level C**). The threshold may be lower for young patients in whom the risk of surgical repair is less and at the same time the risk of lifetime complications related to the aneurysm is greater. In addition, patients with Marfan syndrome or familial thoracic aortic aneurysmal disease, particularly those with a history of dissection, may be treated at even earlier dimensions[68] (**Class IIb, Level C**). There is a current trend to intervene in the setting of Marfan syndrome, even at 4.5 cm. The advent of valve-sparing root operations as described above has promoted this more aggressive approach as the complications associated with implantation of an artificial valve are not imposed upon subjects with such a repair. This is despite thin evidence regarding the long-term durability of this option.[17] Some have argued for indexed criteria, with the predicted risk of rupture

being low at less than 2.75cm/m^2 (approximately 4% per year), intermediate at $2.75–4.24 \text{cm/m}^2$ (approximately 8% per year), and high above 4.25cm/m^2 (approximately 20% per year).[39]

Proximal aneurysms due to dissection may be found incidentally after an undiagnosed acute event or after initial successful replacement of the ascending segment with enlargement of the retained root or arch. In the latter setting, similar criteria for intervention are generally applied as for degenerative aneurysms, although there are some data to support the notion that the risk of rupture in the setting of chronic dissection is greater dimension for dimension.[122] Given that such aneurysms are, in fact, pseudoaneurysms, this is perhaps intuitive. When an otherwise unrecognized and untreated type A dissection is identified, however, it is widely accepted that semi-elective repair should be undertaken (**Class IIa, Level C**).

From a technical standpoint, the operative interventions employed for repair of degenerative aneurysms or chronic dissections of the ascending aorta and root are similar to those noted above in an acute setting. These include tube-graft replacement of the ascending aorta, root replacement, and separate valve and graft. In particular, it should be noted that patients with Marfan syndrome or other known connective tissue disorders should undergo a more radical procedure with complete root replacement preferred over leaving the sinuses of Valsalva behind (**Class I, Level C**). This is generally accepted practice for Marfan syndrome and some would argue should be applied for young patients presenting with dissection in whom a suspicion for a familial thoracic aortic aneurysmal disease may be high.

Approaches to the arch in the setting of chronic disease are also dictated by aortic dimensions. If the aortic arch is a normal dimension, the decision is relatively straightforward. Of note, studies of patients with Marfan syndrome have demonstrated a relatively low risk of arch complications and it is the standard of care to replace only the ascending aorta and root at the time of elective root surgery in Marfan syndrome.[123,124] There is no apparent benefit to prophylactic arch replacement in this setting. More commonly, one is faced with moderate aortic arch enlargement in the patient with bicuspid aortic valve disease. The enlargement of the ascending aorta may extend into the proximal aorta with no discrete neck to the aneurysm or transition to a normal dimension (see Fig. 67.11). In this setting, there are no hard and fast rules. There are no data to substantiate a particularly aggressive approach in this setting. Arch dissection and type B dissection are relatively uncommon in patients with bicuspid aortic valve. It is therefore our practice to only perform hemiarch replacement in the setting of bicuspid disease in the presence of arch enlargement exceeding 5 cm.

The contemporary results of elective aortic arch replacement are far superior to those reported only a decade ago.

Technical improvements have included the introduction of adjuncts for neuron protection such as retrograde cerebral perfusion[125,126] whereby the upper body venous system is perfused with cold blood with the intent of providing oxygenated blood to the tissues akin to retrograde cardioplegia. While some surgical groups use this method regularly and report gratifying results,[100,127] others have questioned the real value of this approach[128,129] and have abandoned it in favor of selective antegrade brachiocephalic perfusion.[12,13,130] There has also been a trend in favor of axillary artery cannnulation for arterial inflow,[131,132] a method that provides for flow away from the cerebral vasculature, potentially protecting patients from embolic phenomena. In combination, these techniques, along with branched-graft reconstruction of the brachiocephalic vessels, may be applied with mortality rates for arch replacement below 5% and similar if not lower stroke rates.[13]

When the distal extent of disease includes the descending thoracic or thoracoabdominal aorta, as it may in the setting of chronic dissection or generalized arteriomegaly. arch replacement may be performed using the "elephant-trunk" technique (Fig. 67.12) via median sternotomy, leaving a segment of graft dangling in the descending thoracic aorta for use in subsequent distal repairs.[133–135] This technique obviates the technical difficulties of obtaining proximal control of the aorta in a previously operated field as the surgeon need only open the aneurysmal distal aorta and clamp the dangling graft. In cases in which both the ascending aorta and descending thoracic aorta must be approached at the same procedure, the transverse thoracosternotomy incision which was popular at the inception of cardiac surgery has been reintroduced, providing access to the entire thoracic aorta.[136] Via this incision, the root, ascending aorta, arch and entire descending thoracic aorta may be replaced in a single procedure.

Descending thoracic and thoracoabdominal aorta

Perhaps as a result of lower hemodynamic stresses, the critical diameter at which rupture risk rises for aneurysms of the descending thoracic aorta is estimated to be somewhat higher. The data from the Yale University database indicate an inflection point for a descending thoracic aortic aneurysmal disease at 7.2 cm.[110] Accordingly, there is general agreement that intervention on the descending thoracic aorta should be undertaken at 6.5 cm (**Class I, Level C**). A lower threshold may be appropriate in patients with chronic dissection in whom the risk of rupture or redissection may be higher, as noted above.[122] Additionally, enlargement at a rate exceeding 0.5 cm over 6 months is commonly held as an indication of an actively remodeling aorta, and one for which surgical intervention is indicated. The risks of rupture also increase with advanced age, the presence of chronic obstructive pulmonary disease, and continued
Figure 67.12 An "elephant trunk" repair leaves a segment or "trunk" of graft dangling in the descending thoracic aorta to facilitate subsequent repair of the descending thoracic aorta by providing an easily accessible site for proximal anastomosis of the second graft. (a) schematic drawing, (b) postoperative CT scan.

tobacco abuse.[36] Unfortunately, these characteristics also increase the operative risk of open repair.

Non-operative management of patients with descending thoracic and thoracoabdominal aortic aneurysms, like those with ascending aortic aneurysms, should include beta-blockade (**Class I, Level B**). This has been demonstrated to be of value particularly in the setting of intramural hematoma of the descending thoracic aorta in preventing progressive dilation.[81]

In the case of IMH, in the chronic phase, aortic remodeling may progress over time to aneurysm in as many as 30–40%.[77,78,81] Conversely complete resolution of the hematoma has been observed in as many as half of patients within 6 months.[86,137] Predictors of progression include presence of a penetrating ulcer[138] while predictors of resolution include younger age,[137,138] diameter less than 4–4.5 cm[34,137,139] and hematoma thickness less than 1 cm.[34,139] It is important to note that Sueyoshi and colleagues suggested a biphasic modality in the behavior of patients with intramural hematoma including shrinkage in the first year but slow growth thereafter.[139] This emphasizes the importance of long-term monitoring. As compared with type B dissection, survival is superior for IMH at 1 year (100% v 83%), 2 years, (97% v 79%), and 5 years (97% v 79%).[138]

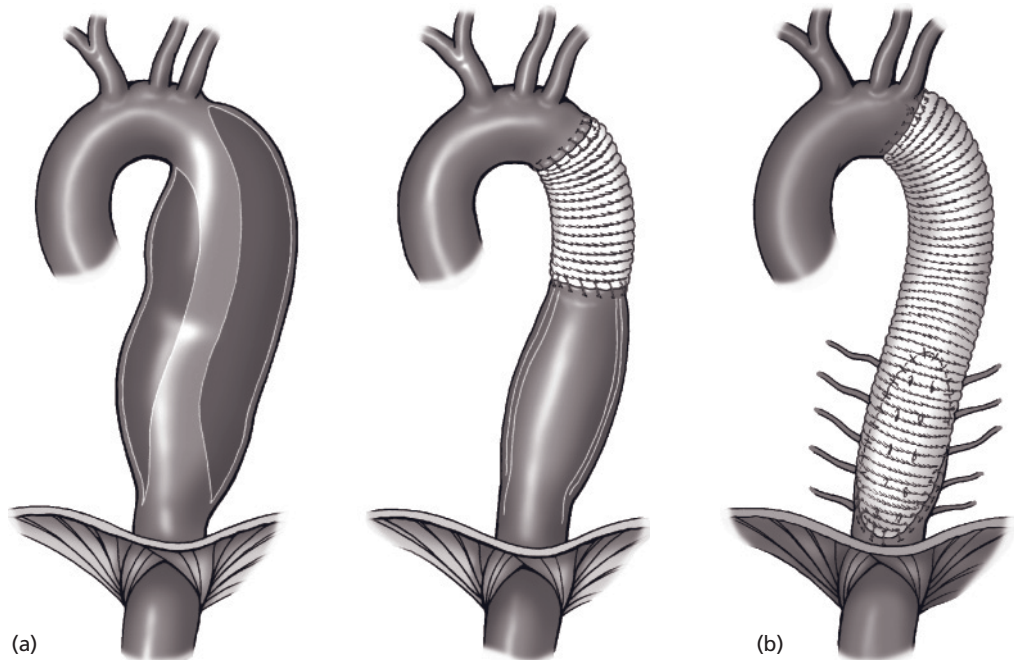
The traditional operative approach is Dacron graft replacement of the involved aortic segment (Fig. 67.13).

With open surgical repair, there is no question that the risks of mortality, as well as morbidity, increase with the extent of resection. The most common morbidity after thoracoabdominal aortic repair is pulmonary failure, followed by renal dysfunction.[140] By far the most dreaded, however, is paraplegia. The blood supply to the anterior spinal cord is highly segmental, with only a single anterior spinal artery in contrast to the paired posterior supply. Further complicating matters, the anterior spinal artery is of highly variable diameter and in some cases may be discontinuous. It is commonly held that the supply to the lower cord is critically dependent upon the arterius radicularis magnus or artery of Adamkiewicz which arises typically between the eighth thoracic and second lumbar vertebra.

As a consequence, repair of aneurysms isolated to the descending thoracic aorta are associated with lower risks of paraplegia than those of thoracoabdominal extent. Safi has classified descending thoracic aneurysms into three type as shown in Figure 67.3. In his series, the incidence of neurologic deficit was 2.3%, with all occurring among patients undergoing replacement of the entire thoracic segment.[14] Similarly, it is well documented that the operative risk as well as risk of neurologic deficit for repair of thoracoabdominal aortic aneurysms correlates with the extent of repair.[16] The risk of repair of thoracoabdominal

Figure 67.13 Repair of the descending thoracic aorta for chronic dissection may be accomplished with a short segment graft or long-segment with beveled distal anastomosis to preserve intercostal vessels and blood supply to the spinal cord.

(a)

(b)


aortic aneurysm has also been correlated with the experience of the operative surgeon, as well as that of the operative team (hospital).[141] Indeed, the operative risk is half that when a surgeon performs seven such procedures per year as compared with those performing only one per year. Similarly, the risk for procedures performed in hospitals with an annual volume of 12 cases is half that for hospitals performing only one such case per year.[142]

The unsettling incidence of neurologic deficit has stimulated the development of several approaches to intraoperative neurologic protection. The most popular is the provision of distal perfusion during the aortic cross-clamp episode by partial left heart bypass associated with moderate hypothermia.[143] The alternative approach is the use of full cardiopulmonary bypass with profound hypothermia and circulatory arrest.[144] Both methods are imperfect, and the morbidity of the surgical incision itself is significant.

Because of the above risks, the option of endovascular stent grafting has been embraced by physicians and patients alike. For descending thoracic aneurysms, the risks associated with stent grafting appear to be quite low, with mortality rates less than 5% and paraplegia rates of similar magnitude.[142] Of note, the risk of stroke is approximately 5% as well, likely due to atheroembolic material liberated by manipulation of wires in the highly atherosclerotic aortic arch. Stent graft technology as applied to thoracoabdominal aneurysms is complicated by the visceral as well as intercostal vessels. Fenestrated and branched grafts are currently being explored, although none is currently FDA approved for use in the United States.[145,146] Experience is growing with debranching procedures as well as with extra-anatomic bypass grafts to the visceral vessels. Morbidity associated with these procedures, however, appears to be quite significant.

Conclusion

Thoracic aortic aneurysmal disease is a highly lethal condition if left untreated, and yet it is eminently correctable with appropriate surgical intervention. The results of the latter have improved dramatically in recent years, making early diagnosis and prophylactic treatment even more important. As the maximum diameter of the ascending aorta approaches 6 cm, the risk of rupture or dissection rises dramatically. Accordingly, intervention on the proximal aorta (root or ascending aorta) is indicated at 5.5 cm. In some cases in which the risk of rupture may be judged to be particularly high (Marfan syndrome, family history of dissection) or in which the risk of surgery is particularly low (younger patients), this threshold may be lowered somewhat. The recent advent of aortic valve-sparing procedures has lowered this threshold for Marfan syndrome patients in particular, and in this case some would advocate surgery at 4.5 cm. Likely because of differences in hemodynamic stresses, the risk of rupture of the descending thoracic aorta is lower, with the critical value being closer to 7.0 cm and recommended criteria for intervention at 6.5 cm. Acute aortic syndromes are often misdiagnosed as acute coronary syndromes, with the most important safety measure being a high index of suspicion. When acute

dissection, intramural hematoma or penetrating aortic ulcer affects the ascending aorta ("type A"), immediate surgical intervention is indicated. When the descending aorta is involved, however, non-operative management is generally accepted unless complications occur such as malperfusion, rapid aortic expansion or continued pain. Medical therapy is beta-blockade and assiduous control of blood pressure. In complicated dissection, however, surgical repair may be required.

More recently, experience is growing in the endovascular treatment of these conditions, with either percutaneous fenestration for treatment of malperfusion or, more recently, endovascular stent graft placement for malperfusion or rupture. By far the best treatment, however, is prophylactic repair.

68 Cardiac transplantation: indications and postoperative management

Barry Boilson and Sudhir Kushwaha
William Von Liebig Transplant Center, Mayo Clinic, Rochester, MN, USA

Historical perspective

The original concept of cardiac transplantation dates to the 1890s, with the work of Alexis Carrel and subsequently Mann and colleagues at the Mayo Clinic in the 1930s.[1] The modern era of human cardiac transplantation started with pioneering work by Vladimir Demikhov in Russia in the 1940s[2] and Norman E Shumway's group at Stanford University throughout the 1950s, the latter associated with the development of cardiopulmonary bypass[3] and perfection of the surgical technique. By the mid 1960s, it was concluded by Shumway that the major barrier to successful mammalian cardiac allotransplantation was rejection.

The first human cardiac transplant was performed by Dr Christiaan Barnard at Cape Town, South Africa, in 1967. Local irradiation, azathioprine, prednisone and actinomycin C were used as immunosuppression. The patient survived 18 days but ultimately succumbed to *Pseudomonas* pneumonia.[4]

Worldwide, further attempts at human cardiac transplantation met with poor outcomes. Most groups discontinued their efforts, but the Stanford group implemented criteria and protocols for detection of acute rejection early post transplant. Initially, this involved ECG, echocardiographic and clinical parameters, but in 1973 histologic criteria on endomyocardial biopsy were developed and remain the mainstay of rejection surveillance. The discovery of ciclosporin A by Professor Jean-François Borel in 1976 and its subsequent introduction into clinical practice

after successful animal studies[5] was the breakthrough in the prevention of rejection which allowed successful cardiac transplantation. Despite these advances, the number of transplants performed worldwide has plateaued, primarily due to lack of donor organ supply.[6] This has instigated research and development of new therapeutic avenues such as mechanical device therapy.

Outcomes

The International Society for Heart and Lung Transplantation (ISHLT) has reported outcome data on transplant recipients on an annual basis for the past 24 years. The most recent data are summarized below.[7]

Demographics

The primary indication for cardiac transplantation has remained unchanged in recent years, almost evenly divided between ischemic (41%) and non-ischemic cardiomyopathy (45%). The remaining indications represent a minority of patients with valvular and congenital heart disease and those retransplanted (all 3%). An increasing number of patients are now on inotropic (40%) or mechanical support (including left ventricular assist devices [LVADs], 27%) at the time of cardiac transplantation.

The age of both donors and recipients has increased in the past 20 years. Almost 25% of cardiac transplant recipients in the past year were over the age of 60 years, with a relative fall in numbers of recipients aged 40–49 years. Donors over the age of 50 years now comprise >12% of donors worldwide. Twenty percent of European donors are over 50 years old, whereas in the US that figure is closer to 10%.
Figure 68.1 Overall survival post cardiac transplantation (ISHLT data 2007).

Outcomes

Since the ISHLT started reporting outcomes in 1982, early survival (up to one year) post transplantation has improved steadily.[8] However, long-term mortality has not changed and the current transplant half-life is 10 years worldwide for adult and pediatric cardiac transplant recipients combined, representing a steady improvement over the past 20 plus years due to the improvements in early survival (Fig. 68.1). In particular, survival for patients retransplanted has improved and is currently similar to those transplanted for the first time (approximately 85% one-year survival in those surviving the first year).

The risk factors for death within one year and, in those surviving the first year, for death within five years are shown in Table 68.1. In the current era, the most significant risk factors for death post cardiac transplantation in the first year remain requirement for short-term extracorporeal mechanical support post transplantation, congenital heart disease as an indication for transplantation and presence of insulin-requiring diabetes mellitus pretransplant. After the first year, the highest risk factors for death within the first five years are need for retransplantation, the development of cardiac allograft vasculopathy and insulin-requiring diabetes mellitus prior to transplantation.

The commonest causes of death up to 30 days, in the first year and up to five years, are shown in Table 68.2. Graft failure remains the commonest cause of death within 30 days, and includes ischemic/reperfusion injury, right heart failure and acute rejection. Beyond 30 days, infection becomes prominent as the commonest cause of death up to the first year (33% of deaths). After this timepoint, cardiac allograft vasculopathy is the most frequent cause of death, representing 30% of all deaths within five years post cardiac transplantation, closely followed by malignancy (22% of deaths).

Recipient selection

The current AHA/ACC recommendations on selection of adult patients for cardiac transplantation are set out in their

Table 68.1 Risk factors for mortality in first year post cardiac transplantation

	95% confidence interval
Risk factors for death within 1 year*	
Need for short-term extracorporeal mechanical support	2.11, 5.42
Adult congenital heart disease	1.47, 3.10
Insulin-requiring diabetes mellitus	1.02, 3.41
Mechanical ventilation at time of transplant	1.36, 2.46
Prior pregnancy	1.05, 1.57
Previous history of CVA	1.00, 1.67
Recent infection (within 2 weeks) requiring IV antibiotics	1.04, 1.55
LVAD *in situ*‡	1.05, 1.55
Prior sternotomy	1.05, 1.42
Risk factors for death within 5 years§	
Retransplantation	1.55, 9.57
Early-onset coronary artery vasculopathy (within first year)	1.55, 2.70
Diabetes mellitus pretransplant	1.25, 1.86
Treated infection during initial transplant hospitalization	1.12, 1.66
Treated rejection episode in first year	1.06, 1.50
Ischemic vs non-ischemic cardiomyopathy pretransplant	0.99, 1.45

practice guidelines for the management of chronic heart failure in the adult.[9] The primary focus is on patients with severe functional impairment and/or dependence on inotropic support. Rarely, recurrent malignant arrhythmias refractory to medical therapy and debilitating refractory angina pectoris secondary to severe non-revascularizable ischemic heart disease may be indications. Contraindications to cardiac transplantation are all relative and dependent on how modifiable they are before surgery. They include pulmonary disease, pulmonary hypertension, diabetes with complications, systemic disease (including malignancy) and peripheral vascular disease. Age is also included, but this is an area of controversy as data regarding outcomes in older recipients have been conflicting.[10,11] The indications for and contraindications to cardiac transplantation are summarized in Box 68.1.

Donor selection

Selection of a donor requires a number of criteria to be met. First, national (and/or regional criteria where these vary, as in the US) for brain death must be met. The ECG and the echocardiogram should be normal. If a donor older than 45 years is being considered, coronary angiography is performed to exclude significant coronary artery disease. Otherwise, the risk factor profile for coronary artery disease should be low and there should be no evidence of untreated acute infection or systemic malignancy. The HIV and hepatitis screens should be checked and confirmed negative. Potential donors with cardiac trauma are usually excluded.

The matching of a suitable donor to a recipient is dependent on a limited number of key issues.

Blood type

ABO matching is mandatory. Matching of rhesus status is not required.

Body size

Generally, the donor should be at least 80% of the body weight of the recipient.

Pulmonary vascular resistance

Where this is high (generally in excess of 4–5 Wood units) in the recipient, a larger donor heart is usually selected to ensure adequate right ventricular functional reserve. In addition to pulmonary vascular resistance, the pulmonary artery pressure is also considered, and in particular the assessment of reversibility of high pulmonary pressures seen in some patients with chronic heart failure.

BOX 68.1 Cardiac transplantation – indications and contraindications

Absolute indications
- Hemodynamic compromise secondary to heart failure
- Refractory cardiogenic shock
- Dependence on IV inotropic support for adequate organ perfusion
- Peak VO$_2$ <10 mL/kg/min
- Severely limiting non-revascularizable ischemic heart disease affecting daily living
- Recurrent symptomatic VT refractory to therapy

Relative indications
- Peak VO$_2$ 11–14 mL/kg/min with significant limitation of functional capacity
- Recurrent unstable angina refractory to current therapy
- Recurrently labile fluid balance/renal function in chronic heart failure despite full patient compliance with therapy

Insufficient indications
- Presence of the following without other indications for transplantation:
  ○ Impaired LV systolic function
  ○ Previous history of class III–IV heart failure
  ○ Peak VO$_2$ >15 mL/kg/min

Contraindications (all relative)
- Pulmonary hypertension (must have evidence of significant reversibility at right heart catheterization)
- Age (controversial – see text)
- Parenchymal lung disease with significant pulmonary function abnormalities (<50% predicted)
- Co-existent systemic illness (e.g. malignancy, infiltrative disorders, infection)
- Acute pulmonary embolus
- Severe peripheral vascular disease
- Irreversible renal and hepatic dysfunction
- Diabetes with severe end-organ damage
- Severe obesity
- Severe osteoporosis
- Psychosocial issues
- Drug addiction, including nicotine

Recipient stability

Where the recipient is unstable (status 1 vs status 2), the urgency of finding a suitable donor heart occasionally requires some compromise on an "ideal" match as outlined above.

Geographic location of donor

This always needs to be considered to ensure the lowest possible cold-ischemic time of the heart after it has been explanted from the donor. Once this rises beyond four

hours, outcomes may be compromised. This is accentuated if there is significant hypertrophy of the donor organ.

Anti-HLA antibody titer

Due to the short time window of permitted cold-ischemic time in the setting of heart transplantation, unlike renal transplants, HLA cross-matching is only performed if titer of preformed antibodies in the recipient (PRA level) is significant. The PRA level is part of the routine pretransplant assessment of the recipient. This titer of recipient anti-HLA antibodies reflects the degree of sensitization of the patient to foreign antigens of HLA A, B and DR subtype. This is performed by incubating recipient serum in different wells with a random panel of donor lymphocytes. The result is represented as a percentage of total wells on a panel which show evidence of a positive reaction, hence the term PRA.[12] Numerous variations in methodology exist, and most recently have included flow cytometric virtual cross-match.[13] However, there is also variation in the interpretation of results – most programs consider a titer greater than 10% to be significant. Some institutions have considered any elevation or only titers greater than 20–25% to be of significance.[14]

The importance of the pretransplant PRA level has been known for some time and elevated PRA titers have been associated with increased risk of hyperacute rejection, antibody and cell-mediated rejection, and also cardiac allograft vasculopathy.[15,16] Therefore, patients with significantly elevated pretransplant PRA levels (>10% according to the American Society of Histocompatibility and Immunogenetics and UNOS) require HLA cross-matching to a donor organ.[17]

Operative details

The original operative technique described by Shumway involved removal of the native heart and anastomosis of the recipient heart at mid-atrial level bilaterally (Fig. 68.2).[18] This so-called "biatrial anastomosis" technique was shown to increase the incidence of atrial arrhythmia, right atrial thrombus and tricuspid valve dysfunction.[19,20] The "bicaval technique" involves preservation of the recipient pulmonary veins and anastomosis of a small cuff of recipient left atrial tissue to the donor left atrium, but retaining the anastomosis of the venae cavae and thus sparing integrity of the donor right atrium.[21] Recent evidence has shown short-term clinical benefits of the bicaval technique when compared to the biatrial technique, with enhanced preservation of atrial contractility, sinus node function and tricuspid valve competence, but there is insufficient evidence to date on long-term outcomes.[22]

Postoperative course

Immunosuppression

There are initial induction strategies and long-term chronic immunosuppression regimens. Induction therapy use has increased from 42% in 1995 to 52% in 2005, with use of antithymocyte globulin stable at 20–22% but the more traditional anti-T cell receptor monoclonal antibody OKT3 used in less then 3% of cardiac transplants in 2005.[6] The rationale for induction therapy is to reduce the risk of early acute rejection through enhanced immunosuppression and, in addition, the risk of postoperative renal dysfunc-

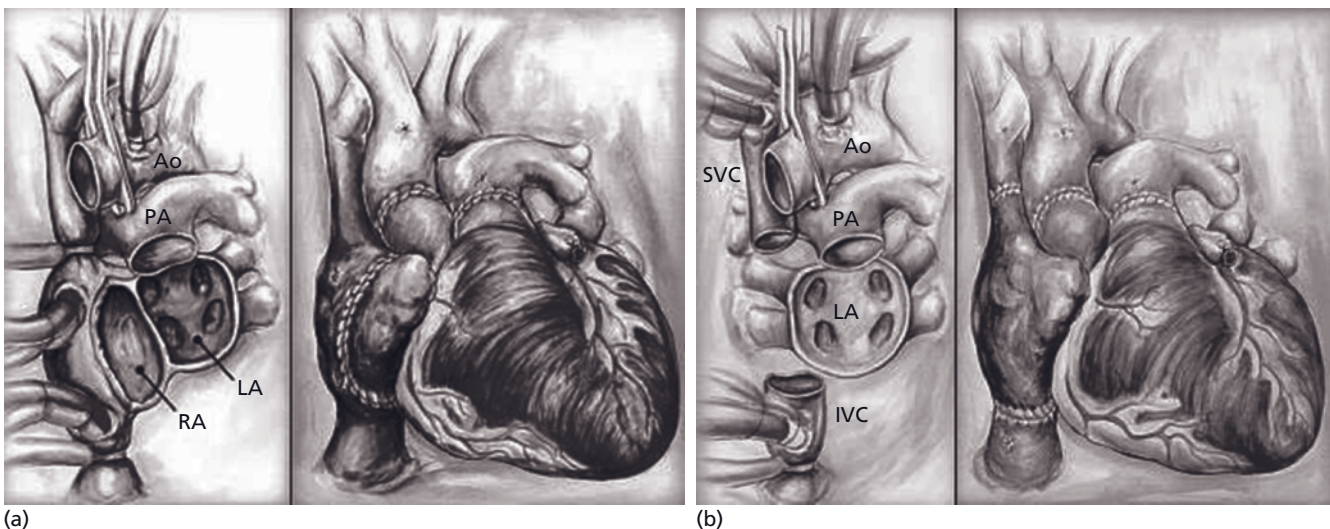
(a)　　　　　　　　　　　　　　　　　　　(b)


Figure 68.2 Standard Shumway anastomosis (a) and bicaval anastomosis (b).

tion through a delay in commencement of calcineurin inhibitor therapy.[23] However, induction therapy is not without risk and substantive evidence has linked it to an elevated risk of development of post-transplant lympho-proliferative disorder.[24] Therefore, the use of induction therapy varies, with many centers avoiding its use completely. The newer interleukin-2 antagonists are currently under evaluation.[26]

Maintenance immunosuppression varies among centers. The traditional model of a calcineurin inhibitor (ciclosporin or tacrolimus), an antiproliferative agent (azathioprine or mycophenolate) and a steroid is usual, but use of tacrolimus in preference to ciclosporin has increased in recent years.[6] Two randomized clinical trials have studied tacrolimus in direct comparison with ciclosporin. A European-based multicenter study on over 300 patients showed a significantly lower incidence of severe rejection in the tacrolimus-treated patients at six months but no difference in patient or graft survival at 18 months.[27] A smaller study from the US in which patients did not receive induction therapy showed no difference in survival or incidence of severe rejection between groups but a significantly lower incidence of renal dysfunction and hyper-triglyceridemia in the tacrolimus-treated patients.[28] In addition, a non-significant trend was observed towards a lower requirement for antihypertensive therapy in the tacrolimus group.

Mycophenolate is currently used in over 70% of transplanted patients at one year. The advantages of mycophenolate over azathioprine post cardiac transplantation include a reduced incidence of acute rejection and mortality, and possibly even of the incidence of cardiac allograft vasculopathy.[29] The underlying mechanisms for this benefit may include preferential anti-B cell activity compared to azathioprine, and reduced production of anti-HLA antibodies post transplantation.[30,31]

A recent study which compared the ciclosporin/mycophenolate/prednisone, tacrolimus/mycophenolate/prednisone and tacrolimus/sirolimus/prednisone combinations showed a significantly lower incidence of grade >3A or hemodynamically significant rejection at one year in the two tacrolimus-based therapy groups compared to ciclosporin-based therapy.[32] The tacrolimus/mycophenolate/prednisone combination resulted in the most optimal preservation of renal function and the lowest triglyceride levels.

Newer agents such as the mTOR inhibitor rapamycin (sirolimus) are increasingly used due to potent immunosuppressive capacity with minimal nephrotoxicity and possible beneficial effects on the incidence of post-transplant cardiac allograft vasculopathy (CAV). Many centers are now switching patients from calcineurin inhibitors routinely as a renal-sparing maneuver.[33,34] An important side effect of sirolimus is impaired wound healing,[35] and therefore this agent cannot be used early post transplant.

Complications

Early complications

Early complications after cardiac transplantation include primary graft failure, acute and hyperacute rejection, arrhythmia, bleeding and infection.

Primary graft failure includes ischemic/reperfusion injury and right heart failure secondary to pulmonary hypertension. It still accounts for up to 40% of deaths within the first 30 days post cardiac transplantation.[6] Extended cold-ischemic time of the donor heart and elevated pulmonary vascular resistance in the recipient pre-transplantation are significant risk factors. Treatment usually requires inotropic support, use of vasodilators to reduce pulmonary and systemic afterload and occasionally mechanical support. In rare circumstances emergency retransplantation is required.

Hyperacute rejection is a rare form of early rejection which is seen as soon as the donor heart is initially perfused with blood from the recipient. This is due to a high titer of preformed donor-specific antibodies in the recipient resulting in severe microvascular injury and thrombosis, with loss of the graft.

Acute rejection is common and usually T-cell mediated (cellular), but sometimes is due to recipient antibodies to donor antigens (humoral). Interestingly, the most recent ISHLT analysis has shown that current practices with induction therapy impact little on this problem. In fact, patients treated with OKT3 induction therapy had more acute rejection episodes in the first year post transplant than patients treated with other forms of induction therapy (i.e. antithymocyte globulin or anti-IL2 antibodies) or no induction therapy at all.[6] Tacrolimus may be superior to ciclosporin early post transplant with fewer rejection episodes in the first year, especially in combination with mycophenolate.[27]

Acute rejection is usually asymptomatic unless fulminant and severe, but its detection is important as frequency of episodes correlates with reduced graft survival (and possibly with the incidence of cardiac allograft vasculopathy).[36] Therefore screening is required with frequent endomyocardial biopsy especially within the first three months post transplant. Alternative approaches are under investigation to reduce the number of endomyocardial biopsies which are associated with an increased risk of tricuspid valve injury. These include the use of microarrays for identification of key (candidate) genes upregulated and downregulated in early rejection.[37] Studies are ongoing to evaluate the utility of this approach for longitudinal analysis of patients in terms of rejection profile.[38]

The ISHLT grading system for acute cellular rejection was changed in 2004. Currently the following system is used (see Plate 68.1):

- Grade 0: no rejection (Plate 68.1a)
- Grade 1 R, mild: interstitial and/or perivascular infiltrate with up to one focus of myocyte damage (Plate 68.1b)
- Grade 2 R, moderate: two or more foci of infiltrate with associated myocyte damage (Plate 68.1c)
- Grade 3 R, severe: diffuse infiltrate with multifocal myocyte damage, with or without edema, hemorrhage or vasculitis (Plate 68.1d).

Humoral or antibody-mediated rejection (AMR) is less well recognized but is associated with an increased incidence of cardiac allograft vasculopathy and mortality.[36,39] Histologically, it is characterized by endothelial swelling and the presence of macrophages and neutrophils in the capillaries with fibrin deposition.[40] Currently, the ISHLT guidelines recommend staining for complement C3d and C4d deposition in interstitial capillaries and for CD68 to highlight macrophages within capillaries.[41] In general, only intense and diffuse (2–3+) staining is considered significant evidence of AMR (Plate 68.2). Analysis of patient serum for the presence of anti-HLA I and II antibodies is also recommended.[42] One recent series has shown that AMR is seen most commonly early post cardiac transplantation and often associated with elevated anti-donor HLA antibodies.[43] However, this is less common in patients developing AMR later in their post-transplant course, where, instead, it is associated with malignancy or recent infection, suggesting activation of antibody-mediated immunity by a new antigen present on an invading pathogen or expressed on tumor cells.[44]

Arrhythmia is common. Frequently, patients are tachycardic due to denervation of the donor heart. Atrial fibrillation can also occur. Bradycardia and junctional rhythms are not unusual, particularly when the cold-ischemic time of the donor heart is prolonged, resulting in sinus and atrioventricular nodal ischemia.[19] Occasionally (4–12% of cases), permanent pacemaker implantation is required before discharging the patient from hospital, and the DDDR mode may be preferable.[45]

Late complications

Coronary allograft vasculopathy (CAV) is the single complication of greatest impact on long-term outcome (see Table 69.2).[42] Allograft vasculopathy occurs in all transplanted solid organs with time.[46] In the transplanted heart, over 50% of adult recipients will have angiographic evidence of CAV at 10 years.[6] However, a high proportion of transplanted patients develop CAV only in the intramyocardial branches of coronary arterioles but with sparing of the smaller arterioles sampled on biopsy, thus making the diagnosis on angiography or endomyocardial biopsy difficult.[47]

Although there is evidence of some reinnervation of cardiac allografts, most transplant recipients do not experience anginal pain with myocardial ischemia or infarction. Therefore, CAV may present as sudden death due to silent myocardial infarction, congestive cardiac failure or arrhythmia.[48]

Risk factors for CAV include hypertension, younger age, male gender and pre-existing coronary artery disease in the donor. The protective effect of older donor age may reflect increased angiographic screening of older donors.[6] Additional risk factors include early and recurrent rejection[49] and metabolic risk factors including diabetes and hyperlipidemia.[37] The role of cytomegalovirus (CMV) infection is controversial – evidence dates back almost 20 years showing an association with CAV.[50,51] However, recent evidence has cast some doubt on the directness of this association.[52]

The diagnosis of CAV has traditionally employed coronary angiography often with intravascular ultrasound (IVUS).[53] However both modalities are limited, the first because CAV involves the entire coronary artery tree longitudinally, and therefore may be missed on angiography; the latter because IVUS only images the larger epicardial arteries and not the smaller vessels and branches. Modalities of additional value for detection of CAV include dobutamine stress echocardiography[54,55] and nuclear scintigraphy[55,56]; cardiac CT and contrast echocardiography may also prove useful in the future as techniques are refined.[57,58]

There is evidence for the role of statins in the prevention of CAV in animal models[59] and in humans.[60] Additional benefits of statins may include prevention of progression of post-transplant renal dysfunction.[61]

There is recent evidence that the use of mTOR inhibitors such as sirolimus (rapamycin) and everolimus, a synthetic derivative, may attenuate the progression of CAV.[34,62,63]

Malignancy is a common complication of long-term immunosuppression.[64] According to current ISHLT figures, by 10 years post cardiac transplantation, the prevalence of malignancy is 32%. Much of this is due to facilitation of chronic opportunistic infection by oncogenic viruses such as Epstein–Barr virus (EBV) in the case of post-transplant lymphoproliferative disorder, HHV8 in Kaposi's sarcoma and human papilloma virus in skin cancers.[65] All immunosuppressive agents have been implicated to some degree, with the possible exception of sirolimus, for which evidence is mounting that the risk of malignancy may be significantly lower.[66] Most of these cancers are skin related (61%), the remainder being solid tumors including prostate, lung, bladder, breast, cervical and renal (total 18%) and lymphoproliferative, including post-transplant lymphoproliferative disorder (PTLD) (6%).[6]

Skin cancer is a common cause of morbidity and rarely mortality post transplant and in the transplant recipient is often recurrent and more aggressive.[67–69] The risk of skin malignancy may vary with different immunosuppres-

sive regimens; recent evidence has suggested that ciclosporin may have a specific carcinogenic effect independent of its immunosuppressive effect[71] and the use of sirolimus as an alternative agent may be protective and may even induce remission of skin cancers in transplant recipients.[71,72]

PTLD has been strongly associated with EBV infection.[73] However, the risk of developing this condition is multifactorial, and also related to immunosuppression and impaired T cell immunity in the setting of foreign antigenicity from the transplanted organ.[74] Other risk factors that have been identified are younger recipient and donor age (<18 years)[75,76] and more than five acute rejection episodes post transplantation.[76] CMV infection may also be a risk factor.[77]

The largest series available on PTLD comes from the Israel Penn International Transplant Tumor Registry based at the University of Cincinatti, Ohio.[78] From their data on 274 cardiac transplant patients with PTLD, the authors reported a 50% mortality within one year. The commonest sites involved were the lung and lymph nodes (34% and 32%), followed by the gastrointestinal tract (24%), the liver (23%), central nervous system (13%), the spleen (11%) and the cardiac allograft itself (10%).

There have been no randomized controlled clinical trials of any treatments currently in use for PTLD. The first strategy employed is minimization of immunosuppressive therapy. The next step is usually anti-B cell monoclonal antibody therapy, most frequently given as rituximab, an anti-CD20 monoclonal antibody, which has had efficacy shown in small studies.[79] Another modality that has been used with success in a small number of patients is anti-IL6 antibody therapy.[80] Failing treatment described above requires salvage chemotherapy, and use of this strategy has recently been described in a small study.[81] A new but promising strategy, adoptive immunotherapy for PTLD, involves the administration of banked HLA-matched or autologous cloned EBV-specific cytotoxic T cells.[82] The results of the first Phase II multicenter clinical trial have been encouraging.[83]

Infection with both the usual community-acquired and opportunistic pathogens is increased in patients on chronic immunosuppression. Common infections include community-acquired pathogens such as common respiratory viruses (e.g. influenza, parainfluenza, respiratory syncytiovirus and adenovirus), and common bacteria such as streptococci, *Mycoplasma*, *Legionella*, *Listeria* and *Salmonella*. Vaccinations for influenza and pneumococcus are recommended but may have reduced efficacy. Endemic organisms such as histoplasma and coccidioides may also be seen in the US.

A specific aspect particular to the transplant population is the issue of reactivation of latent infection and, also, the possibility of acquired latent infection from the donor.

This extends mainly to reactivations of CMV, varicella zoster and herpes simplex virus. However, reactivations of tuberculosis, toxoplasmosis and, in endemic areas, histoplasmosis and blastomycosis may occasionally present.[84–86]

Postoperatively, prophylaxis against cytomegalovirus infection is routine, usually for a period of three months. The benefits of CMV prophylaxis include reduced incidence of acute and chronic rejection, and possibly of CAV and PTLD post transplant.[87] Ganciclovir is the antiviral agent with efficacy against CMV which has been most extensively studied.[88] The major side effect of ganciclovir is myelosuppression.[89] Valganciclovir is a valine ester of ganciclovir which has enhanced oral bioavailability and has proven efficacy as CMV pre-emptive therapy in cardiac transplant recipients.[90] It is rapidly hydrolyzed to ganciclovir, the active metabolite, through enzymes in the gut mucosa and hepatic cells. CMV resistance to ganciclovir (and valganciclovir) has been reported, however.[91] In these cases, foscarnet is the usual agent for CMV therapy but a major dose-limiting side effect of this agent is renal impairment.[89,92] Aciclovir has some efficacy against CMV proven in a meta-analysis of 12 randomized trials.[93] Like ganciclovir, its oral bioavailability is limited but enhanced when delivered as its valyl ester, valaciclovir.[89] Valaciclovir is approved in some European countries for CMV prophylaxis.[89]

The transmission of *Toxoplasma gondii* is a concern in cardiac transplant recipients who are *Toxoplasma* antibody seronegative who receive an organ from a seropositive donor. Therefore, it has been routine to administer anti-*Toxoplasma* prophylactic therapy to this group for at least three months, with pyrimethamine, sulfadiazine or folinic acid. This strategy has been challenged recently, however, as it has been shown that the rates of *Toxoplasma* reactivation in centers which do not employ anti-*Toxoplasma* prophylaxis in at-risk groups is negligible.[94] Efficacy for c-otrimoxazole (trimethoprim-sulfamethoxazole/TMP-SMX) against *Toxoplasma* has also been shown and many groups believe that use of this agent is adequate prophylaxis against both *Pneumocystis jiroveci* and *Toxoplasma*.[95] For cardiac transplant patients (as distinct from heart-lung recipients), antifungal prophylaxis is not routine and not supported by data from clinical trials to date.[96]

Renal insufficiency is seen commonly in cardiac and other solid organ transplant recipients and is multifactorial.[97] However, chronic calcineurin inhibitor therapy is often a major contributor.[98] Analysis of data from 1994 to 2006 has shown that the incidence of renal insufficiency in cardiac transplant recipients has been increasing: at 10 years post cardiac transplant 98% of patients have hypertension, and 14% of patients have renal insufficiency (8% severe with creatinine >2.5 mg/dL and 5% on hemodialysis).[6] There is mounting evidence that replacement of

calcineurin inhibitor therapy with sirolimus permits recovery from calcineurin inhibitor-induced renal insufficiency and is associated with stable renal function at least in the medium term.[99,100] The risk of severe renal insufficiency post cardiac transplantation (i.e. creatinine >2.5 mg/dL or requiring renal replacement therapy) correlates with the presence of renal dysfunction, diabetes mellitus and patient age at the time of cardiac transplant.[6] Additional risk factors are a history of pretransplant hypertension, previous history of high PRA levels, inotropic therapy at the time of transplantation, infection requiring intravenous antibiotic therapy within two weeks of transplantation, and recipient weight.[6]

LVADs as long-term cardiac replacement therapy

At the present time, the gold standard of long-term cardiac replacement therapy remains cardiac transplantation, but the number of cardiac transplants performed is limited by donor organ availability.[101] Therefore, there has been great interest in the development of left ventricular assist devices as destination therapy for end-stage chronic heart failure.

Left venticular assist devices (LVADs) have been in use as a bridge to cardiac transplantation for over 20 years, and the Heartmate XVE ® device (Thoratec Corporation, California, US) was approved by the US Food and Drug Administration (FDA) for this purpose in 1994. Since that time, the Heartmate II ® axial flow device has been FDA approved for use as bridge to transplant in late 2007, and many other LVAD types are currently under evaluation for this indication.

The REMATCH study evaluated the long-term benefit of Heartmate XVE placement compared to optimal medical therapy in end-stage heart failure patients.[102] A 48% reduction in death from all causes was attributable to LVAD therapy compared to best medical therapy in this trial, and on this basis the Heartmate XVE was approved for use as destination therapy in 2002. However, two year survival in the LVAD group was only 23%, with a high incidence of device failure. Furthermore, early mortality was high in both groups of patients, and in this respect Lietz *et al.* showed that using a novel operative risk score encompassing severity of heart failure, nutritional status, renal function and RV function, the patients with the lowest risk had the best early survival.[103] This underlines the importance of patient selection. Up to the present time, the Heartmate XVE is the only LVAD approved for destination therapy in the US, but the Heartmate II continuous axial flow device, which expected superior durability, is under evaluation for this indication.

The newest generation of centrifugal pumps with a magnetically and/or hydrostatically suspended internal spinning rotor have eliminted the need for internal bearings and promise the greatest durability. These pumps such as the Ventrassist ® (Ventracor, Sydney, Australia), Duraheart ® (Terumo Heart, Michigan, US) and HVAD ® (Heartware, Sydney, Australia) devices, are currently under evaluation in clinical trials.

Conclusion

Cardiac replacement therapy in end-stage heart failure is at a crossroads. The art and science of cardiac transplant medicine have been perfected since the first transplant in 1967 and outcomes continue to improve. However, the number of transplants being performed worldwide is far outnumbered by the number of potential candidates, as donor hearts are a very limited resource. Advances in destination device therapy may provide a viable long-term solution for many patients, with either support of the native heart by LVAD therapy or even possibly complete replacement of the heart by a prosthetic device. Completely implantable devices that offer the patient as normal a life as possible with a minimal risk of infection are likely to have the greatest impact in this field. The potential of cell therapy is also under evaluation and the field is still in its infancy but evolving. New insights in this field could potentially open a whole new era in therapy for this devastating condition.

69 Renal dysfunction

Johannes F E Mann[1] and Ernesto L Schiffrin[2]

[1] Munich General Hospital, Munich, Germany
[2] Sir Mortimer B Davis-Jewish General Hospital, Montreal, Quebec, Canada

Chronic kidney disease (CKD) affects many people with cardiovascular disease (CVD) but is often undetected. If present in people with CVD, CKD predicts worse cardiovascular outcomes independent of other cardiovascular risk factors. This chapter reviews the evidence regarding proper detection of CKD, gauging the cardiovascular risk associated with CKD, and treating people presenting with both CVD and CKD. As this book is primarily directed at "cardiovascular" readers, we will not discuss underlying diseases causing CKD and the specific therapy of those renal diseases. Rather, we suggest that all people with CKD (and anyone with proteinuria) should be assessed at least once by a nephrologist (and a diabetologist if diabetes is also present) who can identify the underlying reasons of CKD and suggest strategies to halt or inhibit its progression to end-stage renal disease.

Definition of chronic kidney disease

In 2002, efforts of the National Kidney Foundation (USA) and the international KDIGO group (Kidney Disease Initiative to improve Global Outcomes) led to clinical practice guidelines for the evaluation, classification and risk stratification of CKD.[1] CKD was defined as any renal disease lasting for more than three months with histologic or other signs of renal damage. As depicted in Table 69.1, glomerular filtration rate (GFR) may be decreased or normal in affected people.

Kidney damage can be detected in several ways including urinary dipstick and sediment, measurement of urine protein, kidney histology, imaging studies or measurement of markers of GFR such as serum creatinine or cystatin C.

In the vast majority of cases in adults not presenting with kidney-related symptoms, a reduced GFR or an elevated urinary protein excretion will identify CKD.

Glomerular filtration rate

Normal GFR in young men and women averages about 130 and 120 mL/min/1.73 m[2] respectively.[2] After age 40, people tend to lose GFR by approximately 1 mL/min/year; this mean value, however, shows a wide variability, substantially depending on the presence or absence of atherosclerotic vascular disease.[3,4] GFR changes little in elderly people without renal and atherosclerotic vascular disease and is regulated in health and disease by various factors. For example, sodium and protein intake increase GFR and sympathetic drive decreases it.

Exact measurement of GFR by inulin or iothalamate clearance is cumbersome and costly and therefore not practical in routine clinical practice. Serum creatinine is the usual clinical indicator of GFR. However, this indicator (an amino acid derivative of 0.11 KD) is imperfect. First, creatinine is excreted by both glomerular filtration and tubular secretion; second, serum creatinine concentration depends substantially on muscle mass such that individuals with very low muscle mass may exhibit terminal renal failure at serum creatinine concentrations barely above 2 mg/dL (175 μmol/L). Third, dietary intake of creatinine with meat may also affect serum levels. Indeed, GFR may decrease by up to 30% without a corresponding increase in serum creatinine above the normal range.

Despite those obvious shortcomings of serum creatinine as a marker of GFR, it is possible to estimate GFR (eGFR) from the serum creatinine using various formulas that include age, sex, race or weight (Box 69.1).[2] The Cockcroft–Gault (CG) formula was developed to calculate creatinine clearance from regression computation of data in 249 people with GFR of about 30–130 mL/min, comparing serum creatinine and creatinine clearance. The CG formula

Table 69.1 Stages of chronic kidney disease (CKD), its approximate prevalence in Western societies and associated cardiovascular risk

Stage	GFR (mL/min/1.73 m²)	Approx. prevalence (% of population)	CV risk* (odds ratio)
1	>90	3	Depends on degree of proteinuria
2	60–90	3	1.5
3	30–59	4	2–4
4	15–29	0.2	4–10
5	<15	0.1	10–1000

In population studies, GFR was calculated from serum creatinine or cystatin C. The prevalence data are approximated from surveys in North America. The odds of the cardiovascular risk vary substantially with age. For example, the cardiovascular risk of a 20-year-old dialysis patient is about 1000-fold higher than the risk of his age group; at the age of 70 years, it is about 20-fold.

BOX 69.1 Formulas to estimate glomerular filtration rate

Modification of Diet in Renal Disease (MDRD) formula:

$$GFR\ (mL/min/1.73\ m^2) = 186 \times Screa^{-1.154} \times age^{-0.203} \times 0.742\ \text{if female} \times 1.21\ \text{if black}$$

Cockcroft and Gault formula:

$$Ccrea\ (mL/min) = \frac{(140 - age) \times weight \times 0.85\ \text{if female}}{72 \times Screa}$$

Formulas derived from serum cystatin C:

$$GFR\ (mL/min) = 74 : 8 \times (Cystatin\ C)(mg/L)^{-1.333}\ \text{(Dade-Behring kit)}$$

$$GFR\ (mL/min) = 89 : 12 \times (Cystatin\ C)(mg/L)^{-1.675}\ \text{(Dako kit)}$$

Screa, serum creatinine; age in years, weight in kg; Ccrea, creatinine clearance; GFR, glomerular filtration rate.
There are several formulas developed from the MDRD data set. Above we give the most often used abbreviated formula. Slightly more exact is the following MDRD formula: GFR (mL/min/1.73 m²) = 170 × Screa $^{-0.999}$ × age $^{-0.176}$ × Surea $^{-0.1760}$ × Salbumin $^{+0.318}$ × 0.762 if female × 1.180 if black.

tends to overestimate GFR, especially at low GFR. The MDRD (Modification of Diet in Renal Disease study) formula was based on the relationship between serum creatinine and GFR measured by iothalamate clearance in 1628 people with an elevated serum creatinine. This formula appears to be more accurate than the CG formula, at least in ambulatory people with GFR <60 mL/min, and has been used in people with several renal diseases and different ethnicity. Of note, the calculation of eGFR improves if assays for serum creatinine are calibrated against a standard; a national program for such calibration is in place in the USA. The MDRD tends to underestimate GFR at levels >60 mL/min and may vary from "true" GFR based on inulin clearance by up to 30%. Indeed, above an eGFR of 60 mL/min, the variance of eGFR is so large that many laboratories do not report exact values and just note that the value is >60. The latter approach appears to be reasonable; otherwise eGFR calculations would inflate the number of people with the label "CKD". Thus, people with an eGFR >60 mL/min should only be classified as having CKD if there is other evidence of CKD such as increased urinary protein excretion or kidney damage detected with imaging or histologic studies.

Cystatin C in serum is an alternative to creatinine; it is a 13 KD protein, freely filtered by the glomerulus with extensive tubular reabsorption and catabolism. Its generation as a nuclear degradation product appears to be more stable than the generation of creatinine. Recent data suggest that serum concentration of cystatin C may be a better marker of GFR than creatinine-based eGFR at GFR >60 mL/min. Cystatin C measurements are much more expensive than creatinine (6–10-fold difference) and further research is necessary to establish the role of cystatin C in clinical medicine.

Urine protein

If the kidney leaks proteins, this may reflect underlying renal disease or, in the case of small amounts of albumin, generalized endothelial dysfunction. Common renal diseases are glomerulonephritis, inherited diseases such as polycystic kidney disease, diabetic nephropathy and nephrosclerosis due to smoking or hypertension. Laboratories typically measure either all proteins in the urine or albumin alone; dipsticks detect only albumin. A variety of assays are available and day-to-day variation of urinary protein excretion is substantial, depending on factors such as posture and physical activity. Therefore, urinary protein excretion should be measured more than once to detect kidney damage. Moreover, when urinary protein excretion is measured, it should either be expressed as a ratio to urine creatinine (to account for urine concentration) or as a timed specimen (e.g. per 12 or 24 hours).[1]

Urinary protein excretion is a very strong predictor of cardiovascular risk. This association is progressive; that is, the risk of incident cardiovascular outcomes increases with urinary protein excretion, even within the "normal" range.[5] The term microalbuminuria stems from studies in diabetes and indicates a threshold at which the risk for overt diabetic nephropathy (macroalbuminuria and/or renal insufficiency) suddenly increases severalfold. Such a threshold does not exist in the relationship between urinary albumin excretion and cardiovascular risk. As the term microalbuminuria is well established in clinical medicine, we use it here to describe renal damage and its association with cardiovascular risk.

Low GFR and high urinary protein excretion often coincide. In many studies, however, only one of these standard markers of renal damage is reported, usually serum creatinine. The few studies that documented both parameters suggest that both of these renal-related cardiovascular risk factors are additive and independent of each other.[6,7]

When to measure eGFR and urinary protein excretion?

There is no general consensus regarding when to measure kidney-related cardiovascular risk factors. In general, serum creatinine is measured whenever blood chemistry is ordered. Guidelines support the measurement of serum creatinine whenever a cardiovascular risk profile is evaluated in a person. Urinary protein excretion is usually ordered in the evaluation of kidney disease or at regular intervals in people with diabetes. In a cardiovascular setting, both eGFR and urine protein may be ordered if one is unsure whether to start therapies to prevent cardiovascular disease in a given patient. The presence of increased urinary protein excretion or a low eGFR may then justify such therapy. However, data regarding the additional value of proteinuria and eGFR on top of classic cardiovascular risk are lacking, and some analyses suggest that these measurements are of limited value after accounting for classic cardiovascular disease risk factors.

Population-wide impact of cardiovascular risk associated with renal dysfunction

GFR

A recent systematic review of 39 studies comprising approximately 1.4 million people followed for a median of 4.5 years reported that cardiovascular mortality was increased with reduced eGFR in all but three studies. The univariate risk increase was twofold (range 1–5-fold); this risk was somewhat attenuated after multivariate adjust-
Figure 69.1 Relationship between estimated glomerular filtration rate (eGFR) and cardiovascular outcomes in a general population of >1 million people of a health maintenance organization in California, followed for 2.5 years. Abscissa: GFR estimated from serum creatinine at baseline. Ordinate: relative risk % for death (light gray), for a major cardiovascular event (black) and for hospitalization (gray). Risk of people with a baseline GFR >60 mL/min/1.73 m² was set at 100%. (Modified after Go et al[9], with permission.)

ments.[8] A low eGFR is not consistently associated with cardiovascular risk in the general population[8] due to the low number of cardiovascular outcomes and concomitant low power. However, one study of >1 million participants of the general population in California reported a continuous increase in cardiovascular risk (adjusted hazard ratio) for eGFRs between 45 and 59 mL/min to <15 mL/min from 1.4- to 3.4-fold[9] compared to an eGFR of >60 mL/min (Fig. 69.1); the risk increase for mortality and hospitalization was steeper. Of note, the prevalence of an eGFR <60 mL/min in the general population, especially above age 50, is in the range of 5–10%.[10] Conversely, in people with known cardiovascular disease, the prevalence of an eGFR <60 mL/min is higher than in the general population, in the 15–20% range.[7,10]

Proteinuria

The association of micro- and macroalbuminuria with cardiovascular risk was reported in about 20 longitudinal studies.[7] The overwhelming majority of studies found that both micro- and macroalbuminuria were independent predictors of cardiovascular risk with hazard ratios of 1.5–3.[5,11–13] The association is found in the general population and in high-risk populations. However, the prevalence of increased levels of urinary protein excretion is only 4–7% in the general population and higher (10–30%) in people at high cardiovascular risk, especially in the presence of diabetes.[5,7,12] The largest study in the general population with over 40 000 participants reported that a doubling of urinary protein excretion is associated with a 29% increase of the

relative risk for cardiovascular outcomes (Fig. 69.2).[12] In a study of about 10 000 people with known cardiovascular disease or at high risk, any increase in urine albumin excretion by 0.4 mg/mmol creatinine (approx. 3.6 mg/g) was associated with a 6–7% increase in cardiovascular events, myocardial infarction, stroke and cardiovascular death.[5]

The predictive power of classic cardiovascular risk factors and of eGFR or proteinuria was compared by multivariate techniques. Kidney-related factors exhibit hazard or odds ratios that are not different, in absolute terms, from classic risk factors. Moreover, as noted above, when assessing cardiovascular risk in an individual, the renal-related factors add modestly to the classic risk factors.

Moderately elevated serum creatinine and urine albumin are associated with a doubling in the risk for major cardiovascular events. These two renal-related risk factors are additive, are independent from classic risk factors but add only modestly to classic risk factors for risk calculation.

Why are low GFR and proteinuria risk factors for vascular disease?

The association of CKD and cardiovascular risk may reflect the (unjustified) fact that people with renal damage receive less therapy to prevent or treat cardiovascular disease than people with no renal damage (Fig. 69.3).[14] Renal damage may also be a marker of the severity of underlying vascular disease.[10,15] In other words, the associated hypertension or peripheral vascular disease may be more severe in people with renal damage. Such differences are not accounted for in adjusted analyses and can be considered as residual confounding. Furthermore, the mechanisms underlying renal and cardiovascular damage are similar. Finally, a reduced GFR accelerates atherosclerosis and vascular calcification.

One of the primary pathophysiologic mechanisms involved in accelerated vascular damage in CKD may be endothelial dysfunction.[16] A number of factors that adversely affect endothelial function are altered in CKD, including activation of the renin-angiotensin system,

Figure 69.2 Relative risk for death in a general population from a Dutch town, followed for seven years. (From Hillege *et al.*[32].)
Figure 69.3 Thirty-day mortality in 130 000 people admitted to hospital for acute coronary syndrome. Data are stratified according to creatinine clearance, calculated from serum cratinine at admission according to Cockcroft and Gault. HR, hazard ratio comparing people treated/not treated with the respective drug. (Modified after Shlipak *et al*, *Ann Intern Med* 2002.)

increased oxidative stress, signs of low-grade inflammation with increased circulating cytokines, dyslipidemia and elevated asymmetric dimethylarginin (ADMA), an inhibitor of NO formation.[17–21] Many of those factors occur early in the course of CKD and precede the appearance of vascular and valvular calcifications found in late CKD.[21]

Implications for therapy

The use of cardiovascular drugs in people with kidney disease, specifically with renal insufficiency and a GFR <60 mL/min, may be associated with potential adverse events and potential benefits. We will discuss both aspects and make some general remarks.

Inhibitors of the renin-angiotensin system (RAS), including ACE inhibitors and angiotensin receptor blockers, are given to many people with cardiovascular disease. Acute renal failure and hyperkalemia are among the most feared adverse events of those drugs. Based on the results of the HOPE, ONTARGET and TRANSCEND studies, it appears reasonable to measure serum creatinine and serum potassium in the first few weeks after initiating therapy with an inhibitor of the RAS. In the run-in phase of these three large trials, therapy with an inhibitor of the RAS had to be stopped within the first 2–4 weeks because of increasing serum creatinine in about 0.2% and because of hyperkalemia in about 0.8%.[22,23] During long-term therapy with inhibitors of the RAS, acute renal failure, specifically dialysis dependent, and hyperkalemia were rare (<0.2% during 4–5 years) and not different between inhibitors of the RAS and placebo. As a rule, acute renal failure was related to conditions of potential fluid deprivation.[24] In people with chronic heart failure, the risks of acute renal failure and of hyperkalemia appear to be higher than indicated above, about 1.5% and 0.8% respectively over two years of follow-up and even higher in people with acute heart failure.[25] In people with chronic heart failure, the combined use of ACE inhibitors and angiotensin receptor blockers is sometimes considered. That combination approximately doubles the risk of acute renal failure compared to monotherapy with either ACE inhibitors or angiotensin receptor blockers (ARB).[24,25] Based on pathophysiology, the risk of acute renal failure likely depends on RAS activation. Under conditions of reduced renal perfusion, high renin levels contribute to maintain GFR. Such conditions are typically observed with advanced heart failure, with intravascular, specifically intra-arterial fluid deprivation and with the use of high doses of diuretics. Case reports suggest that the combination of NSAIDs with ACE inhibitors or ARB further increases renal risks when there is fluid deprivation or low cardiac output, especially in people with vascular disease and potentially reduced capacity for renal autoregulation.

> ### Recommendations: Grade C
>
> - Serum creatinine and potassium should be checked in the first weeks after initiating therapy with inhibitors of the renin-angiotensin system, and during ongoing therapy if there are new signs of intravascular fluid deficiency.
> - The concomitant chronic therapy with inhibitors of the renin system and of NSAID is discouraged.

What are the recommendations for the use of inhibitors of the RAS in people with CV disease? It may be wise to inform people treated with inhibitors of the RAS to stop treatment when there is diarrhea, other instances of volume depletion or high-grade fever and to avoid NSAID use apart from low-dose aspirin. When initiating therapy with inhibitors of the RAS or when increasing doses of diuretics, serum creatinine and potassium should be checked.

In chronic heart failure, the potassium-sparing diuretics spironolactone or eplerenone are successfully used. Those aldosterone receptor blockers increase the risk of hyperkalemia with an associated mortality, specifically when used in people with renal insufficiency and at doses higher than used in randomized trials. A cautious recommendation is to avoid such diuretics in people with renal insufficiency. That may not be helpful if people with heart and renal failure exhibit hypokalemia and related arrhythmia. No data are available on how to manage these people. Small trials suggest that hypokalemia is more effectively treated by spironolactone and other potassium-sparing diuretics than by oral potassium supplements. At 25–50 mg/d of spironolactone, serum potassium will increase by approximately 1 mmol/L.

Diuretics should be given at higher doses in people with renal insufficiency, preferentially loop diuretics. With decreasing GFR, less sodium is filtered, so less sodium can be prevented from tubular reabsorption by diuretics. Thus daily negative sodium balance of diuretics in renal insufficiency is reduced and it will take longer to remove excessive sodium and fluid. Sodium output can be easily monitored by collecting urine output. If sodium removal is too slow, hemofiltration may be considered but this procedure is invasive and very expensive. When initiating high-dose diuretic therapy or when large fluid shifts are observed in patients according to a weight change, close monitoring of electrolytes and serum creatinine is mandatory. Negative sodium and volume balance may massively stimulate

vasopressin secretion and thirst. Those changes and the reduced free water clearance in renal insufficiency herald a substantial risk of hyponatremia.

Recommendations: Grade B

- Advanced heart failure may be associated with stimulation of thirst and vasopressin secretion. This stimulation may intensify when diuretic therapy is boosted. Hyponatremia in this situation can be prevented by fluid restriction and possibly by vasopressin antagonists.

Anticoagulants and platelet inhibitors can be used in people with renal insufficiency. Low GFR is associated with disordered coagulation and more bleeding. Some anticoagulant drugs, including heparins, act longer with lower GFR. In one study with clopidogrel, the cardiovascular benefits of clopidogrel in the acute coronary syndrome were preserved in those with renal insufficiency but the relative risk for bleeding associated with clopidogrel was actually less than in participants with normal renal function.[26] There are no further data on the balance of benefits and adverse events of anticoagulants in people with CV diseases and concomitant renal insufficiency, so no evidence-based recommendations can be given.

To our knowledge, beta-blockers have not been analyzed for their cardiovascular benefits in subgroups with renal insufficiency. Some of those agents have a prolonged action with decreasing GFR. This prolonged half-life is usually not a clinical problem since the action of beta-blockers can be easily monitored by heart rate.

Statins have similar benefits and adverse effects in people with and without renal insufficiency, according to a thorough meta-analysis.[27] In people with diabetes and treated by chronic dialysis, however, a large trial showed no significant CV benefit of statins. Some statins are partially eliminated via the kidney. Due to a wide safety margin, only minor dose adjustments are suggested with severe renal insufficiency.

From the above it appears reasonable to administer standard CV therapy in people with renal disease but data from registers found that such people receive standard cardiovascular care less frequently than those without renal disease.[10,14] People with renal diseases derive at least as much benefit from standard cardiovascular care as do people without renal damage.[14,24,27,28]

Invasive therapy for acute coronary syndromes clearly saves lives. Such beneficial therapy is often withheld in the presence of renal damage. There is no evidence that benefit or harm of invasive therapy is different in people with and without renal damage. One study found no difference in the relative risks of percutaneous coronary intervention (PCI) in acute coronary syndrome in people with normal and low GFR.[28] Clearly, measures to prevent contrast nephropathy should be instituted. However, the incidence of clinically significant contrast nephropathy is rare except in people with diabetes *and* both a low GFR *and* macroalbuminuria. In these individuals the risk of dialysis dependency after contrast injection is substantial.[29]

Recommendations: Grade B

- Standard cardiovascular therapy is as effective in people with moderate-to-severe renal insufficiency as in people with normal renal function, according to subgroup analyses of major outcome trials.

On the basis of observational data, it has been proposed to target lower blood pressure values in persons with CKD than in the general population, namely below 130/80 mm Hg and even below 125/75 mm Hg if urine protein is above 1 g/d or above 1 g/g creatinine.[10] There is only epidemiologic evidence to support those recommendations.

Many nephrologists assume that proteinuria reflects kidney damage and contributes to progressive renal damage by itself,[1] due to the increasing demand on the resorptive capacity for protein of renal tubular cells. Such tubular cells will then produce cytokines that initiate interstitial renal inflammation, attracting macrophages which will eventually transform into fibroblasts.[30] This hypothesis assumes that any reduction in proteinuria will halt progressive renal damage. Whereas this is consistent with data in both humans and experimental animals, effects of different proteinuria targets have never been tested in a clinical trial.

All the above considerations do not apply to people with end-stage renal disease. In this specific subgroup, mechanisms of vascular disease and of cardiovascular death are different, as are their risk factors.

70 Pulmonary hypertension

Brendan P Madden
St George's Hospital, London, UK

Introduction

Pulmonary hypertension is defined as a mean pulmonary artery pressure of greater than 25 mm Hg at rest or 30 mm Hg with exercise. The term pulmonary arterial hypertension (PAH) denotes a series of apparently unrelated disorders many of which share the histopathologic entity of plexogenic pulmonary arteriopathy (PPA). Typically in PAH the mean pulmonary capillary wedge pressure is less than 15 mm Hg.

Examples of PAH include idiopathic PAH, familial PAH and pulmonary hypertension associated with scleroderma, hepatic cirrhosis, HIV infection and Eisenmenger's syndrome. It has also been described in association with ingestion of slimming agents, e.g dexfenfluramine, and with other unusual conditions including pulmonary veno-occlusive disease and glycogen storage disorders (Box 70.1).

Pulmonary hypertension can also occur in association with cardiac and respiratory diseases. Examples of the former include left ventricular failure, chronic left atrial hypertension and mitral valve disease and of the latter chronic obstructive pulmonary disease (COPD), interstitial lung disease, disorders of pulmonary development and sleep apnea syndrome. Chronic thromboembolic pulmonary hypertension (CTEPH) affecting proximal or distal pulmonary arteries may occur for unknown cause or may be associated with thrombophilia abnormalities such as protein S and C deficiency or abnormalities in factor V. Prothrombotic states can also accompany connective tissue disorders or malignancy. In addition, pulmonary hyperten-

sion can result from other unusual conditions, e.g. lymphangioleiomyomatosis (see Box 70.1).

Idiopathic PAH was initially described by Romberg as "sclerosis of the pulmonary arteries" over 100 years ago.[1] Dresdale and colleagues termed the condition primary pulmonary hypertension some 50 years later.[2] Wood observed a reduction in pulmonary arterial pressure in response to intravenous administration of acetylcholine and suggested that a "vasoconstrictive factor" was responsible for its pathogenesis.[3] Subsequently clinical experience with vasodilator therapy was disappointing and this was consistent with reports from Wagenvoort and Wagenvoort[4] (4) and Caslin and colleagues which suggested that more extensive vascular injury and remodeling occurred in this process (Fig. 70.1).[5-7] Over the years that followed the term PAH was defined as an umbrella term to link a number of apparently different disease processes which shared similar histopathologic appearances and were associated with severe elevation in pulmonary vascular resistance (PVR). Authors described pulmonary hypertension occurring in association with ingestion of aminorex fumarate (an appetite suppressant) in Western Europe,[8] in association with connective tissue disease,[9] hepatic cirrhosis and portal hypertension[10] and with HIV infection.[11] Traditionally idiopathic PAH was described in young females although with increasing awareness, the condition is now diagnosed in patients beyond the fourth and fifth decades of life. The incidence and prevalence of idiopathic PAH are estimated to be four per million and ten per million of the population respectively. Overall, the prevalence of PAH is estimated to be in the region of 100 per million of the population. The incidence and prevalence of pulmonary hypertension in patients with cardiac and respiratory disorders are not precisely known although they are believed to be considerably higher than for PAH. PAH is associated with a poor survival and a poor quality of life. There is no cure, limited treatment options and incomplete understanding of the disease.[12,13]

Pulmonary arterial hypertension (PAH)
- Idiopathic PAH
- Familial PAH
- Related to:
  - Connective tissue diseases
  - HIV
  - Portal hypertension
  - Anorexigens
  - Congenital heart diseases
- Pulmonary capillary hemangiosis
- Pulmonary veno-occlusive disease
- Others (e.g. glycogen storage disease, splenectomy)

Associated with left heart disease
- Atrial or ventricular dysfunction
- Valvular disease

Associated with lung disease/hypoxemia
- COPD
- Interstitial lung diseases
- Sleep-disordered breathing
- Developmental abnormalities
- Chronic exposure to high altitude

Associated with chronic thrombotic and/or embolic disease
- Obstruction of proximal pulmonary artery
- Obstruction of distal pulmonary artery
- Non-thrombotic pulmonary emboli (e.g. tumor)

Miscellaneous
- Histiocytosis
- Lymphangioleiomyomatosis
- Sarcoidosis
- Compression of pulmonary vessels (adenopathy, tumor, mediastinal fibrosis)

Figure 70.1 Pulmonary arteriole from a patient with PAH showing extensive reduction in vessel lumen as a consequence of smooth muscle cell migration from the inner half of the media. Once in the lumen, the cells become myofibroblasts and proliferate. Note also a surrounding inflammatory infiltrate (H&E, medium power).

Pathology

PPA occurs in a select group of disorders. It is unclear why this histopathologic entity occurs although it is possible that the lung has only a finite number of responses to injury which feed into final common pathway mechanisms. This may explain why similarities occur in patients with conditions such as obliterative bronchiolitis following lung transplantation and those with obliterative bronchiolitis associated with rheumatoid lung disease or respiratory syncytial virus infection in childhood. Similarly many conditions have been implicated as causative in the acute respiratory distress syndrome yet the pathology is similar regardless of etiology.

In PPA the pathophysiologic triggers are not clear. Following initial vasoconstriction smooth muscle migration occurs from the inner half of the media of muscular pulmonary arterioles into the vessel lumen where these cells become myofibroblasts capable of laying down either smooth muscle or fibrous tissue. Once in the lumen, the cells proliferate in a concentric fashion and ultimately obliterate the lumen (see Fig. 70.1). As this process develops the radius of the vessel lessens and in accordance with Poiseuille's law, the resistance to flow increases. When sectioned, these vessels have the appearance under the microscope of a cut onion and the process has been described as "onion skin proliferation". Interestingly, in COPD smooth muscle cells migrate into the vessel lumen but migrate in a longitudinal fashion and although reduced, there is less compromise to the radius than with PPA. At proximal points of weakness in the vessel (often at areas of branching), the vessel distends and ruptures. Hemorrhage follows and primitive blood vessels grow into this area in a haphazard or plexiform arrangement. The combination of concentric laminar intimal ("onion skin") proliferation and plexiform lesions is referred to as PPA. Some authors believe that plexiform lesions represent a type of collateral circulation.

It is not clear why these particular changes occur in diseases with such diverse etiology and clinical presentation. Immunoreactive cells in the lung for gastrin-releasing peptide and calcitonin may be important factors in the smooth muscle cell migration process.[14] Endothelial injury as a consequence of damage by toxins or genetic factors may also be important and indeed, overexpression of endothelin-1 and reduced levels of prostacyclin synthase have been noted in plexiform lesions.[15–20] There is ongoing extensive research into endothelial dysfunction in patients with PAH.

Survival

The natural history of idiopathic PAH has been described and the National Institute of Health Registry followed up 194 patients with this condition enrolled at 32 medical centers between 1981 and 1985. The median survival was 2.8 years with one-, three- and five-year survival rates of 68%, 48% and 34% respectively.[21] Indeed, actuarial five-year survival for untreated patients with PAH who are in class IV New York Heart Association (NYHA) status is significant lower than that for patients with lung, breast, prostate, colon and gastric carcinoma. The following factors are useful in predicting mortality in PAH:

- etiology
- unctional capacity (NYHA or PAH class)
- xercise capacity (unencouraged six-minute walk test)
- hemodynamics (severity of right ventricular dysfunction)
- echocardiographic parameters.

It appears that survival for patients with PAH associated with scleroderma is worse than for patients with idiopathic PAH[22] while survival for patients with PAH associated with HIV infections is similar to those patients with idiopathic PAH.[23] Interestingly, in a number of studies most deaths in patients with HIV infection and PAH were related to PAH. Patients with congenital heart disease may have a better prognosis than those with idiopathic PAH although further experience is necessary to validate this.[24]

As in adults, the prognosis in children with PAH is linked to the underlying etiology.

The incidence and prevalence of pulmonary hypertension in patients with cardiac and respiratory disorders are not precisely known but are believed to be considerably higher than for the causes of PAH. In these conditions expert medical treatment focusing on the underlying cardiac, pulmonary or hematologic abnormalities is key to the management of the co-existing pulmonary hypertension, at least in the first instance.

Higher NYHA functional class (III or IV) is associated with increased mortality in both treated and untreated patients with idiopathic PAH.[21,22,25] Failure to improve NYHA functional class or deterioration in NYHA functional class while on therapy may of itself be predictive of a poor outcome. The unencouraged six-minute walk test is an easy-to-perform and reproducible modality of assessing exercise capacity in patients with PAH and may be an independent predictor of survival for these patients. One study suggested that a six-minute walk test of less than 332 meters was associated with a significantly lower survival rate than for patients whose six-minute walk test exceeded this distance.[26]

In patients with suspected pulmonary hypertension right heart catheterization is performed to confirm the presence and severity of pulmonary hypertension and to help establish the underlying diagnosis. Furthermore, right heart catheterization is required to guide therapeutic intervention. The PVR (mm Hg/L/min) is calculated as follows:

$$\frac{\text{Mean pulmonary artery pressure} - \text{mean pulmonary capillary wedge pressure}}{\text{Cardiac output}}$$

Echocardiography is an integral part of the evaluation of a patient with pulmonary hypertension. Common findings in patients with PAH include right atrial and right ventricular enlargement, reduced right ventricular function, paradoxic movement of the intraventricular septum and tricuspid regurgitation (Fig. 70.2). The presence of a pericardial effusion seems to be associated with a poorer prognosis.[27] Another indicator of an adverse outcome is an elevated Doppler echocardiography right ventricular index.[28]

Correlation between estimated pulmonary artery systolic pressure on echocardiography and at right heart catheterization is not always close. Echocardiographic measurements are usually dependent on assessment of the tricuspid regurgitant velocity and errors with this measurement and with subsequent formulae employed often contribute to inaccuracy.

Quality of life

Patients with PAH have similar quality of life scores when compared with those for patients with COPD and with end-stage renal failure.

Natural history

Early on in the course of their illness, patients with PAH may be asymptomatic or experience dyspnea with exertion. In the early stages of the disease the non-specific nature of the symptoms may lead to either failure of diagnosis or incorrect diagnosis. Many patients have had their symptoms attributed to depression. As the condition

(a)

(b)
progresses, the PVR rises and the cardiac output falls. At this stage patients may change from having relatively few symptoms to experiencing dyspnea, palpitations, chest pain (right ventricular angina), presyncope or syncope. Initially these symptoms may occur with exertion and subsequently at rest. As the condition progresses further peripheral edema, ascites, plethora and more profound fatigue develop as right ventricular dysfunction and tricuspid regurgitation evolve. Ultimately right heart failure and death occur.[12]

Disease progression and response to therapy can be functionally assessed using the World Health Organization classification of functional capacity which is an adaptation of the NYHA system (Table 70.1).

Diagnosis

Since PAH can occur in association with other conditions, symptomatic evidence of a related illness should be considered. For example, orthopnea and paroxysmal nocturnal dyspnea suggest elevated pulmonary venous pressure and pulmonary congestion due to left-sided heart disease or pulmonary veno-occlusive disease. Features such as Raynaud's phenomenon or arthralgias or rash may suggest the possibility of an underlying connective tissue disease. Other lung diseases such as lung fibrosis, COPD and obstructive sleep apnea can be associated with pulmonary hypertension and will need to be assessed and potentially treated in addition to the primary lung disease. One should also exclude pulmonary thromboembolic disease by performing either a ventilation/perfusion (V/Q) or computed tomographic pulmonary angiography (CTPA) scan (Fig. 70.3) or pulmonary angiography. For many patients with pulmonary hypertension associated with other conditions, treatment of the primary condition will significantly improve their pulmonary hypertension.

Table 70.1 WHO classification of functional status of patients with pulmonary hypertension (PH)*

Class	Description
I	Patients with PH in whom there is no limitation of usual physical activity; ordinary physical activity does not cause increased dyspnea, fatigue, chest pain or presyncope
II	Patients with PH who have mild limitation of physical activity. There is no discomfort at rest, but normal physical activity causes increased dyspnea, fatigue, chest pain or presyncope
III	Patients with PH who have a marked limitation of physical activity. There is no discomfort at rest, but less than ordinary activity causes increased dyspnea, fatigue, chest pain or presyncope
IV	Patients with PH who are unable to perform any physical activity and who have signs of right ventricular failure. Dyspnea and/or fatigue may be present at rest, and symptoms are increased by almost any physical activity

Physical examination

The clinical features of pulmonary hypertension can be subtle and may be missed on physical examination. Important features to identify are a loud pulmonary component to the secondary heart sound which reflects increased force of pulmonary valve closure secondary to elevated pulmonary artery pressure. Other auscultatory abnormalities include an early systolic ejection click due to sudden inter-
Figure 70.3 CTPA from a patient with pulmonary hypertension associated with pulmonary thromboembolic disease.

ruption of pulmonary valve opening, a midsystolic ejection murmur caused by turbulent transvalvular pulmonary flow and a right ventricular fourth heart sound. Additional features include a palpable left parasternal lift as a consequence of right ventricular hypertrophy and a prominent jugular "a" wave which suggests high right ventricular filling pressures. As the condition develops further a diastolic murmur of pulmonary regurgitation may be noted together with a pansystolic murmur of tricuspid regurgitation. Tricuspid regurgitation may also be detected by inspection of the neck demonstrating an elevated jugular venous pressure with accentuated V waves, a hepatojugular reflux and a pulsatile liver. Right ventricular failure is associated with a right ventricular third heart sound, distension of the jugular veins, pulsatile hepatomegaly, ascites and peripheral edema. As the disease progresses hypotension and poor peripheral perfusion indicate significant reduction of cardiac output with elevated peripheral vascular resistance. Cyanosis is noted in 20% of patients with idiopathic PAH; clubbing is rare.[12] Other cardiac and respiratory abnormalities may give further clues to other diagnoses and in particular, one must exclude CTEPH and potential underlying causes of this condition.

Routine investigations

In addition to routine hematologic and biochemical indices (full blood count, urea, creatinine and electrolytes, liver function test), one should screen for autoimmune diseases and clotting abnormalities and check arterial blood gas analysis on room air. Genetic screening is also important. A chest X-ray may show enlarged main and hilar pulmonary arteries, peripheral pruning of pulmonary vessels and cardiomegaly of right ventricular configuration. ECG may

be normal, may identify right axis deviation and right ventricular strain or show evidence of right atrial or right ventricular hypertrophy or arrhythmias. Two-dimensional echocardiography can provide useful information of right and left heart function and valvular abnormalities and can provide an estimate of the pulmonary artery systolic pressure. Ventilation perfusion and CTPA scanning can help exclude CTEPH and right heart catheterization can help confirm the presence of pulmonary hypertension and provide important information as to its origin. Full lung function tests may be normal or show abnormalities consistent with other diagnoses, e.g. low transfer factor for patients with lung fibrosis, left heart failure or CTEPH.

Evidence for diagnostic tests in patients with suspected pulmonary arterial hypertension

As PAH is a relatively rare condition, the literature is lacking in large series of appropriately conducted clinical trials which help establish firm guidelines for diagnosis and treatment. Furthermore, there is no effective cure and many treatments available will at best reduce the rate of deterioration of the illness and improve quality of life. Additionally, there is an important cost implication, particularly for long-term use of prostanoids and endothelin receptor antagonists. Therapies such as lung transplantation are limited by donor organ availability. Finally PAH represents a series of diverse conditions which interface at the level of the pulmonary circulation. Efforts to rationalize diagnostic modalities and treatment options are clearly difficult.

As a consequence, a number of expert consensus group meetings were organized to obtain broad agreement as to how patients with PAH should be diagnosed and treated.[13] What is reported in this chapter represents a distillation of current international opinion. Often such expert opinion is based on clinical experience in conjunction with results obtained from clinical trials. Many of these trials provide encouraging results but may be criticized because of design, duration and relatively small numbers of patients. In the light of early results further prospective trials are under way. It should also be stressed that there are currently no firm data based on properly constructed clinical trials to advocate specific management strategies for patients whose pulmonary hypertension is associated with primary cardiac and pulmonary diseases.

Consensus of opinion recommends that for patients with suspected PAH routine hematologic and biochemical investigations be performed and that autoimmune profile and HIV status is assessed (**Class I**). Chest X-ray is considered routine as is 12-lead ECG. Doppler echocardiography is a good screening tool to detect PAH (**Class I**) and is

useful at assessing morphology and abnormalities and in estimating right ventricular and pulmonary arterial systolic pressures (**Class IIa**), to assess left ventricular function (**Class I**) and (with contrast) intracardiac shunting (**Class IIa**).

V/Q scan or CT pulmonary angiography is recommended to exclude chronic pulmonary thromboembolic disease (**Class IIa**) and pulmonary angiography is advocated prior to considering pulmonary thromboendarterectomy (**Class I**). Lung function tests and arterial blood gas analysis are routinely performed (**Class IIa**). Estimate of gas transfer is useful in patients with PAH and scleroderma (**Class IIa**) and chronic pulmonary thromboembolism (**Class IIa**). Lung biopsy is not routinely advocated (**Class I**). Right heart catheter (Box 70.2) is required to confirm the presence of pulmonary hypertension, establish the specific diagnosis and determine its severity (**Class I**) and also to help guide treatment (**Class IIa**). Genetic testing and counseling should be offered to patients with familial PAH (**Class I**) and patients with idiopathic PAH should be advised of the availability of genetic counseling and testing for their relatives (**Class I**).[13]

Genetic aspects

Disease-causing mutations in bone morphogenetic protein receptor II (BMPR2) may underlie familial PAH.[29,30] Mutations have been detected in 55%[29] of families and show autosomal dominance with incomplete penetrance. Thus far up to 26% of sporadic cases (idiopathic PAH) have BMPR2 mutations.[30] Bone morphogenetic proteins are a family of secreted growth factors. BMPR2 regulates cell proliferation in response to ligand binding. Mutations in either BMPR2 or downstream ligand binding or activation lead to a loss of the inhibitory action of bone morphogenetic protein on vascular smooth muscle cell growth. As a consequence of this lack of inhibition, inappropriate cellular proliferation can occur and this may be important in the vascular remodeling that develops in PAH.

Current theories on the pathophysiology of pulmonary arterial hypertension

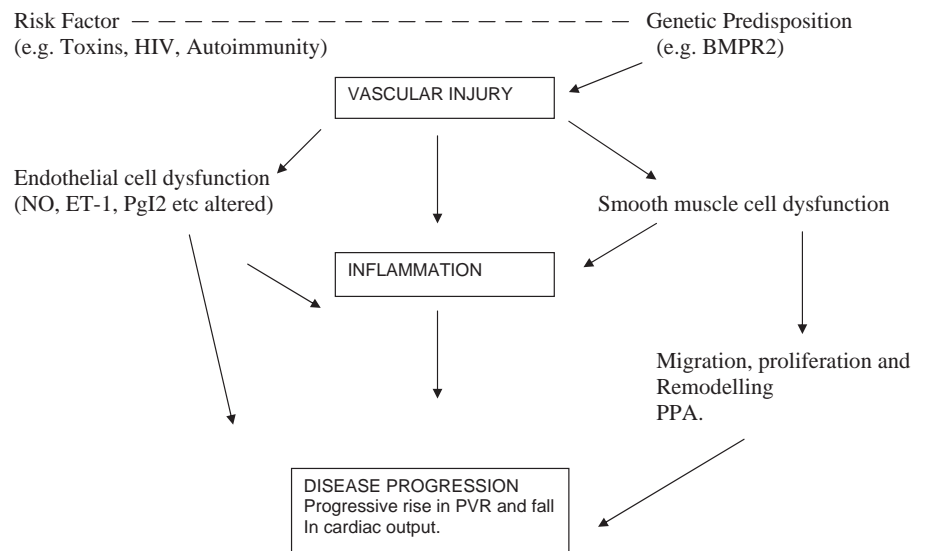
Patients may have a genetic predisposition (e.g. BMPR2 mutation) or have a risk factor such as autoimmune disease or HIV which can facilitate vascular injury. When vascular injury occurs endothelial cell dysfunction follows, giving rise to loss of regulation of local vasomotor tone, inflammation, smooth muscle migration and *in situ* thrombosis. As a consequence, vascular remodeling ensues, disease progression occurs, the PVR rises and cardiac output falls (Fig. 70.4). It should be stressed that the precise


Figure 70.4 Factors involved in the pathogenesis of PAH.

mechanisms underpinning the pathogenesis of PAH are not fully understood.

Therapeutic targets

Abnormalities in endothelial function with respect to vaso-reactivity, intimal proliferation and thrombus formation are believed to be important in the pathogenesis of PAH. Increasing attention has been given to endothelin-1 which is a potent vasoconstrictor and smooth muscle mitogen that may contribute to the vascular remodeling and increased PVR seen in PAH.[15–18] Elevated endothelin-1 production expression and concentration in plasma and in plexiform lesions are demonstrated in patients with PAH.[15–19] There are two distinct endothelin receptor isoforms, namely ET_A and ET_B.[31] When the ET_A receptor is activated vasoconstriction and vascular smooth muscle cell proliferation are facilitated. ET_B receptors are believed to be involved in endothelin clearance, particularly in the pulmonary and renal vascular beds, and they may also be involved in causing vasodilation and nitric oxide release.[31] At present it is unclear whether it is preferable to block both ET_A and ET_B receptors (with agents such as bosentan) or to primarily target the ET_A receptor alone (e.g. with agents such as sitaxsentan). Both bosentan and sitaxsentan have undergone randomied and controlled clinical trials in patients with PAH.[32–36]

Prostacyclin is a metabolite of arachidonic acid produced primarily in vascular endothelium. It is a potent vasodilator of both the pulmonary and systemic circulation and also has important antiplatelet aggregatory effects. There is evidence suggesting that a relative deficiency of prostacyclin may contribute to the pathogenesis of PAH. As a consequence there would be reduced local vasodilation and a tendency to platelet aggregation and it is known that PAH is associated with the presence of *in situ* thromboses. Prostacyclin acts by increasing cyclic adenosine monophosphate (cAMP) and in addition to potentiating vasodilation, it may be antiproliferative. Clinical studies have suggested benefit from long-term treatment with exogenous prostacyclin analogs by intravenous,[37] nebulised[38,39] or subcutaneous[40] administration.

Nitric oxide (NO) acts via cyclic guanosine 3' 5' monophosphate (cGMP) to promote vasodilation and it too may be antiproliferative. It is an important local regulator of vascular function and structure.[41,42] NO is generated by three isoforms of nitric oxide synthase (NOS) which are present in multiple and differing cell types. They are continuously active (constitutive types I and III) in endothelium or inducible (type II) in other cells such as macrophages, bronchial epithelium and vascular smooth muscle. L-arginine is the sole substrate for NOS and the regulation of NOS is multifactorial and is influenced by growth factors,

hormones, oxygen tension and hemodynamics, among others. In the endothelium arginine reaches the interior of the cell by active transport[43] and in the endothelium this transporter is tightly co-localized with NOS.[44] If this linkage were to be disrupted by endothelial injury normal extracellular levels might become insufficient for NO generation and as a consequence, NO deficiency may occur. Indeed, arginine deficiency has been shown to accompany persistent pulmonary hypertension of the newborn[45] and acute L-arginine infusion in infants with this condition has been shown to favorably improve PaO_2 levels.[46] When it became clear that NO production from L-arginine is the endothelium-derived relaxation factor,[47] inhaled NO was found to have a role in the management of a number of different types of conditions associated with pulmonary hypertension.[48]

The vasodilator effects of NO are dependent on its ability to augment and sustain cGMP content in vascular smooth muscle. Once produced, NO directly activates soluble guanylate cyclase. This leads to an increase in cGMP production which activates cGMP kinase which in turn opens potassium channels and promotes vasorelaxation. The effects of intracellular cGMP are transient as it is rapidly degraded by phosphodiesterases.[49,50] These latter enzymes hydrolyze cAMP and cGMP and limit their intracellular signaling properties by generating the inactive products 5'cAMP and 5'GMP. There are at least five classes of phosphodiesterase enzymes in the human body and the highest concentration of phosphodiesterase type V is in the lung and urologic tract. As a consequence, agents which selectively inhibit phosphodiesterase type V pathways should augment pulmonary vasodilation by potentiating the effects of endogenous or inhaled NO.[51] Sildenafil, which is a potent and highly specific phosphodiesterase type V inhibitor, may be useful for selected patients with pulmonary hypertension.[52–57]

A summary of the mechanism of action of prostaglandins, nitric oxide, phosphodiesterase V inhibitors and endothelin receptor antagonists is outlined in Figure 70.5.

Therapeutic options

Current drugs available have improved quality of life and prolonged survival for some patients with PAH. Therapies can be classified into medical and surgical. Examples of medical therapies include:
- supplemental oxygen
- diuretics
- digoxin
- inotropes
- anticoagulants
- calcium channel blockers

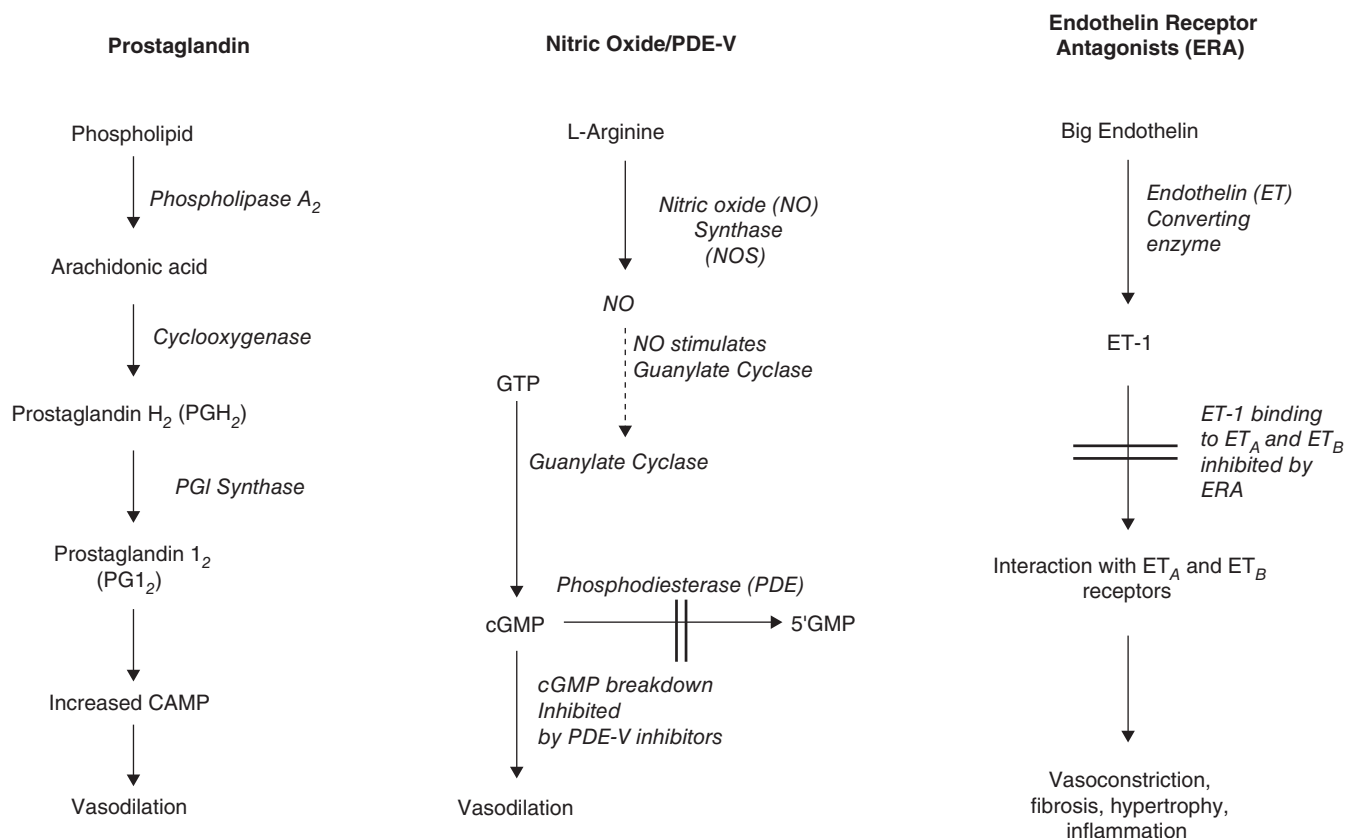
| Prostaglandin | Nitric Oxide/PDE-V | Endothelin Receptor Antagonists (ERA) |


Figure 70.5 Mechanism of action of prostaglandins, nitric oxide, phosphodiesterase V inhibitors and endothelin receptor antagonists.

- angiotensin-converting enzyme inhibitors or receptor blockers
- prostanoids
- L-arginine
- endothelin receptor antagonists
- phosphodiesterase inhibitors
- nitric oxide.

Surgical therapies include:

- atrial septostomy
- bilateral lung or heart and lung transplantation
- pulmonary thromboendarterectomy.

What defines acute vasoreactivity is controversial. An agent such as NO is administered at the time of right heart catheterization. Initially a positive response was defined as a 30% reduction in PVR with a corresponding increase in cardiac output. More recently, it has been defined as a reduction in mean pulmonary artery pressure close to or indeed to normal values with a documented increase in or an unchanged cardiac output. The European Society of Cardiology defined a positive vasodilator response as a fall of mean pulmonary artery pressure of at least 10 mm Hg to less than or equivalent to 40 mm Hg with an increased or unchanged cardiac output. Patients with idiopathic PAH who demonstrate an acute vasodilator response have an

BOX 70.3 Current approach to management of patients with pulmonary hypertension (**Class I**)

Step 1. Fully evaluate the patient; assess whether he or she has PAH or pulmonary hypertension associated with other conditions.

Step 2. Refer patients with an underlying cause to an appropriate specialist, e.g. cardiologist and cardiothoracic surgeon for patients who have pulmonary hypertension associated with mitral valve disease.

Step 3. If the patient has PAH and is in functional classes II, III or IV consider general measures such as anticoagulants (**Class IIa**), diuretics (**Class IIa**), oxygen (as necessary to maintain saturations over 90%) (**Class I**) and digoxin (**Class IIa**). These patients should be managed in centers specializing in diagnosing and treating patients with PAH (**Class I**).

Step 4. If the patient has PAH perform right heart catheter and assess for acute vasoreactivity (**Class I**). The usefulness of acute vasoreactivity in patients with scleroderma or congenital heart disease is less clear (**Class IIb**).

improved survival with long-term use of a calcium channel blocker (**Class IIa**). In practice, however, only a minority of patients with PAH (less than 10%) will respond to oral calcium channel-blocking agents. These patients will require long-term follow-up to assess whether their response is sustained. If not, further treatments may be required. Calcium channel blockers should not be used to treat patients with PAH unless acute vasoreactivity has been demonstrated (**Class I**).

Those patients who are in functional class III who have failed or who are not candidates for calcium channel blockers should be treated with endothelin receptor antagonists (**Class I, Level C1**) or chronic IV epoprostenol (**Class I, Level C1**) or prostonoid analogs (subcutaneous treprostinil, inhaled iloprost or oral beraprost (**Class IIa**) or phosphodiesterase V inhibitors (e.g. sildenafil (**Class I**)). Combination of agents may be necessary. Patients who are in functional class IV are also treated with these agents. In addition, patients in functional class III or IV should be referred to a transplant center for work-up (**Class I**). Atrial septostomy has been used (**Class IIb, Level C2**) to palliate patients with advanced PAH due to its potential to decompress the failing right ventricle and to improve cardiac index.[58] Some patients who have CTEPH may be candidates for pulmonary thromboendarterectomy (**Class I, Level C1**)[59] and others may be suitable for lung transplantation. However, shortage of donor organs and the late complication of obliterative bronchiolitis are limiting factors (**Class I, Level C1**).[60]

The management of PAH is complex and requires multidisciplinary input from physicians, surgeons, nurse specialists, physiotherapists, dieticians and pharmacists in a specialized environment. Additionally, the management of pulmonary hypertension associated with cardiac and pulmonary disease and thrombotic conditions requires management by a multidisciplinary team of many specialists interfacing at the level of the pulmonary circulation. There are no specific guidelines to manage patients with pulmonary hypertension secondary to cardiac and lung diseases. Information is available from non-randomized, non-controlled studies on small numbers of patients.

A number of emerging therapies are being considered in the management of PAH but evidence is at present inconclusive and many studies are currently at an early stage of development and recruitment. In the rat hypoxic model sustained vasoconstriction and increased vasoreactivity are influenced by rho-kinase mediated calcium sensitization.[61] When such animals are treated with the rho-kinase inhibitor fasudil a reduction in pulmonary artery pressure is observed.[62] In a small clinical trial intravenous fasudil was associated with a slight reduction in mean pulmonary artery pressure together with an increase in cardiac index in nine patients with severe PAH although the results did not attain statistical significance. There was, however, a

significant decrease in PVR.[63] It is possible that the benefit of phosphodiesterase type V inhibitors could in part be mediated by rho-kinase inhibition.[64,65]

Platelet-derived growth factor (PDGF) may be important in endothelial cell dysfunction and vascular remodeling in patients with PAH. Interestingly, chronic myeloproliferative disorders such as myelofibrosis are associated with a high incidence of PAH,[66] suggesting an association between PAH and marrow fibrosis.[67] Imatinib is a PDGF receptor antagonist which has obtained approval to treat patients with chronic myeloid leukemia and recently this agent has been used for selected patients with PAH. There are some case reports suggesting that imatinib may be efficient in managing patients with severe PAH[68] although cardiac toxicity is an important long-term concern which may limit its use.[69]

Simvastatin may improve BMPR type II signaling in pulmonary artery smooth muscle and microvascular endothelial cells.[70] In theory, therefore, simvastatin may enhance endothelial function. It may also be effective in inducing apoptosis in plexiform lesions and areas of vascular remodeling.[71] A study demonstrated an improvement in six-minute walk in 16 patients receiving between 20 mg and 80 mg of simvastatin daily.[72] Other potential treatments include ghrelin, an endogenous vasodilator peptide which can also stimulate growth hormone release,[73] and bradykinin which may modulate endothelial function and also potentially induce apoptosis via local nitric oxide and prostacyclin synthesis.[74] Other compounds being explored include vasoactive intestinal peptide (which can promote bronchodilation and systemic and pulmonary vasodilation[75]) which has produced some benefit in patients with PAH when administered as an aerosol.[76] Interestingly, vasoactive intestinal peptide may be reduced in the lung parenchyma and serum of patients with PAH.[76] There is increased lung expression of the 5-hydroxy tryptamine transporter in patients with PAH. This transporter may be involved in the development of PAH by facilitating smooth muscle migration.[77] Fluoxetine is a selective 5-hydroxy tryptamine transporter inhibitor and this agent has been shown to have a beneficial effect on PAH in the monocrotaline animal model.[78] This transporter promotes smooth muscle cell proliferation and demonstrates increased pulmonary expression in patients with PAH. There is also interest in clarifying the role of voltage-gated potassium channels in the pathogenesis of PAH.[79]

Special circumstances

Children

Treatment for children with severe PAH is similar to that for adults with idiopathic PAH (**Class IIa**). Indeed, although

there are limited data, children with severe PAH treated with long-term epoprostenol infusions appear to have at least as good a response as seen with adults with idiopathic PAH.[80] Diagnostic evaluation for pediatric patients is similar to that for adults and in addition acute vasoreactivity is assessed during cardiac catheterization to determine whether some patients may respond to long-term oral calcium channel-blocking agents (**Class I**).

Although treatment regimes are similar for adult and pediatric patients, the doses per kilogram for many of the medications used (e.g. epoprostenol and calcium channel blockers) are often significantly greater for children. Anticoagulants such as warfarin are typically prescribed for children with right heart failure or for those who have a hypercoagulable state (**Class IIa**). Line-related complications appear to be more frequently encountered in younger children than adults. The pharmacokinetics, safety and response to bosentan in the pediatric population have been reported[81] but specific information with regard to pediatric response to prostanoids is lacking in the medical literature.

Neonatal patients with severe PAH are much more responsive than adults to inhaled nitric oxide and multicenter randomized controlled trials have demonstrated benefit with low-dose inhaled NO in the treatment of term newborns with persistent pulmonary hypertension (**Class I, Level A**).[82] Experience with type V phosphodiesterase inhibitors such as dipyridamole or sildenafil is limited in children to small series and anecdotes (**Class IIb, Level C2**).[83]

Pregnancy

Many patients with idiopathic PAH are women of child-bearing age. During pregnancy significant physiologic change occurs with increasing blood volume of between 30% and 50% and a corresponding increase in cardiac output, heart rate (10–20 beats/min), stroke volume and a reduction in systemic blood pressure and vascular resistance. These changes commence during the first trimester and are maximal between 20 and 24 weeks of gestation. Further increases in cardiac output occur during labor and blood pressure increases with uterine contractions. Immediately following delivery cardiac filling pressures increase markedly as a consequence of decompression of the vena cava and return of uterine blood into the systemic circulation. It takes approximately six weeks after delivery for the hemodynamic changes associated with pregnancy to normalize.

Not surprisingly, such circulatory changes present a significant risk and mortality rates between 30% and 50% have been described for pregnant women with idiopathic PAH.[84,85] As a consequence many doctors recommend effective contraception and some advocate early fetal termination.[86]

Aside from hemodynamic issues, hormonal influences may be important adverse factors. There are some reports of mothers who successfully delivered a term infant whose pulmonary hypertension progressed during pregnancy and deteriorated further after delivery. There is also some evidence suggesting an increased incidence of children born with congenital anomalies and born small for gestational age to mothers with idiopathic PAH.

Treatment of PAH in pregnancy is anecdotal. Some encouraging reports have been described using long-term IV epoprostenol,[87] inhaled NO[88] and oral calcium channel blockers.[89] It is believed, however, that such reports are insufficient at present to establish recommendations for the management of PAH during pregnancy. Normally women with PAH are admitted to hospital for monitoring, supportive therapy with appropriate fluid regimes, oxygen, diuretics and perhaps inotropic support if required. It is usually advocated to deploy a pulmonary artery catheter during labor or in cases of deterioration during gestation. This helps not only to provide a fuller picture of the hemodynamic situation but also to guide appropriate therapy.

The optimum mode of delivery for women with PAH is controversial. Normal delivery as opposed to caesarean section may be preferred.[90]

Current guidelines from the American Heart Association and the American College of Cardiology advocate that pregnancy be avoided or terminated in women with cyanotic congenital heart disease, pulmonary hypertension and Eisenmenger's syndrome (**Class I, Level C2**). Maternal mortality may be as high as 36% in Eisenmenger's syndrome, 30% in idiopathic PAH and 56% in pulmonary hypertension secondary to other conditions.[85]

Endothelin receptor antagonists are not recommended during pregnancy (**Class I**).

Portopulmonary hypertension

Patients with chronic late-stage liver disease have an increased prevalence of pulmonary hypertension when compared to the normal population.[91,92] The reason behind this is not clear. Two forms of pulmonary vascular disease have been described in patients with chronic liver disease: the hepatopulmonary syndrome and portopulmonary hypertension. Usually these present independently although occasionally features suggestive of both conditions have been described in a single patient. Both conditions can increase the risks attendant on liver transplantation.

Typical features of the hepatopulmonary syndrome are hypoxia (with low oxygen saturation on room air and failure to appropriately increase oxygen saturation with supplemental oxygen) and intrapulmonary shunting. Other features include orthodeoxia (lower oxygen saturation in the standing position as opposed to lying supine). Treatment is supportive with supplemental oxygen and in

some patients improvement has been noted following successful liver transplantation. Although the histologic appearance of PPA has been described in patients with portopulmonary hypertension, the mechanisms for this are unclear. Some theories suggest that an inability of the liver to detoxify potentially toxic metabolites is causative.

Some differences have been described between portopulmonary hypertension and the clinical presentation of idiopathic PAH. In the former condition, the pulmonary arterial diastolic and mean pressures and systemic and pulmonary vascular resistances seem to be lower and cardiac output higher.[93] As the disease progresses the hemodynamic features approximate to those of idiopathic PAH. Full work-up is of course mandatory for any of these patients to ensure that other disease processes are not contributory (**Class I**).

Data on the treatment of portopulmonary hypertension are limited. This condition can significantly increase the risks attendant on liver transplantation. Current treatment advocates supplemental oxygen and diuretic therapy (**Class IIa**). Anticoagulants should normally be avoided, particularly if patients have significant clotting disturbances and gastroesophageal varices (**Class I**). Acute vasoreactivity testing should be determined as some patients may respond to calcium channel blockers (**Class I**). The dose of calcium channel blockers should be kept as low as possible as higher doses may precipitate liver failure. As with idiopathic PAH, failure to respond acutely to IV epoprostenol does not necessarily predict a failure to respond to this agent when it is administered by long-term IV infusion. Some patients may demonstrate an improvement in pulmonary hemodynamics following liver transplantation[94] although for other patients worsening of pulmonary hypertension after hepatic transplantation has been described. It is therefore very important not to wean patients off pulmonary vasodilator therapy until careful evaluation of their pulmonary hemodynamics has been made.

As endothelin receptor antagonists can cause hepatic toxicity, their use is generally avoided in patients with pulmonary hypertension associated with liver disease (**Class I**).

HIV disease

There is an increased incidence of PAH in patients with HIV although the precise relationship between these two conditions is not clear.[95] The clinical hemodynamic and histologic findings of pulmonary hypertension accompanying HIV infection are similar to that found in patients with idiopathic PAH. Virus and viral DNA is absent in pulmonary endothelial cells[96] and perhaps an indirect action of the virus through second messengers including cytokines and growth factors[97] or endothelin[98] is important. Since the condition only affects a minority of HIV-infected patients genetic factors may also be important.

Currently, uncontrolled studies suggest that patients with severe PAH associated with HIV infection should be considered for long-term infusion of epoprostenol together with combination antiretroviral therapy (**Class IIa, Level C2**). Further experience with other agents used in the management of patients with PAH is awaited before recommendations can be made on the application of these therapies to patients with HIV infection and pulmonary hypertension. Lung transplantation is usually contraindicated for this patient group (**Class I**).

Conclusion

PAH is a progressive and lethal disease whose initial symptoms can be non-specific. A comprehensive diagnostic approach is essential to identify associated medical conditions and to characterize hemodynamics and functional profiles. Although at present there is no cure for PAH, many of the agents currently employed are associated with an improvement in survival and quality of life. It is hoped that by increasing awareness and understanding of disease mechanisms, the development of more effective treatment modalities will be facilitated.

Interestingly, many of the lessons learned from PAH are being applied to patients with other forms of pulmonary hypertension. This not only helps to facilitate diagnostic awareness and physician training but has led to the successful application of a variety of drugs currently employed in the management of PAH to patients with pulmonary hypertension associated with cardiac, respiratory and thromboembolic disease.

IV Clinical applications

Ernest L. Fallen, Editor

71 Clinical applications of external evidence

Ernest L Fallen and Salim Yusuf
McMaster University, Faculty of Health Sciences, Hamilton, Ontario, Canada

External evidence derived from randomized clinical trials (RCTs) provides the practicing physician with a sound, rigorous and secure basis for making management decisions on individual patients. However, even vociferous advocates of evidence-based medicine will caution against the use of external evidence as the sole criterion for treating all patients. It is well to bear in mind that evidence obtained from clinical trials is derived from large population databases. More often than not, the entry criteria tend to define the boundaries of specified interest (for example, acute myocardial infarction), whereas exclusion criteria, such as age, sex, co-morbid disease states, etc., may well have denied entry to the individual patient now awaiting treatment. These exclusions may be based on concerns related to patient safety, lack of applicability, historic considerations or confounders (for example, significant non-cardiac illness) that can affect the evaluation of treatment. Nevertheless, the practicing physician is left inquiring, "Where can I find my patient within the trial's data set?". Here is where interpretation and the application of external evidence require a logical integration of overall trial results with a knowledge of biologic mechanisms, patient risk and clinical circumstances.

Evidence-based versus patient-centered medicine? Not an either/or choice

Few would deny an approach to therapeutic decision making based on proven external evidence combined with clinical experience, knowledge of pathophysiology and sensitivity to individual patient needs. To marry the two effectively is to recognize, and hence to avoid, their respective limitations if either were to be applied alone.

Recognizing the limitations of external evidence

For most RCTs, proving therapeutic efficacy necessitates certain constraints in patient selection. It is not uncommon that many patients in a physician's practice would not have fulfilled the restrictive entrance criteria of most moderate-sized RCTs. For example, some RCTs have an age cut-off that actually excludes more than half of all patients with the disorder. This by no means implies that the reputed benefit of the test drug is not applicable (effective) to the patients excluded, but it does beg the question. Entry criteria alone should never be the sole basis for denying a patient the benefit of proven therapy. Interpatient variability is inevitable in all RCTs and contributes much to the "random errors" seen in small and moderate-sized trials. However, the larger the trial, the smaller the random error, and the more likely that benefit can be reliably extrapolated to some patients who do not necessarily qualify for entry.[1,2] For example, one may observe that the benefits are consistent across different subgroups, suggesting that the results may be applicable beyond the boundaries of patient selection. On the other hand there may emerge reliable evidence for a lack of benefit in certain subgroups.

Evidence-based medicine that depends solely on external evidence is disease oriented rather than patient oriented. In other words, the verifiability of RCT data is often dependent on having a given diagnosis, as opposed to a clinical spectrum of risk associated with the diagnosis. This is the so-called "labeling" dilemma. For example, patients labeled as having "acute coronary syndrome" simply because they present with chest pain associated with non-ST segment elevation are often treated alike in an RCT, whereas the clinical expression of this entity may encompass a wide range from very low- to very high-risk patients. Translating external evidence based solely on a unified diagnosis into practice guidelines or clinical pathways

has the unfortunate consequence of making management decisions dependent on a label rather than the presenting clinical circumstances and risk of the underlying disorder.

Another nagging problem with the "bottom line" of clinical trials is the emphasis on primary endpoints that are measurable. Statistical dependency on hard data such as mortality rates, prespecified clinical outcome events, rehospitalizations, etc., fails to acknowledge the significance of clinically relevant "soft" data, such as impact on symptoms, quality of life, psychosocial well-being, attitudes, economic realities and patient preferences.

Finally, clinical trials all have finite time limits and, not uncommonly, the duration may be inadequate to assess long-term benefits and risks, especially for any new drug. In such cases the information from RCTs may have to be supplemented by other sources of non-randomized evidence.

Recognizing the limitations of patient-centered medicine

Who would have guessed that aspirin could reduce the relative risk of death and adverse coronary events in post-myocardial infarction patients by 25%? Or that beta-blockers would be so effective in class II/III chronic heart failure? Or that inotropic agents, despite improving hemodynamics and clinical well-being in patients with advanced heart failure, do so at the expense of shortened survival? Or that some antiarrhythmic agents, although they achieve cosmetic cleansing of so-called malignant ventricular ectopy from the electrocardiogram, are potentially hazardous?

Previously held concepts of disease mechanisms as the basis for initiating new therapies or persisting with old therapies have been challenged by clinical trials results. And so, what is apparent as a "logical" management approach to a given clinical problem may commit even the most experienced physician to inappropriate prescribing practices. Patient-centered medicine is not a concept that is firmly rooted in empiric medicine.[3] It does not guarantee that a physician, feeling secure in his or her realm of expertise, will be kept abreast of therapeutic advances based on clinical trial results. Unfortunately, this can lead to a tendency to persist in outmoded approaches.

Surely a cogent argument can be made to blend the positive features of patient-centered and evidence-based approaches through a constant awareness of their respective limitations.

Some principles of application

Knowing the person who has the disease is as important as knowing the disease that the patient has.[4] Clinical decision making ought to incorporate the following three ingredients:

- intelligent use of external evidence based on well-established clinical trial results and epidemiologic data whenever available
- clinical expertise, knowledge of fundamental mechanisms of disease, and willingness to listen to the testimony of one's patients
- sensitivity to patients' preferences, values, needs and beliefs.

It is well to bear in mind that for any given diagnosis (label), patients at the greatest risk of a disease will usually derive the greatest benefit from an established treatment, as the absolute benefit usually increases with risk whereas harm due to the treatment remains comparatively fixed across the risk spectrum.[5] Therefore, to avoid the hazard of labeling, it is critical to risk stratify the patient. It is only after one has listened carefully to the testimony of the patient, performed a proper examination and conducted the relevant tests that one can formulate a degree of attributable risk. Remember, it is just as important to identify the patient at very low risk, thereby sparing him or her unnecessary aggressive investigation and/or therapy, as it is to identify the high-risk patient for whom aggressive treatment can be life saving.

The absence of external evidence should not lead to therapeutic nihilism. Not all consensus recommendations are supported by Grade A evidence. In fact, many consensus panel recommendations and clinical practice pathways are based on evidence that ranges from the use of clinical judgment, albeit under a cloud of uncertainty, to Grade B through Grade A evidence.[6,7] When external evidence is lacking, one's own clinical experience, knowledge of pathophysiology, reasoned judgment and awareness of the patient's needs are indispensable substitutes.

One should avoid using the trial entry criteria to determine whether a particular patient would benefit from the active treatment.[2,5] Failure to qualify for entry is determined by many factors, few of which necessarily compromise the potential for therapeutic benefit. For example, if a trial's age cut-off was 65 years then a reasonable risk/benefit assessment can be done for those older by assessing whether, within the trial, age modified the treatment effect.

One should always try to use the best available external evidence science has to offer, but never at the expense of ignoring the patient's psychosocial conditions, beliefs, values and preferences. As medical decisions become more codified, one should not fail to recognize and honor the importance of patient preferences.[8] A patient's medical decision based on his or her particular needs, preferences and beliefs should always be respected, as the patient is given the opportunity to hear the nature of the external evidence. Consensus recommendations are guidelines only. They represent an active process subject to continual

review as new and as yet untested information emerges. When following any recommendation based on external evidence, the physician should always exercise clinical judgment based on a close working interaction with the patient.

Section preview

In the day-to-day practice of clinical medicine, it is not sufficient to know *what* the available external evidence is but also *how* and *when* to apply it to the individual patient. This section is made up of individual case reports that attempt to put a clinical face to a statistical bottom line by illustrating practical solutions to both common and uncommon problems in clinical cardiology. These case studies, encompassing 10 disease categories, are real-life presentations drawn from the files of distinguished consultant cardiologists. Here one finds therapeutic decisions made on the basis of both external evidence and clinical reasoning skills. For each case scenario, the story is presented. A question is posed at each decision point and a commentary follows. The commentary demonstrates how best external evidence is used in the management of the patient while recognizing the importance of sound judgment, a careful examination,

knowledge of cardiovascular pathophysiology and sensitivity to the patient's needs and preferences.

72 Stable angina: choice of PCI versus CABG versus medical therapy

William S Weintraub

Christiana Care Health System, Newark, DE, USA

Case history

A 58-year-old salesman presents to his primary care physician with a chief complaint of chest pain for 3 months. On further questioning, the chest pain is found to happen several times per week, occurring with exertion such as carrying packages up several flights of stairs. The pain is relieved by rest and has never occurred at rest. There have been several episodes, however, occurring with emotional stress. The patient does note that he has been under financial pressure at work and has had some family difficulties at home. The pain does impose some physical limitation on his activity, but it is felt to be mild. The pain does interfere with his quality of life, and the patient notes that he is fearful and worried about the pain. The pain has not been getting worse. The patient has never had a myocardial infarction and has never been hospitalized for his heart.

The patient has known risk factors for coronary artery disease. He has mild, controlled hypertension, taking only a diuretic. In addition, he has a 40-pack/year smoking history. He has no history of diabetes. He does have a history of hyperlipidemia and takes a statin. The patient has had a history of depression, but states that while he is anxious, he is not depressed at present. His lifestyle is entirely sedentary.

On physical exam he is a mildly anxious, slightly obese white male appearing his stated age. His waist circumference is 39 inches and his BMI 29.4. His pulse is 74, blood pressure 136/84. His peripheral pulses are full without bruits. His lung fields are clear. His cardiac exam reveals a barely perceptible apical impulse in the fifth intercostal space, in the mid-clavicular line. His heart sounds reveal an S1 and physiologically split S2, with no murmurs, gallops or rubs.

There is no peripheral edema and the exam is otherwise unremarkable. An electrocardiogram reveals normal sinus rhythm, QRS axis of 60°, normal intervals, somewhat high-voltage QRS complexes, and some T-wave flattening. Laboratory work reveals normal CBC and electrolytes. His fasting blood sugar is 103, HDL 38 and LDL 98 and triglycerides 168. Other than his statin and diuretic, the patient takes no medications.

- What is the diagnosis?
- What tests should be performed?
- What are the best therapeutic choices?

Comment

The patient gives a classic story for angina pectoris.[1] The probability of this being angina pectoris secondary to atherosclerotic cardiovascular disease is very high, probably in excess of 90%. At this level of probability, there is little need for non-invasive testing to establish the diagnosis. Non-invasive testing is most useful in the mid-range of probabilities, when the diagnosis is uncertain.[2] However, the patient also has risk factors which are not well controlled. The patient's blood pressure is controlled but not below the optimal level, below 120/80.[3]. His LDL choles-

terol is below 100. Recent changes to the NCEP ATP guidelines would suggest that this is adequate control, but they recommend an LDL below 70 for high-risk patients.[4,5] That control of LDL cholesterol will reduce cardiovascular events has been shown in multiple trials, and there is evidence that with lower LDL, the event rate will be even lower.[5,6] The patient's blood sugar is also of concern. Recent guidelines from the American Diabetic Association diagnose impaired fasting glucose to be above 100.[7] His lifestyle is a concern. He is sedentary and overweight. In fact, the patient has the metabolic syndrome, being overweight with a history of hypertension, elevated fasting blood glucose, low HDL cholesterol and elevated triglycerides.[8] He actually has all five components of the metabolic syndrome, but the diagnosis could actually be made with just three of these components. He is also not taking aspirin.

Antiplatelet therapy with aspirin has been shown to reduce events in patients with vascular disease in multiple clinical trials, with greater benefit in higher risk patients.[9,10] He also continues to smoke, a major risk factor for cardiovascular events. Smoking cessation advice is highly cost-effective and should be routinely given.[11] The patient also had a history of depression. Patients with depression are at higher risk of cardiovascular disease and should be treated for their depression.[12] However, it is not clear that such treatment can prevent cardiovascular events.

Case history *continued*

His primary care physician recognizes that this may be angina pectoris secondary to coronary artery disease. She also recognizes that he has the metabolic syndrome. She starts him on aspirin, 81 mg, a day as well as sublingual nitrates for episodes of chest pain. She assesses his history of depression carefully, noting that he is not currently depressed. She counsels him strongly on the need to stop smoking. She continues his other medications and refers him to a cardiologist for further evaluation.

The consulting cardiologist confirms the history, physical examination and laboratory values. He also agrees with the diagnosis of almost certain angina pectoris due to atherosclerotic cardiovascular disease. He notes that the pattern of angina has been stable for several months, with no rest pain. He therefore makes a presumptive diagnosis of chronic coronary artery disease. He reiterates the need for the patient to stop smoking.

The diagnosis has been made and initial therapy started. What are the next diagnostic and therapeutic steps?

Comment

The diagnosis of chronic coronary disease was straightforward for the cardiologist, but the next steps are less clear. It would be acceptable at this point to begin to treat the patient medically, deferring diagnostic testing. Smoking cessation advice and aspirin have already been started. The blood pressure control could be strengthened. ACE inhibition has been shown in two clinical trials to reduce the incidence of cardiovascular events in moderately high-risk patients, although this was not confirmed in a third trial.[13–15] Increased physical activity and diet have been shown to be effective in reducing fasting blood sugar and preventing diabetes.[16] The patient's LDL is controlled, although not to the most aggressive level. HDL is also low at 38 and triglycerides mildly elevated. Patients with increased physical activity are also at lower risk of events, although physical activity has not been shown to decrease events in clinical trials.

The major issues concern additional testing, possible cardiac catheterization with coronary arteriography and possible revascularization. Patients can be further risk stratified by stress testing with myocardial perfusion imaging.[17] Patients with reversible ischemia on myocardial perfusion imaging are at increased risk.[18] However, it is not clear that reversal of the ischemia with revascularization reduces risk. Patients who can exercise on a treadmill are also at lower risk than those who cannot.[19,20] There are patients with chronic coronary disease in whom coronary artery bypass grafting (CABG) reduces risk.[21–23]

Case history *continued*

The cardiologist counsels the patient on diet and recommends seeing a nutritionist. The patient declines to see the nutritionist, saying he knows what to do about diet but has trouble doing it. The cardiologist advises the patient to begin a walking program, pointing out that walking is the exercise of choice for adults, and that a more strenuous exercise program is not necessary. He hopes that the exercise program will result in amelioration of multiple components of the metabolic syndrome, lessening the need for additional therapy for serum lipids and driving the fasting blood sugar below 100. He begins a beta-blocker to treat the angina and also to further lower the blood pressure. He is also worried about the electrocardiogram, which suggests left ventricular hypertrophy. Left ventricular hypertrophy can also increase risk, and tight blood pressure control may help reduce it.[26] In order to risk stratify, he orders a stress test with myocardial perfusion imaging. The patient walks on the Bruce protocol for 5 minutes and 40 seconds, without ST changes on his electrocardiogram, but he does have some chest pain at peak exercise. His myocardial perfusion imaging reveals mild reversible ischemia and also shows that his left ventricular function is normal. The cardiologist is now comfortable that while the patient has chronic coronary artery disease, he is not at high risk. He elects to continue medical therapy, deferring catheterization and possible revascularization.

The patient returns 3 months later. He has begun a walking program and is feeling better, with decreased chest pain. He says that the walking program has also improved his overall sense of well-being. He has stopped smoking but has not lost weight. He fasting blood sugar has fallen to 98 and HDL has risen to 41. His LDL is essentially unchanged. His blood pressure is 132/81. His physical exam remains normal and electrocardiogram unchanged. As his blood pressure is not optimal and considering the results of the HOPE and EUROPA trials, the cardiologist begins the patient on an ACE inhibitor and continues his other medications.[13,14] He is now on aspirin, ACE inhibitor, beta-blocker and a statin. He returns 3 months later with blood pressure of 124/76, but now complains that he continues to have chest pain. Given the recurring angina, the physician elects to perform cardiac catheterization, with coronary arteriography and left ventriculography. The catheterization shows an 80% blockage in the left anterior descending coronary artery and a 70% blockage in the right coronary artery. There was mild diffuse disease and normal left ventricular function.

How should this patient be treated now?

In particular, these are patients with left main disease and three-vessel disease with abnormal left ventricular function. These patient groups were defined in the three major clinical trials of CABG from the late 1970s to early 1980s. However, these trials are somewhat historic and do not reflect contemporary medical therapy. There is no group of patients with chronic coronary artery disease in whom percutaneous coronary intervention (PCI) has been shown to decrease the incidence of cardiovascular events. Inability of PCI to prevent events has been shown in multiple clinical trials and recently confirmed in the COURAGE trial.[24,25]

Comment

The COURAGE trial has shown that an initial management strategy of optimal medical therapy will offer the same event rate over 7 years as initial medical strategy of PCI plus optimal medical therapy.[25] However, about one-third of patients in COURAGE crossed over from medical therapy to have revascularization at a median time of 10 months. COURAGE did show that there is better control of angina with PCI. Most of these crossovers were for failure to adequately control angina. There have also been multiple trials comparing balloon angioplasty to CABG and, more recently, coronary stenting to CABG. These trials generally show better control of angina with CABG, but little difference in event rates, except in diabetics, where several studies have favored CABG. As this patient has two-vessel disease and continuing angina on optimal medical therapy, he is a candidate for revascularization with either PCI or CABG.[27–29] PCI can be performed with either drug-eluting or bare metal stents, with little difference in death or myocardial infarction during follow-up, but less restenosis with drug-eluting stents.[30]

Case history *continued*

The patient undergoes stenting of the left anterior descending and right coronary arteries with drug-eluting stents. The procedure is uncomplicated. He has amelioration but not complete resolution of his angina. He is much more functional. His only additional medication is a thienopyridine to prevent stent thrombosis.[31] This is continued for 1 year. He continues his walking program, takes his five medications and does not smoke. He is not rehospitalized for heart-related problems. While the patient does not lose weight, he otherwise continues to do well.

Conclusion

This is a classic story of angina pectoris and chronic stable coronary artery disease. Optimal medical therapy, both pharmaceutic and lifestyle, has been shown in multiple

clinical trials to be associated with a good outcome, and has played a significant role in the reduction in cardiovascular disease mortality in recent decades. Except in special groups, revascularization is largely a treatment for angina. Where angina is disabling, revascularization can have a dramatic effect on quality of life. By beginning with optimal medical therapy, clinical trial data have shown that revascularization can be safely deferred in many patients. When angina pectoris does not improve over time in the medically treated patient, then revascularization with PCI or CABG is indicated.[25]

73 Non-ST segment elevation acute coronary syndrome

David Fitchett
St Michael's Hospital, Toronto, Ontario, Canada

Question

What is your management of this patient?

Comment

This older patient with diabetes and hypertension presents with symptoms that may be attributable to an acute coronary syndrome (ACS). Older patients and those with diabetes not infrequently have atypical symptoms, with dyspnea predominating over chest pain. The level of sus-

picion for ACS is high, yet there are no objective or high-risk features at the time of presentation, such as specific ECG abnormalities indicative of myocardial ischemia or elevation of the biomarker (troponin) of cardiac injury.

As an initial management step, it is necessary to recognize that both ECG and troponin abnormalities may take several hours to become abnormal. Hence it is important that this patient, with a high suspicion for ACS, is observed and both the ECG and troponin are repeated 6–9 hours after the initial presentation. Studies of patients with possible ACS indicate it will take up to 12–14 hours for all patients to develop a positive troponin. Thus even the currently recommended observation period of six hours may not detect an important number of patients with ACS and elevated troponin.

Risk stratification of the patient with a possible ACS is an essential step in the choice of appropriate management. For ACS with no ST segment elevation there are two specific reasons for risk stratification: only high-risk patients benefit from an early invasive strategy, and antithrombotic and antiplatelet therapy has evidence-based support in patients with objective high-risk features.

Features that are associated with a higher risk of adverse outcomes in patients with ACS are shown in Box 73.1. The risk factors are divided between those that will immediately impact on management decisions and those which although associated with increased risk, are unlikely to change the management strategy on their own. For example, a patient with symptoms compatible with an ACS, yet normal ECG and no troponin elevation is unlikely to benefit from an early invasive strategy just because of older age or the presence of diabetes. Yet a similar patient with increased background risk due to diabetes, impaired renal function or known coronary artery disease probably should receive clopidogrel and a heparin during the observation period.

The patient with any one of the high-risk features described in Box 73.1 is at higher risk of an adverse outcome,

Risk score
- Chest pain score ≥ 10 points — 1 point
- ≥2 chest pain episodes in last 24 h — 1 point
- Age ≥ 67 years — 1 point
- IDDM — 2 points
- Prior PTCA — 1 point
Figure 73.1 Death and non-fatal myocardial infarction rates over one year, in patients with symptoms compatible with an acute coronary syndrome yet no increased troponin and no high-risk ECG findings.[1,2,60] A chest pain score >10 is for chest pain symptoms that are likely to have been due to myocardial ischemia.

and justifies an early invasive management strategy. However, the patient with no high-risk features is not necessarily at low risk, especially over the medium and longer term. A recently developed scoring system[1] to identify high-risk patients who have no troponin elevation nor high-risk ECG features is shown in Figure 73.1. This scoring system shows that patients with a score >3 have outcomes similar to a patient with an elevated troponin[2] and in this patient population, the score was a better predictor of outcomes than the thrombolysis in myocardial infarction (TIMI) risk score.

Our patient has no high-risk features that would by themselves indicate high risk. Yet age and the history of diabetes give her a score of 3 according to the scoring system in Figure 73.1. She received dual antiplatelet therapy with aspirin and clopidogrel. An anticoagulant (a heparin, fondaparinux or bivalirudin) was not given.

Comment

The presence of an elevated troponin I level in a patient with symptoms and circumstances compatible with an ACS is objective evidence supportive of the diagnosis of ACS, and indicates:

- a higher risk for recurrent ACS
- benefit from an early invasive strategy of coronary angiography and revascularization when appropriate
- benefit from immediate use of antiplatelet and antithrombotic treatment.

Outcomes related to elevated troponin

The relationship between elevated biomarkers of myocardial necrosis and outcomes has been recognized for many years. The patient with a myocardial infarction and increased biomarkers (transaminases, lactate dehydrogenase (LDH) or creatine kinase (CK)) has substantially increased mortality when compared to the patient presenting with rest pain and no biochemical evidence of infarction, i.e. unstable angina. With the development of troponin as a highly sensitive and specific marker of myocardial injury, approximately 30% of patients with a previously designated diagnosis of unstable angina and normal CK and CKMB have increased troponin. Whereas early mortality relates to both the maximal CKMB and troponin levels, the risk of early myocardial (re-) infarction is more related to low levels of troponin.[3] Small increases in troponin I or T in a patient with a clinical history compatible with an acute coronary syndrome indicate increased risk of recurrent ACS and the need for more aggressive treatment. It should be recognized that many other clinical situations such as pulmonary embolism, septic shock, acute heart failure and renal failure are associated with minor degrees of myocardial injury indicated by elevation of troponin, that are not due to thrombotic coronary occlusion. The

troponin elevation should be evaluated in the clinical context.

Early invasive strategy or conservative management?

The strategy of early cardiac catheterization and revascularization (when appropriate) reduces early recurrent acute coronary syndromes and long-term mortality when compared to a conservative strategy of cardiac catheterization only if the patient has recurrent ischemia or high-risk noninvasive testing.

Four meta-analyses[4-7] have showed that an early (during the index hospitalization) invasive strategy is superior to a selectively invasive approach. A meta-analysis of the seven most recent trials, included 9212 patients and showed that death or myocardial infarction was reduced by 18% (odds ratio (OR) 0.82, 95% confidence interval (CI) 0.72–0.93) over a follow-up period of 17 months (range 6–24 months) with routine early coronary angiography and revascularization (when appropriate), compared to a selective approach[5] (Fig. 73.2). An analysis showed improved outcomes, including reduced mortality, were only achieved when coronary stenting and an aggressive antiplatelet strategy were employed.[6] The early benefit from an invasive strategy is mainly from a reduction of myocardial infarction. However, long-term mortality was reduced in the FRISC 2[8] and the RITA 3[9,10] trials with a 26–30% reduction in 1–5-year mortality compared to patients managed conservatively. High-risk patients with elevated troponin or greater TIMI risk scores benefit the most from the early invasive strategy.[11-13]

Early revascularization within 48 hours in high-risk patients with non-ST segment elevation (NSTE) ACS is supported by data from the CRUSADE registry[14] and the TACTICS/TIMI 18 study.[11] Furthermore, the ISAR COOL trial[15] indicated that there was no benefit from a 72-hour period of medical stabilization with an aggressive protocol of heparin, acetylsalicylic acid (ASA), clopidogrel and glycoprotein (GP) IIb/IIIa inhibitors compared to immediate cardiac catheterization within six hours. Ischemic events occurred more frequently prior to percutaneous coronary intervention (PCI) in the medical stabilization group despite the vigorous treatment. Hence the current evidence supports early angiography within the first 48 hours in the majority of patients identified as being at high risk. For patients with frequent episodes of ischemia, heart failure or hypotension, even more urgent coronary angiography allows immediate revascularization in very high-risk individuals.

The 2007 ACC/AHA guidelines[16] for the management of NSTE ACS have recommended that an initially conservative management strategy can be considered for initially stabilized patients even with high-risk features (**Class IIb, Level C**). This recommendation is based on the results of the ICTUS trial.[17] Patients included had rest pain, elevated troponin and either ECG abnormalities or a known coronary artery disease. The study compared an early invasive management strategy, with coronary angiography and revascularization where feasible within 24–48 hours, with a selectively invasive approach that only progressed to an invasive management with recurrent ischemia or a high-risk stress ECG. In the ICTUS study myocardial infarction was defined as any increase in CKMB beyond the normal range, with no higher threshold for patients undergoing PCI or bypass surgery. During the index hospitalization 98% of the early invasive group and 53% of the selectively

Favors Early Invasive Therapy — Favors Conservative Therapy
Figure 73.2 Meta-analysis of clinical trials comparing an early invasive with a conservative strategy in the management of patients with NSTE ACS.[61]

invasive group underwent coronary angiography. One year after the index ACS event, 67% of the selectively invasive group had undergone coronary angiography. At one year after the ACS event, there was no difference in the primary outcome of death/recurrent myocardial infarction or unstable angina. The ICTUS patients had a low incidence of cardiovascular events (one-year mortality 2.5%). Almost two-thirds of the conservative group underwent coronary angiography and revascularization by the end of the first year. Thus the management strategies mainly differed by the timing of the invasive strategy and the study compared an early invasive with a delayed invasive strategy. It is unlikely therefore that this study alone will change practice.

Antithrombotic and antiplatelet therapy

The vast majority of acute coronary syndromes result from arterial thrombosis occurring with either atherosclerotic plaque erosion that denudes endothelial cells or plaque rupture exposing thrombogenic collagen and tissue factor to the blood. Propagating thrombus may occlude the vessel. However, the size of the thrombus and the activity of intrinsic fibrinolysis may determine whether the vessel remains occluded or is spontaneously recanalized. A high proportion of patients with NSTE ACS have patent culprit coronary arteries when investigated within the first 24 hours. This is in contrast to ST segment elevation ACS (STE ACS) where 80% of patients have an occluded infarct-related artery. In the patient with NSTE ACS the rationale of therapy is to prevent recurrent ACS due to reocclusion of both the culprit artery and other sites of plaque rupture or vulnerability, by using medications (antiplatelet and antithrombotic agents) and revascularization when feasible and indicated.

Medications to reduce thrombosis are the mainstay of early therapy in patients with acute coronary syndromes. Drugs reducing platelet activation and aggregation such as ASA, clopidogrel and GP IIb/IIIa inhibitors, and agents interfering with blood coagulation such as heparins, fondaparinux and bivalirudin have been shown to reduce recurrent ischemic events when administered in the first few hours after the onset of symptoms. The clinical trials for many agents were performed in an era when cardiac catheterization was performed less frequently and usually much later than has become current practice. Consequently, application of the results to current practice requires interpretation and extrapolation often beyond information provided by the individual trials.

Antiplatelet therapy ASA was studied in patients with unstable angina and shown to reduce recurrent events both early and over many months. The benefit was observed in patients receiving no antithrombotic treatment and before

the days of frequent revascularization. In patients with NSTE ACS the CURE trial[18] demonstrated that the addition of clopidogrel 75 mg daily to ASA reduced the primary endpoint (cardiovascular mortality, myocardial infarction or stroke) by a relative 20% (2% absolute risk reduction) over the nine-month period of treatment. Within hours of administration of the 300 mg loading dose, there was a significant reduction of the combined endpoint of cardiovascular death, myocardial infarction (MI) and recurrent severe ischemia. The majority of patients included in the CURE trial had either ECG abnormalities or positive biochemical markers (usually CKMB). However, for the first 3000 patients enrolled, age greater than 60 and a history of coronary artery disease were entry criteria. Across a wide risk spectrum, there was a constant relative risk reduction with clopidogrel. The benefits were achieved with a 1% absolute increase in major bleeding, mainly determined by a 50 g/L fall in hemoglobin or need for transfusion, yet with no increase in life-threatening bleeding. Approximately one-third of patients underwent revascularization after randomization. Patients undergoing both percutaneous coronary intervention[19] and coronary artery bypass surgery[20] had benefit from pretreatment with clopidogrel before revascularization. However, for the few patients undergoing coronary bypass surgery within five days of receiving clopidogrel, major bleeding was increased 50%.[18]

The intravenously administered GP IIb/IIIa inhibitors abciximab, tirofiban and eptifibatide were studied in patients with NSTE ACS before clopidogrel was used in the early management of these patients. A meta-analysis of clinical trials that included over 31 000 patients suggested a modest benefit with one fewer death or MI at 30 days per 100 patients treated.[21] The greatest benefit was observed in higher risk patients, such as those with troponin elevation,[22,23] and diabetes mellitus.[24]

Currently it is unclear whether the addition of a GP IIb/IIIa inhibitor to dual antiplatelet therapy with ASA and clopidogrel improves outcomes. The ISAR React 2 study evaluated the use of abciximab at the time of PCI in patients with recent NSTE ACS pretreated with clopidogrel. Those receiving both clopidogrel and abciximab and with elevated troponin had a 25% reduction of the combined endpoint of death/non-fatal myocardial infarction or urgent target vessel revascularization.

Antithrombotic treatment Activation of the coagulation pathway by agents such as tissue factor initiates a positive feedback system activating platelets and resulting in rapid growth and propagation of the thrombus. Control of the coagulation pathway is important to prevent recurrent ischemic events in patients with acute coronary syndromes. Available agents and their interaction with the coagulation pathway are shown in Figure 73.3.
Figure 73.3 The sites of action of the antithrombin agents currently used in the management of patients with NSTE ACS.

Unfractionated heparin (UFH) An analysis of six clinical trials in patients with NSTE ACS that compared UFH with placebo showed a 33% reduction of death and MI over the short term (OR 0.66, 95% CI 0.44–0.99, P = 0.045).[25] When UFH is combined with ASA and compared to ASA alone, there is a trend to a benefit with the combined therapy.[26] Studies that compare either UFH or low molecular weight heparin combined with ASA with ASA alone show a 39% reduction of death and MI.

Low molecular weight heparin (LMWH) When compared with placebo in patients with NSTE ACS, there is benefit from LMWH (death/MI OR 0.34, 95% CI 0.20–0.58, P < 0.0001).[27] However in this meta-analysis LMWH was not superior to UFH (OR 0.88, 95% CI 0.69–1.12, P = 0.34). However, individual LMWH preparations may be superior to UFH. When enoxaparin is compared to UFH a meta-analysis showed no difference in mortality outcomes at 30 days (OR 1.00, 95% CI 0.85–1.17). Yet death/MI was reduced 9% by enoxaparin (OR 0.91, 95% CI 0.83–0.99).[28] In this analysis there was no increase in bleeding as defined by major bleeding or transfusion needs when enoxaparin was used. A more contemporary use of enoxaparin in the SYNERGY trial[29] included 9978 high-risk patients with NSTE ACS destined to undergo very early coronary angiography and revascularization. Patients were randomized to receive either enoxaparin or UFH. Coronary angiography was performed an average 22 hours after randomization. In the context of aggressive, very early invasive management, enoxaparin was not shown to be superior to UFH. There was a trend to increased major bleeding in patients receiving enoxaparin (OR 1.17, 95% CI 0.99–1.39). As a result of the SYNERGY trial, UFH is preferred over enoxaparin if the patient is likely to go to the catheterization laboratory within the first 24 hours after presentation.

Fondaparinux The synthetic anti-factor Xa inhibitor fondaparinux was evaluated in the large outcome study OASIS 5 (Organisation to Assess Strategies for Ischemic Syndromes 5).[18] In this study, 20 078 patients with NSTE ACS were randomized to receive either fondaparinux or enoxaparin for an average of six days. The primary efficacy endpoint (death, MI or refractory ischemia at nine days) of the two treatment groups (fondaparinux 5.8% vs enoxaparin 5.7%) was not statistically different and satisfied predetermined non-inferiority criteria. The composite efficacy and safety endpoint (death, MI, refractory ischemia or major bleeding) was significantly reduced in patients receiving fondaparinux (fondaparinux 7.3% vs enoxaparin 9.0%). Major bleeding was increased in patients receiving enoxaparin compared to fondaparinux, and was an independent predictor of medium- and long-term mortality (six-month mortality: fondaparinux 5.8%, enoxaparin 6.5%, P = 0.05). The increased mortality at 30 days and at six months in patients receiving enoxaparin is almost entirely accounted for by the increase in major bleeding. The reduced bleeding associated with fondaparinux compared to enoxaparin treatment was observed in a very wide range of patient baseline observations and management strategies. Older patients, women, and those with renal insufficiency had less major bleeding with fondaparinux. Patients undergoing early cardiac catheterization (even within the first 24 hours) and those receiving either a GP IIb/IIIa inhibitor or heparin at the time of the procedure had less major bleeding when they received fondaparinux compared to the enoxaparin group.[30]

Guide catheter thrombosis at the time of PCI was observed more frequently in fondaparinux-treated patients (0.9% vs 0.4%, P < 0.001). Although the additional use of unfractionated heparin with fondaparinux at the time of PCI appears to reduce the incidence of guide catheter thrombosis, the safety of the combined treatment needs further assessment. Fondaparinux has a similar efficacy to enoxaparin for the prevention of recurrent ischemic events but in the protocol used in the OASIS 5 study, the reduction of major bleeding translated into a significantly lower mortality.

Bivalirudin Direct thrombin inhibitors such as bivalirudin were shown in a meta-analysis to be more effective than heparin in reducing death or reinfarction in patients with ACS undergoing early percutaneous coronary intervention.[31] Bivalirudin was evaluated in patients with NSTE ACS in the ACUITY trial.[32] Although there was no difference in the ischemic endpoint between the three strategies of heparin and GP IIb/IIIa inhibitor, bivalirudin and GP IIb/IIIa inhibitor, and bivalirudin alone, patients receiving bivalirudin alone had less major bleeding than those in the other two groups. Bivalrudin is an attractive antithrombin in moderate- to high-risk NSTE ACS patients who will

undergo very early cardiac catheterization in the first 12–24 hours.

Case history *continued*

Our patient now has evidence for a high-risk non-ST segment ACS. Evidence shown above supports referral for early coronary angiography and revascularization, and the use of both antithrombotic and antiplatelet agents.

She was already receiving dual antiplatelet therapy with ASA 81 mg and clopidogrel 75 mg daily (after a 300 mg loading dose). The ASA dose was maintained at 81 mg to minimize the incidence of gastrointestinal bleeding. In the CURE trial the incidence of major bleeding in patients receiving combined clopidogrel 75 mg daily and ASA 75–100 mg daily was less than for those receiving only ASA 325 mg.

On the basis of the ESSENCE[33] and TIMI 11b[34] trials, our patient was given enoxaparin 1 mg/kg daily. It was recognized that she had moderate renal insufficiency with an estimated glomerular filtration rate (eGFR) of 35 mL/min. LMWH and fondaparinux are excreted renally. Although it is recommended that the dose of enoxaparin be reduced 50% to 1 mg daily for patients with eGFR < 30 mL/min, there are no safety data to support this recommendation. The patient was admitted to an ECG monitored bed. A referral was sent to the local cardiac center for coronary angiography, and arrangements made for transfer within the next 48 hours.

Over the next 24 hours our patient had a further episode of chest pain and dyspnea with associated ST segment depression in ECG leads V1–V4. The pain resolved within 10 minutes after administration of nitroglycerin 0.4 mg sublingually.

How will you manage this patient now?

Comment

Our patient now has refractory myocardial ischemia with associated ECG abnormalities. Prior to the current era of the use of early cardiac catheterization and multiple antithrombotic agents, refractory ischemia was the factor most predictive of future adverse outcomes.[35] More recently, the GUSTO 2b study[36] showed that mortality was threefold greater in patients receiving ASA and heparin who developed refractory ischemia associated with ECG changes.

The patient requires urgent transfer to a cardiac center for angiography and, if possible, PCI. The question now is whether there is benefit to starting other medication to reduce recurrent ischemic events. The patient's chest pain did appear to resolve with sublingual nitroglycerin. Thus many physicians would use an infusion of intravenous nitroglycerin at doses of 20–150 μg/h. The use of an intravenous GP IIb/IIIa inhibitor for patients with refractory ischemia has never been evaluated. The clinical trials of GP IIb/IIIa inhibition in patients with NSTE ACS have either recruited patients at the time of presentation[37–39] or during the waiting period for PCI, when the coronary anatomy was known.[40]

Case history *continued*

Our patient is started on an infusion of nitroglycerin at 60 μg/h. It was decided not to use a GP IIb/IIIa inhibitor in addition to ASA, clopidogrel and enoxaparin, because the patient's gender, age, and impaired renal function would substantially increase the bleeding risk. The cardiac center was called and transfer arranged in the next four hours.

At coronary angiography a severe proximal left anterior descending coronary stenosis was found. There were minor stenoses in the other coronary vessels. Left ventricular function was not assessed at this procedure.

Arrangements were made for immediate PCI. As the patient had received enoxaparin four hours previously, no additional anticoagulant was given. However, eptifibatide was started prior to the procedure. The artery was successfully dilated and a 4.0 mm paclitaxel drug-eluting stent deployed. The final result showed no residual stenosis.

Comment

Successful dilation and stenting of the culprit stenosis is not the end of the story. The patient may have other vulnerable coronary plaques that could cause further acute coronary events unrelated to the original culprit lesion; acute stent thrombosis, although rare, may occur and there is a short- and long-term risk of bleeding resulting from the multiple antithrombotic agents. In addition, there is need for evidence-based vascular protective medication and lifestyle modification to reduce progression and atherothrombotic complications of atherosclerosis.

Case history *continued*

Following the successful PCI, our patient returned to the cardiology ward of the cardiac center. The arterial access sheath had been closed with a vascular closure device. There was no hematoma or evidence of bleeding when the patient returned to the ward. An order had been written to discontinue enoxaparin, but to continue eptifibatide at the standard infusion rate of 2 μg/kg/minute for the next 18 hours. In addition, the ASA dose was increased to 325 mg and clopidogrel 75 mg daily continued.

Six hours after the PCI our patient complained of lower back pain and pain over the front of the thigh. The blood pressure had initially been 140/85, but with the onset of pain fell to 90/50.

Question

What is the current problem, how will you make a diagnosis, what is the management, and will it influence long-term outcomes?

Comment

The onset of back and thigh pain in a patient receiving powerful antiplatelet or anticoagulant therapy should raise a high level of suspicion for a retroperitoneal bleed.

There was no visible or palpable hematoma at the femoral access site. The abdominal examination was unremarkable and bowel sounds were present. With the administration of 1.5 litres of 0.9% saline, the blood pressure was restored to the baseline level. The eptifibatide was discontinued. Our patient was sent for a CT scan of the abdomen that confirmed the presence of a large retroperitoneal hemorrhage, on the contralateral side to the arterial access site. The hemoglobin fell from a baseline 135 g/L to 85 g/L when measured the next day. The patient was transfused 2 units of packed red blood cells.

Question

Was this major bleeding event predictable and preventable?

Comment

With the greater use of both antithrombotic medications and early revascularization, bleeding has become an increasingly important problem for patients admitted to hospital with ACS. In fact, major bleeding and the need for transfusion is the most common adverse event and exceeds the incidence of death, myocardial infarction and heart failure.[41] Not only does bleeding result in an immediate threat, but it is also associated with increased coronary heart disease mortality and reinfarction. The older patient, females, those with anemia, renal dysfunction, high-risk ACS, diabetes, hypertension and those undergoing invasive procedures are at high risk for bleeding. Major bleeding, from whatever cause or site, is associated with a 60% increased risk of in-hospital death and a fivefold increase in one-year mortality and reinfarction.[42,43] In addition, patients receiving blood transfusion had a fourfold increase in mortality.[41] Yet the causal link between bleeding, transfusion and increased coronary heart disease events is unproven.

The current paradigm for the management of ACS is to minimize recurrent ischemic events but also to minimize the risk of bleeding. Such a strategy includes matching the ACS risk to the most appropriate treatment, assessing the bleeding risk, using vascular access techniques to minimize bleeding, selecting the antithrombotic agent that is best for the patient, minimizing the duration of exposure to antithrombotic agents, using the correct dose of medications, and recognizing early signs of bleeding.

Our patient had a number of higher risk features that increased her chance for major bleeding. These included: older age, female gender, hypertension, diabetes, renal insufficiency, and recent femoral arterial vascular access. Furthermore, she had received enoxaparin and eptifibatide at standard doses, despite moderately severe renal insufficiency. Excessive dosing of anticoagulants and antiplatelet agents, due to inaccurate estimates of weight and failure to correct doses for renal impairment, is responsible for bleeding in an important number of cases.[44]

> ## Case history *continued*
>
> Fortunately our patient made a good recovery from the retroperitoneal bleeding and left hospital five days after the PCI procedure. She was given a discharge prescription that included ASA 81 mg daily, clopidogrel 75 mg daily, ramipril 10 mg daily, hydrochlorothiazide 25 mg daily, atorvastatin 80 mg daily, metoprolol 50 mg twice daily, and metformin 500 mg bid.

Comment

Vascular protective measures that reduce recurrent ischemic events have a large impact on long-term outcomes. These measures include lifestyle changes and pharmacologic treatment. All patients admitted to hospital for an ACS should receive lifestyle counseling. This should include smoking cessation advice and referral to a smoking cessation clinic. Weight control, increased physical activity and dietary advice are frequently required. Vascular protective medications for patients who have had an ACS should include ASA, a statin, an ACE inhibitor and a beta-blocker. In addition, glycemic and blood pressure control should be optimized.

Long-term treatment: the discharge prescription

Lifestyle counseling is started in hospital prior to discharge. Efforts to promote smoking cessation after an acute coronary event are likely to be more successful than at any other time. However, it is recognized that for success with lifestyle modification, ongoing support in a cardiac rehabilitation center is most likely to result in long term gains.

Abnormal glucose metabolism is present in two-thirds of patients with acute coronary syndromes[45,46] (30% have known diabetes, 15% have newly diagnosed diabetes, 22% have impaired glucose tolerance (IGT), and 5% have impaired fasting glucose (IFG)). The earlier detection and

treatment of diabetes will prevent microvascular disease and may have an impact on preventing recurrent cardiac events.

Statin treatment reduces death, MI and stroke in patients with stable coronary heart disease over a wide range of baseline LDL cholesterol. The MIRACL[47] and PROVE-IT-TIMI 22[48] studies showed that cardiovascular events were reduced within 30 days of initiating treatment by vigorously reducing LDL-C in patients with a recent ACS.[49] Current evidence supports treatment early after an ACS with an intensive statin regimen such as atorvastatin 80 mg daily. Angiotensin-converting enzyme inhibitors or angiotensin receptor blockers (ARB) should be considered in patients with ACS and heart failure or impaired LV ejection fraction (LVEF < 40%) to prevent the development of heart failure and reduce mortality.[50] The VALIANT study demonstrated that the ARB valsartan was not inferior to the ACE inhibitor captopril for the prevention of cardiovascular events in patients with recent myocardial infarction and either heart failure or LVEF < 40%. The SAVE trial[50] also demonstrated that early treatment with captopril reduced recurrent myocardial infarction. A combined analysis[51] of the HOPE,[52] EUROPA[53] and PEACE[54] clinical trials showed that ACE inhibition resulted in a 14% reduction of cardiovascular mortality and 18% reduction of myocardial infarction. The ONTARGET trial[55] showed that the ARB telmisartan was not inferior to ramipril for the prevention of cardiovascular events in high-risk patients. However, none of these four studies with ACE inhibitors or ARB included patients during the first 1–3 months after acute MI. Yet it is likely that ACE inhibitors or ARBs started early after an acute MI will prevent recurrent MI, as suggested by the SAVE results.[50]

Antiplatelet therapy with ASA and clopidogrel, initiated on admission and continued for nine months, was shown in the CURE trial[56] to reduce the combined outcome of death/MI/stroke by 20%. Many patients with NSTE ACS will receive an intracoronary stent as part of an early intervention and revascularization strategy. These patients benefit from combined ASA and clopidogrel continued for one year. Beyond one year, treatment with dual antiplatelet therapy remains controversial. Patients receiving drug-eluting stents, especially with complex anatomy or high-risk locations, may benefit from longer term treatment to prevent late stent thrombosis. The CHARISMA trial[57] in patients with either clinically evident cardiovascular disease or multiple risk factors showed no overall advantage of combined ASA and clopidogrel beyond ASA alone. However, an analysis of patients with established vascular disease showed a significant, albeit modest benefit.[58]

Beta-adrenergic blockers reduce mortality by approximately 25% in patients with MI during treatment for two years or more after the acute event.[59] Patients with non-Q wave infarction were included in these studies.

Case history *continued*

Our patient returned for follow-up with her cardiologist at one and four months after discharge. With the support of her family doctor and pharmacist, she has remained adherent to treatment. She has lost 10 lbs weight and is now walking for 30 minutes daily. Her blood pressure was less than 130/80 at both visits. With a better diet the diabetes is well controlled. A lipid profile shows the LDL cholesterol reduced to 1.9 mmol/L.

74 Acute ST segment elevation myocardial infarction

Ernest L Fallen

McMaster University, Faculty of Health Sciences, Hamilton, Ontario, Canada

Case history

A 55-year-old self-employed male truck driver suddenly experiences, for the first time, severe retrosternal chest pain accompanied by weakness, nausea, and shortness of breath. When his distress fails to abate he presents, within 30 minutes, to the emergency room of a hospital without heart catheterization facilities.

Physical exam reveals a pale, anxious, diaphoretic overweight man with a blood pressure of 110/90 and a regular heart rate of 98 beats per minute. There are sibilant rales at both lung bases bilaterally but his neck veins are flat. On auscultation there is a soft apical systolic murmur and an S4 gallop rhythm. His risk factors include a 10-year history of hypertension for which he is on a thiazide diuretic as his only medication. He is a 40 pack/year smoker with a strong family history of a sister with an MI at age 58 and a father who suffered an MI in his 40s. He is not diabetic and his lipid status is unknown.

An ECG is immediately ordered (Fig. 74.1).

Question

What is your clinical assessment and what action should be taken at this juncture?

Comment

The clinical presentation of persistent chest pain, nausea, weakness, dyspnea and diaphoresis coupled with characteristic ECG findings of elevated ST segments in more than two contiguous leads points to the diagnosis of an acute ST segment elevation myocardial infarction (STEMI) of the anterior wall. The objectives of management at this stage are: (a) relief of symptoms with oxygen, morphine and an intravenous beta-blocker, and (b) rapid restoration of nutrient blood flow through the occluded coronary artery. As to the latter, time is of the essence! There are three therapeutic options:

- fibrinolytic therapy with streptokinase or intravenous tissue plasminogen activator (e.g. reteplase, tenectoplase or alteplase)
- primary percutaneous coronary intervention (PCI)
- facilitated PCI.

Although fibrinolytic therapy is a proven effective strategy for reducing both morbidity and mortality in STEMI,[1] there is now persuasive Level A evidence that primary PCI achieves better short-term (4–6 weeks) and long-term (6–18 months) outcomes when compared to fibrinolytic therapy.[2] The outcomes measured were mortality rates, non-fatal reinfarction, strokes and major bleeds.

Timing and access must be taken into consideration. The earlier the arrival of the patient (less than 30 minutes), the less the advantage of PCI over fibrinolysis becomes apparent, especially if there is an anticipated time delay in transporting the patient across town to another facility.[3] Conversely, many studies have shown the superiority of primary PCI for those patients who require emergency transport to another facility especially if the "time to balloon" can be achieved within 60–90 minutes.[4] The degree of risk has not always been carefully integrated in trial analyses. However, it is safe to assume that those patients at higher risk, as with any of the established interventions, benefit the most. Our patient is an ideal candidate for primary PCI. He is at moderate to high risk (anterior myocardial infarction with evidence of some cardiac decompensation), he appears within the recommended window of 30–60 minutes and has no major contraindications.

Should there be no ready access to an angiographic facility, the preferred treatment would be aspirin 150–
Figure 74.1 12-lead ECG of acute anterior ST elevation myocardial infarction.

350 mg followed immediately by fibrinolysis with, in this particular case, a tissue plaminogen activator. An antithrombin agent is added to help maintain patency of the culprit artery. It should be borne in mind that the combined use of fibrinolytics, antiplatelets and antithrombin agents reduces mortality rates and non-fatal reinfarction at the expense of an increased risk of major and minor bleeding.[5] While low molecular weight heparin offers better outcomes than weight-adjusted unfractionated heparin, the net clinical benefit (i.e. adjusted for major bleeding rates) is less apparent because of the higher rates of bleeding with low molecular weight heparin.[6] The presence of pulmonary rales and an S4 gallop rhythm in this patient with a suspected large anterior wall infarction mitigates against intravenous beta-blocker therapy as long as the chest pain can be ameliorated with oxygen and morphine.[7]

What about opting for a strategy of immediate thrombolysis followed by PCI? This is so-called facilitated PCI. Theoretically, this approach offers quicker patency of the culprit artery on the way to restoration of coronary blood flow with PCI. The 2007 ACC/AHA focused update no longer recommends facilitated PCI for STEMI.[7] Recent analyses have shown a worse outcome with facilitated PCI compared to primary PCI for STEMI.[8]

Case history *continued*

On the basis of the PCI-CURE study, our patient is quickly administered two antiplatelet agents: 150 mg of chewable aspirin and 300 mg clopidogrel loading dose.[9] He is quickly transported to a cardiovascular center situated within one mile of the index hospital. At 90 minutes post symptom onset, a paclitaxel drug-eluting stent (DES) is deployed at the site of an occlusive thrombus in the proximal left anterior descending artery. His angiogram also demonstrates an old distal occlusion of a dominant right coronary artery and a 30% lesion in the obtuse marginal branch of the circumflex artery. He tolerates the procedure without incident. His blood pressure is now 132/70 and he is not in heart failure. He is started on a well-established secondary prevention regimen of an oral beta-blocker (metoprolol 50 mg bid), an angiotensin-converting enzyme (ACE) inhibitor in the form of ramipril starting at 5 mg qam and a HMG Co-A reductase inhibitor (atorvastatin) at 20 mg qhs.[1] Aspirin at 81 mg and clopidogrel 75 mg daily are continued.

The following day he complains of a sharp left parasternal pain exacerbated by movement, coughing and/or taking a deep breath. On his ECG we now see that the ST segment elevation has failed to descend following deployment of the stent and there is new ST elevation in leads II and III (Fig. 74.2). Furthermore, the tachycardia has returned despite the institution of a beta-blocker and clear lung fields. Physical examination confirms the presence of a pericardial friction rub. His blood pressure remains stable at 130/80. His internal jugular veins are not distended.

An echocardiogram shows severe anteroapical hypokinesis of the left ventricle, a pedunculated apical thrombus and an estimated global ejection fraction of 35%. There is no significant pericardial effusion. His troponin I levels increase from 0.8 to 4.5 ng/mL (normal < 0.04). His routine serum electrolytes, urea, creatinine and blood sugars are normal. His white count is only slightly elevated. His hemoglobin on admission was 140 gm/L. It is now 119.
Figure 74.2 Note the new ST elevation in lead II with further ST depression in AVR-all consistent with an acute pericardial reaction.

Question

How would you manage the pericarditis and how aggressive should you be with the LV apical aneurysm and endocardial thrombus?

Comment

In the acute phase of a full-thickness myocardial infarction, pericarditis is not an uncommon complication. It rarely poses a threat and usually runs a benign course. For pain relief a short course of an anti-inflammatory agent, either an increased dose of aspirin (650 mg qid) or a non-steroidal anti-inflammatory agent, suffices. Ibuprofen should probably be avoided as it interferes with the antiplatelet effect of aspirin.[10] It is interesting that in the thrombolytic era, the incidence of pericarditis associated with STEMI has decreased significantly, presumably due to smaller infarct sizes.[11] However, this is also the era of double antiplatelet agents, anticoagulants, antithrombin agents, platelet glycoprotein IIb/IIIa inhibitors and fibrinolytics. Despite these agents the incidence of serious hemorrhagic pericardial effusion in the acute stage of STEMI remains low.

The presence of a pedunculated apical thrombus poses a more sinister threat of systemic embolism. The patient is already on clopidogrel and aspirin. His hemoglobin is falling. What to do? The 2004 ACC/AHA guidelines for treatment of STEMI issue a Level B recommendation for three months of warfarin preventive therapy for patients with a mural thrombus.[1] The decision to add warfarin to this patient's double antiplatelet regimen (already a Level A recommendation) poses a hazard of a major bleed of 0.62%/year[12] versus the risk of a systemic embolus (<0.1%). The mural thrombus is not static and will likely endothelialize within two months. A judgment is made to forego the warfarin.

Case history *continued*

Our patient's condition is now stabilized. He is ambulating well without symptoms. On day four of his hospital course he suddenly develops a severe retrosternal pain not unlike that of his infarct. His ECG (Fig. 74.3) shows evolutionary changes only. However, his troponin I level rebounds from 0.08 to 3.5 ng/mL, clearly indicating new myocardial injury. An urgent coronary angiogram reveals an occlusive thrombus at the site of the drug-eluting stent. An intravenous platelet glycoprotein IIb/IIIa inhibitor (eptifibatide) is quickly administered and the lesion is restented using, once again, a paclitaxel-eluting (Taxus) stent. Shortly following the procedure, our patient develops rigors, fever and an urticarial rash.

Questions

- Do these events alter your management plans?
- What precipitated the allergic reaction?

Comment

Persuasive evidence exists that deployment of drug-eluting stents (DES) such as paclitaxel reduces the incidence of in-stent restenosis compared to bare metal stents.[13] But thrombotic restenosis at the site of a DES is said to occur at a rate of 0.6% at one year.[14] Under these circumstances, the choice of a glycoprotein IIb/IIIa inhibitor such as eptifibatide (Integrilin) appears to offer slightly better protection by improving outcome following stent insertion, according to the ESPRIT study.[15] The propensity for a serious bleed should be borne in mind whenever a third antiplatelet agent is added to aspirin and clopidogrel. This again is a judgment call because the occurrence of an early thrombotic occlusion of his DES does not place our patient neatly into any of the large-scale clinical trials.
Figure 74.3 Evolutionary changes of an acute anterior myocardial infarction.

Other approaches to prevent restenosis have been proposed. One of these is intracoronary gamma radiation, so-called brachytherapy.[16] This is a highly specialized procedure and so far its superiority in preventing restenosis when compared with DES has not been demonstrated.[17] The evidence for the optimum choice in preventing in-stent restenosis at the site of a compromised DES is sparse and requires further study.

As for the allergic reaction, one can only surmise that it was more related to the contrast agent since the incidence of acute allergy to Integrilin was shown to be identical (0.15%) between the placebo group and the drug group in the PURSUIT study.[18]

The allergic event responds well to intravenous corticosteroid and diphenhydramine, following which our patient goes on to make a gradual but satisfactory recovery. There are no appreciable hemodynamic, ischemic or electrical sequelae. At the time of hospital discharge he is pain free and ambulating well. Despite his trials and tribulations, our patient has a new DES in place with restoration of satisfactory flow through an occluded artery. He is pain free and failure free and he is now recovering without major mishap. He is ready for discharge and it is time for a chat.

The objectives of post-MI management are threefold:

1 to restore patient confidence by outlining an activities program commensurate with the gradual healing process of his injured myocardium

2 to advocate and prescribe secondary prophylactic medications proven to be effective in reducing reinfarction and death. These include enteric-coated aspirin, clopidogrel (at least 12 months), a statin, an ACE inhibitor and, preferably, a beta-blocker[1]

3 to advise on risk factor modification and to promote lifestyle changes. The latter include a regular exercise program (initially supervised), weight reduction, nutri-

tional advice and maintenance of a low lipid profile (see Chapters 12, 15, 23).

All this will certainly be a challenge insofar as our patient, who has just sworn off cigarettes, is a self-employed transport driver with erratic eating habits.

What about alternative strategies such as implantation of an intracardiac defibrillator (ICD) to prevent sudden cardiac death? He doesn't quite fulfill the entry criteria for the MADIT II study.[19] His LV ejection fraction at the time of hospital discharge eight days post STEMI is now 40% and probably rising. Besides, the LV ejection fraction during the first week post STEMI is a questionable determinant of future malignant events. His QRS duration is less than 120 msec. Among the several untoward events that complicated this patient's hospital course, a sinister arrhythmia was not one of them.

Conclusion

Clinical decision making is a fine balancing act between application of external best evidence and what the physician deems best for the patient. Here is a case where on two separate occasions rapid restoration of coronary blood flow was indispensable. In both instances the strategies employed were guided by evidence derived from major clinical trials despite unforeseen complications such as acute pericarditis, depressed LV function, mild heart failure, allergic reactions, the presence of a large apical mural thrombus and the threat of a major bleed.

The case also cautions against blind adherence to every consensus recommendation for the individual patient with unique complications. Here is where the physician's clinical judgment ought to be weighed carefully. For example, in this case the decision to add an anticoagulant (warfarin) because of the mural thrombus had to be weighed against

the threat of a major bleed in a patient already on two antiplatelet drugs. The decision not to implant an ICD was a judgment call based on borderline criteria. With deployment of the second stent, the decision to add a platelet glycoprotein IIb/IIIa inhibitor was not based on external evidence pertaining to that particular circumstance but on a supposition that the site of the occluded DES was particularly prone to repeat thrombosis.

75 Secondary prevention strategies post myocardial infarction

Jacques Genest

McGill University Health Center/Royal Victoria Hospital, Montreal, Canada

Case history

The patient is a 69-year-old man who sustained an acute non-ST-elevation myocardial infarction. He has a family history of premature coronary artery disease (CAD), with a brother who had coronary bypass surgery at age 54 and his father died suddenly at age 60. He is a cigarette smoker (1/2 pack per day). The ECG showed ST segment depression in the anterior leads and plasma levels of troponin I (TnI) reached 3.18u/L (normal <0.01). A coronary angiogram showed a proximal 90% stenosis of the left anterior decending (LAD) coronary artery and the decision was taken to place a bare metal stent in the proximal LAD lesion. The left ventricular ejection fraction (LVEF) was 55% with mild anterior wall hypokinesis. The patient was discharged the following day.

Six months later, he is referred for evaluation of a low high-density lipoprotein cholesterol (HDL-C). He is presently on atorvastatin 40 mg and ASA 81 mg; clopidogrel was discontinued after 3 months. He stopped beta-blockers on his own because they made him feel "sluggish". He is currently asymptomatic, in Canadian Cardiovascular Society angina class 1, and his exercise stress test showed no ischemia at a workload of 10 METS.

On physical examination, the BP is 130/82, the heart rate 72 and his Body Mass Index (BMI) is 28. The rest of the examination is normal. The lipoprotein profile is as follows: cholesterol 3.72 mmol/L, low-density lipoprotein cholesterol (LDL)-C 2.1 mmol/L, HDL-C 0.8 mmol/L, triglycerides 1.8 mmol/L, Chol/HDL-C ratio 4.65 (Table 75.1). The thyroid-stimulating hormone (TSH) is normally suppressed, Serum levels of creatine kinase (CK) and alanine transaminase (ALT) are normal.

Question

Are further interventions warranted to further reduce cardiovascular risk?

Comment

This case is seen frequently in the secondary prevention setting. The patient is nearly at the LDL-C goal of <2.0 mmol/L. The argument can be made that in the absence of mortality benefit of lowering the LDL-C <2.0 in the TNT and IDEAL trials, the patient is treated according to the current standard of care. The low HDL-C remains problematic. There is presently a paucity of evidence supporting raising HDL-C pharmacologically on a background of statin treatment. This evidence is derived, in part, from *post hoc* analysis of large-scale studies or from pooled analysis of data. The approach to this patient must first involve lifestyle changes (cigarette cessation, quality of diet, weight reduction, exercise, and possibly moderate alcohol intake) which stand on their own merits, irrespective of their effects on HDL-C levels. Indeed, an elevated serum level of HDL-C might be considered a biomarker for cardiovascular health.

While each lifestyle change is expected to raise HDL-C by ~5%, the cumulative effect of these changes may bring the HDL-C into the low-normal range for age and gender. Unfortunately, few patients implement such changes. Smoking cessation should be a priority of treatment in this patient. My own approach would be to further reduce LDL-C by optimizing the dose of statin. (Table 75.1) shows the expected effects of various pharmacologic manipulations including (1) keeping the current treatment, (2) increasing atorvastatin to 80 mg, (3) switching to rosuvastatin 40 mg, (4) adding niacin (extended release) 2 g, (5) adding fenofibrate 200 mg or (6) adding ezetimibe to atorvastatin 40 mg.

While the lipoprotein profile is improved by the five additional options suggested here, the improvement is relatively small and the clinical significance is uncertain. Niacin extended release seems to have the most favorable improvement in both HDL-C and the Chol/HDL-C ratio. Increasing the statin dose is another option and favors

Table 75.1 Expected effects on LDL-C, HDL-C and the Chol/HDL-C ratio if the current treatment is maintained, if niacin 2 g/d is added, if atorvastatin is increased to 80 mg/d, if atorvastatin is substituted for rosuvastatin 40 mg/d and if ezetimibe 10 mg/d is added. Data are based on large-scale clinical trials (see Table 75.2).

Expected → Treatment ↓	%Δ HDL-C %Δ LDL-C	HDL-C LDL-C (mmol/L)	Chol/ HDL-C	Evidence-based?
Current treatment Atorvastatin 40 mg	No Δ No Δ	0.80 2.1	4.65	Yes*
Atorvastatin 80 mg	No Δ −10%	0.80 1.9	4.39	Yes
Rosuvastatin 40 mg	No Δ −10%	0.80 1.9	4.39	Yes*
Niacin 2 g added	+20% −18%	0.96 1.72	3.45	No
Fenofibrate 200 mg added	+6% No Δ	0.9 2.1	4.04	No
Ezetimibe 10 mg added	No Δ −20%	0.80 1.7	4.14	No

*Based on clinical trials of LDL-C reduction to prevent primary or recurrent cardiovascular events in high-risk populations.

monotherapy. It should be pointed out that of the options presented here, only statins (at either the maximal dose or used to decrease LDL-C <2.5 mmol/L) are currently supported by evidence-based literature. The use of fenofibrate is less well supported by clinical trial data, especially in light of the FIELD trial. Other fibrates, especially gemfibrozil, should not be combined with statins because of the risk of rhabdomyolysis. The addition of ezetimibe to statin monotherapy has the advantage of reducing LDL-C to a greater extent than simply doubling the dose of statin and avoiding side effects and adverse events associated with high-dose statins.

General comments on secondary preventive strategies

National guidelines for the secondary prevention of cardiovascular disease emphasize lifestyle changes (smoking cessation, quality of the diet, in terms of reducing saturated fats, weight reduction, physical activity and decrease in psychologic stress[1–3]). In this case, the immediate period following acute myocardial infarction was discussed, with emphasis on treatment and prevention of thrombotic episodes. Here, we will review an aspect of metabolic heart disease that is more controversial and much less supported by evidence-based medicine.

The data supporting lowering LDL-C for the prevention of recurrent events are well established and entrenched in

clinical practice. Pharmacologic therapy is indicated to reach an LDL-C <2.0 mmol/L and a Chol/HDL-C ratio <4.0. Aspirin is indicated in all subjects unless contraindicated. Beta-adrenergic blockers are indicated post myocardial infarction as are ACE inhibitors if the LVEF is decreased. A goal for HDL-C has not been set because of a lack of effective therapies to raise HDL-C and a lack of solid clinical evidence supporting raising HDL-C pharmacologically for cardiovascular disease prevention. While a low HDL-C is considered a categoric cardiovascular risk factor[2–4] and is the most frequent lipoprotein disorder in premature CAD,[5,6] there is still controversy surrounding the causal role of a low HDL-C in atherosclerosis. Experimental evidence shows that the atheroprotective effects of HDL extend far beyond removing cholesterol from lipid-laden macrophages in the atherosclerotic plaque, an effect known as the reverse cholesterol transport. HDL have anti-inflammatory effects, prevent oxidation of LDL, have antithrombotic properties, modulate vasomotor tone and may improve endothelial cell survival (by preventing apoptosis), migration and proliferation.[7,8]

Current approaches to raising HDL-C pharmacologically include statins, fibrates and niacin. Large-scale clinical studies using statins or fibric acid derivatives (fibrates) have shown a modest effect of these two classes of medication on HDL-C levels, usually in the order of 5–10%, much less than reported in smaller studies[9] (Table 75.2). The drug torcetrapib, an inhibitor of cholesteryl ester transfer protein (CETP), led to marked improvement in all lipoprotein classes when used with atorvastatin, but proved toxic in the large-scale clinical trial ILLUMINATE[10] and showed no benefits on surrogate markers of atherosclerosis such as intravascular ultrasound[11] or carotid intima-media thickness.[12,13] Whether other CETP inhibitors will prove cardioprotective will have to be determined in appropriate clinical trials.

Effects of statins

Statins have a modest effect on HDL-C which may be mediated by the decrease in plasma triglycerides and an indirect effect on the transcriptional regulation of apolipoprotein AI (apo AI).[14] There are presently six large-scale secondary or high-risk prevention trials that have examined the effect of statins on major cardiovascular events, coronary heart disease (CHD) mortality and total mortality[15–20]; the SEARCH trial[21] will compare simvastatin 20 mg to atorvastatin 80 mg. These findings are summarized in Table 76.2. Overall, the increase in HDL-C is modest, between 0% and 10%. The reduction in LDL-C is far more impressive and is considered to be a major factor in the reduction in cardiovascular morbidity and mortality. Meta-analysis of cholesterol reduction trials shows unambiguously the benefits of lowering LDL-C for cardiovascular disease prevention, especially in high-risk individuals.[22] The results of these trials have been incorporated in national treatment guidelines for the prevention of CAD.[1,2]

Effect of fibrates

The use of fibrates for the prevention of cardiovascular diseases had led to more nuanced results. The VA-HIT trial showed a 22% reduction in major cardiovascular events with the drug gemfibrozil in patients with low HDL-C.[23] Conversely, bezafibrate showed no benefits overall in patients post MI in an Israeli study.[24] The FIELD study, in stable diabetic subjects, showed a neutral effect of fenofibrate on cardiovascular endpoints.[25] These studies showed potential benefits of fibrates in subgroup analysis which were, for the most part, not prespecified. Meta-analysis of fibrate trials, based on 17 studies,[26] not including the FIELD trial, suggests that fibrates have a neutral effect on cardiovascular mortality. Generally, fibrates use will increase HDL-C by 5–15%, reduce triglycerides by 20–40% and cause a variable change in LDL-C. In moderate hypertriglyceridemia, fibrates can cause an elevation in LDL-C, because of an increase in lipoprotein lipase activity and increased conversion of VLDL to LDL.

Effects of niacin

Only two relatively large trials, both predating the statin era, have studied the effects of niacin on cardiovascular outcomes. The Coronary Drug Project examined the effects of 3 g/day of nicotinic acid on CHD events.[27] After 6.5 years, there was a reduction in CHD events, but not cardiovascular mortality. A *post hoc* analysis performed 10

years after the end of the study revealed a significant 11% reduction in total mortality, even when most patients were off study drug. The Stockholm Ischemic Heart Disease Study examined the combined effects of clofibrate 2 g/d with niacin 3 g/day in MI survivors. Total mortality was reduced by 26% and cardiovascular mortality by 36%.[28] Niacin has broad and beneficial effects on all lipoprotein subclasses, including lipoprotein Lp(a).[29] An in-depth analysis of all subsequent trials, most of which are angiographic regression studies or surrogate endpoints of atherosclerosis, and underpowered to evaluate cardiovascular morbidity and mortality, suggests that niacin has potent antiatherosclerotic effects.[30] It should be noted that the currently recommended dose of niacin (either in a slow- or extended-release form) is 2 g/d. At this dose, one can expect an increase in HDL-C in the order of 20–25%, a reduction in LDL-C of 15–20% and a reduction in triglycerides of 20–30%, depending on baseline values.

Clinical trial evidence Niacin has been used clinically for the past 50 years, since the observation by Canadian pathologist Aschtul that it can decrease total serum cholesterol.[31] For many years, niacin was one of the few medications available to treat patients with dyslipidemias. The use of bile acid-binding resins and fibrates in the 1970s increased the physician's armamentarium. However, the many side effects of niacin led to a decreased enthusiasm

for its continued use in favor of statins which were first used in the mid 1980s. The side effects of niacin include flushing, now known to be caused by the release of prostaglandin G2 by the Langerhans cells in the epidermis. Blocking the PgG2 receptor DP1 markedly decreases episodes of flushing and may make niacin easier to tolerate.[32] A decrease in flushing is also seen in extended-release forms of niacin, by taking the drug with a small amount of food and taking aspirin which may work by decreasing prostaglandin release. Other side effects include gastritis, elevation of hepatic transaminases, worsening of dysglycemia and diabetes control, and an unusual form of acanthosis nigricans affecting the skin. These side effects, especially vasomotor flushing, cause a marked decrease in compliance, with less than half of the patients continuing treatment at one year.

A recent meta-analysis of published trials with niacin, statins or fibrates in combination concluded that the simultaneous reduction of LDL-C and elevation of HDL-C are associated with independent and synergistic effects of these two approaches.[30] This analysis and another review of IVUS studies[33] suggest that HDL-C elevation brings additional benefits to those observed by lowering LDL-C alone.

Novel approaches to raising HDL-C

CETP inhibitors CETP is a serum enzyme that facilitates the equimolar exchange of cholesteryl esters within HDL particles for triglycerides in triglyceride-rich lipoproteins, such as VLDL. Its role is to facilitate the reverse cholesterol transport from HDL to the liver. Rare deficiencies of CETP in man are associated with a marked increase in large HDL particles that appear biologically functional, in terms of promoting cellular cholesterol efflux.[34] Several CETP inhibitors have been or are in the process of being developed. Initial clinical data on torcetrapib and JTT705[35,36] showed that these agents increase HDL-C in a dose-dependent fashion. Unfortunately, clinical trials with torcetrapib have led to the conclusion that despite a marked (and beneficial) improvement in all lipoprotein subclasses, the drug has toxic features unrelated to its HDL-C rising effects.[10] Whether other CETP inhibitors will show similar problems will be determined clinically. In light of the increased mortality in the ILLUMINATE trial with torcetrapib, it is likely that regulatory agencies will scrutinize this class of products very closely.

Endocannabinoid receptor CB1 antagonists The first of its class, the CB1 blocker rimonabant is designed to be used for the reduction of cardiometabolic risk in subjects with obesity and elevated cardiovascular risk. In large clinical trials of weight reduction, HDL-C increased by ~8%, a finding closely related to weight reduction.[37] This is likely to represent an appealing therapeutic option in patients with abdominal obesity and at elevated cardiovascular

risk. Rinomabant is no longer approved because of concerns about depression and suicide.

Oral phospholipid supplements Lipoprotein researchers have known for some time that phospholipids, the major lipid constituent of nascent HDL particles, can increase HDL-C. A novel approach, the use of orally administered phosphatidylinositol, has been associated with a modest rise in HDL-C when taken in large doses (3–5 g/d).[38] This approach is limited because of a high incidence of gastrointestinal side effects (mostly diarrhea) at the highest doses in small-scale clinical trials.

Intravenous injections of apo AI proteoliposomes A proteoliposome is an artificially reconstituted small (nascent) HDL particle. It consists of apo AI mixed with phospholipids (usually phosphatidylcholine – PC) in a specific ratio of approximately two molecules of apo AI to ~200 molecules of PC. This results in the formation of disk-like structures that have many of the proprietes of nascent HDL particles. Apo AI Milano (Apo AI$_M$) is a naturally occurring mutant of apo AI found in a single kindred living in the northern Italian region of Limone sul Garde. Carriers of Apo AI$_M$ have very low levels of HDL-C but do not develop atherosclerosis and appear to benefit from longevity.[39] In a small clinical trial, apo AI$_M$ proteoliposomes were injected intravenously weekly for five weeks in 47 subjects presenting with an acute coronary syndrome. Intravascular ultrasound of the coronary arteries documented a small but significant 4.2% regression of coronary artery atherosclerotic plaques, suggesting that apo AI$_M$ has rapid antiatherosclerotic effects.[40] A similar trial used wild-type (i.e. normal) apo AI proteoliposomes in patients with acute coronary syndromes. The results of this study showed no evidence of regression of CAD on intravascular ultrasound (IVUS), compared to placebo.[41] Large-scale trials with clinical events are needed to assess the impact of apo AI$_M$ on cardiovascular events. The cost of repeated injections with a protein, the stability and shelf-life of proteoliposomes preparations remain concerns.

The potential benefits of peptide-mimetic substances that share similar properties of the amphipathic α-helical structural domains of apo AI were examined using the synthetic peptide D4F that appears to have anti-inflammatory effects similar to apo AI. The advantage of this compound is that it can be administered orally. In animal studies, D4F has been shown to act synergistically with statins to prevent atherosclerosis in the apo E$^{-/-}$ mouse model.[42] Clinical trials in man have not yet been reported.

Molecular approaches to increasing HDL-C

Drugs that increase the production of apo AI have the potential benefit of raising HDL-C. Statins and fibrates both increase apo AI production.

Patients infected with the human immunodeficiency virus (HIV) who are treated with highly active antiretroviral therapy (HAART) develop, in some instances, a dyslipidemia similar to that observed in partial lipodystrophy and the metabolic syndrome, with a low HDL-C and elevated triglycerides. The non-nucleoside reverse transcriptase inhibitors nevirapine and efavirenz are associated with an increase in apo AI and HDL-C, likely caused by an increased production of apo AI.[43] While the effect on atherosclerotic cardiovascular disease of these compounds has yet to be reported, they represent interesting alternatives in patients on HAART who develop a dyslipidemia. In theory, a compound that increases the transcriptional regulation of apo AI in the liver and intestine could lead to the formation of nascent HDL particles. Several compounds, such as statins and fibrates, may increase apo AI production, albeit weakly.[14] Novel molecules that increase apo AI are currently being explored. Similarly, compounds that increase the ABCA1 transporter may increase the formation of HDL particles. The ABCA1 gene is under the regulatory control of the liver-specific receptor (LxR) family of transcriptional regulators. Several LxR agonists are available for *in vitro* experiments, but these lack specificity for the ABCA1 gene and may cause the upregulation of a multitude of genes, especially in fatty acid metabolism. The search for selective ABCA1 LxR agonists holds theoretic promise.[44]

Conclusion

The prevention of cardiovascular events in high-risk individuals or those at high risk of recurrent events in secondary prevention of CAD requires a multifactorial approach, combining lifestyle changes and intensive medical therapy. The interventions explain more than half the observed reduction in CHD observed between 1980 and 2000.[45] Such therapy has been shown to preclude the necessity of coronary revascularization in patients with chronic, stable angina.[46] The role of LDL-C lowering is well established and current guidelines emphasize this point. The issue of raising HDL-C is presently uncertain.[47] Epidemiologic evidence has consistently shown the inverse relationship between HDL-C and CAD. It has yet to be shown that raising HDL-C pharmacologically prevents atherosclerosis. The current therapies available to clinicians are limited, especially after the failure of torcetrapib to reduce cardiovascular events. The only drug that raises HDL-C reliably is niacin. Statins, fibrates and ezetimibe have a more modest effect on HDL-C. An argument can be made that aggressive lowering of LDL-C is presently the only treatment unequivocally shown to reduce cardiovascular risk. Drug therapy aimed at increasing HDL-C (other than niacin) has been disappointing and the data supporting niacin are weaker than that for statins.

Two large-scale trials are currently under way to assess the effects of HDL-C elevation with niacin on cardiovascular morbidity and mortality. These two trials will examine the effects of adding niacin to the current standard of care in patients at high risk of cardiovascular diseases (information available at http://clinicaltrials.gov/) The AIM-HIGH study will randomize 3300 subjects with atherogenic dyslipidemia to a combination of extended-release niacin and simvastatin or simvastatin alone in the prevention of heart disease. The primary objective will be to examine the composite endpoints of CHD death, non-fatal MI, ischemic stroke or hospitalization for high-risk non-ST segment elevation acute coronary syndrome. The trial is expected to last four years. The HPS THRIVE trial will examine the effects of MK0264a (niacin 2 g/day with the PgG2 DP1 blocker laropiprant 40 mg) or placebo in 20 000 subjects at high cardiovascular risk from the UK, Scandinavia and China over a background treatment with simvastatin 40 mg or simvastatin 40 mg plus ezetimibe 10 mg to reach LDL-C goals. The follow-up will be approximately four years for an expected number of major cardiovascular events of 2300. Results are expected by 2013.

76 Heart failure

Michael M Givertz and Garrick C Stewart
Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA

Case history

A 60-year-old man with type 2 diabetes mellitus and coronary artery disease presents to your office with progressive dyspnea on exertion and lower extremity edema. He is status post anterior myocardial infarction five years ago. Following cardiac rehabilitation, he returned to work full-time as an electrical engineer and remained asymptomatic without angina or heart failure until one year ago when he started to "slow down". Over the last several months, he has noted increasing shortness of breath with usual daily activities, and more recently the onset of bilateral lower extremity edema. He can no longer play with his grandchildren due to fatigue. He denies chest pain, palpitations or lightheadedness. He sleeps comfortably on two pillows and has had no recent change in his weight or appetite. His current medications include captopril 12. 5 mg tid, furosemide 20 mg qd, rosiglitazone 4 mg qd and aspirin 81 mg qd.

On physical exam, he is a well-nourished older-appearing man who appears comfortable lying supine. Blood pressure is 130/70 mmHg and heart rate is 95 beats per minute and regular. Jugular venous pressure is 10 cm of water. Lungs are clear bilaterally. Cardiac exam reveals a laterally displaced point of maximal impulse, grade 2 over 6 holosystolic murmur at the apex, and soft S_3 gallop. The liver edge is palpable 2 cm below the right costal margin, and there is 1+ pitting edema to the mid-calves bilaterally. His feet are warm with intact distal pulses. Lab tests are notable for serum sodium of 136 mmol/L, creatinine of 1. 6 mg/dL and hemoglobin A1c of 6.2%. His electrocardiogram reveals normal sinus rhythm with an intraventricular conduction delay (QRS duration 150 msec) and old anterior myocardial infarction. A transthoracic echocardiogram demonstrates moderate left ventricular dilation (end-diastolic dimension 63 mm) with anteroapical akinesis, left ventricular ejection fraction of 25%, mild right ventricular dysfunction, and 2+ mitral regurgitation with a structurally normal valve.

Question

How would you manage this patient?

Comment

This is a middle-aged man with diabetes and an ischemic cardiomyopathy who presents with New York Heart Association (NYHA) functional class III heart failure. There is clinical and laboratory evidence of left ventricular systolic dysfunction, and "bedside" hemodynamic assessment reveals volume overload without evidence of decreased systemic perfusion. In addition, his echocardiogram shows findings consistent with left ventricular remodeling without intracavitary thrombus formation. He has been compliant with his medications and fluid and salt restriction, and does not drink alcohol. His blood sugars have been well controlled, and he has had no recent infection. A complete blood count and thyroid function tests should be checked to rule out anemia and hyperthyroidism, respectively. One possible precipitating factor in this case is his use of a thiazolidinedione for glucose control, a class of medications that has been shown to worsen heart failure symptoms and may increase the risk of cardiovascular events.[1,2] The patient should be switched to an alternative antidiabetic medication, such as a sulfonylurea or insulin. Metformin is relatively contraindicated in patients with heart failure and renal dysfunction due to a small risk of lactic acidosis.

After identifying and addressing a precipitating factor, it is reasonable to consider treatment of the underlying cause of heart failure.[3] The patient is a diabetic status post myocardial infarction several years ago and may have developed recurrent ischemia, either silent or with dyspnea as an anginal equivalent. An exercise study with imaging should be performed to rule out reversible ischemia. If this is negative, an assessment of myocardial viability with low-dose dobutamine stress echocardiography, resting

thallium scintigraphy or positron emission tomography should be considered.[4] Several studies have shown that patients with ischemic cardiomyopathy and viable myocardium have significant improvement in left ventricular function following surgical revascularization. However, in the absence of angina or inducible ischemia, the superiority of surgery over medical therapy in prolonging survival in patients with ischemic cardiomyopathy remains unproven.

Sleep-disordered breathing is a common co-morbidity in heart failure. As many as 30–40% of heart failure patients may have obstructive or central sleep apnea, or both.[5] Frequent apneic episodes lead to sympathetic activation, hypertension and diastolic dysfunction, which may worsen heart failure symptoms. The most extreme form of central sleep apnea, Cheyne–Stokes periodic breathing, is present in more severe forms of heart failure. Routine screening for sleep apnea should be performed in all heart failure patients by asking the patient and spouse about snoring, nocturnal apneic episodes, and daytime somnolence.[6] The cornerstone of sleep apnea therapy is positive airway pressure, often with supplemental oxygen. Positive pressure therapy has been shown to improve ejection fraction and six-minute walk distance, but not survival.[7] Prospective studies are needed to evaluate the impact of sleep apnea on heart failure outcomes, including sudden death.

The overall goals in the management of heart failure are to eliminate symptoms, improve quality of life, and prolong survival. Non-pharmacologic management of heart failure should be reviewed with the patient and family. The importance of salt and fluid restriction and daily weight monitoring should be reinforced, and alcohol moderation or cessation should be advised. Once euvolemia has been achieved, a submaximal aerobic exercise program (e.g. walking, stationary bicycle) should be encouraged. Exercise training may result in improvement in symptoms and functional capacity, enhanced blood flow and skeletal muscle metabolism, and reduced heart failure hospitalizations.[8,9] In a National Institutes of Health-sponsored trial (HF-ACTION), exercise training had no significant effect on survival in heart failure.[10]

Pharmacologic therapy should be optimized according to consensus guidelines.[11–13] The patient is currently taking captopril, an angiotensin-converting enzyme (ACE) inhibitor, at a relatively low dose. Several large prospective randomized controlled trials have demonstrated the beneficial effects of ACE inhibitors on exercise tolerance, salt and water balance, symptoms, neurohormonal activation, quality of life and survival in patients with chronic heart failure.[14] As demonstrated in SAVE, captopril reduces the risk of recurrent myocardial infarction and stroke in patients with post-MI left ventricular dysfunction.[15] In this patient with mild diabetic nephropathy, ACE inhibitor or angiotensin-II receptor blocker (ARB) therapy may also slow the progression of renal dysfunction. The optimal dosing of ACE inhibitors remains controversial. One prospective study (ATLAS) demonstrated the modest superiority of high-dose versus low-dose ACE inhibitor therapy in patients with chronic heart failure without increased toxicity.[16] Current guidelines recommend increasing the dose of captopril to 50 mg tid as blood pressure and renal function tolerate. For improved medication compliance, a change to once-daily ACE inhibitor dosing may also be considered since these drugs exhibit a class effect. Despite previous concerns that aspirin use may attenuate ACE inhibition, recent studies indicated no adverse effects of combining aspirin and ACE inhibitors.[17,18] Therefore it is reasonable to continue low-dose aspirin for secondary prevention of coronary artery disease.

Treatment of systemic and pulmonary venous congestion warrants more aggressive diuresis. The daily dose of furosemide or other loop diuretic should be increased until the required response is achieved (e.g. absence of jugular venous distension, hepatomegaly and edema). This "dry weight" should be recorded and used as a euvolemic baseline to guide future diuretic therapy, although further weight loss in advanced heart failure may be due to cardiac cachexia.[19] If this strategy is not effective, combination therapy with a thiazide diuretic should be tried. Adequate diuresis will generally result in improved symptoms and may slow the progression of chamber dilation by reducing ventricular filling pressures. However, diuretic therapy may also cause renal dysfunction, electrolyte depletion and neurohormonal activation. It should be emphasized that there have been no randomized controlled trials demonstrating the long-term efficacy and safety of diuretic therapy in patients with heart failure. Furthermore, studies are needed to address the safety and efficacy of diuretic withdrawal in stable heart failure patients.

Case history *continued*

The patient undergoes rest and stress imaging with positron emission tomography, which is negative for ischemia and demonstrates no significant viability of the anterior wall. He diureses eight pounds on an increased dose of oral furosemide, and captopril is titrated to 37. 5 mg tid. Jugular venous distention and lower extremity edema resolve, while blood pressure, heart rate, and renal function are unchanged. Despite adjustment of ACE inhibitor and diuretic therapy, there is minimal improvement in his exertional dyspnea and fatigue.

Question

The patient remains moderately symptomatic despite treatment with an ACE inhibitor and diuretic. What is the next step?

Comment

The next step is to initiate beta-adrenergic antagonist therapy. Multiple randomized controlled trials have demonstrated that beta-blockers improve symptoms and cardiac function, and reduce morbidity and mortality in patients with chronic heart failure due to left ventricular systolic dysfunction.[20–23] Consensus guidelines recommend using beta-blockers, in addition to ACE inhibitors and diuretics, in the management of patients with left ventricular systolic dysfunction.[11] Once euvolemia has been achieved, beta-blocker therapy with carvedilol, bisoprolol or sustained-release metoprolol can be initiated safely at a low dose and titrated gradually at regular intervals (e.g. every 1–2 weeks). Despite concerns that beta-blockers may increase insulin resistance, reduce insulin secretion or mask hypoglycemia, they have been shown to be safe and effective in treating symptomatic systolic dysfunction in diabetic patients.[24] In heart failure patients, carvedilol, a non-selective beta-blocker with alpha$_1$-blocking properties, has a lower rate of new-onset diabetes and diabetic events when compared to metoprolol.[25]

Given this patient's multiple exacerbations of chronic heart failure, complicated by diabetes and renal insufficiency, it would be appropriate to refer him to a comprehensive disease management program in heart failure. Either clinic or home-based disease management programs significantly reduce readmission rates and costs, while improving functional status and quality of life for heart failure patients.[26,27] Such programs promote self-care, emphasize behavioral strategies to increase adherence, increase access to providers, and give early attention to signs and symptoms of fluid overload.[28]

Case history *continued*

Carvedilol is initiated at a dose of 3.125 mg bid. One week later, the patient returns to your office with complaints of increased exertional dyspnea and pedal edema. His clinical evaluation is consistent with worsening heart failure, a known adverse effect of beta-blocker therapy initiation. This responds to a doubling of the furosemide dose for two days. The patient is also enrolled in a heart failure disease management program for comprehensive care. Over the next three months, carvedilol is titrated to a target dose of 25 mg bid. During this period, an exacerbation of heart failure symptoms occurs on one additional occasion. Close monitoring of symptoms and weight, and adjustments in diuretic dosing, enable the patient to achieve a target dose of beta-blocker therapy. Repeat echocardiogram reveals a modest decrease in the left ventricular end-diastolic dimension and an increase in the left ventricular ejection fraction to 30%.

Question

What are your next steps in pharmacologic management if the patient continues to have symptomatic heart failure?

Comment

For persistent heart failure symptoms despite optimal dosing of ACE inhibitor, beta-blocker and diuretic, several adjunctive medications may be considered. Given the patient's reduced ejection fraction and relatively preserved renal function, an aldosterone antagonist is a reasonable next step. Aldosterone, an adrenal mineralocorticoid, plays an important role in the pathophysiology of heart failure, contributing to salt and fluid retention, cardiac and vascular remodeling and ventricular arrhythmias.[29] The addition of spironolactone to standard therapy was shown to reduce mortality in patients with NYHA functional class III–IV heart failure in the RALES trial.[30] Although spironolactone is generally well tolerated, it has antiandrogenic and progesterone-like effects and is associated with a small risk of painful gynecomastia, often prompting a switch to the more selective aldosterone antagonist eplerenone. Eplerenone has been shown to reduce mortality if added to standard therapy within two weeks of myocardial infarction complicated by reduced ejection fraction or heart failure.[31] Both spirinolactone and eplerenone can produce hyperkalemia, a particular risk in older patients with compromised renal function on ACE inhibitors, ARBs or potassium supplements.[32] Serum potassium and creatinine levels must be checked frequently during initiation and titration of aldosterone antagonists. Potassium supplementation should be discontinued unless there is evidence of persistent hypokalemia with serum potassium levels <4 mmol/L. The addition of an ARB to ACE inhibitor and beta-blocker therapy may be considered for heart failure patients with reduced ejection fraction and preserved blood pressure.[33] ARBs have also been recommended for use in heart failure patients with systolic dysfunction who are intolerant of ACE inhibitors, or in addition to ACE inhibitors in patients not treated with beta-blockers.[34]

Another class of medications that may provide symptomatic benefit in heart failure patients is the organic nitrates. Nitrates may be used to reduce both systemic and pulmonary venous congestion and prevent ischemia. As with diuretics, nitrates alone have not been shown to reduce morbidity and mortality in patients with chronic heart failure. However, a fixed combination of hydralazine and isosorbide dinitrate has been shown to reduce morbidity and mortality and improve quality of life in self-identified blacks with heart failure already treated with ACE inhibitors and beta-blockers.[35]

Digoxin is an oral positive inotropic agent with anti-adrenergic effects that has been shown to be safe and

effective in patients with symptomatic heart failure. While the DIG trial showed no difference in survival in heart failure patients treated with digoxin versus placebo, there were fewer heart failure hospitalizations and a trend toward reduced death from progressive heart failure in the digoxin-treated group.[36] For heart failure patients in sinus rhythm, digoxin dosing should be based on lean body mass and renal function, and serum digoxin levels should be maintained less than 0.8–1.0 ng/mL.[37]

Question

Which device-based therapies may be considered for this patient with symptomatic heart failure and reduced ejection fraction?

Comment

In recent years there has been considerable enthusiasm for cardiac resynchronization therapy (CRT) as adjunctive treatment for patients with advanced heart failure. Dyssynchronous contraction, as occurs with left bundle branch block or other intraventricular conduction delays, is mechanically inefficient and over time may lead to a reduction in left ventricular ejection fraction and cardiac output.[38] Simultaneous pacing of the left and right ventricles (biventricular pacing) to resynchronize ventricular contraction has been shown to improve both functional capacity and quality of life as early as one month after device implantation, and is associated with reverse ventricular remodeling as early as six months.[39,40] Two clinical trials, COMPANION and CARE-HF, evaluated the effect of CRT on survival.[41,42] In both trials the risk of all-cause mortality was reduced by CRT as compared to no pacing, although only CARE-HF reached statistical significance. Current indications for CRT include dilated cardiomyopathy of any cause with a left ventricular ejection fraction <35%, intraventricular conduction delay as measured by a QRS interval of at least 120 msec, and NYHA functional class III or stable class IV heart failure despite optimal medical therapy.[43] The REVERSE trial also showed benefits of CRT on hospitalization and ventricular remodeling in patients with mildly symptomatic HF.[44] Of concern, 20–30% of patients will not have significant clinical or echocardiographic improvement with CRT. Establishing criteria to identify CRT responders prior to device implantation is an active area of investigation.

Heart failure patients with reduced ejection fraction are also at increased risk for sudden cardiac death.[45] Implantable cardioverter-defibrillators (ICDs) have been shown to improve survival in patients with left ventricular ejection fraction <30–35% and heart failure due to either ischemic or non-ischemic causes.[46,47] In SCD-HeFT, ICD implantation was superior to both antiarrhythmic therapy with amiodarone and placebo on primary prevention of sudden cardiac death in symptomatic heart failure patients with

low ejection fraction.[48] As with CRT, ICDs are not recommended for end-stage, refractory heart failure patients with little prospect of clinical improvement or survival beyond one year.[49] Primary prevention therapy with an ICD may be considered if there is a persistently reduced ejection fraction despite 3–6 months of optimal medical therapy, including an ACE inhibitor and beta-blocker. Most candidates for CRT are also candidates for ICD placement. An ongoing trial (MADIT-CRT) will evaluate the role of ICDs with or without CRT in a large cohort of minimally symptomatic patients with NYHA class I or II heart failure.

Case history *continued*

The patient is started on spironolactone 12. 5 mg once daily and eventually titrated to 25 mg, with close monitoring of his renal function and serum potassium level. Despite these maneuvers, he still has recurrent symptomatic heart failure and elects to undergo implantation of a CRTD (CRT plus ICD) device. The patient responds clinically to CRT and experiences an improvement in his exercise capacity and quality of life. Two months after implantation he is playing with his grandchildren again with minimal dyspnea. A repeat echocardiogram obtained six months later shows reduced LV dimensions and an increase in ejection fraction to 35%.

77 Atrial fibrillation

Michael Klein
Boston University Medical Center, Boston, MA, USA

Case history

A 40-year-old male was evaluated for intermittent chest tightness without shortness of breath or palpitations. Symptoms occurred with nervousness but not exertion. Family history was notable for the death of his mother at 57 with chronic heart failure and a brother at age 16 of sudden cardiac death while jogging. His father was 75 and previously had both aortic valve replacement and abdominal aortic aneurysm surgery. Personal habits included no smoking, two cups of caffeinated coffee daily, modest alcohol, on weekends mostly. He was physically active including bike riding and water skiing.

Physical exam revealed a robust male with normal peripheral pulses and no bruits or edema. The BP was 136/90 mmHg sitting and 130/86 mmHg right arm after 30 seconds standing. Pulse was 80 and regular. Fundoscopy was normal. The chest was muscular with left precordial hypertrophy. S1 was normal, S2 normally split with $A_2 > P_2$; apical fourth and third heart sounds were audible together with a Grade 2/6 midsystolic murmur. Occasional extrasystoles were noted. ECG (Fig. 77.1) showed normal sinus rhythm with normal PR, QRS, QT intervals, a QRS axis of 9 degrees, narrow Q-waves in aVF. Increased voltage of left ventricular hypertrophy (LVH) with strain effect and left atrial enlargement were present.

A tentative diagnosis of cardiomyopathy with possible outflow tract obstruction was made.[1] Because of the worrisome pattern of LVH with strain which has been associated with non-fatal and fatal cardiovascular events,[2] the family history, and the angina-like symptoms, cardiac catheterization was undertaken.

Coronary angiography revealed a 60–70% left anterior descending artery stenosis. Minimal atherosclerosis was evident elsewhere. Pressures were 107/18 mmHg in the LV, 24/13 mmHg in the PA, and 29/7 mmHg in the RV without evidence for either left- or right-sided outflow tract obstruction at rest. By echocardiogram, the LV was normal in size and had concentric hypertrophy with an interventricular septal thickness of 16 mm. The LVEF was 40%. Left atrial volume was modestly increased at 36 mL/m² with an
Figure 77.1 Initial encounter ECG showing sinus rhythm, left atrial enlargement, left ventricular strain.

emptying time of 190 msec. Mitral inflow velocity profile showed a E/A ratio of 1.2. The low septal early diastolic mitral annular velocity e′ was 8 cm/sec with increased E/e/ ratio. Grade II diastolic dysfunction was calculated.[3]

Based upon these findings, drug therapy was begun with beta-blocker, aspirin, statin and low-dose angiotensin-converting enzyme (ACE) inhibition. Goals included:

- slowing the resting heart rate to 50–60 to maximize diastolic flow-time into the hypertrophied LV
- affording some protection against atrial or ventricular ectopy
- lowering LDL cholesterol to below 130 mg/dL.[4,5]

Four years later the patient developed palpitations and exertional dyspnea. ECG revealed atrial flutter-fibrillation (Fig. 77.2). Transesophageal echocardiography excluded left atrial thrombus or smoke.
Figure 77.2 Four years later. ECG shows atrial flutter fibrillation.

Question

What action would you take at this juncture?

Comment

Sinus rhythm was re-established by cardioversion. Restoration of rhythm control, as opposed to rate control, was believed likely to alleviate symptoms of exertional dyspnea and palpitations, thereby improving lifestyle,[6] even if it did not confer an additional benefit of stroke risk protection.[7] Sequential atrioventricular contraction would maximize diastolic filling of the hypertrophied left ventricle while lowering left atrial pressure and normalizing exertional heart rate increments, enhancing exercise capacity.[8]

Anticoaulation with warfarin to INR 2.0–3.0 was initiated to reduce the risk of atrial fibrillation-induced thromboembolic (TE) stroke.[9] Even though the patient's CHADS$_2$ score was only one, implying an intermediate risk for such TE stroke origin, both this metric and other risk stratification schemes used to predict stroke risk in atrial fibrillation exhibit poor discriminatory ability with c-statistic of 0.56–0.62, distant from the ideal of 1.0.[10] The advanced left ventricular hypertrophy and diastolic dysfunction associated with the patient's cardiomyopathy was likely to result in recurrent atrial fibrillation with sluggish left atrial appendage inflow and outflow velocities posing an appendicular thrombus risk.

Case history *continued*

Within six months, however, palpitations recurred and the ECG documented atrial flutter. An electrophysiology study confirmed the presence of atrial flutter with a 230 msec cycle length and typical cavotricuspid isthmus (CTI) and counterclockwise rotation.

Question

How should you proceed with this information?

Comment

The atrial flutter was thought to present an even greater problem with heart rate control with the potential for quantum jumps in ventricular rate with exertion. Radiofrequency catheter ablation was performed and terminated the flutter with bidirectional conal block documented at the ablation site.[11] The atrial flutter was thought to be related to previous fibrillation-flutter functionally, wherein a line of block (LoB) in the right atrium in the CTI formed.[12] Medical therapy with low-dose aspirin and warfarin was continued. Beta-blocker, angiotensin-converting enzyme inhibitor and statin therapy were also maintained to slow the process of electrical ventricular remodeling associated with hypertrophic cardiomyopathy[13] and retard the processes of mechanical and electrical atrial remodeling predisposing to atrial fibrillation.[14–16]

Case history *continued*

During office visits over the next several years, the patient reported episodes of palpitations and recrudescent atrial fibrillation documented by ECG. INR control was managed via an anticoagulation clinic with documented INRs between 2.0 and 3.0 for more than 85% of measurements. Cardioversion to sinus rhythm was successfully accomplished on two separate occasions nine months apart. Amiodarone, 200 mg/day, was added to the medical regimen in an effort to electrically stabilize the atria and preserve sinus rhythm.[17] However, though remaining physically very active, the patient continued to have palpitations, sporadic chest pressure or dyspnea and a new fatigue and occasional light-headedness. Repeat ECG showed sinus bradycardia of 46–50/min, infrequent single late cycle ventricular premature beats, and an unchanged left ventricular hypertrophy with strain. Blood tests showed a thyroid-stimulating hormone (TSH) of 3.5, HCt 42%, Cr of 0.8 mg/dL, BUN 12 mg/dL, glucose 88, NA 144 mEq/L, K 4.5 mEq/L, cholesterol 188 mg/dL, HDL 45 mg/dL, triglyceride 160 mg/dL, with calculated LDL of 111 mg/dL. A stress echo was performed to clarify the symptoms of exertional chest pressure and shortness of breath. With the BRUCE protocol the patient exercised for 8.2 minutes, stopping with fatigue and chest pressure at a peak heart rate of 114 per minute. The ECG was obscured by LVH with strain. Occasional ventricular and atrial premature beats were observed. Echo recordings indicated preserved LV systolic function, Grade II diastolic dysfunction, and recruitment (thickening) on all regions of the left ventricle except the septum. Based upon these findings, repeat coronary angiography was done which indicated persistent 60–70% left anterior descending artery stenosis and minimal atherosclerosis elsewhere. Symptoms of exertional dyspnea and chest pressure were ascribed to diastolic dysfunction and, possibly, abnormal coronary vasodilator reserve capacity.[18] Amiodarone was discontinued because of fatigue and sinus bradycardia.

On return evaluation six months later, atrial fibrillation was again documented by ECG. The ventricular response rate was 48 per minute. Fatigue and light-headedness symptoms were more prominent and interfering with the patient's active lifestyle and work.

Question

What, if any, intervention should be considered now?

Comment

An electrophysiologic radiofrequency ablation procedure was proposed to the patient because:
• beta-blockers to constrain the atrial fibrillation might have contributed to unacceptable bradycardia
• electrical and mechanical remodeling of the atria might have progressed to a degree where drug therapy alone could no longer suppress the atrial fibrillation

• restoration of co-ordinated atrioventricular contraction would be expected to lower left heart filling pressures and mitigate exertional dyspnea and chest discomfort.[19]

A wide area of substrate radiofrequency ablation was accomplished with the catheter procedure lasting 5.5 hours.[20–22] Sinus rhythm was restored without ensuing complications (Fig. 77.3). Effort dyspnea and fatigue were alleviated. Follow-up Holter monitoring one year later revealed persistent sinus rhythm with occasional isolated ventricular premature beats (VPB) and rare VPB couplets. Repeat echocardiography indicated moderate left atrial volume enlargement of 39 ml/m² but recurrent atrial fibrillation was not observed.[23,24] Medical therapy with
Figure 77.3 Restoration of sinus rhythm following successful cardioversion. Left ventricular hypertrophy with strain is seen again. Ventricular premature beats are present.

beta-blocker, ACE inhibitor, statin, low-dose aspirin, and warfarin was continued. During a repeat treadmill exercise test, to 6.5 metabolic equivalents, sinus rhythm was maintained. VPB and VPB couplets were observed but no ventricular tachycardia (VT). Blood pressure rose from 110/70 to 140/70 mmHg with exertion. Recall the patient's family history that included his brother's sudden cardiac death in adolescence and his mother's mid-life demise with chronic heart failure. Although his ventricular wall thickness of less than 20 mm placed him in a low-risk cohort for sudden death,[25] his combination of coronary and myopathic heart disease and family history presented an unusual hazard for sudden death. He was offered an implantable defibrillator, but declined.

The case for and against implantable cardioverter defibrillators in patients with coronary artery disease

Jeffrey S Healey
Hamilton Health Science, Hamilton, Ontario, Canada

Case history

A 50-year-old steelworker experiences severe retrosternal chest pain. He is brought to a tertiary care hospital by one of his co-workers, approximately two hours after the onset of chest pain. On examination, the patient's pulse is regular at 95 beats per minute and his blood pressure is 145/90. The lungs are clear bilaterally and there is an S4, but no murmurs. The patient's father died of a myocardial infarction at age 52. He has no significant prior medical history and does not have regular health maintenance visits with a physician or nurse. He does not smoke, but is overweight (Body Mass Index is 29) and eats a "fast food" diet. He is physically active at work, but does not engage in additional regular exercise.

An ECG is done in the emergency department which shows evidence of an acute, lateral wall myocardial infarction. He is given 160 mg of aspirin and a total of three doses (0.4 mg) of sublingual nitroglycerin. Approximately 15 minutes later, while a subsequent ECG is being done (Fig. 78.1), the patient loses consciousness. His nurse recognizes that the patient has developed ventricular fibrillation and promptly defibrillates him with a 200 J biphasic shock. The patient is returned to sinus rhythm and regains consciousness. He is given a total of 15 mg of intravenous metoprolol and 300 mg of clopidogrel and is taken promptly to the catheterization laboratory. There he is found to have single-vessel disease, with an occluded proximal circumflex artery. Percutaneous coronary intervention (PCI) is successfully performed and a bare metal stent inserted. With the re-establishment of TIMI-3 flow, it is
Figure 78.1 Patient's ECG in the emergency department.

apparent that the non-dominant circumflex supplies three large marginal branches. A left ventricular angiogram is performed which shows hypokinesia of the entire lateral wall, with an estimated ejection fraction of 35%.

Three days following his myocardial infarction, the patient is doing well. He has had no heart failure, no recurrent angina and no evidence of heart block or ventricular arrhythmias. He is receiving aspirin 81 mg daily, clopidogrel 75 mg daily, metoprolol 50 mg bid, ramipril 5 mg daily and pravastatin 40 mg daily.

Question

What else can be done to reduce the chance of this patient dying suddenly?

Comment

This patient has suffered an acute ST elevation myocardial infarction that was complicated (<48 hours) by the

development of ventricular fibrillation. In this context, the arrhythmia is often referred to as "primary ventricular fibrillation"[1] although this term is often a source of confusion, as the arrhythmia is actually *secondary* to the acute myocardial infarction. Given the potential for confusion with "idiopathic ventricular fibrillation", this term should probably be abandoned.

It is traditionally felt that ventricular fibrillation (VF) occurring within 48 hours of a myocardial infarction does not confer an increased risk of arrhythmic death and thus does not warrant specific therapy, such as an implantable defibrillator (ICD) or antiarrhythmic drugs.[2] This is based

on data from the GISSI-1 trial, which suggests that patients with this type of arrhythmia in the acute phase of an acute (AMI) have a similar prognosis to patients with comparable myocardial infarctions without VF.[3] Accordingly, current guidelines suggest that an implantable defibrillator is *not* indicated in this setting (**Class III**).[2]

However, this decision is contingent on two key facts. First, the arrhythmia in question must be polymorphic ventricular tachycardia or ventricular fibrillation, as the occurrence of monomorphic ventricular tachycardia generally implies the existence of an arrhythmogenic substrate[4] and an unfavorable prognosis,[5] warranting specific therapy. Secondly, it should be clear that the arrhythmia in question occurred in the context of a definite myocardial infarction. As sustained ventricular arrhythmias may increase serum troponin (even in the absence of coronary artery disease), clinicians should have other corroborating evidence of myocardial infarction (history of chest pain, ECG changes, wall motion abnormality, occluded artery) before attributing a potentially lethal ventricular arrhythmia to an acute myocardial infarction.[6] In practice, it can sometimes be difficult to make this distinction, and if there is any doubt, it is generally advisable to pursue specific treatment of the ventricular arrhythmia.

More recently, several reports have called into question the "benign" nature of ventricular fibrillation occurring within 48 hours of acute myocardial infarction.[7,8] It is possible that in the modern therapeutic era for myocardial infarction, the prognostic significance of early ventricular arrhythmias has changed. However, there have been no randomized trials demonstrating a benefit with implantable defibrillators in this group of patients and current guidelines have not been changed.[2,9] Left ventricular ejection fraction remains the strongest predictor of all-cause and arrhythmic mortality following myocardial infarction[10] and arrhythmic mortality remains an important cause of death during the first year following myocardial infarction, in patients with a low ejection fraction.[10]

With the emergence of the ICD as the treatment of choice for cardiac arrest survivors, the DINAMIT study was conducted to determine if the routine use of ICD, 6–40 days following myocardial infarction, in patients with an ejection fraction of ≤35% and with low heart rate variability, reduced mortality.[9] Surprisingly, it did not.[9] Although the implantation of an ICD significantly reduced arrhythmic death, ICD-treated patients experienced a significant *increase* in heart failure death, such that all-cause mortality was unchanged.[9] The increase in heart failure was not due to right ventricular pacing[11] as patients in DINAMIT were only paced in VVI-40 mode.[9] Furthermore, patients dying of heart failure typically had received appropriate ICD shocks before death.[9] In essence, the use of the ICD in these high-risk patients merely converted sudden death to heart failure death.

Given the negative results of DINAMIT, the prophylactic implantation of an ICD early after myocardial infarction is not indicated (**Class III, Level B**).[2] However, if a patient similar to the one described were to develop atrioventricular block requiring permanent pacing, it would be reasonable to implant an ICD instead, given the potential for benefit and the minimal incremental risk to the patient.

Case history *continued*

The patient was discharged home on the fourth day following myocardial infarction. In addition to the usual secondary prophylactic agents, he was also instructed to take 1 g/day of omega-3 fatty acid supplements (EPA/DHA), as this intervention has been shown in the GISSI-Prevenzione trial to lower the risk of arrhythmic death.[12] An ICD was not implanted; however, a follow-up radionuclide angiogram was scheduled in three months' time, to re-evaluate the patient's left ventricular ejection fraction.

Guidelines typically suggest waiting at least 40 days following myocardial infarction and 90 days following revascularization, to allow time for ventricular remodeling (positive or negative) and to ensure that the patient survives the early postmyocardial infarction period.[2,13]

Three months later, the patient was asymptomatic and still taking his medications. The follow-up ejection fraction was 38%. A Holter monitor was also completed and did not show any evidence of ventricular arrhythmias. The patient was seen in consultation by an electrophysiologist who discussed the potential role of an ICD (and its potential complications). A determination was made that an ICD was not indicated at the present time.

Comment

The current ACC/AHA/ESC guidelines suggest that a prophylactic ICD should be considered in patients with coronary artery disease, who are at least 40 days following myocardial infarction and who have a left ventricular ejection fraction of ≤30–40% (**Class I, Level A**).[2] However, not a single randomized trial has demonstrated a benefit for the ICD in patients with an ejection fraction of 36 – 40%. The only ICD trial to include a small number of such patients was the MUSTT trial; however, this was not a randomized trial of the ICD, but rather a strategy of EP testing in patients with coronary artery disease, left ventricular dysfunction and non-sustained ventricular tachycardia.[14] Appreciating that there is a measurement error associated with assessment of left ventricular ejection fraction (even when using radionuclide angiography), many clinicians continue to recommend an ICD to individual patients with a left ventricular ejection fraction of between 35% and 40%. However, there is insufficient evidence to warrant a Class I, Level A recommendation for this group as a whole.

Comment

It appears that the patient's left ventricle has suffered late, negative remodeling, perhaps as a result of uncontrolled hypertension. In the short term, it is important to re-initiate evidence-based therapy for left ventricular dysfunction and to gain control of his blood pressure. Time should be given for this therapy to impact ventricular function before re-evaluating the ejection fraction.

It is a common misconception that if patients are doing well and are many years following myocardial infarction, they do not warrant consideration for an ICD. Although some trials (SCD-HeFT, COMPANION) did require symptomatic heart failure as an inclusion criterion,[15,16] others (MADIT-II) did not.[17] In fact, cost-effectiveness analyses suggest that it is among minimally symptomatic patients that the ICD is the most cost-effective.[18]

Despite the patient's low ejection fraction and prolonged QRS duration, there is currently no indication to implant a cardiac resynchronization device. All major, published studies of this therapy have been in patients with NYHA class III or IV heart failure. Two studies are ongoing (RAFT, MADIT-CRT) that will help determine if this therapy can reduce the incidence of death and heart failure in patients with NYHA class I or II heart failure. Given the increased cost and complexity of cardiac resynchronization devices, pending the results of these two trials, the use of cardiac resynchronization in these patients is not recommended.

Conclusion

The decision to implant an ICD in this patient was based on robust scientific evidence and good clinical judgment.[17] However; unlike most other prophylactic interventions (i.e. vaccines, aspirin), physicians can determine if a specific patient actually derived benefit from their ICD given the ICD's capacity to capture and store records of arrhythmia. Over 21 months mean follow-up, only 23% of similar ICD recipients would be expected to receive an appropriate therapy from the ICD.[19] The fact that this patient has not received therapy from his device should not cause physicians to reconsider the appropriateness of the ICD for this patient, as the application of these guidelines to a population of similar patients is expected to produce a net benefit, with a very respectable number needed-to-treat of only 8 patients, for three years to prevent one death.[20] However, efforts are ongoing to more precisely define patients at risk of ventricular arrhythmias.[21]

Bradyarrhythmias – choice of pacemakers

Pablo B Nery[1] and Carlos A Morillo[2]
[1]University of Ottawa Heart Institute, Ottawa, Ontario, Canada
[2]Hamilton Health Sciences, McMaster University, Hamilton, Ontario, Canada

Case history 1

A 58-year-old woman presents to your office with a three-month history of recurrent presyncope and progressive fatigue on exertion. There is no history of chest pain or dyspnea. She has had two syncopal episodes over the last 10 months, both without prodromes. During the last episode she suffered a Colles' fracture.

Physical examination reveals a patient in no acute distress with a blood pressure of 120/68 and a regular heart rate of 42 beats per minute. Chest exam shows good bilateral air entry and lungs are clear. Neck veins are flat. Heart sounds show a normal S1 and S2. No added sounds or murmurs on auscultation. She was diagnosed with hypertension five years ago for which she is on a thiazide

diuretic as her only medication. She is not a smoker and she has no history of diabetes, coronary artery disease, dyslipidemia or syncope until last year. Her family history is non-contributory. Anemia and thyroid disease were ruled out by her family doctor. Her two-dimensional echocardiogram revealed normal left ventricular size and function.

Baseline 12-lead ECG (Fig. 79.1) and 24-hour Holter monitor were ordered. Of note, she had a presyncopal episode during Holter recording (Fig. 79.2).
Figure 79.1 Twelve-lead ECG from Case 1 showing severe sinus bradycardia at a rate of 37 bpm.
Figure 79.2 Holter monitor recording from Case 1 showing significant bradycardia and a sinus pause lasting 5.8 seconds. This pause was associated with severe presyncope.

Case history 2

A 72-year-old man is brought to the emergency department by his daughter after a syncopal episode. He was sitting on a chair when he suddenly lost consciousness for approximately 40 seconds. He recovered with no residual symptoms. When asked, he denied any prodromes but his daughter noticed transient cyanosis during the episode. Past medical history is significant for hypertension which was controlled after weight loss and low-salt diet.

Physical examination reveals no acute distress with a blood pressure of 112/62 and a regular heart rate of 48 beats per minute. Chest exam shows good bilateral air entry and lungs are clear. Neck veins are 3 cm above the sternal angle. Normal S1 and S2. No added sounds or murmurs on auscultation. He is not a smoker and he has no history of stroke, coronary artery disease or diabetes. There is no previous history of syncope. A recent two-dimensional echocardiogram (three months ago) measured his left ventricular ejection fraction at 60%. A 12-lead ECG was obtained (Fig. 79.3).
Figure 79.3 Twelve-lead ECG from Case 2 showing complete third-degree heart block with right bundle branch block.

Question

What is your diagnosis and what therapy is indicated for each patient?

Comment

In Case 1 the clinical presentation of syncope, presyncope and fatigue, temporarily related to sinus pauses on both the 12-lead ECG and Holter monitor, point to a diagnosis of sinus node dysfunction (SND). Before confirming the diagnosis, it is of key importance to exclude secondary causes of sinus bradycardia such as hypothyroidism or pharmacologically induced bradycardia.

SND constitutes a spectrum of cardiac arrhythmias including sinus bradycardia, sinus arrest, sinoatrial block, and paroxysmal supraventricular tachycardia alternating with periods of bradycardia or asystole. Patients with the latter condition may be symptomatic from paroxysmal tachycardia, bradycardia or both. Correlation of symptoms with the above-mentioned arrhythmias by use of 12-lead ECG, Holter monitoring or event recorder is essential.

Sinus node dysfunction may present as chronotropic incompetence in which there is an inadequate response to exercise or stress. Chronotropic incompetence is defined as failure to achieve 85% of the predicted maximal heart rate during a treadmill stress test. Other more common causes of syncope such as vasovagal syncope should always be ruled out. However, this diagnosis is unlikely given the clinical presentation of syncope, presyncope and progressive fatigue induced by exercise in addition to symptom correlation of presyncope and a sinus pause >3 seconds (see Fig. 79.2).

Simple historic criteria have recently been described and a point score to rule out vasovagal syncope, known as the Calgary Syncope Score, that includes age of onset of syncope before age 35, classic prodrome, evidence of ECG alterations, and other clinical characteristics, has been validated.[1] A point score <–2 had a high sensitivity and specificity for the diagnosis of vasovagal syncope. In both cases the Calgary Syncope Score was –7, which rules out vasovagal syncope. Case 1 has typical clinical and ECG features of SND and has a **Class I, Level C** indication for a permanent pacemaker.[2,3] Sinus bradycardia is a physiologic finding in trained athletes, who frequently have resting heart rates between 40 and 50 bpm at rest. Moreover, rhythm changes during sleep such as sinus pauses >2 seconds, sinus bradycardia (<40 bpm), first-degree atrioventricular (AV) block and type I second-degree AV block are observed in up to 24% of healthy subjects.[4] The patient presented in Case 1 has a **Class I, Level C** indication for a permanent pacemaker**.** Current **Class I, Level C** indications for sinus bradycardia syndromes are as follows; permanent pacemaker implantation is indicated for:

• SND with documented symptomatic bradycardia, including frequent sinus pauses that produce symptoms
• symptomatic chronotropic incompetence
• symptomatic sinus bradycardia that results from required drug therapy for medical conditions.

The patient presented in Case 2 has a clear presentation of abrupt syncope with no prodrome and ECG documentation of third-degree AV block associated with right bundle branch block (see Fig. 79.3). Patients diagnosed with high-degree AV block – third-degree or second-degree type 2 – are clearly at risk for adverse cardiovascular events if not treated with permanent pacemaker implantation.[5,6] Therefore, this patient unquestionably benefits from a permanent pacemaker and also has a **Class I, Level C** indication.

Both cases may benefit from a single-chamber pacemaker. In Case 1 an atrial-based single-chamber pacemaker is appropriate and in Case 2 a single-chamber ventricular pacemaker may also be adequate. The need for a temporary

transvenous wire is advocated by current ACLS guidelines[7] for patients with second-degree AV block type 2 or third-degree AV block associated with signs or symptoms of poor perfusion secondary to bradycardia. Transvenous pacing may increase the risk of postoperative infection[8] and cardiac perforation[9] and should be reserved for carefully selected patients although these issues have not been addressed by randomized controlled studies.

Question

Which is the most beneficial pacing mode for each patient?

Comment

The use of dual-chamber pacing offers theoretic advantages over ventricular pacing, such as maintenance of AV synchrony and preservation of normal ventricular activation through the His–Purkinje system (only in SND and depending upon a programmed long AV delay). Given the higher cost, greater complexity and increased complications of dual-chamber permanent pacemaker (PPM), several clinical studies assessed their potential benefit. In patients with SND, retrospective studies involving approximately 1400 patients suggest a significant survival benefit of dual-chamber PPM.[10–16] However, this is observational information and randomized clinical trials are needed to establish the benefit of dual-chamber pacing.

The first prospective, randomized controlled trial was published in 1994 by Andersen and colleagues.[17] This study assigned 225 patients with SND to receive a single-chamber atrial or ventricular PPM. A second analysis was published when the mean follow-up in these patients was 5.5 years[18] showing a significant lower risk of atrial fibrillation in the atrial pacing group, with a relative risk reduction of 0.54 (P = 0.012). There was also a reduced incidence of thromboembolic events and cardiovascular death. These results should be interpreted with caution since this study was small. The second analysis was *post hoc*. Thus no conclusive information could be derived but the exercise was useful as hypothesis generating.

The Danish group provided important data on the safety of atrial pacing in carefully selected patients with SND.[17,18] They excluded patients with bifascicular bundle branch block, atrial fibrillation with R-R interval longer than 3 seconds, PQ interval >220 ms (or >260 ms if age >70 years), and those who could not support 1:1 AV conduction with atrial pacing at 100 bpm. The population studied was shown to be at low risk for AV block, with an incidence of 0.6% per year.[18] The final word on atrial-based pacing for SND will be provided by the DANPACE study, a randomized multicenter study comparing single-chamber atrial pacemaker (AAI) versus dual-chamber pacemaker (DDD) pacing in patients with sick sinus syndrome which will complete enrollment in 2008.

The Mode Selection Trial (MOST) in SND followed 2010 patients for a median of 33.1 months. No advantage for dual-chamber pacing over single-chamber ventricular pacing in terms of the trial's primary endpoint – death from any cause or non-fatal stroke – was observed.[19] However, there was a significant reduction in the incidence of atrial fibrillation, with a relative risk reduction of 0.21 (P = 0.008). The effect of dual-chamber pacing was probably underestimated in this study since more than 30% of patients randomized to ventricular pacing were crossed over to dual-chamber mode. Moreover, the potential benefit of dual-chamber pacing may have been counteracted by the hazardous effects of unnecessary right ventricular pacing associated with short AV delay programmed in patients with SND and dual-chamber devices.[20,21]

The Canadian Trial of Physiological Pacing (CTOPP) compared clinical outcomes in 2568 patients who were randomized to atrial-based or ventricular pacing for a mean follow-up period of 3.5 years. Among the study population, SND was the indication for pacing in 42% and AV block in 58%. The study found no difference between the two groups in the combined incidence of stroke or death or in the likelihood of hospitalization for heart failure. Nevertheless, after two years of follow-up, physiologic pacing was associated with 18% relative risk reduction in the development of chronic atrial fibrillation (AF). The subgroup of patients paced for SND showed no benefit from physiologic pacing in terms of mortality or stroke.

The United Kingdom Pacing and Cardiovascular Events (UKPACE) was the most recently published of the major trials. It randomized 2023 patients greater than 70 years of age with high-grade AV block to dual- or single-chamber devices, showing no significant difference in overall survival after a mean follow-up period of 4.6 years. The incidence of stroke, atrial fibrillation or heart failure hospitalizations did not differ between groups. The UKPACE was the largest appraisal of pacing mode in patients with AV block and hence provides the best estimate of treatment effect in this population.

The Pacemaker Selection in the Elderly (PASE) trial – the only randomized trial specially designed to address quality of life (QoL) – enrolled 407 patients with indication for pacing, half of them with AV block. No significant difference in total mortality was shown between treatment groups (rate-responsive, single-chamber ventricular pacemaker [VVIR] vs. rate-responsive, dual-chamber pacemaker [DDDR]). Nevertheless, QoL improved after 30 months, corroborating with data from MOST and CTOPP substudies.[22] Of note, QoL improvement in PASE and MOST was mainly through a reduction in pacemaker syndrome, a "questionable" endpoint showing distinct incidence among series.[23]

A recently published meta-analysis confirmed that the bulk of data available to date is inconclusive for pacing mode selection and survival. Nevertheless, this meticulous

review showed that atrial-based pacing reduces the incidence of atrial fibrillation.[24] This careful analysis suggests that the benefit was mainly observed in patients with SND. It also verified the higher complication rate associated with atrial-based PPM, generally secondary to lead dislodgment. Of note, atrial-based pacing translates to dual-chamber pacing in all studies but the first published by Andersen and colleagues.[17] Also, dual-chamber devices cost more, do not last as long and have a higher incidence of minor complications.[24] A few retrospective studies[25–27] as well as current guidelines[2,3] support the use of single-lead capable of dual sensing and ventricular pacing devices – so-called

VVD pacemakers – in patients with atrioventricular block and preserved sinus node function. Table 79.1 summarizes the current recommendations on mode selection in patients requiring permanent pacemaker implantation.

Conclusion

What about our patients? Case 1 has SND and is at low risk for complete heart block given her normal PR interval and QRS width less than 120 msec. The first choice for a PPM in her case would be a single-chamber atrial device.[2] Implanting a dual-chamber device capable of minimizing ventricular pacing would be an acceptable option as well in patients considered at higher risk for AV block (**Class IIa**) and indeed, the recommended mode when AV block was previously documented (**Class I, Level C**). Both strategies intend to avoid or reduce unnecessary ventricular pacing and may decrease the burden of atrial fibrillation in patients with SND.[18,28] Case 1 underwent an AAI pacemaker implantation after documenting 1:1 AV conduction when atrial paced at 110 pulses per minute, a simple test performed during the procedure.

It is well recognized in patients with AV block (as is also true for SND) that mortality is mainly a reflection of the severity of underlying disease, and less dependent on the conduction system status or pacing mode. Thus, it is not surprising that no significant difference in mortality between single- or dual-chamber PPM has been encountered to date. In view of the above, Case 2 underwent a single-chamber ventricular (VVIR) PPM implantation.

Table 79.1 Pacemaker mode in selected indications for pacing[2]

Pacemaker Generator	Sinus Node Dysfunction	Atrioventricular Block
Single-chamber atrial pacemaker	No suspected abnormality of atrioventricular conduction and not at increased risk for future atrioventricular block Maintenance of atrioventricular synchrony during pacing desired	Not appropriate
Single-chamber ventricular pacemaker	Maintenance of atrioventricular synchrony during pacing not necessary Rate response available if desired	Chronic atrial fibrillation or other atrial tachyarrhythmia or maintenance of atrioventricular synchrony during pacing not necessary Rate response available if desired
Dual-chamber pacemaker	Atrioventricular synchrony during pacing desired Suspected abnormality of atrioventricular conduction or increased risk for future atrioventricular block Rate response available if desired	Rate response available if desired Atrioventricular synchrony during pacing desired Atrial pacing desired Rate response available if desired
Single-lead, atrial-sensing ventricular pacemaker	Not appropriate	Desire to limit the number of pacemaker leads

80 Peripheral arterial disease with suspect coronary artery disease

Victor Aboyans[1] and Michael H Criqui[2]
[1] Department of Thoracic and Cardiovascular Surgery and Angiology, Dupytren University Hospital, Limoges, France
[2] Department of Medicine, University of California, San Diego, CA, USA

Case history 1

A 63-year-old man presents with progressive right leg discomfort, with his walking distance gradually decreasing to less than one block over the last 2 months. Standing still provides complete relief within 5 minutes. His claudication is now very disabling. He has smoked 20 cigarettes daily for 40 years. He is treated with ramipril for hypertension and takes 325 mg of aspirin daily since a transient ischemic attack (TIA) 3 years ago.

On examination, his blood pressure is 140/90 mmHg in the right arm and 130/85 mmHg in the left arm. His resting pulse is regular at 85 bpm. He does not report any chest pain or shortness of breath. Chest and neck auscultation are normal. There is a right femoral bruit, with reduced femoral and popliteal pulses and absent pulses distally. On the left side, a reduced femoral pulse is present, and none of the other pulses are palpable. The remainder of the physical examination is normal.

A resting ECG reveals normal sinus rhythm with no abnormality. The chest radiograph is normal. Routine hematology and chemistry values are normal except for an abnormal fasting blood lipid profile: triglycerides, 280 mg/dL; total cholesterol, 305 mg/dL; HDL cholesterol, 42 mg/dL; LDL cholesterol, 195 mg/dL.

The Ankle Brachial Indexes (ABI) are 0.70 on the right, 0.45 on the left. After walking 99 yards (90 m) on a treadmill (10% incline, 1.5 mph) and the occurrence of bilateral (left > right) hip and thigh claudication, his post-exercise ABIs are 0.25 on the right and 0.20 on the left, consistent with severe peripheral arterial occlusive disease. Duplex ultrasound reveals a 2.5 inch (6 cm) long severe stenosis (90%) at the level of the right common and external iliac arteries, and an occlusion of the left external iliac artery, with femoral reperfusion by collaterals. An MRA confirms these observations. The arteries below these lesions are free of any significant stenosis.

You decide to refer the patient to a vascular surgeon who eventually schedules an aortic–bifemoral bypass.

Question

In this patient, what is your strategy to avoid any cardiac ischemic events during the perioperative period?

Comment

We are confronted here with a middle-aged patient with severe proximal peripheral arterial disease (PAD), without any clinical evidence of coronary artery disease (CAD). In the classic study of Hertzer *et al*,[1] performing systematic coronary angiography in 1000 patients undergoing peripheral vascular surgery, the prevalence of >70% coronary stenosis was 60%. More recently, using rest and stress echocardiography in a similar popluation, Feringa *et al*[2] reported a prevalence of 23% and 28% of unrecognized myocardial infarction and silent ischemia, respectively.

Several risk scores are used to assess the risk of perioperative cardiovascular events in non-cardiac surgery. According to the 2007 ACC/AHA guidelines,[3] the clinical risk factors are: ischemic heart disease, compensated or prior heart failure, diabetes mellitus, renal failure and cerebrovascular disease. This leads us to classify our patient at intermediate risk level with one risk factor (prior TIA suggestive of cerebrovascular disease). According to these guidelines,[3] preoperative heart rate control with beta-blockers is recommended. Of note, it still remains unclear whether lowering heart rate alone or the use of beta-blockers *per se* is beneficial. No substantial data regarding the potential interest of other treatments reducing heart rate (i.e. calcium channel blockers) are currently available. In addition, even the interest in beta-blockers according to these guidelines might be tempered by more recent data. In the POISE trial,[4] the benefit of metoprolol versus placebo to prevent myocardial infarction during non-cardiac surgery was counterbalanced by an excess risk of death and disabling stroke, although the high dosage of metoprolol and the lack of titration in this study have been criticized. Besides, in a retrospective analysis of a large

database in the United States, Lindenauer et al[5] found a neutral effect of preoperative use of beta-blockers. However, beta-blockers appeared harmful in patients at low risk of perioperative events, but beneficial for those at a high level of perioperative risk.

According to the ACC/AHA guidelines,[3] non-invasive testing might only be considered if it could change management. The randomized Coronary Artery Revascularization Prophylaxis (CARP) trial[6] failed to demonstrate any additional prognostic benefit of preoperative coronary revascularization in such cases, but led to extended vascular surgery delays.

Beyond the perioperative period, the Clinical Outcomes Utilizing Revascularization and Aggressive Drug Evaluation (COURAGE) trial[7] also failed to demonstrate any prognostic improvement of patients with stable coronary artery disease when undergoing coronary revascularization, compared to those with optimal medical management. In the DECREASE-II study,[8] patients at intermediate risk prior to vascular surgery were randomized into two strategies comparing tight heart rate control (60–65bpm) using beta-blockers with the use of non-invasive testing followed by coronary angiography and revascularization

when appropriate. At 3 years, the cardiac event rates were similar between both groups.

Thus, we propose for our patient an optimal medical management. Smoking cessation is essential to improve the long-term vital prognosis[9] and reduce the progression of PAD.[10] Additionally, smoking cessation within the weeks prior to surgery is associated with a significant reduction of perioperative complications.[11] Beta-blockers could be proposed to decrease his resting heart rate to within the 60–65bpm range, being careful to avoid a large drop in systolic blood pressure. In a longitudinal study,[12] patients who had their beta-blocker therapy prolonged beyond the perioperative period presented a better prognosis than those who had their treatment discontinued. Finally, the use of statins (and possibly combined lipid-lowering therapy) is highly recommended for the long-term management of this patient, with the aim to lower LDL cholesterol below 100mg/dL.[13] The use of statins can also be beneficial in the first months following revascularization: in a randomized study comparing atorvastatin 10mg with placebo in patients undergoing vascular surgery,[14] an 18% event risk reduction was noted in the statin group.

Case history 2

A 72-year-old woman presents with progressive leg pain atypical for claudication in the right calf and ankle over the past year. Standing still provides complete relief but her walking distance has gradually shortened to two blocks. She also sometimes experiences this pain at rest when sitting on a chair or during the night. She notes similar but less severe discomfort in the left ankle, occurring only when walking. When asking for other cardiovascular symptoms, she also reports occasional epigastric pain when climbing a flight of stairs, and sometimes even at rest. The pain does not radiate elsewhere and usually disappears after a couple of minutes.

She has taken metformin for type 2 diabetes for 12 years. She stopped smoking 5 years ago (overall amount is 35 pack-years). She is hypertensive, treated by hydrochlorothiazide 25mg daily.

On examination her blood pressure is 150/90mmHg (both arms), resting pulse is regular at 90bpm. Chest and neck auscultation are normal. The popliteal, posterior tibial and dorsalis pedis pulses are absent on the right. On the left, the popliteal and posterior tibial pulses are moderately reduced. The dorsalis pedis pulse is absent.

Resting ECG (Fig. 80.1) shows normal sinus rhythm with Q-waves located at leads II, III and aVF, associated with abnormal repolarization in the same leads as well at V3–V6 and D1 and aVL, suggesting past inferior myocardial infarction as well as apical and lateral silent ischemia. Routine hematology and chemistry values are normal but glycosylated hemoglobin is elevated at 9%. Blood lipids profile is as follows: total cholesterol, 180mg/dL; HDL-C,

52mg/dL; LDL-C, 118mg/dL. Resting ABI is 0.8 on the right but cannot be measured on the left due to incompressible arteries. Duplex ultrasound reveals an occlusion of the right popliteal artery and a very attenuated flow through a calcified fibular artery. Left distal arteries (posterior tibial, fibular and anterior tibial) present multiple stenoses and diffuse calcifications.

You decide to assess her coronary state prior to referring her to a diabetes care center. She undergoes dobutamine stress echocardiography (DSE). At rest, the prior myocardial infarction is confirmed by the presence of akinesis at the inferior wall (basal, mid and apical segments). The ejection fraction is estimated at 52%. After dobutamine infusion, an extended hypokinesia of the anterior and lateral walls occurs at the level of 68% of the maximal theoretical heart rate. She denies any chest pain.
Figure 80.1 Case 2 – ECG at rest.

Question

How would you proceed at this point?

Comment

This case deals with the management of multifocal athero-sclerotic disease in an elderly diabetic patient. Clinical symptoms may be atypical and may occur at a more advanced stage of the disease, possibly due to the associated diabetic neuropathy with impaired sensory feedback.[15] In addition, walking impairment related to PAD may reduce the patient's physical efforts and limit the occurrence of angina. In this case, the modest limb symptoms, the absence of critical ischemia and the poor distal arterial state preclude peripheral revascularization at this point. However, the coronary artery disease revealed by interrogation and ECG is a matter for concern.

Dobutamine stress echocardiography is a valuable tool to detect CAD in PAD patients with limited ability to perform a satisfactory exercise test.[16] The DSE data in this patient are highly suspect for severe CAD, possibly affecting several arteries, which is frequent in diabetic patients.[17] In this situation, revascularization can improve prognosis.[18] Thus, we referred the patient for coronary angiography. This exam revealed triple-vessel disease, including a 80% stenosis of the left main coronary artery. Of note, in the COURAGE trial[19] comparing percutaneous coronary revascularization to optimal medical treatment alone, patients with these types of severe lesions were excluded from the study.

The patient was referred for coronary artery bypass grafting, which was ultimately successful despite a prolonged intensive care unit stay for poorly tolerated atrial fibrillation. Overall, the long-term management of CAD in PAD is similar to any other patient.[20] It should, however, be emphasized that in cases of concomitant PAD, the short- and long-term prognosis of patients with CAD is more severe, even with revascularization.[21,22] Beyond coronary revascularization, our patient should benefit from statins with the aim of lowering LDL below 70 mg/dL. Beta-blockers are also indicated because of the history of myocardial infarction.[23] Finally, according to the results of the HOPE[24] and EUROPA[25] trials, she should benefit from an ACE inhibitor. Blood pressure should be controlled under 130/80 mmHg in this diabetic patient.

81 Valvular heart disease: timing of surgery

Jon-David R Schwalm and Victor Chu
McMaster University/Hamilton Health Sciences, Hamilton, Ontario, Canada

Case history 1

A 63-year-old male carpenter is referred to a cardiologist for consultation regarding a newly diagnosed systolic ejection murmur noted by his family physician during his annual physical examination. His medical history is significant for a remote 20 pack-year smoking history and type 2 diabetes mellitus for which he is on an oral hypoglycemic agent. Upon close questioning, he does not report any cardiovascular limitations despite an active lifestyle. Specifically, he denies any symptoms of shortness of breath, angina, exertional presyncope or syncope.

Physical examination by the consulting cardiologist reveals a grade IV–VI, late-peaking, systolic murmur at the right upper sternal border with radiation to both carotid arteries. S2 is diminished and an apical-carotid delay is noted. The heart rate is 72 beats per minute and the blood pressure 110/88 mmHg.

His baseline electrocardiogram is within normal limits, demonstrating no evidence of left ventricular hypertrophy. Transthoracic echocardiogram confirms a calcific bicuspid aortic valve with an area of $0.9\,\text{cm}^2$, and a mean transvalvular gradient of 46 mmHg. There is mild aortic insufficiency and the aortic root dimension is within normal limits. There is preserved left ventricular function with no wall motion abnormalities and no evidence of left ventricular hypertrophy.

Question

What is the appropriate initial management and follow-up for this patient? Is aortic valve replacement indicated at this time?

Comment

This case is meant to highlight the appropriate investigations, follow-up, and management of patients found to have an asymptomatic murmur of severe aortic stenosis on routine physical exam. Aortic stenosis is the most common

valvular condition across Europe and North America, affecting 2–7% of individuals over the age of 65 years.[1] The most common cause of aortic stenosis is calcification of either a congenitally bicuspid valve (more common if under 70 years of age) or a tricuspid valve (more common over 70 years of age).[2]

Aortic stenosis is a progressive condition with significant interpatient variability. A prospective study has shown an average increase in mean aortic gradients of 7 mmHg per year and a decrease in valve area of $0.1\,\text{cm}^2$ per year.[3]

While severe aortic stenosis carries an increased risk of sudden cardiac death, this rarely occurs (<1%/year) without the development of any of the classic symptoms including angina, heart failure, and syncope.[3] Symptoms tend to develop when the aortic valve area is less than $1\,\text{cm}^2$ or the mean transvalvular gradient is more than 40 mmHg. Thus, severe aortic stenosis is defined as a valve area less than $1\,\text{cm}^2$, mean gradient greater than 40 mmHg or jet velocity greater than 4.0 m per second.[4] Following the onset of symptom development in patients with severe aortic stenosis, the mean survival is 2–3 years without surgical intervention.[5] Conversely, aortic valve replacement is not indicated in asymptomatic patients despite having severe aortic stenosis and preserved left ventricular function.

Given the strong association of increased mortality with symptom development, close clinical follow-up is recommended. The frequency of clinical follow-up depends on multiple factors including the degree of stenosis, left ventricular function, functional capacity, and patient compliance. Patient education regarding the natural history of aortic stenosis and how to properly interpret their symptoms is essential to clinical follow-up. Often, patients will not report one or more of the classic triad of symptoms. A slight change in exercise capacity or exertional dyspnea may be their only tell-tale sign of progressing disease. Due to the gradual onset of symptoms related to aortic stenosis, it is not uncommon for patients to fully appreciate the severity of their symptoms after their aortic valve has been replaced. The ACC/AHA 2006 practice guidelines recommend (**Class I**) that patients with severe aortic stenosis undergo yearly echocardiograms to evaluate the severity of aortic stenosis, left ventricular hypertrophy, and function.[4]

Until recently, aortic stenosis was a **Class I** indication for the use of antibiotics in preventing bacterial endocarditis.[6] However, more recent guidelines have removed acquired and congenital valvular disease as an indication for the use of prophylactic antibiotics in the prevention of bacterial endocarditis. Antibiotics continue to be recommended with dental procedures in patients with a prosthetic valve.[7]

Case history 1 *continued*

The patient returns for his one-year follow-up visit. He remains asymptomatic with no significant change noted on either physical examination or echocardiogram. He states that he has joined a cycling club and plans to undertake some long-distance trips. Given this planned increase in exercise, an exercise stress test is arranged.

He exercises on the bicycle ergometer for 8 minutes and 57 seconds, reaching a peak heart rate of 127 beats. His blood pressure rises appropriately with exercise and he has no anginal symptoms. The reason for terminating the test is leg fatigue and significant ST segment depression of 3 mm. After review of the exercise stress test results, his consulting cardiologist is concerned regarding possible silent ischemia and the patient is advanced for cardiac catheterization. Catheterization reveals no flow-limiting coronary artery disease with a mean gradient across the aortic valve of 45 mmHg.

Question

Can this patient with severe but asymptomatic aortic stenosis undergo activities requiring significant exertion? What is the role of exercise stress testing in aortic stenosis? Was the cardiac catheterization indicated at this time?

Comment

This patient, with a history of severe but asymptomatic aortic stenosis, wants to undertake a new level of exercise. The ACC/AHA practice guidelines recommend against competitive sports with high dynamic or static muscular demands.[4] However, can we risk stratify the average patient who wants to undertake an increase in exercise?

Currently, the evidence suggests that routine exercise stress testing of patients with aortic stenosis is not warranted.[8] With confounding variables such as left ventricular hypertrophy and reduced coronary flow reserve, ST segment depression during exercise stress testing of patients with aortic stenosis adds little prognostic value. Electrocardiographic ST segment depression during exercise occurs in 80% of patients with asymptomatic aortic stenosis. However, exercise stress testing in patients with asymptomatic severe aortic stenosis may add other prognostic information including exercise-induced symptoms and abnormal blood pressure response (fall of >10 mmHg or a blunted blood pressure rise of <20 mmHg).[4,8] Stress

testing may also help provide the patient with an exercise prescription.[9] Exercise testing should not be performed in symptomatic patients with severe aortic stenosis.

Cardiac catheterization is recommended for patients before planned aortic valve replacement who are at risk of coronary artery disease or to help clarify the severity of aortic stenosis in symptomatic patients when non-invasive imaging was inconclusive.[4] Given that ST segment depression is common with aortic stenosis during exercise stress testing and the patient was asymptomatic with a normal blood pressure response, cardiac catheterization could be postponed at this time.

In summary, this patient remains asymptomatic with respect to his severe aortic stenosis. Despite close clinical and echocardiographic follow-up, he has not demonstrated progression of his disease. Given these findings, he should not be advanced for aortic valve replacement. As per the ACC/AHA 2006 guidelines, patients should not undergo aortic valve replacement until they become symptomatic, develop left ventricular dysfunction (ejection fraction less than 50%) or are scheduled to undergo another cardiac surgical procedure (e.g. coronary bypass surgery).[4]

Despite these fairly simple and clear-cut guidelines, timing of valve replacement surgery for patients with "asymptomatic" severe aortic stenosis remains one of the more common dilemmas in clinical practice. Many factors, such as patient age, surgical risk profiles, choice of prosthesis types, and the need for long-term anticoagulation, can play a significant role in the decision process. It is important for the treating physician to carefully balance the risks and the potential pitfalls of continued medical therapy against the risks of an elective operative procedure before making a recommendation to the patient.

Case history 2

An 86-year-old retired office manager is referred to a cardiologist for review of progressive symptoms of exertional syncope and Canadian Cardiovascular Society class III angina. She has multiple co-morbidities including poorly controlled diabetes mellitus, hypertension, obesity, current cigarette smoking with a 50 pack-year history, chronic obstructive lung disease, and atrial fibrillation. Despite these co-morbidities, she has a reasonable quality of life but is significantly limited by her cardiovascular symptoms. Her medications include insulin, metformin, salbutamol inhalers, ramipril, simvastatin, diltiazem, and warfarin.

Her electrocardiogram demonstrates controlled atrial fibrillation averaging 78 beats per minute and left ventricular hypertrophy with strain pattern. Transthoracic echocardiogram reveals severe aortic stenosis with a valve area of 0.7 cm^2 and a mean gradient of 50 mmHg. She has mild left ventricular dysfunction with an ejection fraction of 45%. Left ventricular hypertrophy with a mass index of 140 g/m^2 is noted. Cardiac catheterization reveals a peak-to-peak gradient of 45 mmHg but no flow-limiting coronary artery disease is seen.

Question

Is this patient considered to be too high a risk for traditional aortic valve replacement? Are there other management options available for the treatment of aortic stenosis?

Comment

This case is meant to highlight the risk stratification of patients being considered for traditional aortic valve replacement surgery and to address possible alternative interventions for high-risk elderly patients with multiple co-morbidities.

Aortic valve replacement surgery is a well-established procedure which has been perfected since the early 1960s. The average perioperative mortality is 3% for isolated aortic valve replacement and 6% when combined with coronary bypass surgery.[10] However, the 30-day mortality rate for the octogenarian population is approximately 17%, with 40% mortality after one year.[11] These rates are highly center dependent.

For our patient, the perioperative morbidity and mortality are considered to be prohibitively high with traditional aortic valve replacement as estimated using the EuroSCORE.[12] Considering the yearly rate of sudden death with severe aortic stenosis is 1% (the patient is 86 years old), the upfront risk of the surgery far outweighs the expected reduction in mortality with aortic valve replacement. However, the patient may accept an increased perioperative mortality risk considering she is significantly limited by her symptoms. Often, octogenarians undergo aortic valve replacement to improve their quality of life, rather than for an improvement in overall prognosis. Unfortunately medical therapy does not offer a significant reduction in morbidity or mortality. Aortic stenosis is a mechanical problem, requiring a mechanical solution. While percutaneous balloon aortic valvotomy is indicated in treating the pediatric population and young adults, its only indication for treating aortic stenosis in the adult population is for palliation in inoperable patients or as a bridge to surgery.[4]

Another novel and still experimental option is that of percutaneous aortic valve replacement. This procedure was first reported in a human subject in 2002 using a Cribier–Edwards valve (Edwards Lifesciences Inc, Irvine, CA), constructed from a tubular slotted stainless steel stent with an attached equine pericardial trileaflet valve.[13] This procedure is done without the need for cardiopulmonary bypass and two approaches are currently being studied. The first method is via a femoral transarterial approach with retrograde access to the aortic valve.[14] More recently, a transapical approach has been developed, which is particularly effective in patients with significant peripheral vascular disease, thus limiting a peripheral approach.[15] For all methods of percutaneous aortic valve implantation, rapid pacing of the ventricle is required at the time of valve deployment to reduce both transaortic flow and cardiac motion.

Percutaneous aortic valve implantation is a reasonable option for patients deemed to be too high a risk for traditional aortic valve replacement. However, this procedure is still under development with immediate hemodynamic and early clinical improvement only reported in a small number of patients.

This 86-year-old patient was deemed to be too high a risk for traditional aortic valve replacement surgery. She is currently being evaluated for percutaneous aortic valve replacement.
